The inlet and outlet portions of the safety valves are hydrostatically tested with water at the appropriate pressures in accordance with the applicable section of the ASME B&PV Code. The set pressure of each safety valve is verified using steam and restricted lift of the valve. The set pressure is adjusted as needed and shall be made by selecting a valve ring setting combination that provides stable valve operation. The selection of the valve ring setting combination is based on the results from the EPRI Safety Valve Test Program[1]. The final set pressure is then verified using steam. Steam is also utilized to check for seat leakage.

5.4.13.4.2 Main Steam Safety Valves

The inlet and outlet portions of the safety valves are hydrostatically tested with water at the appropriate pressures in accordance with the applicable section of the ASME B&PV Code. The set pressure of each safety valve is verified using steam and restricted lift of the valve. The set pressure is adjusted as needed. The final set-pressure and seat leakage are verified using steam. Another acceptable method of testing each safety valve is to test the valve while it is installed on the main steam line using steam produced by the plant and a hydraulic assist device. Seat leakage may also be verified using steam produced by the plant and a hydraulic assist device.

5.4.14 COMPONENT SUPPORTS

5.4.14.1 Design Basis

The criteria applied in the design of the Reactor Coolant System supports are that the specific function of the supported equipment be achieved during all normal, earthquake, and Loss-of-Coolant Accident (LOCA) conditions. Specifically, the supports are designed to support and restrain the Reactor Coolant System components under the combined Safe Shutdown Earthquake and Loss-of-Coolant Accident loadings in accordance with the stress and deflection limits of Section III, ASME Code.

5.4.14.2 Description

Figure 5.4-12 illustrates the Reactor Coolant System support points. A description of the supports for each supported component follows:

A. Reactor Vessel Supports

The reactor vessel is supported by four vertical columns located under the vessel inlet nozzles. These columns are designed to flex in the direction of horizontal thermal expansion and thus allow unrestrained heatup and cooldown. They also act as holddown devices for the vessel.

Horizontal keyways located alongside the upper portion of the column guide the vessel during thermal expansion and contraction of the Reactor Coolant System and maintain the vessel centerline.

Four horizontal keys are welded to the bottom vessel head. The column base plate acts as a keyway for these keys to restrain the bottom of the vessel.

The supports are designed to accept normal loads and seismic and pipe rupture accident loads.

Reactor vessel supports are shown in Figure 5.4-13.

B. Steam Generator Supports

The steam generator is supported at the bottom by a sliding base bolted to an integrally attached conical skirt. The sliding base rests on low friction bearings which allow unrestrained thermal expansion of the Reactor Coolant System. Two keyways within

the sliding base mate with embedded keys to guide the movement of the steam generator during expansion and contraction of the Reactor Coolant System and, together with a stop and anchor bolts, limit movement of the bottom of the steam generator during seismic events and following a LOCA.

A system of keys and snubbers located on the steam drum guide the top of the steam generator during expansion and contraction of the Reactor Coolant System and provide support during seismic events and following a LOCA or a steam line break.

Typical steam generator supports are shown in Figure 5.4-14.

C. Reactor Coolant Pump Supports

Each reactor coolant pump is provided with four vertical support columns, four horizontal support columns, and two horizontal snubbers. The rigid structural columns provide support for the pumps during normal operation, earthquake conditions, and any Design Basis Pipe breaks in either the pump suction or discharge line. An illustration of the pumps supports is shown in Figure 5.4-15.

For the case of pipe break in the pump discharge line, a structural stop is provided to limit the pump motion. Pipe stop structures which limit pipe motion also prevent overloading of the pump support columns due to a pipe rupture at either the steam generator or reactor vessel nozzles.

D. Pressurizer Supports

The pressurizer is supported by a cylindrical skirt welded to the pressurizer and bolted to the support structure. The skirt is designed to withstand deadweight and normal operating loads as well as the loads due to earthquakes and LOCA. Four keys welded to the upper shell provide additional restraint during a postulated seismic event.

E. Where appropriate, load limiting devices are used to reapportion the loading applied to elements of redundant supports.

5.4.14.3 Evaluation

The structural integrity of the reactor coolant system support components is ensured by quality assurance inspections in accordance with Section III of the ASME Code during fabrication. The non-integral supports are procured by individual equipment specifications which impose appropriate quality assurance requirements commensurate with the respective component's functions.

During pre-operational testing of the Reactor Coolant System, the support displacements will be monitored for concurrence with calculated displacements and/or clearances. Subsequent inspections of supports which are integral with Reactor Coolant System components will be in accordance with Section XI of the ASME Code.

5.4.15 REACTOR COOLANT REDUCED INVENTORY OPERATIONS

There are limited periods during plant operation when the reactor coolant system may be operated with reduced inventory while irradiated fuel is in the reactor vessel. Examples include refueling outages or maintenance evolutions. A reduced inventory condition, which includes mid loop conditions, exists whenever the reactor coolant system level is lower than the 111 ft elevation, which is three feet below the vessel flange. This section describes the administrative controls and instrumentation relied upon during reduced inventory operations.

Generic Letter 88-17, Loss of Decay Heat Removal, was issued to address continuing problems that were occurring throughout the industry with respect to maintaining decay heat removal capability.

5.4.15.1 Generic Letter 88-17, Loss Of Decay Heat Removal

The following measures have been implemented to address the potential for the loss of decay heat removal when fuel is in the core and the head is located on the reactor vessel during RCS reduced inventory operations:

- At least two core exit thermocouples (CETs) are manintained except during the short period of time immediately following reactor head placement and prior to head removal. Shutdown cooling heat exchanger inlet temperature is credited for monitoring RCS temperatures during this period.
- An RCS hot side vent (e.g., pressurizer manway removal) is established to prevent core uncovery due to pressurization of

the hot leg side from any potential boiling of the core coolant. The vent is established prior to establishing cold leg RCS openings in excess of one square inch or blocking both hot legs with nozzle dams.

- At least two available means for adding inventory to the RCS are provided. The available paths ensure that makeup water will not bypass the reactor vessel (e.g., gravity feed from the RWT, HPSI, and/or charging).

- Administrative controls provide for timely containment closure should a loss of shutdown cooling occur.

In response to Generic Letter 88-17, and to address pump protection issues, a low flow alarm for the pumps used for shutdown cooling (i.e., LPSI and CS) provides visible and audible indication in the control room if flow decreases below the low flow set point during shutdown cooling operations. Administrative controls are also provided to preclude CS pump operation for normal operations when the RCS water level is at or below the top of the hot-leg (elevation 103’-1”) to protect against possible surface vortexing and consequential air entrainment into the CS pumps suction.

5.4.15.2 Refueling Water Level Indication System

A permanent refueling water level indication system (RWLIS) was installed in each of the units and is used to monitor RCS inventory. The installation of this system was a commitment from Generic Letter 88-17 and replaced reliance upon temporary level indication devices and related procedures.

This permanent system was designed as a non-safety grade system that would provide a high degree of reliability. This system is shown in engineering drawings 01, 02, 03-M—SIP-001, and -002 and is referred to as the refueling water level monitoring system.

The RWLIS provides continuous refueling water level indication for each reactor coolant system hot leg to the control room. The control room indications consists of narrow and wide range level indication for each hot leg and a common level recorder. The level signals are inputted into the plant computer for trending and into the plant annunciator system for control room alarms. The control room alarms provide visible and audible indication to the operator in the event of a low or low-low refueling water level condition.

In accordance with the recommendations of Generic Letter 88-17, the RWLIS provides an independent level monitoring channel for each reactor coolant system hot leg. Channel independence is maintained up to the common reference leg isolation valve and tap, and up to the control room alarm input selector switch. Channel independence is not maintained in the instrument reference legs due to the very low probability that this small section of tubing and associated valve would become plugged. Channel independence also is not maintained in the RCS low level alarm input circuitry to give the operator the flexibility to select the appropriate alarm inputs such that spurious or nuisance alarms may be reduced or eliminated, as described below.

The RWLIS is provided with flow compensation from the shutdown cooling system. This compensation is required due to the location of the RWLIS instrument taps on the shutdown cooling system and due to the effects of shutdown cooling flow. As the shutdown cooling system flow increases, the pressure at the RWLIS instrument taps decreases, which results in the indicated level being lower than the actual level. Each shutdown cooling loop provides flow information to the respective RWLIS channels. This information is used to modify the actual level signals such that accurate refueling water levels are indicated in the control room.

During periods of reduced inventory operation in the reactor coolant system, the RWLIS associated with the operating shutdown cooling loop may experience nuisance low and low-low level alarms. These alarms result from the reduced inventory in the reactor coolant system and the minor flow oscillations that occur in the shutdown cooling line as a result of the lowered inventory condition. In order to maximize control room operator awareness, a selector switch is provided in the main control room that will allow the operator to select the non-operating shutdown cooling loop RWLIS for control room alarm input. This action essentially removes all nuisance alarms and ensures that the operator will not be distracted from responding to an actual low or low-low refueling water level condition. Both channels of level indication, however, will still provide control room level indication regardless of this selector switch's position.

A rapid vent connection is provided upstream of the flow restricting orifice in the reactor head vent piping. This

connection increases the venting area for the system in order to minimize lags between RWLIS indication and level in the reactor vessel at reduced inventory conditions.

TABLE 5.4-42
REACTOR COOLANT PUMP PARAMETERS

Number of Units	4
Type	Vertical, single stage centrifugal

TABLE 5.4-43
SHUTDOWN COOLING DESIGN PARAMETERS (CESSAR TABLE 5.4.7-1)

System Design Parameters

Shutdown cooling system startup	Approximately 3.5 hours after reactor shutdown or trip
Reactor coolant system maximum cooldown rate (at initiation of shutdown cooling)	75°F/hr
Refueling water temperature	135°F
Nominal shutdown cooling flow	9000 gpm per HX

Component Design Parameters
Shutdown Cooling Heat Exchanger Data

Quantity	2
Type	Shell and tube, horizontal U-tube
Service transfer rate, Btu/hr-°F-ft^2	378.8
Heat Transfer area (ft^2/Hx)	7515
Tube Side	
Fluid	Reactor coolant
Design pressure, psig	650
Design temperature, °F	450
Material	Austenitic stainless steel
Code	ASME Section III, Class 2
Fouling resistance (hr-ft^2-°F/Btu)	0.00025
Shell Side	
Fluid	Component cooling water
Design pressure, psig	150
Design temperature °F	250
Material	Carbon Steel
Code	ASME Section III, Class 3
Fouling resistance (hr-ft^2-°F/Btu)	0.0005

At 27-1/2 hours after shutdown: (if containment spray pumps are used)

Tube Side	
Flow, million lb/hr.	4.44
Inlet temperature, °F	125.0
Outlet temperature, °F	115.1
Shell Side	
Flow, million lb/hr.	6.96
Inlet temperature, °F	105.0
Outlet temperature, °F	111.3
Heat load, million Btu/hr	43.8

TABLE 5.4-44
INTERFACE REQUIREMENTS FOR COMPONENT COOLING WATER
(CESSAR TABLE 5.4.7-2)

Mode	Shutdown Cooling (3.5 hrs.)	Shutdown Cooling (27.5 hrs)	Recirculation Following LOCA (Large Break)
Supply Temp °F (Max)(1)	120°	105°	120°
Outlet Temp °F	144.6°	114.5°	(Note 2)
Flow per SDCHX (gpm)(3)	11,000 min.	11,000 min.	11,000 min.
Total Heat Load (10^6 $\frac{Btu}{hr}$) For Both SDCHX	268	87.6	(Note 2)

NOTES: (1) For maximum supply temperatures lower than those listed, the minimum flow listed may be reduced provided that the heat removal capability of the Shutdown Cooling System is not adversely affected. Conversely, for Component Cooling Water supply temperatures lower than those listed, it may be necessary to reduce flow, so that the heat capacity of the ultimate heat sink is not exceeded.

(2) This outlet temperature and heat load are dependent upon the Applicant’s containment design and are a function of sump water temperature. For example, for shell side parameters of 11,000 gpm at 120°F, the heat load for a tube side temperature of 270° and flow rate of 3500 gpm is 164 x 10^6 Btu/hr per SDCHX. See Applicant’s SAR for details.

(3) Maximum allowable component cooling water flow through each shutdown cooling heat exchanger is 13,000 gpm.

APPENDIX 5A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

APPENDIX 5A

<u>QUESTION 5A.1</u> (NRC comment on subsection 5.2.4) (6/18/80) (5.2.4)

Only addresses accessibility of inspection areas.

RESPONSE: The response is given in amended subsection 5.2.4.

<u>QUESTION 5A.2</u> (NRC comment on paragraph 5.3.1.6) (6/18/80) (5.3.1.6)

Only addresses Unit 1 reactor vessel.

RESPONSE: The response is given in amended paragraph 5.3.1.6.

<u>QUESTION 5A.3</u> (NRC Question 410.6) (5.2.5)

Provide the following additional information concerning leakage from the reactor coolant pressure boundary:

a) Provide further detail of how the reactor drain tank (RDT) can be used to detect leakage of primary coolant to the shutdown cooling system as identified in FSAR paragraph 5.2.5.1.5.

b) Describe the means of detection of leakage of primary coolant from the CVCS, reactor coolant pump seals, and other radioactive fluid sources to normally nonradioactive systems such as the nuclear cooling water system.

c) Verify that the containment radioactive gas and air particulate monitor has a sensitivity for detecting a 1 gallon per minute RCPB leak in 1 hour in accordance with the guidelines of Regulatory Guide 1.45.

RESPONSE:

a) The response is given in amended paragraph 5.2.5.1.5.

b) The response is given in amended paragraph 5.2.5.1.5.

c) The response is given in Section 1.8, Regulatory Guide 1.45.

QUESTION 5A.4 (NRC Question 121.1)

Information supplied in FSAR Technical Specifications Section 16.3/4.4.5 concerning steam generator tube inspection is either incomplete or inadequate. In order to demonstrate compliance with NRC requirements, revise the following areas of this FSAR section to be consistent with NUREG-0212, Revision 1, "Standard Technical Specifications for Combustion Engineering Pressurized Water Reactors":

1. Change the wording with regard to the first tube samples in Section 4.4.5.2.b to be consistent with the corresponding section in NUREG-0212;

2. Change the wording with regard to the second and third tube samples in Section 4.4.5.2.c to be consistent with the corresponding section in NUREG-0212;

3. Include the additional requirements listed in NUREG-0212 regarding eddy current testing in Section 4.4.5.2.b.3;

4. Change the wording in Section 4.4.5.3.b to be consistent with the corresponding in NUREG-0212;
5. Include additional requirement listed in NUREG-0212 regarding preservice inspection in Section 4.4.5.4.a.9;
6. Include additional requirement listed in NUREG-0212 with regard to the reporting requirements in Sections 4.4.5.5.a, 4.4.5.5.b, 4.4.5.5.c.

RESPONSE: Refer to Technical Specifications for steam generator tube inspection requirements.

QUESTION 5A.5 (NRC Question 251.1) (5.2)

Specify the edition and addenda to which all reactor coolant pressure boundary components were fabricated.

RESPONSE: The response is provided in amended table 5.2-2.

QUESTION 5A.6 (NRC Question 251.2)

To demonstrate compliance with the beltline material test requirements of Paragraph III.C.2 of Appendix G, 10CFR Part 50:

a) Provide a schematic of the reactor vessel showing all welds, plates, and/or forgings in the beltline. Welds should be identified by shop control number, weld procedure qualification number, the heat of filler metal, and type and batch of flux. Provide the chemical composition for these welds (particularly Cu, P, and S content). Identify material specification, type, and grade of all base metal.

b) Provide dropweight NDT and complete CVN curves of energy and lateral expansion versus temperature for the weld metal(s) in the beltline.

c) Provide dropweight NDT and complete CVN curves of energy and lateral expansion versus temperature for the base metal in the beltline.

d) If beltline welds were fabricated using submerged arc or shielded metal arc electrode, the heat affected zones are considered acceptable and no additional data is required; otherwise fracture toughness data in accordance with Paragraph NB-2330 of the ASME Code must be provided.

e) Indicate the post-weld heat treatment used in the fabrication of the test welds.

f) Identify the plates used to fabricate the test welds.

g) Indicate whether the test specimen for the longitudinal seams were removed from excess material and welds in the vessel shell course following completion of the longitudinal weld joint.

RESPONSE:

a) A schematic of the reactor vessel beltline region showing weldseam numbers and plate code numbers is shown in figure 5.2-6.

Weld procedure qualification numbers and associated fracture toughness data from weld procedure

qualification tests for the reactor vessel are given in tables 5.2-10, 5.2-10A, and 5.2-10B.

Weld metal used in the fabrication of the reactor vessel beltline and its fracture toughness properties from weld metal certification tests is given in tables 5.2-9, 5.2-9A, and 5.2-9B.

Chemical composition of welds in the reactor vessel beltline is given in tables 5.3-2, 5.3-4, and 5.3-6.

Chemical composition of plates in the beltline is given in tables 5.3-1, 5.3-3, and 5.3-5.

b) Dropweight NDT and RT_{NDT} for weld metal used in the beltline of the reactor vessel are given in tables 5.2-9, 5.2-9A, and 5.2-9B.

Full CVN curves for the weld metals in the beltline are given in figure 5.2-1 (sheets 7 through 20).

c) Dropweight NDT and RT_{NDT} for the base metal used in the beltline of the reactor vessel are given in table 5.2-5.

Full CVN curves for the base metal in the reactor vessel beltline are given in figure 5.2-1 (sheets 1 through 6).

d) The response is given in amended paragraph 5.2.3.3.1.1.

e) The response is given in amended paragraph 5.2.3.3.1.1.

f) The response is given in amended paragraph 5.2.3.3.1.1.

g) The response is given in amended paragraph 5.2.3.3.1.1.

QUESTION 5A.7 (NRC Question 251.3)

To demonstrate compliance with the fracture toughness requirements of Paragraph IV.A.1 of Appendix G, 10CFR Part 50:

a) Provide the RT_{NDT} for all RCPB welds and ferritic base metals which may be limiting for operation of the reactor vessel. If the RT_{NDT} has been determined by methods other than that specified in Paragraph NB-2330 of the ASME Code, identify the method and provide technical justification.

b) Indicate whether there are any RCPB heat affected zones which require CVN impact testing per Paragraph NB-4335.7 of the ASME Code. Provide CVN impact test data for these heat affected zones which may be limiting for operation of the reactor vessel.

RESPONSE:

a) Limiting RT_{NDT} values for the RCPB base metals and weld metals which may be limiting for operation of the reactor vessel was provided along with the pressure temperature limit curves (NRC Question 251.6).

b) All base metal used in the fabrication of the reactor vessel are of P number 3 classification. The heat affected zone CVN impact test data obtained from weld procedure qualification tests (NB-4335.2) is given in tables 5.2-10, 5.2-10A, and 5.2-10B.

   The RT_{NDT} in the reactor vessel heat affected zone that may be limiting for operation of the reactor vessel was

provided along with the pressure temperature limit curves (NRC Question 251.6).

