  2. Entergy Operations, Inc. letter CNRO-2003-00033 to the NRC, "Relaxation Request to NRC Order EA-03-009," dated August 15, 2003

Dear Sir or Madam:

In the referenced letters, Entergy Operations, Inc. (Entergy) requested relaxation from Section IV.C(1)(b) of NRC Order EA-03-009 for Arkansas Nuclear One, Unit 2 (ANO-2) and Waterford Steam Electric Station, Unit 3 (Waterford 3) pertaining to the control element drive mechanism (CEDM) nozzles.

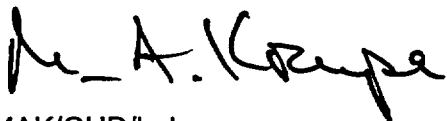

On September 16, 2003, a telephone conversation was held between representatives of the NRC staff and Entergy to discuss these requests. In that call, the staff requested that Entergy provide a copy of Engineering Report M-EP-2003-004, Rev. 0, which supports the Waterford 3 request, marked to identify the differences between it and Engineering Report M-EP-2003-002, Rev. 1, which supports the ANO-2 request. This marked-up engineering report, which high-lights the differences, is provided in the enclosure to this letter.

This letter contains no new commitments.

AIDI

If you have any questions or require additional information, please contact Guy Davant at (601) 368-5756.

Sincerely,

A handwritten signature in black ink, appearing to read "M. A. Kope". The signature is fluid and cursive, with the first name "M." followed by a hyphen and "A.", and the last name "Kope".

## 1.0 Introduction

The US Nuclear Regulatory Commission (NRC) issued Order EA-03-009 [1], which modified licenses, requiring inspection of all Control Element Drive Mechanism (CEDM), In-Core Instrumentation (ICI), and vent penetration nozzles in the reactor vessel head. Paragraph IV.C.1.b of the Order requires the inspection to cover a region from the bottom of the nozzle to two (2.0) inches above the J-groove weld. In the Combustion Engineering (CE) design the CEDM nozzles have a guide-cone attached to the bottom of each CEDM. Figure 1 [2] provides a drawing showing the attachment detail and a sketch showing the typical CEDM arrangement in the reactor vessel head. The attachment is a threaded connection with a securing set-screw between the guide-cone and the CEDM nozzle. The CEDM nozzle is internally threaded and the guide-cone has external threads. Thus, the CEDM nozzles in the region of attachment, including the chamfered region, become inaccessible for Ultrasonic Testing (UT) to interrogate the nozzle base material. The design of the UT probes result in a region above the chamfer (0.200 inch [reference 3a & 3b]) that cannot be inspected. Therefore, the region of the CEDM base metal that can be inspected begins at about 1.544 inches above the bottom of the CEDM nozzle and extends to two (2.0) inches above the J-groove weld. The unexamined length (here after called the blind zone) constitutes the threaded region, the chamfer region, and the UT dead zone ( $1.250 + 0.094 + 0.200$ ). The terms used in this report are defined as follows:

- Freespan = (bottom of weld – blind zone); this area below the weld is accessible for volumetric examination.
- Propagation Length = (bottom of weld –top of crack tip); area available for crack growth.

*Note: For an outside diameter (OD) surface crack, this length is always less than the freespan; for through-wall it is equal to the freespan; and, for an inside diameter (ID) surface crack, the criterion is the propagation length and a through-wall penetration condition.*

- Augmented Inspection Area: The axial and circumferential extent of the CEDM below the blind zone subject to an OD surface examination to ensure sufficient region for crack growth in one (1) cycle of operation without compromising the weld. This region may include weld material when the weld extends into the blind zone.

The nozzle as-built dimensions were determined by a detailed review of applicable Waterford Steam Electric Station Unit 3 (WSES-3) design drawings and UT data from sister plant (Plant A), since no volumetric inspection has been performed at WSES-3. These two units are of similar CE NSSS design and both are rated at 3410 mwt. The results of the comparison are provided as Attachments four (4) and five (5) in Appendix A. The results of this assessment was used to develop the finite element model which obtains the prevailing stress distribution (Residual+Operating) used in the deterministic fracture mechanics analyses. The deterministic fracture mechanics

analyses, in turn, assess the potential for primary water stress corrosion cracking (PWSCC) in the blind zone of the nozzles. The details of the stress analysis including the finite element models are discussed in Section 2. The UT data from Arkansas Nuclear One Unit 2 (ANO-2) was not used because the reactor vessel design for ANO-2 is significantly different from that of WSES-3. The reactor vessel design for Plant A is very similar to that for WSES-3 because of a common design platform. Therefore a more accurate estimate for the as-built configuration for WSES-3 could be achieved by using the UT data from Plant A.

In order to exclude the blind zone from the inspection campaign, a relaxation of the Order is required pursuant to the requirements prescribed in Section IV.F and footnote 2 of the Order [1].

The purpose of this engineering report is to:

1. Determine if sufficient propagation length between the blind zone and the weld exists to facilitate one (1) cycle of axial crack growth without the crack reaching the weld, and
2. For nozzles not meeting 1 above, determine how much of the blind zone combined with the available freespan is required to facilitate 1 cycle of crack growth without the crack reaching the weld. This area is subject to augmented surface examination.

Figure 1 below shows the general arrangement of the CEDM nozzles with connection details. In this figure the various regions are defined. This figure provides a general overview of the CEDM penetration and the regions planned for volumetric inspection, and the regions that cannot be inspected (blind zone) by the volumetric UT method.

**Figure 1:**

Details of guide cone connection to CEDM[2]. A sketch of a typical CEDM connection showing regions of interest is provided.

- a) CEDM nozzle tube.
- b) Details of the chamfer in the machined recess of the threaded region. Provides dimensions for the threaded and chamfer regions.
- c) Details of guide-cone connection to CEDM [2].
- d) Sketch of a typical CEDM penetration showing the region of interest.

Detail extracted from Drawing 1564-4086 R1 (WSES-3) [2]. The threaded region in the CEDM is 1.344 inches (Threads plus Recess plus chamfer).

The detail of the guide-cone-to-nozzle connection shows that the threaded + chamfer region is 1.344 inches in height. The UT dead band, determined to be 0.200 inch above the top of the threaded plus chamfer region in the nozzle, is based on a typical inspection probe sled design [3b] (shown in Figure 2).

| Position | Mode                | Diameter | Description                               |
|----------|---------------------|----------|---|
| 1        | Transmit            | 0.25"    | Circumferential Scan Using TOFD           |
| 2        | Receive             | 0.25"    | Circumferential Scan Using TOFD           |
| 3        | Transmit            | 0.25"    | Axial Scan Using TOFD                     |
| 4        | Receive             | 0.25"    | Axial Scan Using TOFD                     |
| 5        | Transmit<br>Receive | 0.25"    | Standard Zero Degree Scan                 |
| 6        | Transmit<br>Receive | 0.25"    | Standard Zero Degree Scan                 |
| 7        | EC                  | NA       | Standard Driver/Pickup Eddy Current Probe |

**Figure 2:** Sketch of a typical inspection probe sled [3a]. The UT dead band is shown with respect to the thread + chamfer region

Based on the probe design and the geometry of the nozzle at the threaded connection, the explanation provided in Reference 3b shows the UT dead band to extend 0.200 inch above the chamfer region immediately above the threads. Therefore, to account for the thread region, chamfer and the UT dead band, the blind zone height is determined to be 1.544 inch ( $1.250" + 0.094" + 0.2"$ ) above the bottom of the nozzle.