<u>QUESTION 5A.8</u> (NRC Question 251.4)

Demonstrate compliance with ASME Code, Paragraphs NB-2332 and NB-2333, on the following ferritic reactor coolant pressure boundary components: ferritic piping, pumps, valves, and bolts and fastening materials.

a) Provide the ASME Code and Addenda which the applicant utilized for fabrication of the above materials.

b) If the applicant's RCPB materials do not comply with the requirements of Section 50.55a, 10CFR Part 50, submit CVN impact data for each heat and lot of material.

RESPONSE:

a) The response is given in amended table 5.2-1.

b) The RCPB materials comply with the requirements of 10CFR50, Section 50.55a.

<u>QUESTION 5A.9</u> (NRC Question 251.5)

Provide data on the qualifications of the personnel performing the fracture toughness tests to demonstrate compliance with Paragraph III.B.4 of Appendix G, 10CFR Part 50.

RESPONSE: The response is given in amended paragraph 5.2.3.3.1.1.

<u>QUESTION 5A.10</u> (NRC Question 251.6)

Provide pressure-temperature limit curves for the reactor pressure vessel.

RESPONSE: Pressure-temperature limit curves are provided in the Pressure-Temperatures Limits Report in the TRM.

<u>QUESTION 5A.11</u> (NRC Question 251.7)

Provide the following data on the surveillance materials:

a) Origin of heat affected zone and base materials (heat number, plate identification number, and chemical composition),

b) Origin of weld metal (weld wire type, heat of filler metal, production welding process, plate material used to make weld specimens, chemical composition of deposited weld metal),

c) The lead factor of each surveillance capsule with respect vessel inner wall.

RESPONSE: The response is given in amended paragraph 5.3.1.6 and table 5.3-16.

<u>QUESTION 5A.12</u> (NRC Question 440.1) (5.2.2)

A description of the design features which will be used to mitigate the consequences of overpressurization events while operating at low temperatures is not provided in the CESSAR System 80 FSAR. Provide a description of the features which will be provided on the CESSAR System 80. Specific design criteria

regarding overpressurization protection while operating at low temperatures are as follows:

1. <u>Operator Action</u>: No credit can be taken for operator action for 10 minutes after the operator is aware of the transient.

2. <u>Single Failure</u>: The system must be designed to relieve the pressure transient given a single failure in addition to the failure that initiated the pressure transient.

3. <u>Testability</u>: The system must be testable on a periodic basis consistent with the system's employment.

4. <u>Seismic and IEEE 279 Criteria</u>: Ideally, the system should meet Seismic Category I and IEEE 279 criteria. The basic objective is that the system should not be vulnerable to a common failure that would both initiate a pressure transient and disable the overpressure mitigating system. Such events as loss of instrument air and loss of offsite power must be considered.

An alarm must be provided to monitor the position of the pressurizer relief valve isolation valves to assure that the over-pressure mitigating system is properly aligned for shutdown conditions.

In demonstrating that the mitigation system meets these criteria, the applicant should include the following information in his submittal:

1. Identify and justify the most limiting pressure transients caused by mass input and heat input.

2. Show that overpressure protection is provided (do not violate Appendix G limits) over the range of conditions applicable to shutdown/heatup operation.

3. Identify and justify that the equipment will meet pertinent parameters assumed in the analyses (e.g., valve opening times, signal delay, valve capacity).

4. Provide a description of the system including relevant P&I drawings.

5. Discuss how the system meets the criteria.

6. Discuss all administrative controls required to implement the protection system.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR responses to NRC questions.

QUESTION 5A.13 (NRC Question 440.2) (5.2.2)

Provide details of your proposed preoperational and initial startup test program to show that they are consistent with the requirements of Regulatory Guide 1.68.

RESPONSE: The response was provided on the CESSAR docket for those tests in the CESSAR scope. See CESSAR FSAR responses to NRC questions. For remaining tests not in CESSAR scope, the response is provided in sections 1.8 and 14B.11.

APPENDIX 5A

QUESTION 5A.14 (NRC Question 440.3) (5.2.2)

Check valves in the discharge side of the high-pressure safety injection, low-pressure safety injection, RHR, and charging systems perform an isolation function in that they protect low pressure systems from full reactor pressure. The staff will require that these check valves be classified ASME IWV-2000 Category AC, with the leaktesting for this class of valve being performed to code specifications. It should be noted that a testing program which simply draws a suction on the low-pressure side of the outermost check valves will not be acceptable. This only verifies that one of the series check valves is fulfilling an isolation function. The necessary frequency will be that specified in the ASME Code, except in cases where only one or two check valves separate high- to low-pressure systems. In these cases, leaktesting will be performed at each refueling after the valves have been exercised. Identify all check valves which should be classified Category AC as per the position discussed above. Verify that you have the necessary test lines to leak test each valve. Provide the leak detection criteria that will be in the Technical Specifications.

RESPONSE: The response was provided on the CESSAR docket for check valves classified Category AC, which are leaktested. See CESSAR FSAR responses to NRC questions. The PVNGS design differences from the CESSAR design modifies the list as follows:

Safety Injection (SI) Valves

SI V-215	SI V-522
SI V-217	SI V-523
SI V-225	SI V-532
SI V-227	SI V-533
SI V-235	SI V-540
SI V-237	SI V-541
SI V-245	SI V-542
SI V-247	SI V-543

Adequate test connections and lines, as shown in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003 have been provided to facilitate testing of the above-listed valves to ASME IWV-2000 Category AC requirements. The leak detection criteria of 1/2 gallon per minute per 1 inch of nominal valve diameter, not to exceed 5 gallons per minute, has been included in the Technical Specifications.

<u>QUESTION 5A.15</u> (NRC Question 440.4) (5A)

On page 5A-2, it is indicated that a negative Doppler coefficient of -0.8×10^{-5} $\Delta k/k/F$ is assumed in the bounding overpressure transient (loss of load). It is our position that overpressure protection of system be demonstrated without taken credit for either Doppler or moderator temperature reactivity feedback (SRP 5.2.2, Section III.6). Reanalyze the bounding overpressure transient without credit for Doppler feedback, demonstrating that

primary system pressure does not exceed 110% of the design pressure.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR responses to NRC questions.

<u>QUESTION 5A.16</u> (NRC Question 440.5) (5A)

On page 5A-1, it is indicated that the worst case transient, loss of load, in conjunction with a delayed reactor trip, is the design basis for the primary safety valves. It is our position that the high-pressure reactor trip or second safety grade trip signal, whichever occurs later, should be used for sizing the primary system safety valves. Confirm that the CESSAR System 80 safety valves are sized sufficiently to accommodate a reactor trip on the second safety grade trip signal.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR responses to NRC questions.

<u>QUESTION 5A.17</u> (NRC Question 440.6) (5.4.7)

Palo Verde must have the capability to take the plant from full power to a cold shutdown using only safety grade equipment, per the requirements of BTP RSB 5-1. Address your compliance with all provisions of that position and respond to the detailed question below.

Question 1. Describe the sequence for achieving a cold shutdown condition within 36 hours, assuming the most limiting single failure with only onsite power availability. Identify all manual actions inside

or outside containment that must be performed and discuss the capability of remaining at hot standby until manual actions (or repairs) can be performed.

1a. If the steam generator dump valves, operators, air and power supplies are not safety grade, justify how you would cool down the primary system in the event of loss of offsite power and an SSE.

1b. Describe the sequence for depressurizing the primary system using only safety grade systems, assuming a single failure. Identify all manual actions inside or outside containment that must be performed.

1c. Discuss the boration capability using only safety grade systems, assuming a single failure. Identify all manual actions inside or outside containment that must be performed. If the proposed boration method utilizes the charging pumps (assuming a letdown line failure is proposed), provide an evaluation of this approach with regard to concentration of boron source and liquid volume in primary system.

Question 2. Discuss the provisions for collection and containment of RHR pressure relief valves discharge.

Question 3. Describe tests which will demonstrate adequate mixing of the added borated water and cooldown under natural circulation conditions with and without a single

failure of a steam generator atmospheric dump valve. Specific procedures for plant cooldown under natural circulation conditions must be available to the operator. Summarize these procedures.

Question 4. Discuss the availability of the Seismic Category I auxiliary feedwater supply for at least 4 hours at hot shutdown plus cooldown to the RHR system cut-in based on longest time for the availability of only onsite or only offsite power and assuming a single failure. If this cannot be achieved, discuss the availability of an adequate alternate Seismic Category I water source.

Question 5. What provisions in natural circulation cooldown methods have been made to account for possible upper head void formation?

RESPONSE: The response will be provided on the CESSAR docket. Additional clarification is provided as follows:

1a. PVNGS provides, as a backup to the instrument air system, safety grade nitrogen accumulators to operate the steam generator atmospheric dump valves (ADVs). The remaining response is given in amended paragraph 10.3.2.2.4.

1b. The response is given in amended subsection 5.4.7 and paragraph 6.3.1.3. There is no single failure which could result in the opening of all SIT isolation valves or could preclude RCS depressurization.

1c. The response is given in amended paragraph 9.3.4.1.

2. Residual heat removal pressure relief discharge piping is provided with a sparger that is located at the bottom of the containment emergency sump. On that basis, no direct steam flow would be directed toward any personnel.

3. Cooldown under natural circulation conditions was analytically modeled and positively confirmed following two events at an operating C-E reactorplant. St. Lucie Unit 1 (Docket No. 50-335) performed two natural circulation cooldowns following a reactor trip from full power conditions in 1977 and in 1980. Natural circulation for System 80 was conducted as part of power ascension testing. Testing was also conducted to verify adequate boron mixing under natural circulation conditions and the ability to perform a natural circulation cooldown and a plant depressurization to shutdown cooling initiation conditions.[a]

a. Letter from E. E. Van Brunt, Jr., APS, to G. W. Knighton, NRC, dated January 31, 1985, (ANPP-31829), provided a description of the PVNGS Natural Circulation Test Program.

4. The CST tank is designed to provide sufficient auxiliary feedwater supply for 4 hours at hot standby plus 6.5 hours of operation to reach cold shutdown under natural circulation conditions[a].

   Refer to subsection 9.2.6 for a discussion on single failure analysis.

   PVNGS meets C-E's interface requirements for a water volume as described in subsection 9.2.6. Other non-Seismic Category I supplies are also provided:

   - A 550,000-gallon reactor makeup water tank at each unit which can be manually aligned to provide water to the auxiliary feedwater system.

   - Refer to subsection 9.2.3 for a discussion on the demineralized water system.

---

a. Letter 102-03578-WLS/AKK/GAM, Dated January 5, 1996, to the NRC, provided a revised Report on Natural Circulation Cooldown for the Palo Verde increase in Licensed Reactor Power to 3876 MWt. This report verifies the CST design is adequate.

   The adequacy of the CST design (volume of condensate required and duration required) with respect to compliance with the requirements of Branch Technical Position RSB 5-1 are currently docketed in Amendments 108 (NPF-41), 100 (NPF-51) and 80 (NPF-74) for plant changes implemented under the power uprate project. The values for the volume of condensate required and duration of use of the CST for power uprate remain bounded by the natural circulation cooldown testing and reconciliation analyses performed under the submittal of PVNGS' report to demonstrate compliance with the testing requirements of Branch Technical Position RSB 5-1 (ANPP-40069-JGH/BJA/98.05; Letter from J. G. Haynes, PVNGS to G. W. Knighton, NRC, dated February 9,1987).

5. Specific natural circulation and natural circulation cooldown operator guidelines have been prepared by C-E for the C-E Owner's Group. These guidelines were transmitted in CEN-152 to the NRC for review (June 1981). These guidelines provide instruction to avoid void formation in the reactor vessel upper head that could occur during natural circulation conditions. Also included are instructions that deal with the symptoms and followup actions for a condensable reactor vessel void if one should occur.

QUESTION 5A.18 (NRC Question 440.7) (5.4.7)

Provide detailed information on the sizing criteria used to determine the relief capacity of the SDCS suction line pressure relief valves.

Did the version of the ASME Code that the SDCS relief valves were sized to require establishing liquid or two-phase relief capacity with testing? If so, describe in detail the test program and results. If the liquid or two-phase relief capacity was not established by test, show that the difference between the rated and maximum required relief capacity is more than sufficient to bound liquid and two-phase relief rate uncertainties.

Provide details on the alarms and indications which would inform the operators that a SDC suction line isolation valve has closed while the plant is in shutdown cooling. Is there any common failure which would result in both valves being closed while in shutdown cooling.

When LPSI pump miniflow isolation valves are closed during shutdown cooling, what would prevent pump damage if a pressure transient were to occur which caused RCS pressure to exceed LPSI deadhead pressure.

When the plant is in the SDCS mode, is there any single failure which could cause the suction of both SDC pumps to be switched from the hot leg piping to the dry sumps?

RESPONSE: Detailed information on relief valve sizing criteria and ASME Code requirements will be provided on the CESSAR docket.

A discussion of alarms and indications which would inform the operators that a SDC suction line isolation valve has closed will be provided on the CESSAR docket.

Refer to subsection 5.4.7 for a discussion on interlocks and control room indication.

<u>QUESTION 5A.19</u> (NRC Question 440.8) (5.4.7)

Provide the following information related to pipe breaks or leaks in high or moderate energy lines outside containment associated with the RHR system when the plant is in a shutdown cooling mode:

1. Determine the maximum discharge rate from a pipe break in the systems outside containment used to maintain core cooling.

2. Determine the time available for recovery based on these discharge rates and their effect on core cooling.

3. Describe the alarms available to alert the operator to the event, the recovery procedures to be utilized by the operator, and the time available for operator action.

A single failure criterion consistent with Standard Review Plan 3.6.1 and Branch Technical Position APCSB 3-1 should be applied in the evaluation of the recovery procedures utilized.

RESPONSE: The response is given in amended paragraph 5.4.7.2(c).

QUESTION 5A.20 (NRC Question 440.9) (5.4.7)

Indicate whether there are any systems or components needed for shutdown cooling which are deenergized or have power locked out during plant operation. If so, indicate what actions have to be taken to restore operability to the components or systems.

It is the staff's position that all operator actions necessary to take the plant from normal operation to SDCS entry should be performed from the control room. If the present design does not meet this position, please commit to revise it accordingly.

RESPONSE: The response is given in amended subsection 5.4.7. Additional information is provided on the CESSAR docket.

QUESTION 5A.21 (NRC Question 440.10) (5.4.7)

Provide additional information regarding the power sources supplied to the SDCS isolation valves. The staff's position is that a single failure of a power supply will not prevent isolation of the SDCS when RCS pressure exceeds its design pressure. Additionally, loss of a single power supply cannot

result in the inability to initiate at least one 100% shutdown cooling train.

RESPONSE: The response is given in amended paragraph 5.4.7.2(c). Additional response is provided on the CESSAR docket.

QUESTION 5A.22 (NRC Question 440.83) (18.II.B.1)

Your response to Item II.B.1 of NUREG-0737 requirements is not sufficient. Provide the following:

1. Provide diagrams and description of the vent discharge vicinity. Verify that adequate ventilation is provided and that equipment in this area is capable of withstanding discharge of gases and liquids from the vents.

2. What size are the flow limiting orifices and what are the calculated flow rates through the vent system for both gas mixtures and liquids at operating pressures?

3. Provide drawings of the piping system from the vessel head and pressurizer through the discharge paths. In particular, show the location of the solenoid-operated valves and consider potential missile hazards from them.

RESPONSE: Refer to the revised response to NUREG-0737, Item II.B.1, provided in subsection 18.II.B.1.

QUESTION 5A.23 (NRC Question 440.87) (5.4.1 and 9.2.2)

If the RCP tests demonstrate that the RCPs are not able to operate with loss of component cooling water supply for longer than 30 minutes without loss of function and the need for

operator protective action, safety grade instrumentation to detect the loss of component cooling water to the RCPs and to alarm the operator in the control room should be provided.

The entire instrumentation system, including audible and visual status indicators for loss of component cooling water should meet the requirements of IEEE Std. 279-1971/1974. The above requirements should be specified in the applicable section (e.g., Section 5.4.1 or 9.2.2) of CESSAR System 80 FSAR as interface requirements.

RESPONSE: The response was provided in the CESSAR response to NRC Question 440.82 on the CESSAR docket. Refer to paragraph 9.2.2.2.8 for a discussion on NCWS instrumentation, and section 7.6 for a discussion on annunciators and how they meet the requirements of IEEE Standard 279-1971.

APPENDIX 5B

OVERPRESSURE PROTECTION FOR COMBUSTION ENGINEERING SYSTEM 80 - PRESSURIZED WATER REACTORS

APPENDIX 5B

OVERPRESSURE PROTECTION FOR COMBUSTION ENGINEERING SYSTEM 80 - PRESSURIZED WATER REACTORS

ABSTRACT

This Appendix documents the adequacy of overpressure protection provided for Combustion Engineering's (C-E's) System 80 pressurized water reactor, steam generators, and Reactor Coolant System.

Overpressurization of the Reactor Coolant System and steam generators is precluded by means of primary safety valves, secondary safety valves and the Reactor Protective System. Pressure relief capacity for the steam generators and Reactor Coolant System is conservatively sized to satisfy the overpressure requirements of the ASME Boiler and Pressure Vessel Code, Section III. The safety valves in conjunction with the Reactor Protective System, are designed to provide overpressure protection for a loss-of-load incident with a delayed reactor trip.

The loss of load transient used to size the primary safety valves is not intended to be used as a design transient for any other NSSS equipment.

APPENDIX 5B

OVERPRESSURE PROTECTION FOR COMBUSTION ENGINEERING SYSTEM 80 - PRESSURIZED WATER REACTORS

LIST OF FIGURES

APPENDIX 5B

1.0 INTRODUCTION

Overpressure protection for C-E's System 80 pressurized water reactor, steam generators, and Reactor Coolant System is in accordance with the requirements set forth in the ASME Boiler and Pressure Vessel Code, Section III. Overpressure protection is considered by means of primary safety valves, secondary safety valves, and the Reactor Protective System. Analysis of all reactor and steam plant transients causing pressure excursions is conducted. The worst case transient, loss-of-load, in conjunction with a delayed reactor trip, is the design basis for the primary safety valves. The primary safety valves, secondary safety valves, and Reactor Protective System maintain the Reactor Coolant System below 110% of design pressure during worst case transients. The secondary safety valves are sized conservatively to pass steam flow at greater than the proposed licensed power level of 3817 Mwt. Steam generator pressure is limited to less than 110% of steam generator design pressure during worst case transients.