The analysis used to determine the impact of not examining the blind zone independently evaluates a part through-wall axial crack initiated from the ID, a part through-wall axial crack initiated from the OD, and a through-wall axial crack.

#### Part Through-Wall Cracks

The initial crack depth obtained from Reference 4 is 0.04627 inch deep for an ID axial crack and 0.07932 inch deep for an OD axial crack. The crack length is based on the detected length of 4 mm (0.157 inch) from Reference 4. In the deterministic fracture mechanics analyses, the part through-wall crack lengths are doubled to 0.32 inch and the crack center is located at the top of the blind zone. Thus, the crack spans both the blind zone and the inspectable region. The postulated crack sizes and depths are two times the detectable limits with one-half (0.16 inch) of the flaw length being located in the examinable area. This provides for a conservative evaluation because:

- A) By extending the postulated crack 0.16 inch into the inspectable region, it places the crack tip closer to the weld where the hoop stresses are higher; and
- B) It assumes that 0.16 inch of the inspectable region is already cracked, reducing the remaining area for crack propagation.

#### Through-Wall Crack

In addition to evaluating the part through-wall cracks, this evaluation also conservatively evaluates a through-wall axial crack. The through-wall axial crack is postulated to exist from the top of the blind zone down to a point where the hoop stress is  $\leq 10$  ksi. This is a very conservative assumption, since for a crack to initiate on the surface and propagate through-wall while being totally contained within the blind zone would result in an unrealistic aspect ratio. As can be concluded from the following analysis, the length of a part through-wall crack would propagate into the inspectable region long before its depth reaches a through-wall condition. However, evaluation of the through-wall crack provides completeness to this assessment and ensures all plausible crack propagation modes are considered. Like the part through-wall crack, the hoop stresses at the top of the blind zone were used as the initial stress with adjustments to account for the increased stresses as the crack approaches the weld.

The analyses include a finite element stress analysis of the CEDM nozzles and a fracture mechanics-based crack growth analysis for PWSCC. These analyses are performed for four nozzles (the nozzles were chosen at four head angles 0°, 7.8°, 29.1°, and 49.7°) in the reactor vessel head to account for the varied geometry of the nozzle penetration. In this manner the analysis provides a bounding evaluation for all CEDM nozzles in the reactor vessel head. The sections that follow contain a description of the analyses, the results, and conclusions supported by the analyses.

## 2.0 Stress Analysis

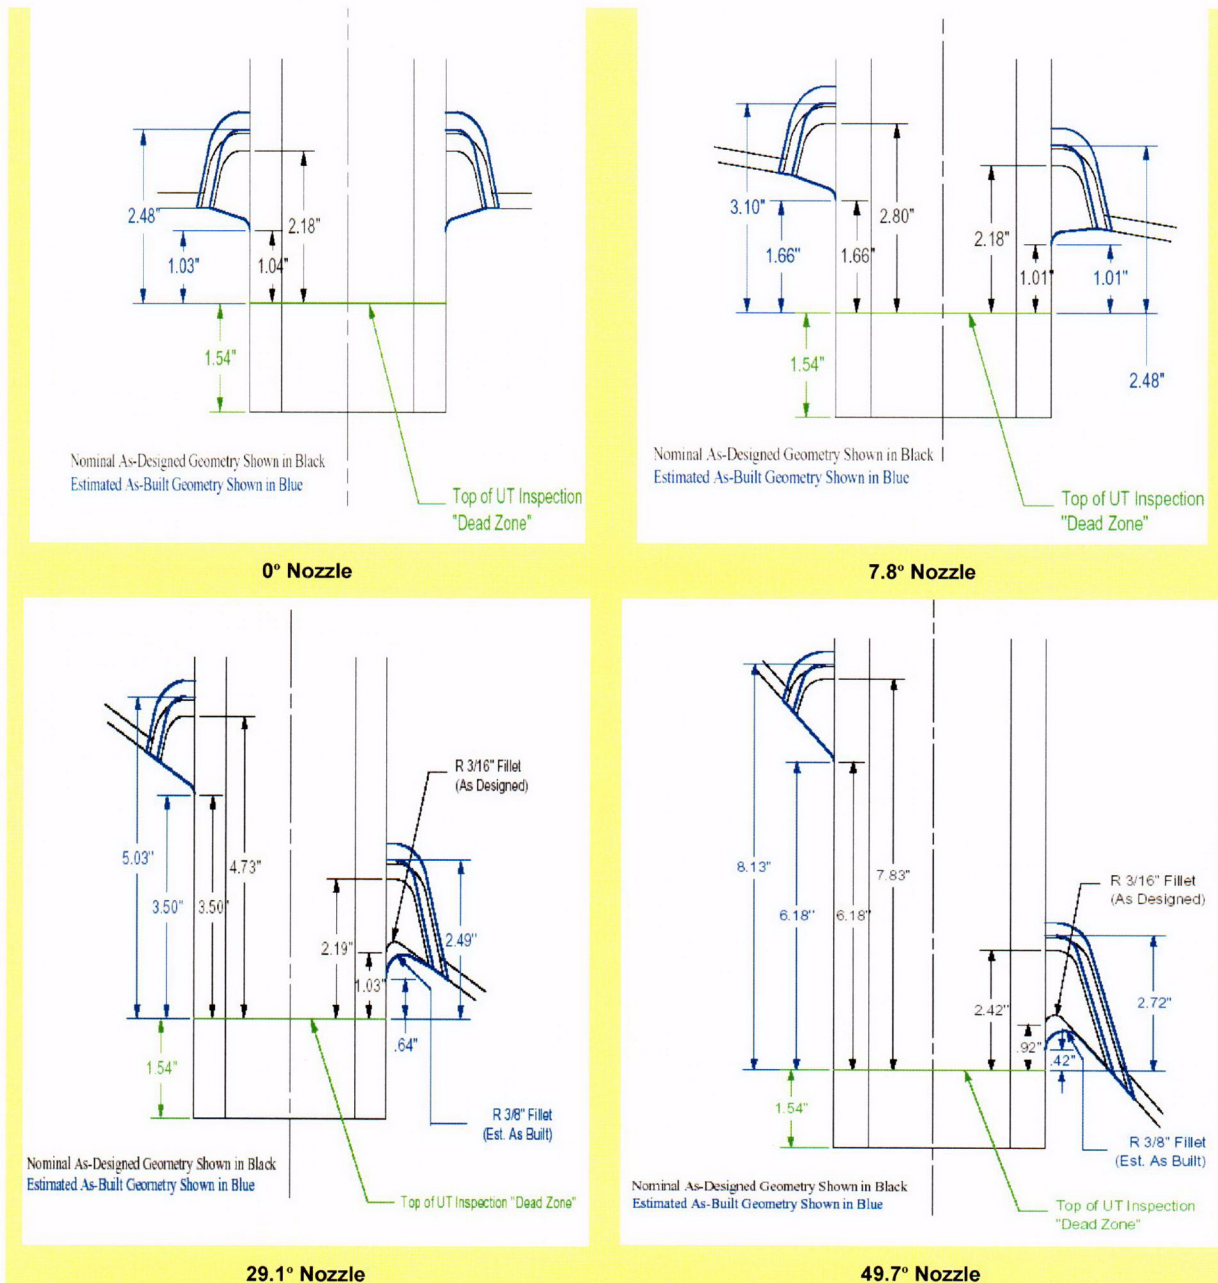

Finite element-based stress analyses for WSES-3 CEDM penetrations, using the highest tensile yield strength for each group of nozzles, were performed using the best-estimate geometries based on Plant A UT and WSES-3 design information. The UT data obtained from Plant A were reviewed to determine the locations of the top and bottom of the J-weld at two azimuthal locations, downhill (0°) and the uphill (180°). The UT data obtained from this analysis is presented in Attachment 4 to Appendix A. This UT data was compared to the design information obtained from design drawings for WSES-3 using an Excel spreadsheet to estimate the as-built condition. The spreadsheet used in this analysis is presented in Attachment 5 to Appendix A. In the evaluation five nozzle groups were considered in order to ensure the accuracy of the evaluation. The nozzle groups considered were 0°, 7.8°, 29.1°, 42.4°, and 49.7°. These evaluations showed the following:

- 1) In all cases the measured length from the blind zone to the top of the weld was consistently higher than the estimated length from design drawings. The average difference was about 0.3 inch.
- 2) The downhill side fillet welds on the peripheral CEDM nozzles (29.1°, 42.4° and 49.7°) have a longer leg than estimated from the design information. A fillet weld radius of 3/8 inch instead of the specified 3/16 inch provided the fillet weld leg length that matched the UT data. This evidence was also observed in another CE fabricated reactor vessel head. The fillet weld on the uphill side matched the information on the design drawing. Thus, only the downhill side fillet weld leg was extended for the model. The weld length on the uphill side matched the design information.
- 3) The larger length estimated in Item 1 above indicated that the attaching J-weld must have been longer than the design drawings specification. When the longer J-weld lengths were used, the difference between the as-measured and as-built estimate were considerably reduced. The longer J-weld length, in accordance with the design specification, would increase the radial dimension of the weld at the ID surface of the head. Thus, a larger weld size was developed for the finite element model. This larger weld size, in turn, would increase the magnitude of the residual stresses in the weld region.

The evaluation to estimate the as-built dimensions of the CEDM configuration, taking into consideration the Plant A UT data and design information, consisted of the following steps:

- 1) The blind zone elevation of 1.544 inches from the nozzle bottom was taken to exist for all CEDM nozzles.
- 2) The design lengths for freespan at both the downhill and uphill locations were established (design length from weld bottom – blind zone).

- 3) The design dimensions were compared to the measurements obtained from the Plant A UT data analysis. The differences were recorded.
- 4) The design length to the top of the J-weld was compared to the measured length from the Plant A UT data for both the downhill and uphill locations and the differences recorded.
- 5) The weld lengths from design drawings were compared to the as measured data from the Plant A UT results. This was done for both the downhill and uphill locations. The differences were recorded.
- 6) The differences were evaluated to assess the variation between the design and as-measured data. This comparison showed that the differences for the length from the blind zone to the top of the weld to be 0.3 inch larger for the Plant A UT measurement. Thus, the J-weld size was increased to accommodate the longer as-measured length. The higher hillside angle nozzles (29.1° and 49.7°) showed the variation to be more on the downhill side indicating a longer fillet weld leg length. This variation was minimized when the fillet weld radius was changed to 3/8 inch instead of the design specified value of 3/16 inch. Similar findings have been observed for another reactor vessel head fabricated by CE. Therefore, the increased fillet weld radius reasonably explains the larger fillet weld leg length observed in the Plant A UT data. For these nozzles the fillet weld leg length was increased. Figure 3 presents the sketches for all four nozzle groups considered in this analysis. The original design is represented by the black lines and the estimated as-built configuration by the blue lines. The location of the blind zone top, based on the NDE consideration, is located 1.54 inches from the nozzle bottom and is shown in green. These figures clearly show that the top of the J-weld is at a higher elevation than the specified elevation. In addition these sketches show that the attaching J-weld is larger than specified. The larger weld would tend to produce higher residual stress and hence provide a bounding estimate for the residual stress field. This geometry was used to develop the estimated as-built finite element model.

**Figure 3:** Estimated as-built nozzle configuration based on evaluation of Plant A UT and WSES-3 design data. For all nozzle groups evaluated the J-weld height was found to be 0.3 inch longer. The downhill fillet welds on the higher angle nozzles (29.1° and 49.7°) were estimated to have a larger fillet radius. Thus the fillet weld bottom (intersection with the nozzle OD) was determined to be at a lower elevation. The modified geometry, representing the best estimate of as-built configuration, were used to develop the finite element geometric model.

The finite element modeling for obtaining the necessary stress (residual+operating) distribution for use in fracture mechanics analysis followed the

process and methodology described in Reference 5a. The modeling steps were as follows:

- 1) The finite element mesh consisted of 3-dimensional solid (brick) elements. Four elements were used to model the tube wall and similar refinement was carried to the attaching J-weld.
- 2) The CEDM tube material was modeled with a monotonic stress strain curve. The highest yield strength from the nozzle material bounded by the nozzle group was used. This yield strength was referenced to the room temperature yield strength of the stress-strain curve described in Reference 5a. The temperature dependent stress strain curves were obtained by indexing the temperature dependent drop of yield strength.
- 3) The weld material was modeled as elastic-perfectly plastic for the weld simulation. This approximation is considered reasonable since most of the plastic strain in the weld metal occurs at high temperatures where metals do not work-harden significantly (Reference 5c). The temperature in the weld is always high during the welding process and once the weld begins to cool, the temperatures in the weld at which strain hardening would persist are of limited duration (Reference 5c). This was borne out by the comparison between the analysis based residual stress distribution and that obtained from experiments (Reference 5d).
- 4) The weld is simulated by two passes based on studies presented in Reference 5a.
- 5) After completing the weld, a simulated hydro-test load step is applied to the model. The hydro-test step followed the fabrication practice.
- 6) The model is then subjected to a normal operating schedule of normal heat up to steady state conditions at operating pressure. The residual plus operating stresses, once steady state has been achieved, are obtained for further analysis. The nodal stresses of interest are stored in an output file. These stresses are then transferred to an Excel spreadsheet for use in fracture mechanics analysis [5b].