2.0 ANALYSIS

2.1 METHOD

C-E has performed a parametric study to determine the design basis incident for sizing the primary safety valves. The design basis incident is a loss-of-load with a delayed reactor trip. The analysis is performed using digital computer codes which accurately model the thermal, hydraulic, and nuclear performances of the Reactor Coolant and Steam Systems. The digital codes used in the transient analysis include reactor

kinetics, thermal and hydraulic performance of the Reactor Coolant System, and the thermal and hydraulic performance of the steam generators. The computer simulation includes effects of reactor coolant pump performance, elevation heads, inertia of surge line water and friction drop in the surge line. Worst case initial conditions and nuclear parameters are assumed for the parametric analysis. The reactor is assumed to trip at a RCS pressure of 2450 psia, while the primary safety valves are assumed to lift at a pressure of 2525 psia, which is 25 psi above the system design pressure. During the analysis, the throat area associated with these valves is increased parametrically until the above design basis incident analysis indicates that a further increase in throat area will not result in a significant decrease in RCS peak pressure. The performance of the digital codes employed in the analysis have been verified by transient data from operating plants.

2.2 ASSUMPTIONS

a. At the onset of the loss-of-load transient, the Reactor Coolant and Main Steam Systems are at maximum rated output plus a two percent uncertainty. By choosing the highest possible power output, the heatup rate of the primary loop is maximized, hence the rate of pressurization is also maximized.

b. Moderator temperature coefficient is zero. Analytical studies supported by core data show that the moderator temperature coefficient can vary between zero and -3.5×10^{-4} for various phases of core life.

Therefore, a coefficient of zero is chosen to maximize the power/pressure transient.

c. Doppler coefficient of $-.8 \times 10^{-5}$ $\Delta K/K/F$ is used in the loss-of-load analysis. Actual operating coefficients can be expected to range from -1.4×10^{-5} at zero power to $-1. \times 10^{-5}$ $\Delta K/K?F$ at full power. By choosing a relatively small Doppler coefficient, the reduction in reactivity with increasing fuel temperature is minimized, thereby maximizing the rate of power rise.

d. No credit is taken for letdown, charging, pressurizer spray, turbine bypass, or feedwater addition after turbine trip in the loss-of-load analysis. Letdown and pressurizer spray both act to reduce primary pressure. By not taking credit for these systems, the rate of pressurization is increased. By not taking credit for the addition of feedwater, the steam generator secondary inventory will be depleted at a faster rate. This in turn reduces the capability of the steam generator to remove heat from the primary loop, thereby maximizing the rate of primary pressurization.

e. The analysis reflects consideration of plant instrumentation error and safety valve setpoint errors. For example, all safety valves are assumed to open at their maximum popping pressure. This extends the period of time before energy can be removed from the system. The reactor trip setpoint errors are

always assumed to act in such a manner that they delay reactor trip, again resulting in maximum pressurization.

f. Pressurizer pressure at the onset of the incident is 2200 psi. By using the lower limit of the normal plant operating pressure, the time required to trip the plant on high pressure is increased.

2.2.1 SECONDARY SAFETY VALVE SIZING

The discharge piping serving the secondary safety valves is designed to accommodate rated relief capacity without imposing unacceptable backpressure on the safety valves.

The secondary safety valves are conservatively sized to pass excess steam flow. This limits steam generator pressure to less than 110% of steam generator design pressure during worst case transients. A plant's secondary safety valves consist of three banks of valves with staggered set pressures. The valves are spring loaded type safety valves procured in accordance with ASME Boiler and Pressure Vessel Code, Section III.

Figure 5B-2 depicts the steam generator pressure transient for this worst case loss-of-load incident. As can be seen in Figure 5B-2, the steam generator pressure remains below 110 percent of design pressure during the incident.

2.2.2 PRIMARY SAFETY VALVE SIZING

The reactor drain tank, inlet and discharge piping are sized to preclude unacceptable pressure drops and backpressure which would adversely affect valve operation.

Primary safety valve backpressure is limited by the design pressure of the valve bellows. These bellows prevent any accumulated backpressure from being imposed on the valve spring, thus allowing valve operation at its design setpoint rather than at its setpoint plus backpressure.

The design basis incident for sizing the primary safety valves is a loss of turbine-generator load in which the reactor is not immediately tripped. No credit is taken for any pressure-reducing devices except the primary and secondary safety valves. In reality, the incident would be terminated by a number of reactor trips. These include:

a. Steam generator low level trip;

b. High pressurizer pressure trip;

c. Manual trip.

If the high primary pressure trip were to become inoperative, other reactor trips would proceed to shut the reactor down as their setpoints are exceeded.

A series of loss-of-load studies are run with various sizes of primary safety valves. As can be seen in Figure 5B-1, after the safety valve capacity increases to a certain size, additional increase in capacity has negligible effect in reducing the maximum system pressure experiences during the loss-of-load transient. C-E's primary safety valves are chosen so as to minimize the maximum pressure experienced during the loss-of-load transient. The minimum specified safety valve capacity is identified on Figure 5B-1.

Figures 5B-2, 5B-3 and 5B-4 present curves of steam generator pressure, maximum Reactor Coolant System pressure and core power versus time for the worst case loss of turbine-generator load. As can be seen on Figures 5B-2 and 5B-3, the maximum steam generator pressure and reactor coolant loop pressures remain below 110% of design during this worst case transient.

The first, second, and third banks of secondary safety valves open at approximately 3.7, 5, and 6.2 seconds, respectively. The secondary safety valves remove energy from the Reactor Coolant System and thus mitigate the pressure surge. The primary safety valves are conservatively assumed to open at 1 percent above the normal Reactor Coolant System design pressure 5.7 seconds after the initiation of the upset condition.

The analysis of a complete loss of load incident is described in Chapter 15, Section 15.2. As demonstrated in this analysis, if a complete loss of load occurs without a simultaneous reactor trip, the protection provided by the high pressurizer pressure trip, primary safety valves and secondary safety valves is sufficient to assure that the integrity of the RCS and main steam system is maintained and that the minimum DNB ratio is not less than the SAFDL.

2.2.3 ACCEPTABILITY OF SAFETY VALVE BLOWDOWN

2.2.3.1 Background

Full scale, full pressure prototypical testing of pressurizer safety valves was performed by EPRI in 1981.[1] The blowdown settings required to insure stable valve operation during the blowdown from the set pressure were above the 5% setting

specified in the ASME Code. In order to insure that the extended blowdown would not adversely affect overpressure protection or plant operation, analyses were performed to evaluate the NSSS response. The analyses described below demonstrate that a blowdown setting, including associated uncertainties, of 14.0% is acceptable.

2.2.3.2 Results of Evaluation

An extended blowdown of the safety valves could result in swelling of the pressurizer liquid level due to flashing and possible liquid carryover through the safety valves. Since the safety valve design specification specifies dry saturated steam flow conditions, it is desirable to show that these conditions are maintained during the extended blowdown. It is also desirable to verify that the RCS remains in a subcooled condition in order that the steam bubble formation in the RCS is precluded.

A computer analysis was performed of the Loss-of-load event with delayed reactor trip, similar to that used in safety valve sizing, except that a conservative 20% safety valve blowdown and initial conditions biased to maximize pressurizer liquid level were assumed. The purpose of this analysis was to determine the pressurizer liquid level response and the RCS subcooling under these conservative conditions. For additional conservatism, an additive adjustment was made to the computer-calculated pressurizer levels on the basis of a very conservative pressurizer model. This model assumed that the initial saturated pressurizer liquid did not mix with the cooler insurge liquid, that the initial liquid remained in the

equilibrium with the pressurizer steam space, and that the steam which flashed during blowdown remained dispersed in the liquid phase and caused the liquid level to swell. The adjusted pressurizer water level vs time curve showed a maximum of 98%(2) (1730 ft^3), below the safety valve nozzle elevation of 100%, so that dry saturated steam flow to the safety valves is assured throughout the blowdown. The computer analysis also showed that adequate subcooling was maintained in the RCS during the blowdown, so that steam bubble formation is precluded.

(1) CEN-227, "Summary Report on the Operability or Pressurizer Safety Relief Valves in C-E Designed Plants", December 1982.

(2) Water level expressed as the percentage of the distance from the lower level nozzle to the upper level nozzle.

In addition, the System 80 safety analyses of pressurization events were re-evaluated to determine the impact of assuming an 18.5% blowdown below the original nominal set pressure of 2500 psia for the pressurizer safety valves in lieu of the 5% specified by the ASME Code. The evaluation indicated that, for the FWLB event analysis, which produces the greatest increase in pressurizer level, the increased blowdown would not result in the pressurizer liquid level reaching the safety valve nozzle elevation and thus normal safety valve operation would be assured. Further, subcooling in the RCS wars maintained during the blowdown.

Since the performance of CEN-227 and PSV setpoint tolerance changes, PVNGS changed some plant operating conditions (i.e.,

10°F reduction in the core inlet temperature, and 2% increase in nominal power level to 3876 MWt combined with 2°F additional reduction in the core inlet temperature) which affected the initial conditions used in the CEN-227 analysis. Increased initial power level and lower RCS temperature result in larger swelling of the RCS during a heatup transient. Therefore, an analysis was performed by PVNGS using a blowdown of 14% below the minimum PSV set pressure of 2450 psia (2475 psia - 1% tolerance) and initial conditions set to maximize the pressurizer liquid level. The analysis demonstrates that, for the limiting transient (LFWLB with LOP), the maximum pressurizer liquid level for PVNGS unit's remains below the PSV nozzles and subcooling is maintained during the period when the PSVs are open.

Power has been increased by an additional 3% (3990 MWt) with installation of replacement steam generators. This configuration also affects the initial conditions used in CEN-227. Accordingly, an analysis was also performed with a 14% blowdown and bounding initial conditions given a core power of 3990 MWt with replacement steam generators. This analysis also confirms that, for the limiting transient (LFWLB with LOP and single failure), the maximum pressurizer liquid level for PVNGS units remains below the PSV nozzles and subcooling is maintained during the period when the PSV's are open.

In summary, analyses show that adequate plant overpressure protection and RCS subcooling are ensured during a blowdown of 14.0% below the minimum pressurizer safety valve set pressure.

3.0 CONCLUSIONS

C-E's System 80 pressurized water reactor, steam generators, and Reactor Coolant System are protected from overpressurization in accordance with the guidelines set forth in the ASME Boiler and Pressure Vessel Code, Section III. Peak Reactor Coolant System and Secondary System pressures are limited to 110% of design pressures during worst case loss of turbine-generator load. Overpressure protection is afforded by primary safety valves, secondary safety valves, and the Reactor Protective System.

APPENDIX 5C

NATURAL CIRCULATION COOLDOWN ANALYSIS

APPENDIX 5C

NATURAL CIRCULATION COOLDOWN ANALYSIS

TABLE OF CONTENTS

APPENDIX 5C

1.0 INTRODUCTION

In the PVNGS System 80 design, residual heat removal is provided by the Shutdown Cooling (SDC) System. As described in UFSAR 5.4.7, the SDC system is typically placed in service when reactor coolant temperature is below 350°F and pressurizer pressure is less than 410 psia. Since shutdown cooling cannot be initiated with the unit in Hot Standby, additional systems are required to cool and depressurize the primary system down to shutdown cooling entry conditions.

Per the NRC Standard Review Plan, systems used to take the reactor from normal operating temperature and pressure down to cold shutdown conditions are expected to meet the requirements of Branch Technical Position (BTP) Reactor System Branch (RSB) 5-1. The functional requirements of BTP RSB 5-1 ensure that the cooldown can be accomplished within a reasonable time after reactor shutdown using only safety-grade systems that satisfy General Design Criteria 1 through 5. Following reactor trip, the plant must have the capability to maintain Hot Standby conditions for at least 4 hours prior to commencement of the cooldown. The credited systems must function using either onsite electrical power system operation (assuming offsite power is not available) or offsite electrical power system operation (assuming onsite power is not available) and assuming a single failure. Systems must be capable of remote operation from the control room although limited operator action outside of the control room is acceptable to mitigate the effects of postulated single failures.

Since the PVNGS design was complete and the construction permit was docketed before the original issue of BTP RSB 5-1, partial implementation of the functional requirements was permitted for PVNGS as a "Class 2" plant. Exceptions were taken for portions of the Chemical and Volume Control System (CVCS), which constitutes the primary method for reactivity control, reactor coolant makeup, and RCS pressure control during the cooldown to SDC entry conditions. The CVCS did not fully meet BTP RSB 5-1 criteria because (1) two of the three credited gravity-fed boration pathways cannot be aligned from the control room, (2) not all required components were safety grade, (3) the system was not tolerant of all credible faults, and (4) more than "limited" action outside the control room is needed to recover from some postulated failures.

To achieve an acceptable level of reliability, PVNGS committed to a number of engineering and administrative controls, which are described in UFSAR 9.3.4.4.5. In addition, supplemental engineering analysis was performed to demonstrate that the safety-grade High Pressure Safety Injection (HPSI) and the Reactor Coolant Gas Vent System (RCGVS) provided a diverse and redundant method for taking the unit from Hot Standby to SDC entry conditions. In March 1999, the NRC accepted the PVNGS design with respect to natural circulation cooldown based in part on probabilistic risk assessment submitted by PVNGS to show that the safety benefits afforded by further modification of the CVCS were not commensurate with their costs.

The capability of the CVCS for supporting a natural circulation cooldown was demonstrated by an in-plant test conducted in January 1986. Although the HPSI/RCGVS method has been

demonstrated analytically, the method has not been verified by field test at PVNGS. Therefore, the HPSI/RCGVS method has only been approved as a backup means of RCS cooldown and depressurization. Neither the CVCS nor the HPSI/RCGVS methods individually can satisfy the BTP RSB 5-1 requirements fully.

2.0 METHODS

Specific requirements for the method of analysis are not contained in BTP RSB 5-1. Although a natural circulation cooldown may occur during the recovery and long term plant stabilization after accidents analyzed in UFSAR Chapter 15, natural circulation cooldown is not required to mitigate the transients themselves. Consequently, NRC has accepted conservative analysis in lieu of the bounding type safety analysis conventionally employed to evaluate Chapter 15 events.

The natural circulation cooldown analysis has been performed using computer codes that have been previously reviewed and approved by NRC for the purposes of licensing activities. The codes are maintained and used in accordance with a software quality assurance program that meets the requirements of 10 CFR 50 Appendix B. Use of computer codes is consistent with their intended scope as well as any limitations specified in the accompanying safety evaluation reports.

Given the licensing position of PVNGS as a Class 2 plant with respect to BTP RSB 5-1, the natural circulation cooldown analysis involves three parts:

1. Cooldown from Hot Standby to SDC entry conditions with CVCS

2. Cooldown from Hot Standby to SDC entry conditions using HPSI/RCGVS

3. Cooldown from SDC entry to Cold Shutdown using the SDC system

The cooldown to SDC entry was analyzed with a "full scope" NSSS simulation code capable of accurately modeling the principal dynamics of the primary system performance:

- Reactor coolant heat removal using main steam safety relief valves (initially) and atmospheric dump valves to steam the steam generators
- Reactor coolant heat removal and steam generator inventory recovery using auxiliary feedwater pumps taking suction from the condensate storage tank
- Core cooling flow rate established by thermal driving head (difference in hot and cold leg temperatures)
- Variation in pressurizer level due to coolant temperature change, mass addition by charging or high pressure injection, and coolant losses by leakage and controlled bleed-off
- Pressurizer pressure response to level changes and operation of auxiliary spray or head vents
- Steam bubble formation, expansion, and contraction in the reactor vessel upper head

The cooldown to mode 5 entry conditions was analyzed using a code capable of modeling the heat transfer capability of the shutdown cooling heat exchanger. The overall heat exchanger

performance is determined with a standard analysis technique such as Log Mean Temperature Difference (LMTD) or the Number of Transfer Units (NTU) methods. The temperature of Essential Cooling Water (EW) on the shell inlet may be treated as a boundary condition provided the values are conservative with respect to the anticipated plant conditions. The temperature of the reactor coolant system is time-dependent and varies principally as a function of thermal input from core decay heat, heat removal by the shutdown cooling heat exchanger, and the heat capacity of the reactor coolant and primary system metal.

Use of nominal input data instead of worst-case values has historically been accepted as long as the overall plant performance is not overestimated. Given the conservatism of the design scenario itself, application of instrument uncertainty has not been required, nor has parametric study to determine the worst combination of initial conditions been required to demonstrate compliance.

3.0 INPUT AND ASSUMPTIONS

The natural circulation cooldown analysis has been performed for reactor power of 3990 MWt and reactor coolant volume of approximately 14,250 ft^3 (assumes nominal pressurizer level at full power). These parameters bound the limiting reactor plant design.

The anticipated response of plant systems is consistent with a loss of offsite electrical power followed by a failure of one emergency diesel generator (DG) to start and load one vital

4160 VAC bus. Unless otherwise specified, the loss of the DG is taken as the postulated single failure. Except as described below, only safety grade equipment is assumed to function during the cooldown. Per BTP RSB 5-1, cooldown may not commence until 4 hours after reactor trip to allow operators time to prepare for cooldown.

Analysis indicates that local loss of subcooling in the reactor vessel upper head during cooldown and de-pressurization will result in formation of a steam bubble there. In both the CVCS and HPSI cases, operation of the reactor head vents is expected to restrict the steam bubble size so that natural circulation flow is not impeded.

The initial cooldown ends when the shutdown cooling system has been placed in service. Manual alignment of shutdown cooling requires approximately 1 hour to accomplish once entry conditions are established.

All assumed operator actions described in this appendix, including contingencies, are supported by station procedures and operator training. The response times include reasonable delays for communication, preparation, transit, and device manipulation. Consistent with the requirements of BTP RSB 5-1, operator actions outside the control are considered "limited" in extent.

3.1 Cooldown with CVCS

At the start of the event, the minimum number of charging pumps required by the Technical Requirements Manual are operating. Following a loss of offsite power and failure of one emergency

diesel generator, only one charging pump is available to perform the cooldown.

Once the vital 4160 VAC buses are de-energized, the charging pump breakers are "anti-pumped" and must be manually reset and restarted from the control room. Therefore, no charging flow is assumed for 30 minutes after the time of trip to allow for resetting the breaker and performing manual alignment of one of three gravity-fed boration pathways to the charging pump suction. When operating, the charging pump delivers a nominal flow of 42 gpm.

The Technical Requirements Manual requires that only two of three boration flowpaths be available. In the event that the gravity feed path from the RWT bottom is nonfunctional, the useful borated water inventory located above the high suction nozzle must provide sufficient reactor coolant makeup during the cooldown. The useful water volume is based on the minimum required by the Technical Requirements Manual and does not include that located below the level where vortexing could entrain air to the charging pump suction.

The loss of offsite power results in a loss of non-class instrument and control power. In addition, the instrument air system is also lost because the compressors are powered from a non-class power supply, and neither instrument air nor its nitrogen backup are safety grade equipment. With no instrument air, the charging backpressure control valve fails closed, and the main RCS return flow is diverted through spring-loaded check valve CH-435. The loss of instrument air also causes the reactor coolant pump seal injection flow control valves to fail

open. In the analysis, the assumed auxiliary spray flow from one valve is consistent with these postulated hydraulic conditions.