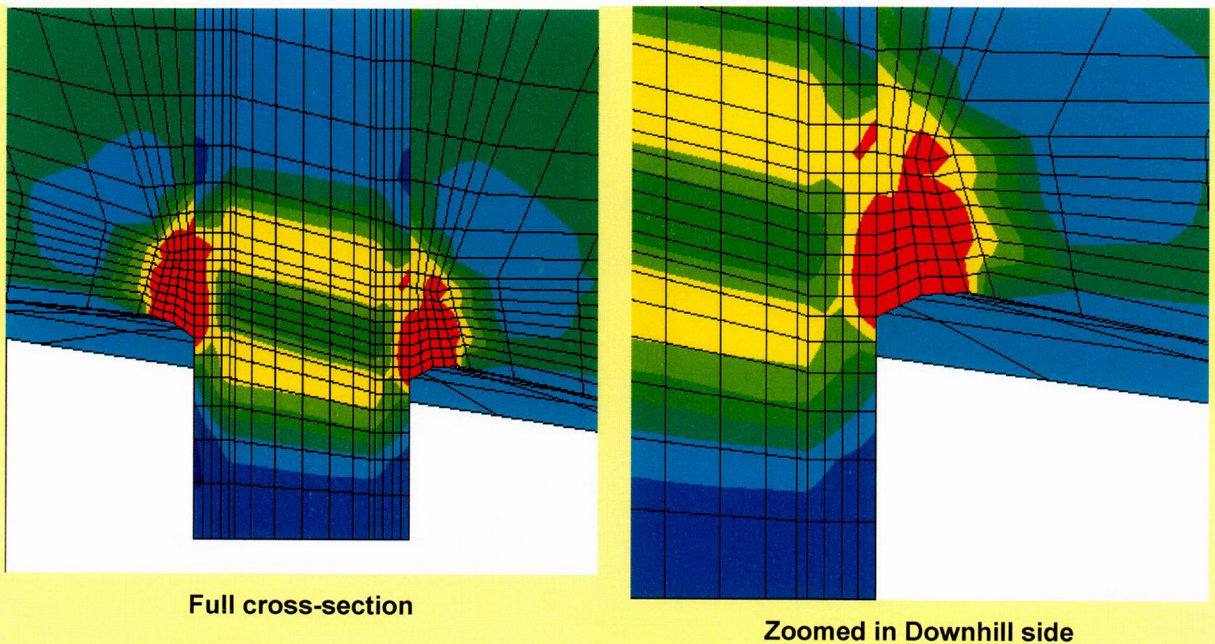

The stress contours for the four nozzle groups obtained from the finite element analysis are presented in Figures 4 through 7. The stress contour color scheme are as follows:

|                       |  |
|-----------------------|--|
| <b>Dark Navy blue</b> | <i>from Minimum (Compression) to -10 ksi</i> |
| <b>Royal blue</b>     | <i>from -10 to 0 ksi</i>                     |
| <b>Light blue</b>     | <i>from 0 to 10 ksi</i>                      |
| <b>Light green</b>    | <i>from 10 to 20 ksi</i>                     |
| <b>Green</b>          | <i>from 20 to 30 ksi</i>                     |
| <b>Yellow green</b>   | <i>from 30 to 40 ksi</i>                     |
|                       | <i>from 40 to 50 ksi</i>                     |
| <b>Red</b>            | <i>from 50 to 100 ksi</i>                    |

The nodal stresses for the locations of interest in each of the four nozzle groups were provided by Dominion Engineering Inc. and were tabulated in Reference 5b. The nodal stresses and associated figures representing the OD and ID distributions along the tube axis are presented in tables and associated figures in the following pages. The location of the weld bottom was maintained at the node row ending with "601". The blind zone location is shown on the associated figure. The three azimuthal locations downhill (0°), uphill (180°), and mid-plane (90°) are shown in the figures presented in the following pages. The zone of compressive stress is also marked in the figure.

From the tables and associated figures, a full visualization of the stress distribution in the nozzle, from the nozzle bottom (located at 0.0 inch) to the top of the J-weld is obtained. These figures are also shown in the Mathcad worksheets provided in the Appendix "C" attachments. The nodal stress distribution, provided by Dominion Engineering, is used to establish the region of interest and the associated stress distribution that will be utilized in the subsequent analyses. In the low angle nozzle groups (0° and 7.8°) there exists a well defined compression zone. The higher angle nozzle groups (29.1° and 49.7°) tensile stresses were found to exist at the nozzle bottom. Hence there was no well defined compression zone in these nozzles. In most cases the tension stress magnitude was low (<10.0 ksi), and the distribution through the wall thickness had compressive stresses. For these nozzles the presence of a low magnitude tensile stress on one surface is not expected to cause PWSCC initiation. In one isolated case (49.7° nozzle at the mid-plane) the ID surface had a tensile stress of 19.02 ksi but the OD surface was in compression. This location was selected for further evaluation using deterministic fracture mechanics and is discussed in a later section.

In the following pages, the stress data from the Excel spreadsheet provided by Dominion Engineering (Reference 5b) and plots representing the axial distribution at the ID and OD locations are presented for each nozzle group with the specific azimuthal location that is evaluated. The location of the compression zone the blind zone and bottom of the weld are marked by colored reference lines.

**Table 10:** Nodal stress for 49.7° nozzle at the mid-plane location. The weld location is shown by the shaded row.

**Figure 17:** Plot showing hoop stress distribution along tube axis for the 49.7° nozzle at the mid-plane location. The top of blind zone and the bottom of the weld are shown. No compression zone exists because the ID surface has a 19.02 ksi tensile stress.

The nodal stress data presented in the previous pages are the data imported into the respective Mathcad worksheet (discussed later) for further processing to obtain the pertinent stress distributions required for the fracture mechanics analysis. The processing of the nodal stress data is described in Section 4.

### 3.0 Analytical Basis for Fracture Mechanics and Crack Growth Models

#### *Fracture Mechanics Models*

##### *Surface Crack*

The mean radius-to-thickness ratio ( $R_m/t$ ) for the CEDM nozzle was about 2.5. The fracture mechanics equation used in the proposed revision to the ASME Code Section XI is based on the solution from Reference 6. This solution is valid for an outside radius-to-thickness (" $R_o/t$ ") ratio from 4.0 to 10.0. The CEDM nozzle " $R_o/t$ " ratio is lower (3.06), indicating that the CEDM nozzle is a thicker wall cylinder than those considered in Reference 6. Therefore, the fracture mechanics formulations presented in Reference 7 were chosen (the applicable " $R_m/t$ " ratio is from 1.0 to 300.0).

The stress intensity factor (SIF) for the postulated crack under an arbitrary stress distribution was obtained from Reference 7. The model was for both an internal and external part through-wall surface crack subjected to an arbitrary stress distribution. This model is valid for a ratio of mean radius ( $R_{mean}$ )-to-thickness ( $t$ ) between 1.0 and 300.0. Since the ratio for the CEDM nozzle is about 2.5, this model is considered applicable.

The equation for the SIF for the deepest point of the crack is given as [7]:

$$K_I = \left(\frac{\pi}{Q} a\right)^{0.5} * \left[\sum_{i=0}^3 \sigma_i G_i\right]$$

Where:

$$K_I = \text{SIF } \{ \text{ksi}\sqrt{\text{in.}} \}$$

$Q$  = Crack shape factor; defined as

$$Q = 1 + 1.464 * \left(\frac{a}{c}\right)^{1.65} \text{ when } a/c \leq 1.0 \text{ and,}$$