The net makeup to the reactor coolant system is the total charging pump discharge flow minus losses to RCP controlled bleed-off (CBO) and RCS leakage. Due to loss of offsite power, the individual CBO isolation valves, which are non-class and motor-operated, fail "as-is" in the open position. Although the containment isolation valves on the CBO header will close due either to the loss of instrument air or by operator action, CH-507 fails in the open position. Thus, CBO flow will continue via relief valve CH-199 to the reactor drain tank (RDT) and cannot be terminated without containment entry for local operation of isolation valves. Although this operation is possible, the analysis assumes that CBO losses persist for the duration of the cooldown with the magnitude decreasing as a function of reactor coolant pressure. Based on historical data, nominal reactor coolant leakage of 1 gpm at normal operating pressure and temperature may also be assumed during the cooldown.

3.2 Cooldown with HPSI

The credited HPSI discharge flow rate is consistent with the pump curves for minimum design flow specified in UFSAR section 6.3. Since the flow instruments on the cold leg injection lines contain square root extractors that do not register flow below approximately 75 gpm, this value may be used as a minimum flow.

The mass flow rate of steam out of the pressurizer vent is determined considering the limiting flow path, the A train line containing the 7/32"x1" flow orifice. Estimates of mass flow are based correlations that are consistent with prevailing thermodynamic conditions of the steam in the pressurizer.

Use of auxiliary feedwater and ADVs for RCS heat removal are the same as for cooldown using CVCS. This is also the case for assumptions regarding inventory losses through RCP controlled bleed-off flow and coolant leakage. In addition, other operator actions such as control of voids in the reactor vessel upper head and alignment of SDC will also be the same.

However, without charging flow, there is no auxiliary spray or seal injection flow. Since HPSI takes suction from the bottom of the RWT, the available coolant makeup is not limited to the upper portion of the tank.

3.3 Cooldown with SDCHX

The last portion of the analysis consists of shutdown cooling operation to reach cold shutdown. The essential cooling water (EW) temperature entering the SDCHX is consistent with the essential cooling and spray pond system thermal performance analysis, which is conservative for the expected conditions during natural circulation. After the loss of offsite power, EW must carry heat loads from spent fuel pool cooling heat exchangers, the diesel generators, and the essential chillers. Since the limiting single failure in the analysis is the loss of one emergency diesel generator, only one train of essential cooling water and associated spray pond may be assumed to be in operation. Design values for spray pond temperature and

essential cooling water pump flow rate have historically been used.

The heat transfer coefficient for the SDCHX includes mechanical effects of fouling and tube plugging and is conservative with respect to the expected fluid temperatures and flow rates.

During the cooldown, makeup for contraction and system losses is normally provided by the boration systems in CVCS. With nominal assumptions, there is sufficient inventory above the high suction nozzle to support the cooldown all the way to mode 5. If this inventory is depleted, charging suction can be aligned via CH-327 from the bottom of the RWT. If the CH-327 pathway is not functional, then, as described in the emergency operating procedures, HPSI, which also takes suction from the bottom of the RWT, may be used for inventory control.

3.4 Operator Action Outside the Control Room

In accordance with the provisions of BTP RSB 5-1, NRC has accepted "limited" operator action outside of the control room to mitigate the consequences of postulated single active failures, considering that only onsite or offsite power is available. The Failure Modes and Effects Analysis for CVCS is contained in UFSAR 9.3.4.8. The following discussion summarizes those failures related to natural circulation for which operator action outside the control room may be required.

As described above, operators must manually reset the charging pump breaker following LOP and restoration of power to a vital 4160 VAC bus. If the Train E pump is nonfunctional because its power supply is de-energized, power may be realigned to the

pump motor from the opposite train. This contingency requires local operator actions in the Control Building (Switchgear Room) and the Auxiliary Building (100' elevation).

If A train power is available, the charging pump suction can be lined up to the RWT from the control room via CH-536. In the event that A train is not available or CH-536 is failed in the closed position, a gravity-fed boration pathway may be aligned through either CH-514 or CH-327. Both of the latter pathways require operator action outside the control room to establish flow. None of the motor-operated valves involved (including the associated VCT outlet valve CH-501) are fully safety-grade components.

In the unlikely event that gas binding may result from entrainment of VCT cover gas or evolution of dissolved gas out of solution at low pressure conditions, the charging pumps will trip on low suction pressure. Once adequate NPSH has been re-established, the auxiliary operators can vent the charging pumps prior to restart. The current plant design permits the venting of charging pumps to the vent receiver tank on the 88' foot level of the Auxiliary Building following a loss of offsite power. Venting can be achieved without radiological or industrial safety hazard for the operator, creation of a flammable or explosive atmosphere, or an unmonitored release of radioactive materials to the environment. This capability was physically demonstrated to NRC staff in 1986.

The Nuclear Cooling (NC) Water System provides the normal cooling for the spent fuel pool. Since the NC pumps are powered from the non-class electrical distribution, NC flow

will be lost upon a loss of offsite power. In this case, either train of Essential Cooling Water (EW) can be cross-connected through safety grade piping to provide cooling for the associated Fuel Pool Heat Exchanger (FPHX). Since the EW also provides cooling for the shutdown cooling heat exchanger used during the second portion of natural circulation, the assumed EW temperatures include effects of the added FPHX heat load.

Administrative controls have been established to maintain the RWT outlet valve CH-532 in the high suction line and the charging pump discharge valve CH-524 locked open with their actuators de-energized. In this passive configuration, spurious closure is not a credible malfunction.

Once shutdown cooling conditions are established, some actions outside the control room are required as part of normal operations to place a train of shutdown cooling and supporting systems in service.

3.5 Supplemental Design Features

The Palo Verde units were designed before the guidance in BTP RSB 5-1 was issued and do not meet all of its requirements. As permitted by the SRP, exceptions to the requirements have been granted to Palo Verde as a Class 2 plant in part because the overall design provides an acceptable level of reliability. Reliability is provided by some non-safety design features that are not directly credited in the analysis.

Although the motors for emergency boration valve CH-536 and VCT outlet valve CH-501 are not seismically qualified, both motor-

operated valves are energized from a class power supply to enhance their availability. In addition, both have provisions that allow the valves to be locally operated by hand, if necessary.

Following a loss of offsite power, letdown will isolate automatically due to the loss of nuclear cooling water to the letdown heat exchanger or by operator action. When charging is restarted, the resulting mismatch between letdown and charging will cause VCT level to decrease. To reduce the chance of losing suction to the charging pumps, VCT level is monitored by two non-safety grade instrument channels. Alarms are provided on low level and if the two channels differ significantly. The use of two channels of different types (one has a wet reference leg and the other is dry) decreases the probability of operator error in aligning the boration systems should one channels fail.

On VCT lo-lo level on LT-227, a non-safety grade interlock is provided to automatically open CH-514, start the boric acid makeup pumps (BAMPs), close the BAMP recirc valve CH-510, and close VCT outlet valve CH-501. The BAMPs are started because gravity feed to the charging pump suction through CH-514 cannot provide adequate NPSH unless the boric acid filters are bypassed, and this requires operator action outside the control room. Thus, if offsite power is available, no operator action outside the control room is needed to realign charging pump suction via CH-514.

With a loss of offsite power, neither the BAMPs nor the motor for CH-514 will be available should a VCT lo-lo level occur.

Therefore, an additional non-safety grade interlock is provided to automatically open CH-536 if VCT has a lo-lo level and the CH-514 motor is de-energized. This automatic alignment following a loss of offsite power and successful operation of Diesel Generator A reduces the chance of the operator failing to realign charging pump suction before the VCT empties.

The Train E charging pump is capable of being energized from either train of vital 4160 VAC emergency buses. Thus, the available charging flow would likely be double that assumed in the cooldown analysis. The E Train pump provides additional assurance that shutdown cooling entry conditions can be achieved under some conditions not necessarily bounded by the analysis. Examples would include reactor coolant leakage up to Technical Specification limits, elevated RCP controlled bleed-off or leak-off due to pre-existing seal degradation, and consideration of worst-case instrument uncertainty.

In order for the pressurizer to be considered operable per Technical Specifications, two back-up banks of pressurizer heaters capable of being energized from vital power supplies must also be operable. Although the heaters themselves are not seismically qualified and analysis shows they are not required during natural circulation cooldown, the availability of heaters following a loss of offsite power enhances pressure control and reduces the chance of losing subcooling margin by operator error.

Notwithstanding these design enhancements, some credible CVCS malfunctions cannot be mitigated under the BTP RSB 5-1 guidelines without extensive operator action or repair. In

these unlikely cases, cooldown will be accomplished using HPSI and RCGVS.

4.0 RESULTS

The analyses demonstrate that natural circulation flow provides adequate core cooling. Throughout the cooldown to shutdown cooling entry conditions:

- Power-to-flow ratio remained less than unity.
- The temperature difference across the core less stayed less than that at full power.
- Subcooling margin was maintained within the limits specified in the emergency operating procedures.
- Volume of steam formed in the reactor vessel was limited to the upper head and never obstructed flow by extending into the outlet plenum of the hot leg.

Plant systems are capable of supporting a natural circulation cooldown to shutdown cooling entry conditions conducted using only the Technical Specification minimum values of:

- Nitrogen gas contained in the atmospheric dump valve accumulators
- Condensate available in the condensate storage tank.
- Borated makeup water available above the RWT high suction line nozzle

Pressure and inventory control during a natural circulation cooldown to shutdown entry conditions may be accomplished with

either (1) charging and auxiliary spray or (2) HPSI and the reactor head vent system. Both methods are capable of:

- Complying with the RCS P/T limits
- Maintaining pressurizer level within the band specified by the emergency operations procedures
- Restricting thermal conditions of the RCP seal packages below values that would result in excessive controlled bleed-off or face seal leak-off
- Establishing shutdown cooling entry conditions within 13.33 hours, including a 4 hour hold in hot standby prior to commencement of cooldown

Once shutdown cooling was placed into service, cold shutdown conditions can be established within 36 hours from the time of reactor trip.

Adequate reactivity control is demonstrated in separate design calculations used to substantiate the bases for the Technical Specifications and Technical Requirements Manual. The capability of the reactor coolant system to provide sufficient mixing of boric acid solution was verified experimentally during the 1986 functional testing.

5.0 CONCLUSION

With the assumptions described, plant systems can support a natural circulation cooldown to cold shutdown conditions within a reasonable time without jeopardizing critical safety functions. The initial portion of the analysis relies in part on non-safety grade equipment and does not provide for

mitigation of every credible malfunction. To compensate for these limitations, design features have been added to CVCS to enhance reliability, and the availability of a redundant, safety-grade, alternate method for cooling to shutdown cooling entry conditions has been demonstrated by analysis. Therefore, the overall design has been accepted for meeting the provisions of Branch Technical Position RSB 5-1 as a Class 2 plant.

STRUCTURAL EVALUATION OF STEAM LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

APPENDIX 5D

STRUCTURAL EVALUATION OF STEAM LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

ABSTRACT

This report documents the adequacy of the steam generator internals to steam line rupture conditions.

The separator deck, shroud and tubes are subjected to a hypothetical large pipe break accident. The resulting stresses in the structures are compared to ASME Boiler and Pressure Vessel Code, Section III allowables to determine the adequacy of the structure.

APPENDIX 5D

STRUCTURAL EVALUATION OF STEAM LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

TABLE OF CONTENTS

LIST OF TABLES

LIST OF FIGURES

1.0 INTRODUCTION

The hydraulic loading on the steam generator internals has been postulated by a complete rupture at the main steam line nozzle. This condition is defined as a Main Steam Line Break (MSLB) accident. A one-dimensional, two-phase flow model of the steam generator was formulated and its blowdown characteristics were simulated using the CEFLASH-4B computer code. The FLASH model is shown in Figures 5D-1A and 5D-1B. The MSLB accident loads obtained from the FLASH run are presented in Table 5D-1 of this report. These loads are used to establish the adequacy of the tube bundle, separator deck, and shroud. ANSYS structural models were developed to determine the maximum stresses due to MSLB loads. The resulting stresses were compared to elastic allowables defined in ASME Code, Section III (Reference 1).

2.0 ANALYSIS

2.1 MODEL DESCRIPTION

2.1.1 STEAM SEPARATOR DECK

The steam separator deck and shroud were modeled on the ANSYS finite element program (Reference 2). Since the structure is symmetrical, only 90 degree segment of the structure was required. The appropriate boundary conditions were applied to maintain symmetry. The deck is modeled as an effective plate with modified material properties. The deck stiffeners are modeled with holes. In the ANSYS model, shell elements are used for all structural members. The F.E. model is shown in Figure 5D-2.

2.1.2 TUBE BUNDLE

The analysis of the tube bundle upper region was performed using ANSYS. The tube bundle was modeled as a 3-D structure (straight and curved pipe elements for the tubes and 3-D beam elements for the vertical strips and batwings); the finite element model is shown in Figure 5D-3.

The model was composed by 66 equivalent tubes, representing all the 171 tube rows. In fact, to reduce the model dimensions, a single tube model represented three adjacent tube rows. Also the vertical strips and batwings were modeled by the same approach, properly accounting for the in-plane and out-of-plane support to the tubes.

2.2 ASSUMPTIONS

a. Structure is symmetrical, therefore only a 90 degree section was modeled.

b. Peak pressure load was applied across the separator deck and shroud.

c. For 0%, 15%, and 100% load cases a break opening time of 0.001 seconds was assumed for the rupture of the 28 inch steam line (ANSI/ANS-58.2-1988, paragraph 6.2.3).

d. The Henry-Fauske/Moody critical flow correlation was used with discharge coefficient of 1.0 (ANSI/ANS-58.2-1988, paragraph 6.2.5).

e. Operating pressure of 2250 psi was used as primary pressure and the secondary pressure was assumed to decay to zero.

2.3 HYDRAULIC FLOW LOADS

Main Steam Line Break (MSLB) accident loads are shown in Table 5D-1. For 15%¯ load, a maximum pressure differential of 18.78 psi at 0.17 seconds is the peak pressure applied upward across the separator deck. An outward pressure of 24.05 psi is applied across the shroud. For the tube bend region the flow forces per unit length of tube are determined using the equation below:

$$F = C_F * d * (g * V_g^2/2 * g)$$

where:

C_F = .14 drag coefficient

d = .75 in tube outer diameter

g = 42.28 lbs/ft^3 = 0.0245 lbs/in^3 specific weight (Ref. 3)

V_g = 8.08 * 1.797 = 14.44 ft/s = 173.28 in/s gap velocity (Ref. 3)

g = gravity acceleration

The resulting force per unit length on a single tube is 0.1000 lbs/in.

This force, multiplied by the number of tubes in each equivalent row, is applied on the bend and horizontal part of the tubes in the model.

The loads defined are used to determine the maximum stresses in the separator deck and shroud, and tube bundle models developed.

2.4 PRESSURE LOAD

During the MSLB event, the tube differential pressure was conservatively considered to be 2250 psi. This is based on the operating primary pressure with the assumption that the secondary pressure has decayed to zero.

2.5 STRESS RESULTS

2.5.1 SEPARATOR DECK

In the finite element model, the separator deck is treated as a perforated plate with modified elastic constants ν^* and E^*. The maximum membrane stress is 4.9 ksi, which is less than the allowable of 0.7 x S_u = 49 ksi for SA-515 Gr.70 material. The membrane plus bending stress is 45.5 ksi, which is less than 1.5 x (0.7 x S_u) = 73.5 ksi.

2.5.2 DECK STIFFENERS

The separator deck stiffeners are loaded by the uniform pressure applied across the deck. Stress in the plane of the stiffeners is membrane plus bending and is 19.9 ksi, which is less than the allowable of 1.5 x (0.7 x S_u) = 73.5 ksi for SA-515 Gr.70 material.

2.5.3 SHROUD

The shroud stresses due to an outward pressure result in a maximum local membrane stress intensity of 5.4 Ksi at the junction with the separator deck whereas the maximum primary membrane plus bending stress intensity (close to the same location) is 26.6 Ksi. Both stresses are less than the allowable of 1.5 x (0.7 x S_u) = 73.5 ksi for SA-515 Gr.70 material.

2.5.4 TUBES

The maximum membrane plus bending stress in the tubes due to hydraulic flow loads is 11.7 ksi.

2.6 PRESSURE STRESS

As a consequence of the main steam line break, the differential pressure inside the tubes rises to a value which was conservatively assumed equal to the full operating pressure in the primary circuit, i.e., 2250 psia, concomitant with a secondary pressure = 0.

The stress due to pressure are:

$$\sigma_x = (p_i - p_o) * \frac{r}{2 * t} = 9.5\ Ksi$$

$$\sigma_\theta = (p_i - p_o) * \frac{r}{t} = 19.0\ Ksi$$

$$\sigma_r = \frac{(p_i + p_o)}{2} = -1.1\ Ksi$$

where:

p_i = internal pressure = 2250 psia

p_o = external pressure = 0

s_x = axial stress

s_q = hoop stress

s_r = radial stress

r = mean radius of tube = (.75 - .042)/2 = .354 in

t = tube thickness = .042 in

3.0 CONCLUSIONS

The results show that the separator deck and shroud are within the elastic allowable limits.

The resultant tube stress intensity due to hydraulic flow loads and pressure differential is 22.3 Ksi, which is less than the membrane plus bending allowable of 84 ksi.

(*) This value is due to an effect of numerical 'water packing' occurring in the lower part of the DC. The duration of the effect is about 0.005 sec. and is due to the disappearing of the steam in the node 26. The effect of level oscillation occurring during the transient is responsible of the appearing and disappearing of the steam in the lower part of the DC that provides to generate numerical water packing. The maximum physical value occurs in the first second of transient and is less than 20 psi.

APPENDIX 5E

STRUCTURAL EVALUATION OF FEEDWATER LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

APPENDIX 5E

STRUCTURAL EVALUATION OF FEEDWATER LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

ABSTRACT

This report documents the structural adequacy of the steam generator internals to withstand a feedwater line rupture.

The steam generator economizer divider plate, support cylinder, cold leg flow distribution plate and feedwater box are subjected to a hypothetical feedwater line break during 100% power operation. The resulting stresses in the structures are compared to ASME Boiler and Pressure Vessel Code, Section III allowables to determine their acceptance.

APPENDIX 5E

STRUCTURAL EVALUATION OF FEEDWATER LINE RUPTURE FOR THE STEAM GENERATOR INTERNALS

TABLE OF CONTENTS

LIST OF TABLES

LIST OF FIGURES

1.0 INTRODUCTION

The hydraulic loading on the steam generator internals resulting from the double-ended guillotine break of one 12.5 inch ID feedwater nozzle were calculated. The CEFLASH-4B computer code was employed to perform the thermohydrodynamic analysis of this condition defined as Feedwater Line Break (FWLB) accident. The FLASH model is shown in Figures 5E-1A and 5E-1B. The FWLB accident peak pressure loads obtained from the FLASH run are presented in Table 5E-1 of this report. These loads were used to establish the adequacy of the economizer divider plate, support cylinder, blowdown duct, cold leg flow distribution plate and feedwater box. ANSYS structural models were appropriately developed to determine the maximum stresses due to FWLB loads. The resulting stresses were then compared to the faulted (Service Level D) allowables as specified in the ASME Code, Section III (Reference 1).

2.0 ANALYSIS

2.1 MODEL DESCRIPTION

2.1.1 ECONOMIZER DIVIDER PLATE

The ANSYS computer program (Reference 2) was used to set up a finite element model of the economizer divider plate, support cylinder and blowdown assembly, using 3-D shell elements with four nodes and six d.o.f each. The divider plate, support cylinder and blowdown rectangular tube were modeled taking advantage of the symmetry to the plane through the steam generator axis and perpendicular to the divider plate. Appropriate boundary conditions were selected to simulate the

symmetry and the support provided by adjacent structures. The model is shown in Figure 5E-2.

2.1.2 COLD LEG FLOW DISTRIBUTION PLATE

The flow distribution plate was modeled using 3-D shell elements which, taking again advantage of the symmetry, simulated half of the 180° plate. The perforated region of the plate was modeled as an equivalent solid plate with modified properties (i.e., modulus of elasticity and Poisson's ratio) except in the area of the solid rim near the support cylinder. Vertical out-of-plane displacements were fixed at the tie rod locations and along the outer edge of the plate, whereas appropriate symmetry conditions were imposed on the nodes at the x=0 plane (see Figure 5E-3).

2.1.3 FEEDWATER BOX

The finite element model used 3-D shell elements for the box parts (inner cylinder, intermediate and lower rings, ending plates) and 3-D beam elements for the set screws. The z-axis is along the SG axis, the x-axis is along the divider plate and the y-axis is perpendicular to the plate, right-hand-rule oriented. By symmetry considerations only one of the two segments of the structure was modeled. The model, depicted in Figure 5E-4, extended over a 84° amplitude arc starting from 3.5° from the xz plane up to 2.5° to the plane yz.

2.2 ASSUMPTIONS

2.2.1 HYDRODYNAMIC ANALYSIS

a. A double-ended guillotine break at the safe-end of one FW nozzle was considered.

b. A downcomer FW split of 50/50 (hot/cold) was assumed for the 100% power.

c. The break opening time of 0.001 seconds was assumed for the rupture of the 12.5 inch FW line, according to ANSI/ANS-58.2-1988, paragraph 6.2.3.

d. The Henry-Fauske/Moody critical flow correlation was used with discharge coefficient of 1.0 (ANSI/ANS 58.2-1988, paragraph 6.2.5).

2.2.2 STRUCTURAL ANALYSIS

a. Linear elastic behavior was assumed.

b. Peak pressure loads were assumed to occur simultaneously on each structural model.

c. These peak pressures were applied as static loadings.

2.3 HYDRAULIC FLOW LOADS

Feedwater Line Break (FWLB) accident loads are shown in Table 5E-1. The 15%+- load gives the more severe conditions in terms of maximum differential pressure across the structures analyzed.

Pressure differences were applied across the divider plate, across the support cylinder walls and across of the lateral

walls of the blowdown tube. The plate, divided into 10 rectangular regions (5 horizontal overlain belts divided by a vertical line) was loaded with 10 different pressure values. The support cylinder was likewise divided into 10 regions. The blowdown tube was divided by a vertical line into 2 different pressure regions. Pressure grows from the top (cylinder and plate upper ends) to the bottom (near the tubesheet) and the region of maximum pressure was located at the plate base near the shell.

A pressure difference directed inward on the FW box, equal to 958.1 psi was applied on the box inner cylinder and on the two ending plates.

Different values of pressure were applied on three concentric areas of the flow distribution plate. In fact, the pressures applied to the equivalent solid plate region were corrected to account for the presence of the holes.

2.4 STRESS RESULTS

Since the FWLB is a faulted (Service Level D) condition, the membrane stress allowables for elastic analysis are 0.7 x Su.

2.4.1 ECONOMIZER DIVIDER PLATE

The primary stress of concern in the divider plate are membrane plus bending. The maximum primary membrane plus bending stress intensity occurs at the junction of the plate with the stay cylinder and is 51.3 Ksi, which is less than the allowable of 1.5 x 0.7 x Su = 73.5 ksi for SA-516 Gr.70 material. The blowdown duct has maximum membrane plus bending stress of 59.6

Ksi compared to the allowable of 1.5 x 0.7 x Su = 60.9 ksi for the A 500 Gr. B material.

2.4.2 SUPPORT CYLINDER

The maximum stress on the support cylinder occurs at the junction with the tubesheet, where the structure has all the degrees of freedom restrained, and is 50.6 Ksi, which is lower than the allowable of 1.5 x (0.7 x Su) = 73.5 ksi for the SA 508 Cl 1A material.

2.4.3 COLD LEG FLOW DISTRIBUTION PLATE

The max membrane + bending stress intensity in the solid region of the plate is 52.51 ksi. The maximum ligament membrane plus bending stress intensity in the perforated region occur at the boundary with the inner ring and is 53.42 Ksi.

The allowable for the SA-540 Type 405 material is 1.5 x (0.7 x Su) = 58.7 ksi.

For the most loaded tie rod, the maximum stress intensity (categorized as Pm) is 32.1 Ksi which is lower than the allowable of (0.7 x Su) = 40.7 ksi for the SA-36 material.

2.4.4 FEEDWATER DISTRIBUTION BOX

The highest primary membrane plus bending stress intensity (72.9 Ksi) occurs at the box inner wall. The allowable limit is 1.5 x (0.7 x Su) = 73.5 ksi for the SA-516 Gr.70 material.

The highest primary membrane plus bending stress intensity at the box junction with the upper support ring is 71.9 Ksi, less than the above allowable limit.

The highest shear stress in the threaded connection between box wall and set screws is 26.1 Ksi, less than the allowable limit of 0.6 x (0.7 x Su) = 29.4 ksi.

3.0 CONCLUSIONS

The results show that the economizer divider plate, support cylinder, cold leg flow distribution plate and feedwater box are adequately designed to withstand a hypothetical Feedwater Line Break Accident.

6. ENGINEERED SAFETY FEATURES

6.1 ENGINEERED SAFETY FEATURE MATERIALS

See CESSAR Section 6.1 for ESF materials within the C-E scope of supply.

6.1.1 METALLIC MATERIALS

6.1.1.1 Materials Selection and Fabrication

6.1.1.1.1 Specifications for Principal ESF Pressure-Retaining Materials

Principal ESF pressure-retaining materials are listed in table 6.1-1.

6.1.1.1.2 Engineered Safety Features Construction Materials

Materials located inside containment potentially exposed to boric acid spray and the containment spray solution following a LOCA are indicated in table 6.1-2. These materials are chosen to be compatible with these chemical solutions.

Material corrosion within the containment is minimized by restricting the use of zinc, aluminum, and mercury. Since aluminum can be degraded in a high temperature, high moisture environment (i.e., post-LOCA), the amount of aluminum present inside the containment is the lowest practical amount. The use of zinc in the containment is controlled to minimize the generation of hydrogen due to the zinc-boric acid oxidation-reduction reaction. Because mercury and mercuric compounds adversely affect aluminum, stainless steel, NiCrFe Alloy 600, and alloys containing copper, mercury is not utilized within the containment for permanent equipment.

Section 6.2.5.3.A.3 discusses the amounts of aluminum and zinc that are assumed to be present in the containment and that could potentially be exposed to a corrosive environment. An estimate of their expected corrosion rate is given in Table 6.2.5-5.

6.1.1.1.3 Integrity of ESF Components During Manufacture and Construction

6.1.1.1.3.1 Control of Sensitized Stainless Steel. The NSSS ESF components comply with the recommendations of Regulatory Guide 1.44 in the following manner.

All raw austenitic stainless steel, both wrought and cast, used to fabricate pressure retaining components of the engineering safety features, is supplied in the annealed condition as specified in the pertinent ASME Specification; viz, 1900-2050F for 1/2 to 1 hr/in. of thickness and rapidly cooled below 700F. The time at temperature is determined by the size and type of component. In addition, vendor fabrication procedures have been reviewed to assure that unstablized austenitic stainless steel with a carbon content greater than 0.03% is not exposed to the temperature range of 800 to 1500F other than during welding.

Duplex, austenitic stainless steels, containing >5 FN delta ferrite (weld metal, cast metal, weld deposit overlay), are not considered unstablized, since these alloys do not sensitize; i.e., form a continuous network of chromium-iron carbides. Specifically, alloys in this category are:

CF 8M	Cast stainless steels (delta ferrite controlled
CF 8	to 5 FN to 33FN)
Type 308	Singly and combined
Type 309	stainless steel weld filler
Type 312	metals (Delta ferrite
Type 316	controlled to 5 FN to 23FN deposited)

In duplex austenitic/ferritic alloys, chromium-iron carbides are precipitated preferentially at the ferrite/austenite interface during exposure to temperatures ranging from 800 to 1500F. This precipitate morphology precludes intergranular penetrations associated with sensitized 300 series stainless steels exposed to oxygenated or otherwise fault environments.

The non-NSSS ESF components are consistent with the recommendations of Regulatory Guide 1.44, except as indicated in section 1.8.

6.1.1.1.3.2 Cleaning and Contamination Protection Procedures.

Specific requirements for cleanliness and contamination protection are provided for NSSS components which provide contamination control during fabrication, shipment, and storage as recommended in Regulatory Guide 1.37.

Contamination of austenitic stainless steels of the 300 type by compounds that can alter the physical or metallurgical structure and/or properties of the material was avoided during all stages of fabrication. Painting of 300 series stainless steels is prohibited. Grinding is accomplished with resin or

rubber bonded aluminum oxide or silicon carbine wheels that have not previously been used on materials other than 300 series stainless alloys.

Internal surfaces of completed components are cleaned to produce an item that is clean to the extent that grit, scale, corrosion products, grease, oil, wax, gum, adhered or embedded dirt, or extraneous material are not visible to the unaided eye.

Degreasing solvents, acetone or isoprophyl alcohol, may be used on metallic surfaces. Water used for cleaning is inhibited with 30-100 ppm hydrazine.

The specifications for water quality is:

Halides	
Chlorine, ppm	<0.60
Fluoride, ppm	<0.40
Conductivity, μmhos/cm	<5.0
pH	6.0-8.0
Visual clarity	No turbidity, oil or sediment

To prevent halide-induced intergranular corrosion which could occur in aqueous environment with significant quantities of dissolved oxygen, flushing water is inhibited via additions of hydrazine. Many experiments conducted by C-E have proven this inhibitor to be effective.

Onsite and preoperational cleaning of ESF components is in accordance with the recommendations of Regulatory Guide 1.37 as discussed in section 1.8.

Non-NSSS ESF components are suitably cleaned and suitably protected against contaminants capable of causing stress corrosion cracking during fabrication, shipment, storage, construction, testing, and operation.

6.1.1.1.3.3 Cold Worked Stainless Steel. Cold worked austenitic stainless steel is not utilized for ESF components.

6.1.1.1.3.4 Nonmetallic Insulation. All non-metallic insulation materials installed on stainless steel piping and equipment of the ESF are made of calcium silicate, expanded pearlite, fiberglass fiber, or similar materials (ASTM C533, C547, C553, C610, C612) and are consistent with the recommendations of Regulatory Guide 1.36.

6.1.1.1.4 Weld Fabrication and Assembly of Stainless Steel ESF Components

The recommendations of Regulatory Guide 1.31 are followed as discussed in section 1.8.

6.1.1.2 Composition, Compatibility, and Stability of Containment and Core Spray Coolants

Borated water is stored in the austenitic (type 304L) stainless steel-lined safety injection tanks and the refueling water tank. Extensive tests and operating experience show that this coolant will not produce significant corrosion of the tank lining material.

The initial containment spray is borated water taken from the refueling water tank. With a concentration of 4000 to 4400 ppm boron as boric acid and a temperature of 60°F to 120°F, the solution has a pH of about 4.2.

Long-term chemistry control of the recirculated sump solution is accomplished by the containment spray system (subsection 6.2.2).

The long-term recirculation sump fluid pH is controlled by dissolution of anhydrous trisodium phosphate (TSP), which is stored in side-screened baskets located in the vicinity of the containment sumps. Each unit has installed nine baskets of dimensions 2-feet x 2-feet x 2-feet and eight baskets of 4-feet x 4-feet x 4-feet for a total capacity of approximately 580 cubic feet. PVNGS utilizes a minimum of 524 cubic feet (approximately 25,325 pounds) per unit of bulk anhydrous TSP to raise the containment sump pH. In granular form, TSP has a lower bulk density of approximately 48.4 pounds per cubic foot. Its solubility in water at 122°F is 330 grams per kilogram (liter).

As the baskets are submerged in break flow and containment spray, the TSP dissolves into solution. Within 4 hours after a Recirculation Actuation Signal (RAS), the sump solution will reach neutral pH conditions. The sump fluid will have a nominal chemical composition of approximately 4200 ppm boron as boric acid and 3.2 grams per liter of TSP.

The TSP ensures that the final recirculation sump fluid pH will be greater than or equal to 7.0 and less than or equal to 8.5.

This sump solution promotes the long-term retention of iodine. The pH is also sufficient to avoid the stress-corrosion cracking of austenitic stainless steel and to avoid excessive generation of hydrogen by the corrosion of containment metals.

The quantity, solubility, and buffering capability of the trisodium phosphate is periodically verified as described in the Technical Specifications and bases.

The analysis of post-LOCA hydrogen generation is discussed in subsection 6.2.5.

6.1.2 ORGANIC MATERIALS

6.1.2.1 Protective Coatings

Protective coatings used inside the containment, excluding components limited by size and/or exposed surface area, meet the intent of ANSI N101.2 (1972), Protective Coatings (Paints) for Light-Water Nuclear Reactor Containment Facilities, and recommendations of Regulatory Guide 1.54, Quality Assurance Requirements for Protective Coatings Applied to Water-Cooled Nuclear Power Plants. Refer to subsection 6.2.2 for a discussion of the sump design and consideration given to screen clogging.

A list of surface coatings and applicable conditions for their use inside containment is given in table 6.1-3.

Approximate paint film thickness and exposed surface area for major components and structures inside containment is given in the containment passive heat sink table 6.2.1-8. The painted

areas of valve operators, miscellaneous parts on the reactor coolant pump drives, and instrumentation are considered insignificant.

6.1.2.2 Other Materials

A listing of other materials in the containment is included in table 6.1-4.

Table 6.1-3

COATING MATERIALS USED IN CONTAINMENT

Surface to be Coated	Type of Coating
Steel surfaces at temperature of less than 300F	Epoxy Inorganic zinc
Uninsulated steel surfaces at temperature more than 300F	Inorganic zinc
Decontaminable concrete wall surfaces	Epoxy
Concrete floors	Epoxy

Table 6.1-4

OTHER ORGANIC MATERIALS IN CONTAINMENT

Item	Material	Amount
Reactor coolant pumps lubricant	Petroleum base oil	1600 gallons (400 gallons per pump)
Cable insulation	EP/Hypalon XLPE/Neoprene XLPE/Hypalon FR-ER/CPE	39,500 pounds[(a)] (37,600 + 5%)
UGS Storage Area alignment pins (6)	Delrin 150 SA Acetal Homo-polymer	160 lbs.

a. The major organic polymer in the cable insulation is flame-retardant ethylene propylene rubber and chlorinated polyethylene.

b. Reference DMWO 752491 (Unit 1 6th Refueling Outage.

6.1.3 REFERENCES

6.2 CONTAINMENT SYSTEMS

The containment systems include the containment structure, the containment heat removal systems, the containment air purification and cleanup systems, the containment isolation system, and the containment combustible gas control system.

This section provides the design criteria and evaluations necessary to demonstrate that the systems listed above will function within the specified limits throughout the station operating lifetime.

6.2.1 CONTAINMENT FUNCTIONAL DESIGN

A physical description of the containment and the design criteria relating to the construction techniques, static loads, and seismic loads are provided or referenced in section 3.8. This section pertains to those aspects of containment design, testing, and evaluation that relate to the accident mitigation function.

6.2.1.1 Containment Structure

6.2.1.1.1 Design Bases

The containment design basis is to limit release of radioactive materials, subsequent to postulated accidents, such that resulting calculated offsite doses are less than the guideline values of 10CFR100. In order to meet this requirement, a design (maximum) containment leakage rate has been defined in conjunction with performance requirements placed on the engineered safety features (ESF) systems.

The capability of the containment structure to maintain design leaktight integrity and to provide a predictable environment for operation of ESF systems is ensured by a comprehensive design, analysis, and testing program that includes consideration of:

A. The peak containment pressure and temperature associated with the most severe postulated accident coincident with the operating basis earthquake (OBE) or safe shutdown earthquake (SSE).

B. Maximum external pressure loading condition to which the containment may be subjected as a result of inadvertent containment systems operations that potentially reduce containment internal pressure below outside atmospheric pressure.

6.2.1.1.1.1 Containment Structure Accident Conditions. The postulated accidents considered in determining design containment peak pressure (and temperature) and external pressure are summarized in table 6.2.1-1. These analyses were performed at 102% of Licensed power, i.e., at 4070 MWt.

For the containment structure peak pressure analysis, it is assumed that each postulated accident is concurrent with the most limiting single active failure in systems required to mitigate the consequence of the accident or to shut down the plant. In addition, if the postulated accident causes a turbine or reactor trip, loss of offsite power is also assumed. Main steam line breaks are evaluated with offsite power available since secondary side breaks are more severe with no loss of offsite power. No two accidents are postulated to

occur simultaneously or consecutively. For conservatism, containment leakage is not incorporated into the PVNGS containment peak pressure analysis.

The design basis accident (DBA) for each of the categories of containment peak pressure (and temperature) and containment maximum external pressure is defined as the most severe accident postulated for each case. The DBAs and calculated pressures are given in table 6.2.1-2. In the event of a postulated LOCA or MSLB, the release of coolant from the rupture area will cause the high temperature, high pressure fluid to flash to steam. The release of mass and energy raises the temperature and pressure of the containment atmosphere. The severity of the resulting temperature and pressure peaks developed depends upon the nature, location, and size of the postulated rupture, as well as the containment design.

In order to establish the controlling rupture for containment design, a spectrum of primary and secondary breaks, described in Table 6.2.1-1, are analyzed to determine their effects. Mass/energy source terms for hot leg cases and MSLB cases are not generated after the end of blowdown. For hot leg cases, most of the reflood fluid does not pass through a steam generator prior to being released to the containment; hence, in contrast to a cold leg break, there is no physical mechanism to rapidly remove the residual steam generator secondary energy during or after reflood. For a MSLB, following blowdown of the affected generator, the decay heat is transferred to the unaffected generator which, in turn, will vent to the atmosphere when its safety valves open. For both cases, then,

there is no mechanism for the release of significant amounts of mass or energy to the containment after the end of blowdown.