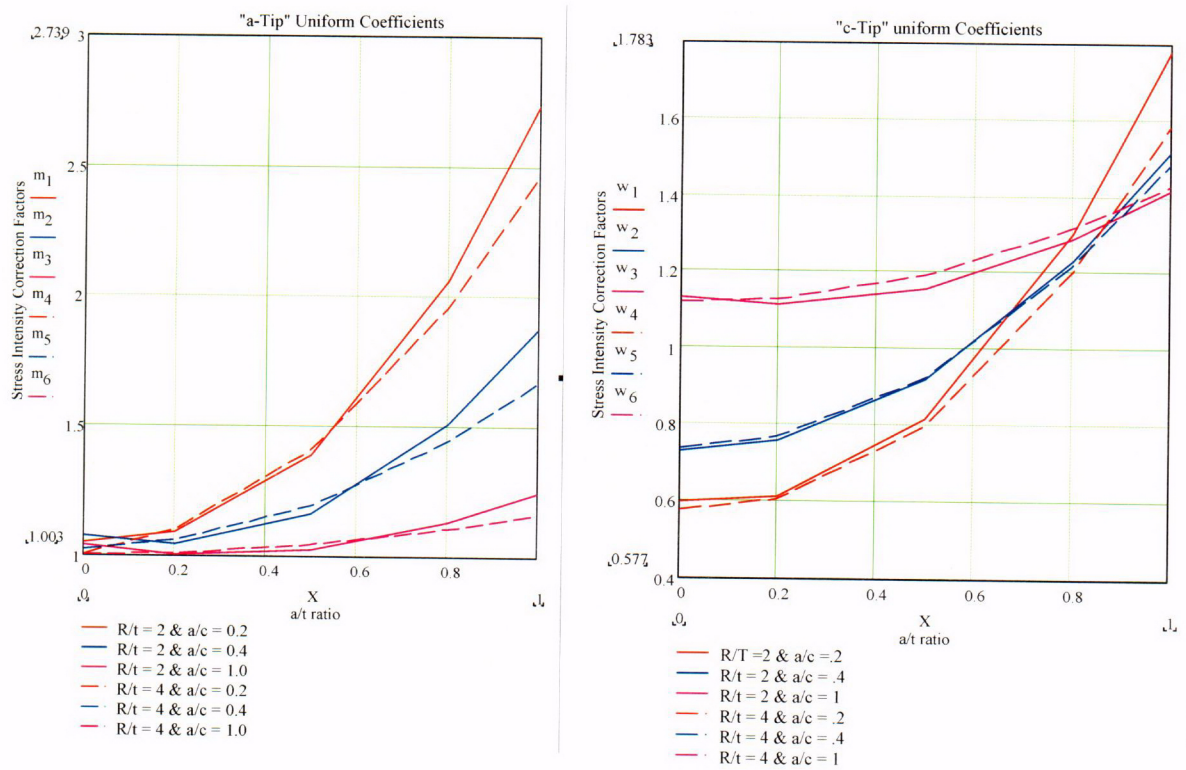

$$Q = 1 + 1.464 * \left(\frac{c}{a}\right)^{1.65} \text{ when } a/c > 1.0$$

$a$  = Crack depth {inch}

$\sigma_i$  = Coefficients of the stress polynomial describing the hoop stress variation through the crack depth. Describes the power loading on the crack face.

$G_i$  = Stress Intensity Correction Factors (SICF), which are provided in tables in Reference 7.

In Reference 7 SICF is presented for both the depth point of the crack ("a-tip") and for the surface point of the crack ("c-tip"). Separate tables are provided for the internal (ID) and external (OD) surface cracks. In addition the values are provided in association with the  $R_m/t$  ratio,  $a/c$  ratio (crack aspect ratio), and  $a/t$  ratio (normalized crack depth). The SICF tables are large and a suitable interpolation scheme is necessary to obtain proper coefficients dependent on crack size and shape for a given cylindrical geometry. Selected SICF from the tables for internal cracks for two different  $R_m/t$  ratios and  $a/c$  ratios are presented in Figure 18 below.

**Figure 18:** SICF shown as a function of normalized crack depth for the "a-tip" (left figure) and the "c-tip" right figure. These figures show that simple linear interpolation would not provide accurate coefficients. These figures also show that a proper  $R_m/t$  is essential to provide a reasonably accurate estimate of the SIF.

The figure above shows two features that are significant;

- 1) The interpolation used to obtain the SICF must be carefully performed such that the value accurately represents the crack geometry. This is accommodated by selecting a suitable order for the polynomial prior to performing an interpolation to obtain the specific value. This aspect is discussed in further detail in the section describing the analysis method.
- 2) The correct  $R_m/t$  ratio is essential for obtaining a reasonably accurate estimate of the SIF. Using a higher ratio will tend to underestimate the SIF and hence under predict the crack growth.

Both these features have been considered in the development of the analysis model such that a reasonable, yet conservative, estimate of the SIF is obtained.

#### *Through-Wall Axial Crack*

The analysis for a through-wall axial crack was evaluated using the formulation of Reference 8. This formulation was chosen since the underlying analysis was performed considering thick-wall cylinders that had an " $R_o/t$ " ratio in the range of the application herein. The analysis used the outside surface (OD) as the reference surface and, hence, the same notation is used here.

It was noted in Reference 8 that the formulations based on thin shell theory do not consider the complete three-dimensional nature of the highly localized stress distribution. This would be the case for the residual stress distribution from welding. The nonlinear three-dimensional stress distribution coupled with shell curvature must be properly addressed to account for the material behavior at the crack tip, which controls the SIF, such that the SIF is not underestimated. The information presented in Reference 8 compared the results from formulations derived using thin shell theory and those derived using thick shell formulation, these results highlighted the need to use thick shell based formulation for situations such as the current application to CEDM nozzle through-wall axial cracks.

The formulation provides the correction factors, which account for the " $R_o/t$ " ratio and crack geometry ( $\lambda$ ), that are used to correct the SIF for a flat plate solution subjected to similar loadings. The correction factors were given for both "extension" and "bending" components. The flat plate solutions for both membrane and bending loads were to be used to obtain the applied SIF. The formulations for SIF were given as [8]:

$$K_{outer} = \{ A_e + A_b \} * K_p \quad \text{for the OD surface;}$$

and,

$$K_{lmer} = \{A_e - A_b\} * K_p \text{ for the ID surface;}$$

where:

$A_e$  and  $A_b$  are the “extension” and “bending” components; and,  
 $K_p$  is the SIF for a cracked Flat Plate subject to the same boundary condition and loading as the cracked cylinder.

The flat plate SIF solutions are written as:

$$K_{p-Membrane} = \sigma_h * \sqrt{\pi * l} \text{ for membrane loading, and}$$

$$K_{p-Bending} = \sigma_b * \sqrt{\pi * l} \text{ for bending loading.}$$

Where:

$\sigma_h$  and  $\sigma_b$  are the membrane and bending stresses and “ $l$ ” is one-half the crack length.

The reference surface used in the evaluation was the OD surface. The stresses at the ID and OD at the axial elevation of interest were decomposed into membrane and bending components as follows:

$$\sigma_h = \frac{\sigma_{res-OD} + \sigma_{res-ID}}{2} \text{ for membrane loading; and}$$

$$\sigma_b = \frac{\sigma_{res-OD} - \sigma_{res-ID}}{2} \text{ for bending loading.}$$

where:

$\sigma_{res-OD}$  is the stress (residual+operating) on the OD surface; and,

$\sigma_{res-ID}$  is the stress (residual+operating) on the ID surface.

The data presented in the tables in Reference 8 for determining the  $A_e$  and  $A_b$  components were curve fit using a fifth order polynomial such that they could be calculated knowing the parameter  $\lambda$ , which is defined as [8]:

$$\lambda = \{[12 * (1 - \nu^2)]^{0.25} * \frac{l}{(R * t)^{0.5}}\}$$

where  $\nu$  is Poisson's ratio and  $R$  is the mean radius.

The data obtained from the tables in Reference 8 were curve fit using a fifth order polynomial. The curve fitting was accomplished using Axum 7 [9]. The curve fit results for the components are presented in Figure 19 below.

### Extension and Bending Constants for Throughwall Axial Flaws R/t = 3.0

**Figure 19:** Curve fit equations for the “extension and “bending” components in Reference 8. Tables 1c and 1d for membrane loading and Tables 1g and 1h for bending loading of Reference 8 were used.

### Crack Growth Model

To evaluate the potential for crack growth due to PWSCC, the crack growth rate equation from EPRI-MRP 55 [10] was used. The crack growth rate as a function of the SIF with a correction for temperature effects is given as [10a]:

$$\frac{da}{dt} = \exp\left[-\frac{Q_g}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \alpha (K - K_{th})^\beta$$

Where:

$da/dt$  = crack growth rate at temperature  $T$  {m/s}

$Q_g$  = thermal activation energy for crack growth {31.0 kcal/mole}

$R$  = universal gas constant  $\{1.103 \times 10^{-3} \text{ kcal/mole-}^\circ\text{R}\}$

$T$  = absolute operating temperature at crack tip  $\{^\circ\text{R}\}$

$T$  = absolute reference temperature for data normalization  $\{1076.67 \text{ }^\circ\text{R}\}$

$\alpha$  = crack growth amplitude  $\{2.67 \times 10^{-12}\}$

$K$  = crack tip SIF  $\{\text{Mpa}\sqrt{\text{m}}\}$

$K_{th}$  = threshold SIF for crack growth  $\{\text{MPa}\sqrt{\text{m}}\}$

$\beta$  = exponent {1.16}

The above equation represents the seventy-fifth percentile curve. Since the PWSCC crack growth of interest is in the primary water, this model would provide a reasonably conservative crack growth. The operating temperature of 604 °F was verified to be a conservative upper bound based on the information provided in References 10b and 10c.

#### 4.0 Method of Analysis

##### *Mathcad Worksheet Format*

The analytical scheme was developed using Mathcad [11] which facilitates calculations (including recursive) in a logical manner. Appendix B provides annotated versions of the three sets of worksheets used in the current analysis. The three sets are for the ID surface crack, the OD surface crack and for the through-wall crack. In the paragraphs below the general approach used to develop the worksheet is presented.

The first part of the worksheet is common to all three sets and requires the proper identification for the analysis being performed. In this region the component and the reference location in that component are identified. Immediately below the identification entry are the geometric landmark entries. For the surface cracks three entries are required and these are:

- 1) The location of a reference line (e.g. blind zone location) referenced to the nozzle bottom  $\{\text{Ref}_{\text{Point}}\}$ .
- 2) The location of the crack with respect to the reference line (Upper crack tip at the reference line, center of crack at the reference line or lower crack tip at the reference line)  $\{\text{Val}\}$ ;
- 3) The location of the bottom of the weld measured upwards from the nozzle bottom  $\{\text{UL}_{\text{Strs.Dist}}\}$ .

For the through-wall crack the location of the crack upper tip is always at the reference line, while the two other land mark entries (reference point and bottom of weld) are similar to that for the surface crack. This completes the entries on the first page of the worksheet.

The second page of each Mathcad worksheet contains the inputs for crack dimensions, tube geometry, internal pressure, years of operation, iteration limit, operating temperature, and the constants for the PWSCC crack growth parameters. It should be noted that the crack growth is performed using metric units; hence, those constants are required to be in metric units. The remainder of this sheet does not require user input. The calculation shown is simple arithmetic to determine the values necessary for the analysis.

The third page of each worksheet is designed to import the entire nodal stress data from the Excel spreadsheet provided by Dominion Engineering (described earlier). After the required data has been imported, the graph below the data table depicts the ID and OD stress distributions along the axial length of the nozzle. This graph is needed to aid in the selection of the nodal stress data to be used in the subsequent analysis. Once the data needed for the evaluation has been selected, it is pasted onto the third sheet at a variable defined as "Data". No further user input is required. The worksheets presented in Appendix C reflect this design.

#### *Determination of Stress Field (Distributions)*

The first step in the analysis is to develop the appropriate stress distribution to be used in the determination of the SIF. This is needed because the SIF formulation is based on use of a uniform stress distribution along the length of the tube. However, the stress field at the bottom portion of the nozzle, starting from the nozzle bottom, increases in magnitude as the bottom of the weld is approached. Consequently, if an assumed crack located in the vicinity of the reference line were to grow by PWSCC, it would be subjected to an increasing stress field. Thus, to use the stress distribution at the initial crack location would lead to an underestimate of the SIF since the SIF is directly proportional to the applied stress. In order to obtain a reasonably representative SIF under the prevailing stress field variation, a moving average scheme was developed. This scheme is as follows:

- 1) For the initial crack location the stress distribution at the two crack tips (lower and upper) and the crack center are averaged to produce an average stress field that is applied to the crack. It is this stress distribution that is used to ascertain whether there exists a potential for PWSCC crack growth. This method is considered reasonable since it is similar to the superposition principle used in finite element based SICF determination.
- 2) The remaining portion of the nozzle extending from the upper crack tip to the bottom of the weld is divided into twenty (20) equal segments.
- 3) The stress distribution in the first segment, above the upper crack tip, is an arithmetic average of the first three initial crack region distribution (Lower tip, center of crack and the upper tip) plus the distribution in the first segment. Thus, when the crack enters the first segment the magnitude of the stress distribution is appropriately increased to account for the increased applied stress. Similarly, as the crack progresses upward to the weld bottom through the various segments, the applied stress distribution is

adjusted accordingly. The small extent of the length between the reference line and the bottom of the weld can be sufficiently accommodated by the twenty-segment characterization.

To accomplish this averaging scheme, the nodal stresses at the five (5) nodal locations through the tube thickness and its variation along the length of the nozzle are individually regressed with a third order polynomial. Hence, it is important to ensure that the axial distribution can be described by a third-order polynomial. The regression is performed along the nozzle axis at each of the five (5) locations individually. The result of the regression provides the spatial coefficients required to describe the stress distribution. The nodal stress data representing the region of interest, from the nozzle bottom to an elevation just above the bottom of the weld, is selected. In this manner, it is expected that proper representation of the stress distribution, pertinent to crack initiation and growth, can be accurately described.