Breaks in the main feedwater piping would result in blowdown that is less limiting than the MSLB. Effective break areas for the main feedwater line break (MFLB) are limited by the steam generator internals design. Fluid enthalpy for the MFLB is less than the enthalpy of the fluid in the MSLB; therefore, MFLB's are not analyzed. Blowdown data for the spectrum of breaks shown in Table 6.2.1-1 are evaluated to determine the most limiting mass and energy release rates with respect to containment peak pressure analysis. These cases, and their results, are presented in this chapter. The most limiting of these accidents are identified in table 6.2.1-4. Containment design parameters are given in table 6.2.1-3. The difference between the design pressure (60 psig) and the calculated peak pressure of the as-constructed design (57.9 psig) results in a design margin of approximately 3.5%.

6.2.1.1.1.2 Containment Internal Structures Accident Conditions. The reactor coolant system (RCS) breaks defined in Section 3.6.2 are analyzed and form the design basis for the loads on containment internal structures and equipment. The simultaneous occurrences are the same as discussed in paragraph 6.2.1.1.1.1. The design pressures for the steam generator and pressurizer compartments are given in table 6.2.1-3. The currently calculated values for the as-built design are listed in table 6.2.1-2.

6.2.1.1.2 Design Features

The design features of the containment structure and internal structures are provided in subsections 3.8.1 and 3.8.3, respectively.

6.2.1.1.2.1 Protection From the Dynamic Effects of Postulated Accidents. The containment structure, subcompartments, and engineered safety feature systems are protected from loss of safety function due to the dynamic effects of postulated accidents. Containment design has provided separation and inclusion of barriers, restraints and supports when required to protect essential structures, systems, and components from accident generated missile, pipe whip, and jet impingement forces. The detailed criteria, locations, and descriptions of devices used for protection are given in section 3.6.

6.2.1.1.2.2 Codes and Standards. Codes and standards applied to the design, fabrication, and erection of the containment and internal structures are given in table 3.2-1 and in paragraph 3.8.1.2. In each case, the codes and standards used are consistent with the equipment safety function.

6.2.1.1.2.3 Protection Against External Pressure Loads. The containment system is designed to maintain its structural and functional integrity during and after the most extreme loading conditions due to inadvertent operation of containment heat removal systems and other possible modes of plant operation (e.g., containment purging as listed in table 6.2.1-1) that could potentially result in significant external structural

	98-square inch SI-A or B line
	129-square inch SDC line
	123-square inch FW Guillotine
	Pressurizer compartment
	161-square inch pressurizer surge line guillotine break
External pressure	Inadvertent operation of the containment heat removal systems[a]
	Misoperation of the containment normal purging system

a. Calculated by simple ideal gas law relationship.

Table 6.2.1-2

CALCULATED VALUES FOR CONTAINMENT PRESSURE PARAMETERS

Parameter	Design Basis Accident[a]	Calculated Value (PSIG)
Peak Pressure (4070 MWt)	DEDL slot, max. ECCS	57.9
Peak subcompartment pressure	Reactor cavity	
	N/A	N/A
	Steam generator compartment	
	129-square inch SDC line (3990 MWt)	19.5
	Pressurizer compartment wall	
	161-square inch surge line guillotine	72.4
External pressure loading	Inadvertent operation of the containment spray system	3.5[b]

a. See table 6.2.1-1 for definition of abbreviations used.

b. The maximum external pressure that would occur as a result of this transient is 3.5 psig based on an initial containment pressure of −1.0 psig (the lower Technical Specification limit plus instrument uncertainty) and the calculated pressure drop of 2.5 psig.

Table 6.2.1-3

PRINCIPAL CONTAINMENT DESIGN PARAMETERS

Parameter	Peak Value
Containment	
Internal design pressure, psig	60.0
Design temperature, °F	
High mean during normal operation	120.0
Maximum, DBA	300.0
External design pressure loading, psig	4.0
Net free volume, ft^3	2.62×10^6
Design leak rate, percent free volume per day at 60.0 psig	0.1
Subcompartments	
Reactor cavity design wall loading, psid	110[a]
Steam generator compartment design wall loading, psid	30[a]
Pressurizer compartment design wall loading, psid	73[a]

a. This value does not include the dynamic load factors which were used in the design as described in paragraph 3.8.3.3.1.4.

loadings. The resulting pressures are lower than the design containment external pressure. Details of this evaluation are provided in paragraph 6.2.1.1.3.6.

6.2.1.1.2.4 Potential Water Traps Inside Containment. The design of the containment minimizes potential trapping of safety injection and containment spray water which might otherwise prevent return and subsequent recirculation via the containment emergency sump. The reactor cavity and associated ventilation ducts are the only locations that trap significant quantities of water. These locations are shown in Engineering drawings 13-P-OOB-002, 13-P-OOB-007, and 13-P-OOB-008. As a result of a LOCA and subsequent safety injection system operation, the reactor cavity and the ventilation ducts that penetrate the lower portion of the cavity shield wall could fill with water to an elevation of 96.8 feet (to a depth of approximately 42 feet above the reactor cavity floor). At this elevation, water will overflow to the surrounding floor of the containment. The quantity of water trapped by the cavity and ducts is 18,452 ft^3 (approximately 138,000) gallons.

Based on initial availability of 104,730 ft^3 (approximately 783,400 gallons) from the refueling water tank (maximum capacity), the contribution of the RCS inventory, and the four safety injection tank volumes, the resulting maximum water level will be approximately 91 ft, or 11 feet above the containment floor.

For net positive suction head (NPSH) calculations, the minimum required RWT volume, less a specified volume of water diverted to the chemical volume and control system and water postulated

to be held on wetted surfaces and delayed in containment, results in a minimum containment volume outside the reactor cavity corresponding to an approximate containment water level of 84.5 feet (4.5 feet above the containment floor).

The safety injection and containment spray pumps are located in the auxiliary building and are placed low enough below containment emergency sump elevation to assure the availability of the NPSH requirements listed in table 6.3.2-1.

During normal plant operation, drains from the refueling canal floor (elevation 98.5 feet and elevation 90.5 feet) to the containment floor (elevation 80 feet) are open with flange removed to preclude trapping of water. The drain line consists of approximately 10 feet of 10-inch diameter piping. Plugging of the drain line is precluded by its large diameter. No water will be permanently contained by the refueling canal.

Since the expected maximum pumped fluid temperature will exceed 212F, NPSH for the safeguards pumps was calculated by assuming that the temperature of the pumped liquid is at saturation for the containment pressure, and that the vapor pressure is equal to the containment pressure. These assumptions ensure that no credit is taken for containment pressure since the containment and vapor pressure terms cancel out of the NPSH equation which then reduces to:

$$NPSH_{available} = \Delta Z - h_L$$

ΔZ = elevation head

h_L = suction line loss

6.2.1.1.2.5 Containment Cooling and Ventilation Systems. During normal reactor operation, the containment atmosphere is maintained below 120F by continuous operation of the containment normal ventilation system.

Only one-half of the cooling units installed are required to remove the normal plant operating heat load, the remaining one half is used as a standby. Temperature is thermostatically controlled.

Before entering, the containment is purged, if necessary, to permit occupancy. All air supplied is taken from outside, filtered, and delivered through the purge supply system. The exhaust unit discharges through a filter to the plant vent stack and maintains stack velocity at a rate that ensures adequate dispersion in the atmosphere against design wind pressures.

Containment normal ventilation systems are described in detail in subsection 9.4.6.

6.2.1.1.3 Design Evaluation

6.2.1.1.3.1 Containment Peak Pressure and Temperature Analysis. In the event of a postulated loss-of-coolant accident (LOCA), or main steam line break (MSLB), the release of coolant from the rupture area will cause the high-temperature, high-pressure fluid to flash to steam. This release of mass and energy raises the temperature and pressure of the containment atmosphere. The severity of the resulting temperature and pressure peaks developed depends upon the nature, location, and size of the postulated rupture.

A. Pipe Break

In order to establish the controlling rupture for containment design, the primary and secondary breaks, described in table 6.2.1-1, were analyzed to determine their significance in selecting a containment design basis. Mass/energy source terms for the hot leg case and MSLB cases were not generated after the end of blowdown. For the hot leg case, most of the reflood fluid does not pass through a steam generator prior to being released to the containment; hence, in contrast to a cold leg break, there is no physical mechanism to rapidly remove the residual steam generator secondary energy during or after reflood and the mass/energy release rate from the break will be less than for a cold leg break. For a MSLB, following isolation and blowdown of the ruptured unit, the decay heat is transferred to the intact unit which, in turn, will vent to the atmosphere when its safety valves open. For the MSLB, then, there is no mechanism for the release of significant amounts of mass or energy to the containment after the end of blowdown. Effective break areas for the main feedwater line break (MFWLB) are limited by the steam generator internals design and fluid enthalpy for the MFWLB is less than the enthalpy of the fluid in the MSLB. Consequently, breaks in the main feedwater piping would result in blowdown that is less limiting than the MSLB; therefore, MFWLBs are not analyzed. Blowdown data for the spectrum of breaks shown in table 6.2.1-1 are evaluated to determine the

most limiting mass and energy release rates with respect to containment peak pressure analysis. Those limiting cases for an analyzed core power of 4070 MWt are presented in tables 6.2.1-4 and 6.2.1-5. The most severe of these accidents, identified in listing D is the controlling containment DBA.

B.1 Initial Conditions and Input Data

The containment pressure analysis input data are based upon the final plant design as shown in tables 6.2.1-3 and 6.2.1-6. A conservative prediction of LOCA and MSLB consequences was assured by determining upper and lower bounding values of containment initial conditions, geometric parameters, and thermodynamic properties, and by applying these values in the manner producing maximum pressure results.

The initial conditions within the containment system and the reactor coolant system prior to accident initiation are given in table 6.2.1-6. The maximum containment normal pressure is assumed to be at 2.5 psig, design maximum inside and maximum outside temperature are used to minimize calculated heat transfer during the postulated accident. The reactor coolant system is assumed to be at 102% of Licensed Power.

For the purpose of the containment peak pressure and temperature analysis, the safety injection system and the containment heat removal systems (i.e., containment spray system) were assumed to operate in the mode that

maximizes the containment peak pressure as shown in table 6.2.1-7. For the safety injection system, both maximum and minimum ECCS performances were evaluated. For the containment heat removal systems, minimum system capacity is conservative for calculating containment peak pressures.

Passive heat sink data is provided in table 6.2.1-8. Part A of the heat sink table is a detailed list of the geometry of each heat sink and part B describes the resulting simplified heat sink models used for computer input. Node spacing used for concrete, steel, and steel-lined concrete heat sinks is fine enough to ensure an accurate representation of the thermal gradient in each slab. In concrete, the node spacing varies from 0.003274 to 0.004233 foot depending on the total thickness of the slab. In the steel, node spacing varies from 0.000455 to 0.006943 foot. For composite steel (liner)-concrete heat sinks, the node spacing used is the same as that given above for individual steel and concrete slabs. A 0.0087 foot air gap, equivalent to a thermal conductance of 20 Btu/h-ft^2-F, is assumed to exist between the containment steel liner and concrete wall for peak pressure calculations. It is further assumed that heat is transferred only by conduction across the air gap. The same gap conductance is presumed for the interface between the stainless steel refueling canal liner and the concrete.

[a] 70 psia containment back pressure

[b] Direct ECCS Spillage is the ECCS flow which goes directly to the containment without entering the NSSS. Vessel Spillage is the sum of all liquid leaving the break. For the double ended suction leg break, there is no spillage since the water fed to the cold leg would not spill out of break against the RCP inertia and high flow resistance.

Table 6.2.1-4
MOST SEVERE MASS AND ENERGY RELEASE FOR CONTAINMENT PEAK PRESSURE AND TEMPERATURE ANALYSIS - ANALYZED AT 102% OF 3990 MWt (Sheet 10 of 18)

C.2: CORE REFLOOD & POST REFLOOD MASS AND ENERGY RELEASE DATA

For the hot leg break, there is no viable path for the steam in the reactor vessel to go through the steam generators. Therefore, the reflood and post-reflood mass and energy releases are zero.

C.3: VESSEL CONDENSATION AND SPILLAGE MASS AND ENERGY RELEASE DATE

Direct ECCS Spillage is the ECCS flow which goes directly to the containment without entering the NSSS. Vessel Spillage is the sum of all liquid leaving the break. For the double ended hot leg break, spillage is zero since all ECCS injection flow would be induced into the core before it would be discharged into the containment.

D. Most severe secondary system break

Break Type: Main steam line Double ended guillotine break
Pipe ID: 24.459 inches
Break area: 6.526 square feet (plus expansion)
Reactor Power: 0%

TIME (sec)	MASS RATE (lbm/hr)	ENERGY RATE (Btu/hr)	ENTHALPY (Btu/lbm)

MASS AND ENERGY RELEASE FOR SUBCOMPARTMENT
PEAK PRESSURE ANALYSIS

A. 100-square inch hot leg guillotine break

Pipe ID: 42 inches

Refer to CESSAR Tables 6.2.1-25A and 6.2.1-25B

B. 350-square inch discharge leg guillotine break

Pipe ID: 30 inches

Refer to CESSAR Tables 6.2.1-27A and 6.2.1-27B

C. 600-square inch hot leg guillotine break

Pipe ID: 42 inches

Refer to CESSAR Tables 6.2.1-26A and 6.2.1-26B

D. 480-square inch discharge leg guillotine break

Pipe ID: 30 inches

Refer to CESSAR Tables 6.2.1-28A and 6.2.1-28B

E. 430-square inch suction leg guillotine

Pipe ID: 30 inches

Refer to CESSAR Tables 6.2.1-29A and 6.2.1-29B

F. 592-square inch suction leg guillotine break

Pipe ID: 30 inches

Refer to CESSAR Tables 6.2.1-31A and 6.2.1-31B

G. 161-square inch pressurizer surge line guillotine break

Pipe ID: 10.1 inches

Refer to CESSAR Tables 6.2.1-32A and 6.2.1-32B

Table 6.2.1-6
INITIAL CONDITIONS FOR CONTAINMENT PEAK PRESSURE ANALYSIS – ANALYZED AT 102% OF 3990 MWt (Sheet 1 of 2)

Parameter	Value
Reactor coolant system	
Reactor power level, MWt[(a)]	4070
Assumed Tcold °F	568.2
Mass of reactor coolant system liquid, lbm	626,310
Mass of reactor coolant system steam, lbm	6173
Liquid plus steam energy, 10^6 Btu[(b)]	541.221
Containment	
Pressure, psia (worst case)	
a. MSLB	13.2
b. LOCA	16.7
Temperature, °F (maximum normal)	120
Relative humidity, %	
a. MSLB	0
b. LOCA	0
Essential cooling water temperature assumed constant for 24 hr., °F	135
Refueling water temperature °F (maximum) (nominal 90°F)	120
Outside air temperature, °F	130
Net free volume, ft^3	2.62×10^6
Stored water (as applicable)	
Refueling water storage tank, gal (minimum)	400,000
All accumulators (safety injection tanks), ft^3 @ PSIA	7656 @ 652
Condensate storage tank temperature, (F)	120
Nitrogen from Accumulators, ft^3	1968

Table 6.2.1-7
ENGINEERED SAFETY SYSTEMS OPERATING ASSUMPTIONS FOR CONTAINMENT PEAK PRESSURE ANALYSIS - AT 102% OF 3990 MWt (Sheet 3 of 4)

System/Item	Value
Credited Set points to generate a signal during;	
1. LOCA	
a. SIAS due to generation of CIAS (psig)	Note (a)
b. CSAS due to high pressure in containment (psig)	10.00
2. MSLB	
a. Main steam Isolation due to generation of CIAS (psig).	19.2
b. Reactor trip due to generation of CIAS (psia),	19.2
c. Reactor trip due to Low SG pressure. (psia)	915
d. Differential Pressure between SGs (lock out signal). (PSID)	325
f. AFAS actuation on Low SG Level. (Percent of wide range)	32
e. CSAS due to high pressure in containment (psig)	10.00
Closure time during MSLB	
a. Main steam isolation valve closure time. (sec)	5.0
b. Main feed water isolation valve closure time. (sec)	10.0

(a): SI flow is not credited during blowdown phase of the event, but SIAS is assumed to occur prior to end of blowdown.

Table 6.2.1-7

ENGINEERED SAFETY SYSTEMS OPERATING ASSUMPTIONS FOR CONTAINMENT PEAK PRESSURE ANALYSIS – AT 102% OF 3990 MWt (Sheet 4 of 4)

System/Item	Value
Delay times	
c. Signal delay time for MSIS / FWIS. (sec)	1.0
e. Delay time from SG delta P setpoint until all flow is directed to the intact SG (lock out). (sec)	18.0
f. Delay time from AFAS until AFW flow reaches steam generators. (sec)	7.0
Physical system parameters used for MSLB	
a. Auxiliary feed water flow rate (run-out per two pump). (gpm)	3200
b. MSIV Area per valve. (ft^2)	2.127
c. Main Steam Safety valves	
MSIV / steam line	5/4
Maximum Opening setpoint (PSIG)	1287.5
Maximum Full open pressure. (PSIG)	1394
Total flow Area of MSSV. (ft^2)	1.11184
Steam line volume from MSIV to SG outlet. (ft^2/SG)	1850
Steam line volume from MSIV to Turbine stop valves. (ft^3)	3390
Volume of fluid between the upstream MFIV and each steam generator. (ft^3/SG)	<537[b]

b: Includes 2% Expansion Factor

The containment building dome, containment building cylinder (above grade), and containment building wall area with buttress sections detailed in heat sink table 6.2.1-8, part B, are exposed to the containment atmosphere on their inside surfaces and ambient air on their outside surfaces. The initial temperature distribution in these three heat sinks is established by assuming a heat-transfer coefficient of 2 Btu/h-ft^2-F exists at inside and outside surfaces. Following the LOCA or MSLB, Tagami or Uchida condensing heat-transfer coefficients apply to the inside surfaces which a value of 2 Btu/h-ft^2-F continues to be used on the outside surface. Other heat sinks are either entirely within the containment building envelope or are bounded by the earth at their outside surface where thermal insulation is conservatively assumed. Consequently, these other heat sinks are initialized at the initial containment temperature prior to the MSLB or LOCA. The initial containment temperature is the design maximum for reactor power operation. Most of the building structure and cold components would be cooler than the design maximum temperature; a few regions, notably the reactor cavity walls, may be warmer. The warmer heat sinks comprise a small area and, as a result, the average heat sink temperatures would initially be less than the design maximum.

Minimum heat sink areas (i.e., nominal minus tolerance given in table 6.2.1-8) are used for the short-term and long-term containment pressure-temperature transient analysis of primary or secondary pipe ruptures inside containment. Most individual structural or component heat sinks have some uncertainty associated with the exposed surface area. The minimum area was used to provide the most conservative assumptions.

Table 6.2.1-8, part C, lists the thermophysical properties used in analyses. Metal, concrete, and protective coating properties are typical values for the temperature range observed.

B.2 Mass and Energy Release Analyses for Postulated Loss of Coolant Accidents

LOCA mass/energy release analyses can be classified into the following phases: blowdown, refill, reflood, post reflood, and long term. The blowdown period extends from time zero until the primary system depressurizes to essentially the containment pressure. During blowdown, most of the initial primary coolant is released to the containment as a two phase mixture. Following blowdown, the water for releases is provided by the ECCS.