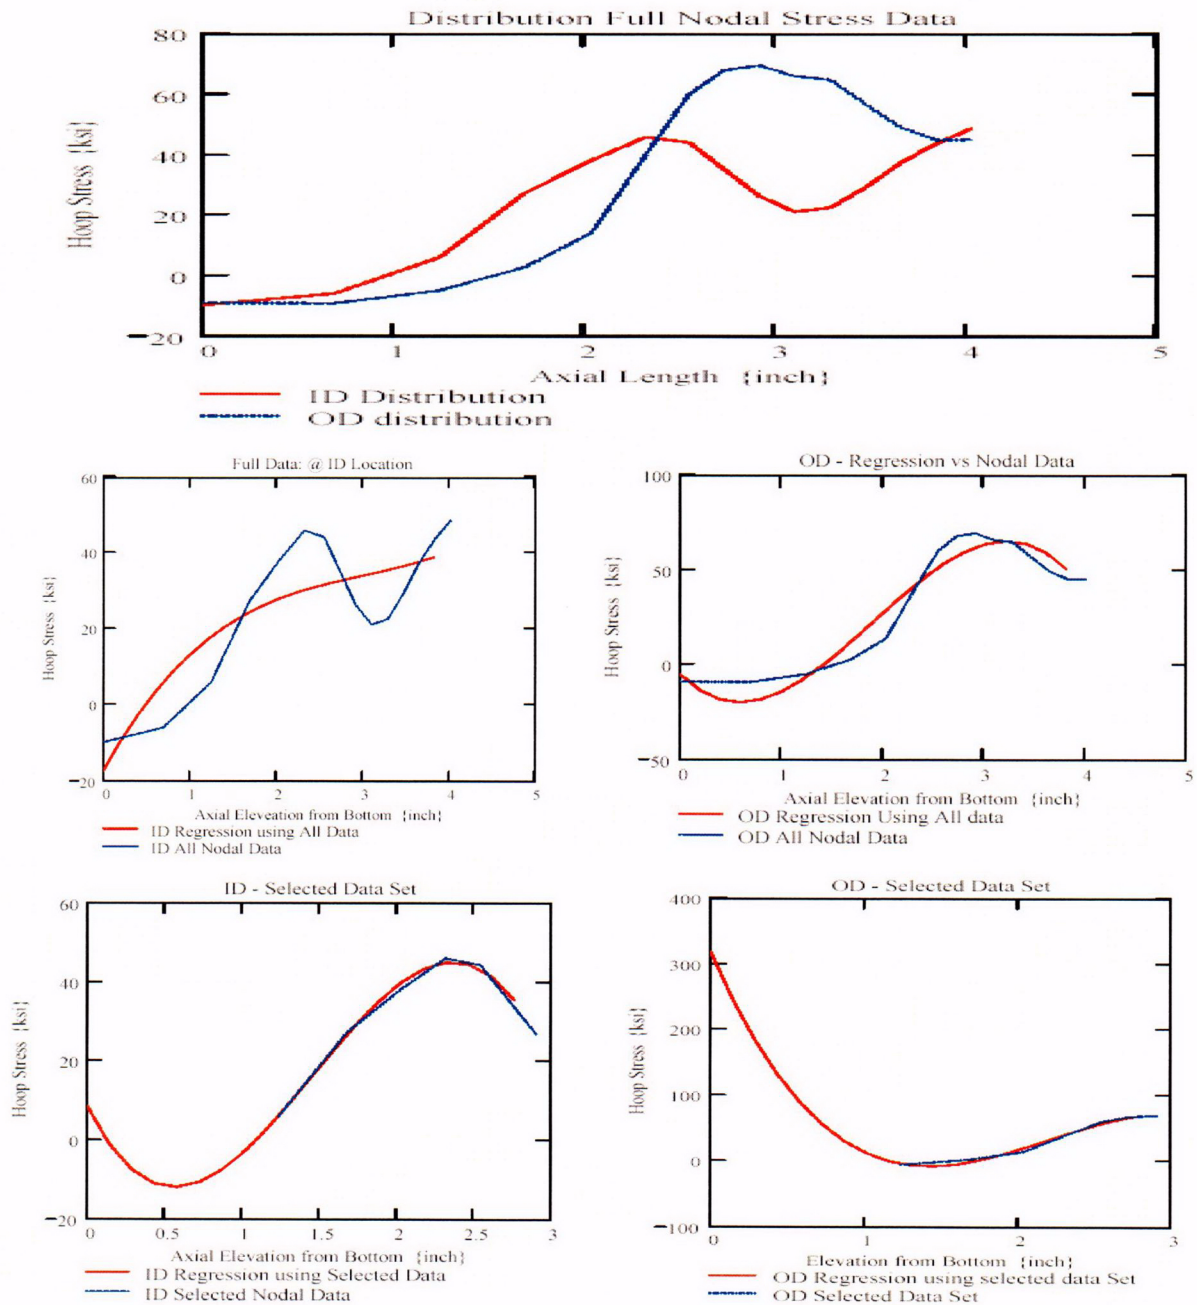

An example of this approach is presented in Figure 20 below. In this example, the stress at the ID and the OD locations were selected from a typical set of nodal stress data. The graphs immediately below show the individual stress distribution and the result from the third-order polynomial fit. In the first set, the entire data set from the bottom of the nozzle to the top of the J-weld was used. The regression curve shows that the general trend is captured; however, the fit in localized regions are not accurate representation of the original data. Significant variation that might cause errors in the determination of the SIF could occur, which in turn could lead to an inaccurate estimate in crack growth.

The two lower plots follow the scheme utilized in the current analysis. In this process the nodal stress data from the bottom of the nozzle to an elevation just above the bottom of the J-weld is selected. In this manner the stress distribution in the region of interest is chosen for the regressed curve fitting. This is necessary since the stresses in the weld region show significant variation (top plot) and cannot be adequately represented by a third-order polynomial. Limiting the stress distribution data to the region of interest would limit the variation and results in a more accurate fit. The plots in the lowest row, in Figure 20, show the improvement in the accuracy of fitting. The regression fit does provide an accurate representation of the stress distribution of the region. Therefore, the stress distribution used in the fracture mechanics analysis would be a reasonably accurate representation of the actual stress distribution in the region where the initial crack and subsequent crack growth are of interest.

This example and the associated plots in Figure 20 show that the regression method, as developed for the current analyses, provides an adequate representation of the stress distribution.

The analysis worksheets (Appendix C) contain a cautionary statement such that inaccurate regression is avoided. The Mathcad worksheet used to develop this example is presented in Appendix D, Attachment 1. However, it should be

noted that this attachment is not annotated but does follow the method used in the analysis worksheets.

**Figure 20:** Plots showing effect of nodal data selection on the accuracy of polynomial regression fit. The first plot represents all nodal stress data from the nozzle bottom to the top of the J-weld.

The two plots, in the middle row, are the comparison of regression fit with nodal stress data; the full data set of nodal data for the ID and OD distribution was used.

The two plots, in the lower row, use a limited data set comprising the axial length to the bottom of the weld. The regression curve shows a significantly improved fit to the data.

Once the five polynomial equations for the axial distribution are established, the through-wall stress distribution for the three locations defined by the crack and the twenty segments are established. The distributions at the twenty-three locations are subjected to a third order polynomial regression to obtain the coefficients describing the through-wall distributions. These coefficients are used within the recursive loop to assign the coefficients based on the current crack location. The five axial distributions are used for the surface cracks (ID and OD) whereas only two are required for the through-wall crack (ID and OD distributions).

#### *Iterative Analysis to Determine SICF*

For the surface cracks (ID and OD) the SICF coefficients were incorporated in two data tables. The first table contains the geometry data ( $R_m/t$ ,  $a/c$  and  $a/t$ ) and the second table consists of the SICF data for the appropriate cylinder and crack geometry. The values for the data were obtained from Reference 7. The data contained in the two tables were regressed into function statements with an appropriate polynomial order. The data for cylinder geometries from  $R_m/t$  ranging from one (1) to four (4) were regressed with a third-order polynomial, and for those above four, a second-order polynomial was used. The selection of the polynomial order was based on matching the value in the table given, for a selected set of independent variables, with that obtained from the interpolation performed using the regressed coefficients. In this manner the accuracy of the regression-interpolation method was established. The interpolation equation was defined outside the recursive loop and function call was made inside the loop using the pertinent variables at the time of the call.

The through-wall crack SICF was obtained using the fifth-order polynomial equation presented earlier. These equations were provided inside of the recursive loop.

The recursive loop starts the calculation scheme to determine the crack growth for a specified time period under the prevailing conditions of applied stress. The first few statements are the initialization parameters. The calculation algorithm begins with the assignment of the through-wall stress coefficients based on the current crack location. Once the four coefficients (uniform, linear, quadratic and cubic) are assigned, the through-wall stress distribution is used as the basis to establish the stress distribution along the crack face in the crack depth direction. That is, the stresses through the thickness are used to determine the stress along the crack face for application in the determination of the SIF in accordance with Reference 7. Once again, five locations along the crack depth were used to define the crack face distribution. The stresses representing the crack face values were regressed with a third-order polynomial to obtain the stress coefficients that would be used in the determination. At this point, the internal pressure is added to the stress coefficient (SICF) for the uniform term. Therefore, the crack face is subjected to an additional stress representing the internal pressure.