There is an important distinction between hot leg breaks and cold leg breaks for LOCA post blowdown analyses. For a hot leg break, the majority of the ECCS supplied water leaving the core can vent directly to the containment without passing through a steam

generator. Therefore, since there is no mechanism for releasing the steam generator energy to the containment for a hot leg break, only the blowdown period must be considered. Conversely, for cold leg breaks, the water must pass through a steam generator before reaching the containment so that post blowdown releases to the containment must be considered for cold leg breaks.

The first post blowdown period is refill. During refill, the ECCS water refills the bottom of the reactor vessel to the bottom of the core. This period is conservatively omitted from the analysis.

The second post blowdown period is the reflood period. During reflood, ECCS water floods the core. Reflood is assumed to end when the liquid level in the core is 2 feet below the top of the active core. During reflood, a significant amount of the ECCS water entering the core is postulated to be carried out of the core by the steaming action of the core to coolant heat transfer process. This fluid then passes through a steam generator where reverse (i.e., secondary to primary) heat transfer heats it before it reaches the containment. The residual steam generator secondary energy is sufficient to convert all of this fluid to superheated steam during the initial part of the reflood period. Subsequently, as the generators are cooled by this process, there is not enough heat transfer to boil all of the fluid passing through the tubes. This causes the break flow to change from pure steam to two phase. In time, as the entire NSSS cools,

the flow to the containment will be subcooled since the safety injection water is subcooled. The onset of the two phase release to the containment may or may not occur before the end of reflood; typically, this occurs close to the end of reflood. The potential release of subcooled fluid to the containment does not occur during reflood when conservative system parameters are utilized.

The third post blowdown period is the post reflood period. During this time frame, the dominant process is the continued cooling of the steam generators by the ECCS water leaving the core. The release to the containment during this time frame is generally two phase due to the cooling of the steam generators. The post reflood ends when the affected steam generator has essentially reached the containment temperature.

The final post blowdown period is the long term period, which begins at the end of post reflood. During long term, the dominant mechanisms for release rates are the decay heat and the cooling of all NSSS metal. Long term ends when the containment pressure and the environment pressure are essentially equal.

B.2.1 Mass and Energy Release Data

Mass and energy release data for most severe breaks (the suction leg, discharge leg and hot leg) break cases analyzed. For cold leg breaks (pump suction and discharge), some of the post blowdown ECCS water is postulated to spill directly to the containment

floor whenever the reactor vessel annulus is full. The data associated with these breaks are given in Table 6.2.1-4. Additionally, for discharge leg breaks, some of the ECCS water is postulated to spill directly to the containment floor without first entering the reactor vessel. This direct spillage is in addition to the vessel spillage discussed above.

Also, for the discharge leg breaks, 1 out of the 4 available safety injection tanks is assumed to be unavailable due to the break; accordingly, the discharge leg break energy balances show the inventory of this tank in the sump category. Direct flow spillage data for each discharge leg break is given in Table 6.2.1-4.

B.2.2 Energy Sources

The following sources of generated and stored energy in the reactor coolant system and secondary coolant system are considered:

- primary coolant
- primary walls (including reactor internals),
- secondary coolant,
- secondary walls,
- safety injection water,
- core power transient and decay heat,
- steam generator forward and reverse heat transfer.

- Decay heat
- Metal water reaction energy

The initial reactor coolant system water volumes are conservatively calculated based on maximum manufacturing tolerances for the reactor vessel and steam generator tubes. Expansion of the loop components from cold to hot operating conditions is also considered. The pressurizer water volume includes an allowance for level instrumentation error.

The initial conditions in the reactor coolant system are given in table 6.2.1-6. The decay heat utilized in the preparation of mass and energy release and sensible heat for this analysis is provided in Table 6.2.1-21 and is based on the 1979 ANS 5.1 Standard plus a two sigma uncertainty and modified implementation of the actinide correction factor. The containment analysis model (COPATTA) also employs this decay heat. This decay heat standard is used during the blowdown, reflood/post-reflood and long term cooldown phases of a postulated LOCA event (ABB CENP Codes; CEFLASH-4A, FLOOD3 Mod 2 and CONTRANS2). The initial core power assumed in this analysis is 4070 MWt (3990 MWt plus 2% for instrumentation uncertainty). A tabulation of sources and amounts of stored energy for this plant configuration is given in table 6.2.1-11.

Metal-Water Reaction

Energy addition to the containment atmosphere resulting from the maximum allowable 1% zirconium water reaction is based on a zirconium mass in the active core of 58498 lbm. Using a molecular weight of 91.22 for zirconium and a reaction energy of 252900 Btu/lbm mole, the 1% metal-water reaction produces 1.622 x 10^6 Btu. This energy is added directly to the containment. This energy is not included in the mass/energy source terms of Table 6.2.1-4, since this energy will have a very small effect on the rate of blow down.

B.2.3 Single failure

Assuming the loss of non-emergency power is conservative for the LOCAs, since it results in a longer time to actuation of ECCS and injection. The most severe random single failure for the containment peak pressure analyses is failure of a active component in containment spray system (CSS), which it would result in loss of a train of CSS. This minimizes the rate of heat removal from containment structure and would result in maximum peak pressure.

B.3 Mass and Energy Release Analysis for Postulated Secondary System Pipe Ruptures Inside Containment

Following a postulated main steam line break (MSLB) or a main feedwater line break (MFLB) inside the containment, the contents of one steam generator (affected) will be released to the containment. The

contents of the other steam generator (unaffected) will be isolated by the main steam isolation valves (MSIV) and main feedwater isolation valves (MFIV).

Containment pressurization following a secondary side rupture depends on how much of the break fluid enters the containment atmosphere as steam. MSLB break flows can be pure steam or two-phase. MFLB flows are two-phase. With a pure steam blowdown, all of the break flow enters the containment atmosphere. With two-phase blowdown, part of the liquid in the break flow boils off in the containment and is also added to the atmosphere, while the rest falls to the sump and contributes nothing to containment pressurization. For MSLB cases with large break areas, steam cannot escape fast enough from the two-phase region of the affected steam generator, and the two-phase level rises rapidly to the steam line nozzle. A two-phase blowdown results. The duration of this blowdown is short; therefore little primary-to-secondary heat transfer takes place and the break flow is largely liquid.

For MSLB cases with small break areas, steam can escape fast enough from the two-phase region of the affected steam generator so that the level swell does not reach the steam line nozzle. A pure steam blowdown results. Because of the pressure reducing effects of active and passive containment heat sinks, the highest peak containment pressure resulting from a MSLB for a given set of initial steam generator conditions occurs for that case where the break area is the maximum at which

a pure steam blowdown can occur. The potential for steam generator two-phase level swell following a MSLB increases as power level decreases; therefore, a spectrum of power levels must be analyzed to determine which one results in the peak MSLB containment pressures.

The feedwater distribution box is below the steam generator water level; therefore, MFLB cases always result in two-phase blow downs and do not produce peak containment pressures as severe as MSLB cases.

To permit a determination of the effect of MSLB upon containment pressure, analyses are performed at an analyzed core power of 4070 MWt using ABB-CE computer code SGNIII at 102, 75, and 0 percent power[1]. The largest slot and guillotine breaks at which a pure steam blowdown can occur are determined. The breaks are conservatively assumed to be at the nozzle of one of the steam generators. The cases analyzed for this plant configuration are listed in Table 6.2.1-1.

The Palo Verde plants have integral flow restrictors in the nozzles of the steam generators. Credit for the flow restrictors is taken in the analysis. In the plant, the main steam isolation signal (MSIS) of the engineered safety features actuation system (ESFAS)

[1]LOCA blowdowns provide limiting parameters for consideration of peak containment pressure. The power level cases were selected to identify peak MSLB containment temperature. A review of prior analyses of record indicated that neither a 25% nor a 50% power case would provide limiting containment temperature conditions for MSLB.

closes the MSIV's, MFIV's and the emergency feedwater isolation valves. MSIS is generated by a steam generator low pressure signal or a containment high pressure signal high steam generator level signal. The MSIV's close in 5 seconds. The valve closures have been considered in the analysis.

The auxiliary feedwater system functions automatically during MSLB to ensure that a heat sink is always available to the reactor coolant system by supplying cold feedwater to maintain an adequate water inventory in the unaffected steam generator. The affected steam generator is identified and isolated while a controlled flow path is provided to the unaffected steam generator.

B.3.1 Mass and Energy Release Data

Mass/energy release data for limiting MSLB cases listed in Table 6.2.1-4.

B.3.2 Energy Sources

For the MSLB analysis, the following sources of heat generation and stored energy are addressed.

- Primary Coolant,
- Primary wall (including reactor vessel internals),
- SG inventory on unaffected unit prior to MSIV closure,

- SG inventory on affected unit including main feed water addition from both trains,
- Auxiliary feedwater flow to affected unit,
- SG secondary walls on the affected unit,
- Core power transient and decay heat,
- Steam line inventory to turbine stop valves and steam line inventory up to MSIVs after valve closure.
- Feed water line inventory to MFIVs on the affected SG.
- RCP heat
- Fuel Decay heat

Expansion of the primary loop components from cold to hot operating conditions is considered. This maximizes the RCS volume and therefore stored energy to be transferred to the affected SG during the blowdown to containment. A similar volumetric expansion of secondary side inventory, including the main steam and feedwater lines is also assumed. Identical values for initial core power and decay heat described for LOCA are assumed for MSLB (refer to table 6.2.1-25).

B.3.3 Single Failure

Assuming the availability of non-emergency power is conservative since it allows the continuation of reactor coolant pump operation. This maximizes the

rate of heat transfer to the affected steam generator which maximizes the rate of mass/energy release. With non-emergency power, a diesel failure need not be postulated.

There is an MSIV in each main steam line. The MSIV's have been designed to close based on a conservative calculation which maximizes the dynamic pressure loading on the valve for all possible flow rates and qualities. Each valve has dual solenoid valves to assure closure even with a single failure in the control system. Single failure of the actuation signal will not prevent valve closure since both trains of MSIS actuation are provided to each MSIV. Any failure would result in the valve going to the closed position so that no additional steam could be added to the containment. The other MSIV isolates the unaffected steam generator. Each valve is tested periodically. However, conservatively, the random failure is assumed to be a failure of an MSIV in the broken steam line this would maximize the forward and reverse flow to the break and it would maximize the consequences of the event.

There are two MFIV's in series in each main feedwater line. If one MFIV fails, the second MFIV would provide isolation. All cases analyzed considered the flashing of the fluid in the lines from the upstream MFIV's to the affected steam generator; therefore, there is no need to do a separate analysis assuming MFIV failure.

C.1 Method of Mass and Energy release analysis

C.1.1 Loss of Coolant Accident

The analytical simulation of the LOCA event is divided into four distinct phases. These are blowdown, reflood, post-reflood and long term cooldown and explained below,

C.1.2.1 Blowdown:

Blowdown mass and energy release rates are calculated using the CEFLASH-4 A computer code (NRC approved in 1985). A description of the CEFLASH4 code including the conservatism's in modeling is given below. These analyses are performed in accordance with the Appendix K of 10CFR50. Additional conservatism has been include as required by Standard Review Plan (NUREG-087) to maximize the release of mass and energy to containment.

1. The appendix K prediction of fuel clad swelling and rupture is not considered. This will maximize the energy available for release from the core.

2. Calculation of heat transfer from core to coolant assume nucleate boiling. This will maximize the energy transfer to the exiting RCS coolant. While nucleate boiling is assumed for a portion of appendix K transient, as core conditions change, different heat transfer correlation may be selected by the code. To maximize fuel/cladding temperature, once an

alternate means of heat transfer is selected, the model will not go back to this high heat transfer regime.

3. The initial mass of water in the RCS is based on the temperature and pressure condition existing at 102% of full licensed power. This defers from the appendix K assumption of using nominal (cold) volume without inclusion of P/T expansion.

4. Some typical appendix K assumptions are to isolate the steam generators at the initiation of the event and include the addition of main feed water during the blowdown. For containment analyses calculation, steam flow was conservatively isolated at initiation of the event, however, a time dependent main feedwater addition to steam generators is assumed.

5. Containment pressure temperature analysis conservatively assumes that there are no degradation of steam generators and all steam generator tubes are available for secondary to primary heat transfer.

Since the refill phase (the time period during which the reactor vessel fills with SI liquid from the bottom of reactor vessel to the bottom of active core) is conservatively omitted from containment calculation, the next phase of the transient simulation is reflood.

C.1.2.2 Description of Core Reflood Model;

Reflood (applicable to cold leg breaks) is defined as the time period during which the reactor vessel level reaches an elevation of two feet below the top of the active core. At this point, the core is quenched. Reflood mass and energy release rates are calculated using the FLOOD-MOD2 computer code (ABB-CE). Heat transfer is conservatively modeled for core, vessel walls, vessel internals, loop metal, steam generator tubes, steam generator secondary, and steam generator secondary walls. The FLOOD3 (updated version of FLOOD-MOD2 NRC approved methodology) code hydraulics calculates flow rates and pressure. The heat transfer process predicts fluid enthalpies. Fluid densities are calculated as functions of pressures and enthalpies. The conservatisms in the model are as follows:

1. Depending on containment design, reflood containment pressures on System 80 plants are typically 55 psia or 70 psia.

2. A one-dimensional heat transfer model is used for all wall heat transfer calculations. It has been demonstrated that one dimensional models yield a more conservative result than identical two-dimensional models.

3. A nucleate boiling heat transfer coefficient of 10000 Btu/hr-ft^2-°F is used to model the heat

transfer from the steam generator tubes to the fluid. This coefficient represents an upper limit, and is conservatively used at all times throughout the tubes.

4. During reflood, calculations are made on the steam generator secondaries to predict the liquid levels. These calculations show that a conservatively calculated fraction (~25%) of the tube heat transfer area is in contact with the secondary steam; the remainder of the tubes is in contact with the secondary liquid. A conservative Nusselt condensation heat transfer coefficient of 2250 Btu/hr-ft^2-°F is used in conjunction with the tube 2 area exposed to steam; a natural circulation coefficient of 5 Btu/hr-ft^2-°F is used for the rest of the tube area.

5. The thermal resistance corresponding to the steam generator tubes is 0.00034 (Btu/hr-ft^2-°F)$^{-1}$. This value is also used in calculating secondary to primary heat transfer.

6. The carryover rate fraction (CRF) used during reflood is 0.05 up to the 18 inch core level, increases to 0.80 at the 24 inch core level, and is kept at 0.80 until the 10.5 foot level is reached. 10.5 feet is 2 feet below the level of the top of the active core. Other variables, such as core inlet temperature, pressure, flow rate,

linear heat rate, or other experimental data are not used to determine the CRF.

7. Reflood is assumed to terminate when the 10.5 foot quench level in the core is reached.

8. The decay heat utilized in the preparation of mass and energy release and sensible heat is based on the 1979 ANS 5.1 Standard plus a two sigma uncertainty and modified implementation of actinide correction factor without any further conservatism. The decay heat standard used is shown to be conservative enough for this application.

9. During reflood, credit is taken for the condensation of steam in the discharge legs by the cold ECCS water. As a conservatism, credit is not taken unless the reactor vessel annulus is full since the computer code assumes that the ECCS flow is injected directly into the annulus. Also, as an additional conservatism, credit is not taken when the ECCS rate is too low to thermodynamically condense all of the steam in the discharge legs. The percentage of the total steam flow condensed varies slightly with time for each case. For suction leg cases, credit is taken for the condensation of approximately 42% of the total steam flow when the annulus full and the thermodynamic criteria are simultaneously met; for discharge leg cases, the percentage varies from 42% to 50%.

C.1.2.3 Description of Post Reflood Model

This Post Reflood Model is identical to the reflood model, including the carryout rate fraction (CRF), which is kept at 0.8 for the remainder of the event. The flow rates are further enhanced by the fact that the core liquid height is now constrained at the 10.5 foot level, which maximizes the available driving head between the annulus level and the core in the FLOOD3 flooding equation. All heat transfer coefficients are kept at the values used for the reflood analysis. Condensation is analyzed as previously described; however, there is not sufficient spillage to completely thermodynamically condense the steam so that credit for condensation has not been taken.

C.1.2.4 Description of Long Term Cooling Model

The heat generation rate from shutdown fissions, heavy isotope decay, and fission product decay is shown in table 6.2.1-21. For conservatism the long-term analysis assumes that decay heat is added to the reactor vessel water at two standard deviation greater rate than that predicted by the decay heat curve.

Following the post reflood period outlined above, the mass/energy source terms for long-term containment analysis are computed concurrently with the containment back pressure in the

containment code. The steam flows out the break will be a function of the depressurization of the containment (and the variable ECCS inlet enthalpy when in the recirculation mode), decay heat (plus margin) and primary metal-to-primary fluid heat transfer. The steam generator secondary fluid, tube, thick and thin metal stored energy are used to superheat the steam prior to discharge into the containment.

The reactor coolant system is assumed to be a vessel containing a constant mass of saturated water. The pressure in the vessel is assumed to be the containment pressure. ECCS water is injected into the vessel. Steam is formed at a rate determined by decay heat, RCS metal-to-coolant heat transfer, and the rate of containment depressurization. Since the water in the vessel is saturated, boiling will occur even without decay heat or metal heat transfer as the containment pressure decreases. The difference between the ECCS injection rate and the steaming rate is the spillage rate to the sump.

The long-term decay heat and primary and secondary energy input was prepared using ABB CENP’s NRC-approved containment analysis code CONTRANS (Ref. 12). The time dependent energy addition due to this sensible heat, as calculated by CONTRANS, was input to the COPATTA mass & energy release

calculation. The decay heat and sensible energy addition data are presented in Table 6.2.1-11.

C.2 Main Steam line Break

C.2.1 Description of Blowdown Model

The secondary system pipe break analysis was performed using SGNIII version sgn 3.898 ml digital computer code (Reference 8). The version used for analysis is essentially equivalent to those used during the original plant design calculation. Some differences include a feed water expansion calculation (down stream of the affected side MFIV) which is now an integral part of the SGNIII computer model and a plant specific main steam line arrangement in the blowdown calculation.

The contribution to containment pressure due to feedwater flow is handled by feedwater flow addition to the affected steam generator and the boiling off of the feedwater by primary to secondary heat transfer. The feedwater flow is the sum of the pumped feedwater flow prior to isolation plus the isentropic expansion of the fluid in the feedwater line between the affected steam generator and its MFIV. No degradation of the feedwater flow occurs until the closure of the MFIV's. For consistency, no feedwater is added to the unaffected steam generator. Following closure of the MFIV's, there is an inventory of feedwater between the MFIV and the affected steam generator. As the affected steam

generator depressurizes, this inventory starts to boil. As steam in the line expands this feedwater inventory is pushed into the steam generator and is boiled off by primary to secondary heat transfer. The expansion of the feedwater inventory into the affected steam generator has been considered in the analysis. The expansion is assumed to be isentropic.