Following the determination of the stress coefficients, the function call to obtain the four SICF coefficients is made. In this case the two function calls were necessary to account for the "a-tip" and the "c-tip". The crack shape factor ("Q") was then computed using the appropriate crack dimensions. The SIF is calculated separately for the "a-tip" and the "c-tip" using the stress coefficients, appropriate SICFs and crack dimensions.

In the through-wall crack solution; the fifth-order polynomial equations were solved using the current crack dimensions. The SIFs were computed for both the ID and OD locations and were then averaged. This averaged SIF was used for crack growth calculation. The crack growth calculation and the remainder of the program for both the surface cracks (ID and OD) and through-wall crack are identical.

The calculated SIFs were converted to metric unit for the computation of crack growth. The crack growth rate, based on the prevailing SIF was computed in metric units. Once this was done, a conditional branch statement was used to calculate the crack growth within the prescribed time increment. The crack growth was computed in English units by converting the calculated crack growth rate in meters-per-second to inches-per-hour. Thus, the crack growth extent was obtained in inches for the specified time period. Since the operating time was selected to be four years and the number of iterations chosen at one thousand five hundred (1500), the time increment for each crack growth block was about twenty-four (24) hours. After the calculations were performed, all necessary information (crack growth, SIFs etc.) was assigned to an output variable such that it is stored in an array. The last step of the recursive loop consisted of updating the essential parameters (namely, the index, crack length, time increment etc.).

Graphical displays of the results using both Mathcad and Axum plots complete the work sheet. The Mathcad plots are used to determine whether or not the crack reached the bottom of the weld in one operating fuel cycle and the Axum plots were generated for incorporation into this report.

The three attachments in Appendix B are sufficiently annotated to provide summary details for each major step in the program.

## **5.0 Discussion and Results**

### ***Discussion***

The goal of the inspection program designed for the reactor vessel head penetrations is to ensure that the postulated crack in the vicinity of the blind zone does not reach the weld during the upcoming operating cycle following the refueling outage when the inspections are performed. Safety analyses performed by the MRP have demonstrated that axial cracks in the nozzle tube material do not pose a challenge to the structural integrity of the nozzle. Axial cracks, if allowed to exist undetected for sufficient periods of time can produce a primary boundary leak that can cause

damage to the reactor vessel head (carbon steel) and create a conducive environment for initiating and propagating OD circumferential cracks. These conditions challenge the pressure boundary; hence, critical importance is paid to proper periodic inspection and to the disposition of cracks that may be discovered. Therefore, proper analyses are essential to ascertain the nature of axial crack growth such that appropriate determination can be accomplished.

The analyses performed in this report were designed to capture the behavior of postulated cracks that might exist in the blind zone for the CEDM nozzle. The growth region for the postulated cracks was to the bottom of the weld along the tube OD.

The design review of the reactor vessel head construction, the detailed residual stress analyses, the selection of representative nozzle locations, selection of representative fracture mechanics models, and the application of a suitable crack growth law have provided the bases for arriving at a comprehensive and prudent decision.

The axial crack geometry is selected for evaluation because this crack has the potential for propagation into the pressure boundary weld (the J-groove weld); and since the circumferentially oriented cracks will not propagate towards the pressure boundary weld, this crack type is not evaluated. The hoop stress distribution at the downhill location ( $0^\circ$ ), at the Mid-Plane location ( $90^\circ$  rotated from the downhill), and at the uphill ( $180^\circ$ ) location were chosen for evaluation. The axial distribution of the hoop stress magnitude for both the ID and OD surfaces shows that at an axial location below the evaluated elevation, the stresses drop off significantly and become compressive except for the specific group of nozzles identified earlier. In nozzles where a compression zone exists or where localized low tensile stress exists at the nozzle bottom, the potential for PWSCC crack growth would be significantly low to non-existent in these locations. For the isolated location ( $49.7^\circ$  nozzle at mid-plane) where the tensile stress on the ID surface was 19.02 ksi, an additional fracture mechanics analysis was performed. The analysis and the results are presented in the following section.

The fracture mechanics evaluation considered the crack face to be subjected to the operating reactor coolant system (RCS) pressure. This is accomplished by arithmetically adding the RCS pressure to the uniform stress coefficient in the surface crack analysis and to the membrane stress for the through-wall crack analysis. In this manner, the stress imposed on the crack is accurately and conservatively modeled.

In order to ensure that the moving average technique did not create numerical errors, a Mathcad worksheet was created by using the stress averaging portion of the regular analysis worksheet. In this worksheet, the data table, which is used to import data from an Excel spreadsheet, was entirely populated with a linear through-wall stress distribution. The axial distribution of the stresses along the axis was kept constant. In this manner, the moving average method should provide results that have the same distribution at all locations along the tube axis. This implies the through-wall distribution is invariant along the length of the tube. The example and

the associated worksheets are provided in Appendix D, Attachment 2. The results of the experiment show that the stress distribution across the wall remained unchanged along the axis of the tube. Therefore the moving stress averaging method is validated.

The through-wall axial crack could have been considered as a single edge crack in a plate. For this model to work properly, it is essential that the plate geometry be described accurately. The CEDM nozzle is welded to the head; hence the nozzle OD surface is clamped at the bottom of the weld. Therefore, the plate height would be equal to the length of the nozzle from the bottom of the nozzle to the bottom of the J-weld. When this plate height is assumed and the length of the through-wall axial crack is taken to be the length (height) of the blind zone, then the ratio of crack length to the plate height (assumed) violates the pre-requisite for the SICF of 0.6. It is possible to assume the plate height to be equal to the nozzle height or some lower elevation (e.g. length equal to top of the J-weld). These assumptions tend to keep the crack-to-plate height ratio within the limit; however, the resulting SICF is lower than the membrane SICF from the model used in this analysis. A Mathcad worksheet showing the comparison is presented in Appendix D, Attachment 3. The results presented in this attachment demonstrate that the SICF for the model used in the current analysis is higher than the SICF produced by an edge crack model with longer plate lengths. In addition, the bottom zone of the CEDM nozzle is in compression, as shown in Figures 8-12, which further argues against postulating an edge crack for evaluating a through-wall crack. Therefore, for the two reasons cited herein the model developed for through-wall crack is considered valid and provides an accurate (but conservative) estimate of the SIF. The SICF comparison is presented in Figure 21 below.

**Figure 21:** Comparison of SICF for the edge crack configurations with the membrane SICF for current model. The current model results in a higher SICF value for the application considered.

The models used in the analysis presented here were compared with the conventional approach used by the industry. The OD surface crack evaluated shows that the model used provides a higher SIF and, in addition, has the capability of separately evaluating the SIF at the two crack locations (the “a-tip” and the “c-tip”). The SIF comparison for a sample case from Appendix D, Attachment 4 is shown in Figure 22.

**Figure 22:** Comparison of SIF for the current model and conventional model.

The conventional approach for the through-wall axial crack is the Center Cracked Panel (CCP) with an SICF of one (SICF = 1.0). This conventional model is compared to the current model used within this analysis. The Mathcad worksheet for this comparison is presented in Appendix D, Attachment 5. The results presented in this attachment clearly demonstrate that the SIF obtained by the current model is significantly higher than that from the conventional approach. Therefore, the estimated crack growth would be higher for the current model than that estimated using the conventional approach. This would lead to an underestimate of the crack growth, by the conventional model, leading to a non-conservative propagation length estimate. Figure 23 shows a comparison between the conventional and current models. Though the SIF for both models are below the threshold SIF of 8.19 ksi/in., it is clear from this figure that the conventional model SIF is lower.

**Figure 23:** SIF comparison between current model and conventional model.