The isentropic expansion of the feedwater downstream of the MFIV is determined in a calculation separate from SGNIII. Since it is assumed that the pressure in the feedwater line downstream of the MFIV is the same as the affected steam generator pressure, iteration with SGNIII is required. As the affected steam generator depressurizes, the feedwater expands. At first the feedwater is subcooled and the fluid which expands into the affected steam generator is liquid. Once the steam generator pressure drops below the saturation pressure of the feedwater, flashing starts to occur and then the fluid which expands into the steam generator is two-phase.

The feedwater flow from isentropic expansion is added to the pumped feedwater flow. The pumped feedwater flow is conservatively assumed to be a constant 200% of the initial feedwater flow until the MFIVs close.

The MSLB mass/energy data given in Table 6.2.1-4 represent the total release from the NSSS - steam generator and secondary to the containment.

C.3 Containment Response Analysis

The containment pressure analyses are performed using the Bechtel COPATTA computer program that was derived from the CONTEMPT program written for the AEC loss-of-fluid test (LOFT) program.

The COPATTA model predicts both the pressure and temperature within the containment regions and the temperatures in the containment structures. Separate blowdown and core thermal behavior studies were made by ABB C-E to determine mass and/or energy input rates from sources such as: the release of reactor coolant, chemical reactions, decay energy, and sensible heat release, which may cause heating or boil-off of residual water in the reactor vessel or super-heating of steam as it passes through the steam generator and enters the containment through the postulated point of RCS rupture.

The COPATTA model treats the containment and the heat transfer surfaces following a DBA. Included in this model are ESF system parameters and analytical techniques that enable calculation of their effects upon the containment. Several options are incorporated in the model to facilitate use of these features.

COPATTA calculates a pressure-time transient with stepwise iteration between the thermodynamic state points. The iterations are based on the laws of the conservation of mass and energy together with their thermodynamic relationships. Superposition of heat

input functions is assumed so that any combination of coolant release, decay heat generation, and sensible heat release can be used with appropriate ESF features to determine the containment pressure-time-history associated with a DBA.

The program uses a three-region containment model consisting of the containment atmosphere (vapor region), the sump (liquid region), and the water contained in the reactor vessel. Mass and energy are transferred between the liquid and vapor regions by boiling, condensation, or liquid dropout. Evaporation is not considered. A convective heat transfer coefficient can be specified between the sump liquid and atmosphere vapor regions. However, since any heat transfer in this mode is small, a conservative coefficient of zero is generally assumed. Each region is assumed homogeneous, but a temperature difference can exist between regions. Any moisture condensed in the vapor region during a time increment is assumed to fall immediately into the liquid region. Noncondensable gases are included in the vapor region.

D. Accident Identification and Results

The containment pressure and temperature response and sump water temperature response versus time are given in figures 6.2.1-1 through 6.2.1-6 for the most severe LOCA breaks and the most severe MSLBs. It has been demonstrated in reference 1 where main steam line breaks produced a high degree of superheat that typical safety-related equipment surface temperatures remained

at or near the containment saturation temperature as a result of the short time frame at superheat conditions due to spray actuation.

Pipe break locations, break areas, peak pressures and temperatures, times of peak pressure, and total energy released to containment are summarized in table 6.2.1-9 for each LOCA and MSLB analyzed. Based on the results presented in table 6.2.1-9, the double-ended discharge leg slot break LOCA with maximum ECCS was identified as the pipe break with the highest peak pressure for an analyzed core power of 4070 MWt. The calculated value is 57.85 psig (72.05 psia)[1], which is below the design pressure value of 60 psig.

Figures 6.2.1-7 through 6.2.1-9 are plots of the containment condensing heat transfer coefficient versus time for the most severe RCS discharge and suction leg breaks and secondary coolant system breaks.

6.2.1.1.3.2 Long-Term Containment Performance. Long-term analyses of the worst case pump discharge leg break, and the worst case pump suction leg break were performed to verify the ability of the containment heat removal system (CHRS) to maintain the containment below the design conditions. These evaluations were based upon conservatively assumed performance of the engineered safety features. The CHRS long-term operating mode is assumed to include one containment spray train.

[1]Includes the effect of SIT Nitrogen discharge

The containment pressure-time responses for the DBA for the pumps discharge leg and the pump suction leg cases out to 8.64E+4 seconds (24 hours) are shown in figures 6.2.1-3 and 6.2.1-4 for the ESF performance mode outlined in table 6.2.1-7.

The containment pressure-time response for the highest pressure MSLB case (102% power) is shown in figure 6.2.1-6. The analysis shows that within 24 hours the containment pressure is reduced to 1/2 of peak containment pressure. No further analysis is performed for the MSLB since, after isolation and blowdown, there is no further energy input to containment. The maximum pressure of 55.2 psia occurs at 199.5 seconds in 102% power MSLB case. The energy distributions in the containment versus time are shown in figures 6.2.1-10 through 6.2.1-12 for DBA LOCAs and MSLBs. Mechanisms of energy removal from and transfer within the containment are addressed. Included are the vapor energy (steam plus air), sump (liquid) energy, energy contained in heat sinks, energy removed by the shutdown cooling heat exchangers, and energy transferred by sprays from the vapor to the sump.

6.2.1.1.3.3 Accident Chronology. Accident chronologies for the most severe reactor coolant system breaks and MSLBs are provided in table 6.2.1-10. It is assumed that time equals zero at the start of each accident.

6.2.1.1.3.4 Energy Balance. For the most severe reactor coolant system pipe breaks and the most severe secondary coolant system pipe break, a detailed energy balance is presented in table 6.2.1-11.

Table 6.2.1-9

SUMMARY OF CALCULATED CONTAINMENT PRESSURE AND TEMPERATURES

ANALYZED AT 102% OF 3990 MWt[1]

Loss-of-Coolant Accident Results	DEHLS 19.24 ft^2	DESLS 9.82 ft^2 Max ECCS	DESLS 9.82 ft^2 Min ECCS	DEDLS 9.82 ft^2 Max ECCS	DEDLS 9.82 ft^2 Min ECCS
Peak pressure, psia	67.06	68.65	68.31	72.05	69.62
Peak temperature, °F	276.6	300.55	299.64	308.41	304.07
Time of peak pressure, seconds	11.4	95.0	90.4	204.0	340
Energy released to containment up to the end of blowdown, 10^6 Btu	412.82	397.34	397.34	409.44	409.44
Main Steam Line Break Results	**102% Power 6.526 ft^2 Guillotine with Cooling Failure**	**75% Power 6.526 ft^2 Guillotine with Cooling Failure**	**0% Power 6.526 ft^2 Guillotine with Cooling Failure**		
Peak pressure, psia	55.19	55.54	55.27		
Peak temperature, °F	405.55	404.03	400.11		
Time of peak pressure, seconds	199.5	210.5	219		
Energy released to containment up to the end of blowdown, 10^6 Btu	375.7	380.9	380.6		

[1] Limiting containment peak pressure is based on LOCA. Peak containment temperature is based on MSLB. A review of prior analyses of record indicated that neither a 25% nor a 50% power case would provide limiting containment temperature conditions for MSLB.

Table 6.2.1-10

ACCIDENT CHRONOLOGIES - ANALYZED AT 102% OF 3990 MWt

(Sheet 1 of 7)

A. Worst case hot leg break

Break type: Double-ended hot leg slot break

Time (s)	Event
0.0	Break occurs
8.2	Start core flood tank injection
11.4	Peak containment pressure 67.06 psia (52.86 psig) (blowdown)
12.2	Start ECCS injection phase
12.2	End of blowdown
95	Start spray injection

Table 6.2.1-10

ACCIDENT CHRONOLOGIES - ANALYZED AT 102% OF 3990 MWt

(Sheet 2 of 7)

B. Worst case suction leg break

Break type: Double-ended suction leg slot break minimum ECCS

Time (s)	Event
0.0	Break occurs
17.5	Start core flood tank injection
20.8	Start ECCS injection phase
20.8	End of blowdown
94.6	End of core reflood
90.4	Peak containment pressure, 68.0 psia (53.8 psig)
95	Start spray injection
114.1	End of steam generator energy release: post reflood
3003	End of ECCS injection; start ECCS recirculation
3003	End of spray injection; start spray recirculation
5400	ECCS realigned: 50% to hot leg and 50% to cold leg
86400	Addition of RCS sensible heat completed
86400	Depressurization of containments, 36.62 psia, (22.42 psig). Containment Pressure is Less Than 1/2 containment peak pressure.

Table 6.2.1-10

ACCIDENT CHRONOLOGIES - ANALYZED AT 102% OF 3990 MWt

(Sheet 3 of 7)

C. Worst case discharge leg break

Break type: Double-ended discharge leg slot break maximum ECCS

Time (s)	Event
0.0	Break occurs
11.4	Start core flood tank injection
17.1	Start ECCS injection phase
17.1	End blowdown
95	Start spray injection
169.4	End of core reflood
204	Peak containment pressure subsequent to end of blowdown, 72.05 psia (57.85 psig)
288.9	End of steam generator energy release: post-reflood
1403	End of ECCS injection; start ECCS recirculation
1403	End of spray injection; start spray recirculation
5400	ECCS realigned: 50% to hot leg and 50% to cold leg
86400	Addition of RCS sensible heat completed
86400	Depressurization of containment, 35.59 psia (21.39 psig). Containment pressure is less than 1/2 of peak containment pressure.

F. Worst case main steam line break (temperature)

Break type: 102% power MSL slot break Loss of cooling train (cont)

Time (s)	Event
9.03	Main steam isolation valves closed
14.03	Main feedwater isolation valves closed (see paragraph 1.9.2.4.10)
66.11	AFW Actuates
77.11	AFW to the affected SG is isolated
90.0	Containment spray at full flow initiated inside containment building
90	Peak containment temperature of 405.55°F occurs
199.5	Peak containment pressure of 55.19 psia occurs
500	Blowdown ends

6.2.1.1.3.5 Functional Capability of Containment Normal Ventilation Systems. Containment maximum and minimum design pressures are based on conservative assumptions of initial atmospheric pressures and temperatures within the containment. The functional capability of the containment normal ventilation systems to maintain initial containment atmospheric conditions within the range of temperature and pressure defined for normal plant operation is discussed in section 9.4. The Technical Specifications give the limiting conditions of containment temperature and pressure for normal plant operation and describe the action that will be taken if these conditions are exceeded.

6.2.1.1.3.6 Protection Against Severe External Loading. The DBA for containment external pressure design has been determined to be inadvertent actuation of the containment spray system. Consideration was also given to misoperation of the containment normal purging system (i.e., operation of the exhaust train with the supply train isolated), but the maximum feasible differential pressure for this case is limited to a few inches of water (gauge) based on the exhaust fan operating curve.

As a conservative estimate of the consequences of an inadvertent spray actuation, a calculation of the minimum containment pressure has been made assuming ideal gas behavior, Dalton's laws, and a reduction in containment air temperature to the minimum spray water temperature. The assumptions used in the analysis of an inadvertent containment spray system actuation are listed in table 6.2.1-12. The maximum external

pressure that would occur as a result of this transient is 3.5 psig based on an initial containment pressure of –1.0 psig (the lower Technical Specification limit plus instrument uncertainty) and the calculated pressure drop of 2.5 psig. This calculated value is less than the 4.0 psi value used in the containment design. Measures taken to prevent inadvertent actuation are covered in paragraph 6.2.2.2.

6.2.1.1.3.7 Post-Accident Containment Pressure/Temperature Monitoring. One channel each of containment pressure and temperature instrumentation will be recorded in the main control room. Containment emergency sump temperature is not recorded since it is not required to mitigate the consequences of a DBA. Section 7.5 contains a detailed discussion of range, accuracy, and response of the instrumentation used and the type and accessibility of recorders provided. The tests conducted to qualify the instruments for use in the post-accident containment environment are discussed in section 3.11.

Table 6.2.1-11
REACTOR CONTAINMENT BUILDING ENERGY DISTRIBUTION[1]
AT 102% OF 3990 MWt (Sheet 1 of 7)

A. WORST CASE HOT LEG BREAK

BREAK TYPE: DOUBLE - ENDED HOT LEG SLOT BREAK
BREAK AREA: 19.24 SQUARE FEET

Energy Description	Energy [(10 E+6) Btu]	
	Prior to LOCA	End of blow down
Reactor Coolant system water internal energy	541.221	53.860
Safety Injection Tank Water internal energy	41.657	35.315
Energy Stored in core	33.747	13.430
Energy Stored in RV Internals	34.854	30.583
Energy Stored in RV walls	89.234	88.446
Integrated core power including decay heat	0.000	5.570
Energy stored in primary system metal including SG tubes	136.863	126.558
Energy stored in steam generator secondary walls	128.995	<128.995
Secondary coolant internal energy (in steam generators)[2]	270.276	235.680
Energy content of Containment Building[3]	Refer to figure 6.2.1-10 sheet 1	
Energy content of Containment Building internal structures[4]		
Energy of recirculation intake water (sump)

ASSUMPTIONS USED IN ANALYSIS OF INADVERTENT CONTAINMENT SPRAY SYSTEM ACTUATION

Item	Assumed Value
Initial temperature, F (max)	120
Initial pressure, psia (min)	13.2
Relative humidity, %	90
Refueling water temperature, F	60
No heat input to containment from structure or primary and secondary system components	-
Ideal gas behavior of air in containment	-

6.2.1.2 Containment Subcompartments

6.2.1.2.1 Design Bases

Subcompartments within containment, principally the reactor cavity, the steam generator compartments, and the pressurizer compartment, are designed to withstand the transient differential pressures and jet impingement forces of a postulated pipe break. Venting of these chambers is employed to keep the differential pressures within structural limits. In addition, restraints on the coolant pipes, reactor vessel, and steam generators are designed so that neither pipe whip nor forces transmitted through component supports threatened the integrity of the subcompartments or of the containment structure.

The spectrum of pipe breaks analyzed for each subcompartment are listed in table 6.2.1-1. The characteristics of the main coolant pipe ruptures were determined in accordance with the methods and criteria of subsection 3.6.2. The accident that results in the maximum differential pressure across the walls of the respective compartment is designated as the subcompartment DBA. Calculated DBA differential pressures are compared to the design differential pressure values used in the structural design of subcompartment walls and equipment to ensure that calculated values are less than design values.

The application of Leak-before-Break (LBB) to sub-compartment analysis require that the requirement be met.

a. A confirmation is made that the as-built facility design substantially agrees with the design described in the CE submittal of December 23, 1983; specifically, the piping

loads should be no greater than those cited in that submittal.

b. A confirmation that a leak detection system that is consistent with the guidelines of RG 1.45 so that it can detect leakage of 1 gpm in 1 hour.

6.2.1.2.2 Design Features

6.2.1.2.2.1 Reactor Cavity. No high energy line breaks are postulated in the Reactor Cavity due to application of Leak Before Break Criteria.

6.2.1.2.2.2 Steam Generator Compartment. The walls of the steam generator compartment are constructed of reinforced concrete that serves to support the equipment enclosed and provides radiation shielding. Engineering drawings 13-P-OOB-002 through -005 and 13-P-OOB-008 present views of the steam generator compartment arrangement.

The steam generator compartment encloses the steam generator vessel, two reactor coolant pumps and other smaller equipment. The compartment is very nearly symmetrical about the vertical plane through the two generators and the reactor vessel. The nodal model of the steam generator compartment is provided in figure 6.2.1-15. The control volume and vent path descriptions are given in Tables 6.2.1-15 and 6.2.1-16.

6.2.1.2.2.3 Pressurizer Compartment. The pressurizer compartment consists of a small, nearly square compartment that completely encloses the pressurizer vessel, as shown in engineering drawing 13-P-OOB-003 and -007. The pressurizer

vessel is supported on a pair of concrete beams which form a partial slab at elevation 110 feet. The most severe accident in this compartment is the surge line break at the vessel nozzle. This break is located within the vessel mounting skirt and produces the largest vessel uplift force. It also produces the largest compartment wall loads due to differential pressures.

The model of the pressurizer compartment used for the analysis of the surge line break consists of nine nodes and is depicted in figure 6.2.1-16. The control volume and vent path descriptions are given in tables 6.2.1-17 and 6.2.1-18.

6.2.1.2.3 Design Evaluation

6.2.1.2.3.1 Computer Codes. The computer codes used to calculate mass and energy release from postulated pipe breaks and to calculate the subsequent pressure transient response of the subcompartment are discussed below.

A. Blowdown Code: Mass and energy release rates from a postulated pipe break were calculated with the CEFLASH-4A computer program. See sections 6.2.1.1.3.B.3 and 6.2.1.1.3.C.2.

B. Pressure Transient Code

   Analysis of the pressure transients in the reactor cavity, steam generator compartments, and pressurizer compartment were performed using the COPDA computer program. Refer to BN-TOP-4.[2]

Table 6.2.1-13

REACTOR CAVITY NODAL DESCRIPTION (Sheet 1 of 8)

A. 100 Square Inches Hot Leg Guillotine Break
Break location: volume numbers 2 and 3

Volume No.[(a)]	Description	Height (ft)	Cross-Sectional Area (ft^2)	Initial Conditions[(b)]			Peak Calculated Differential Pressure (psig)	Net Free Volume (ft^3)
				Temperature (°F)	Pressure (psia)	Humidity (%)		
1	Cavity above shield plug between adjacent to broken pipe and excore detector	14.1	13.3	120	14.4	25	16	198
2	Adjacent to node 1 and hot leg at plant north	14.1	15.7	120	14.4	25	27	229
3	Adjacent to node 2 and the excore detector	14.1	15.7	120	14.4	25	27	229
4	Adjacent to node 3 and the next cold leg	14.1	13.3	120	14.4	25	16	198
5	Adjacent to node 4 and the next cold leg	14.1	29.0	120	14.4	25	7	439
6	Adjacent to node 1 and the next cold leg	14.1	29.0	120	14.4	25	7	439
7	Adjacent to node 6 and the next excore detector	14.1	13.3	120	14.4	25	4	198
8	Adjacent to node 7 and the hot leg at plant south	14.1	15.7	120	14.4	25	4	229

a. Refer to figure 6.2.1-13.

b. The NRC Standard Review Plan indicates that as low as possible initial relative humidity and pressure should be used in subcompartment analysis.

Paragraph 2.3.1.1.4 shows that the average atmosphere relative humidity is 36%. The value of 25% as used in the subcompartment analysis is, therefore, conservatively low.

Subsection 2.4.3 gives plant (Unit 3 nominal) elevation as 951 feet (msl). This corresponds to an atmospheric pressure of 14.2 psia. By including the effect of humidity on the containment atmosphere, a total pressure of 14.6 psia is realized. This is conservatively lowered to 14.4 psia in the subcompartment analysis.

Table 6.2.1-13

REACTOR CAVITY NODAL DESCRIPTION (Sheet 2 of 8)

A. 100 Square Inches Hot Leg Guillotine Break
Break location: volume numbers 2 and 3

Volume No.[a]	Description	Height (ft)	Cross-Sectional Area (ft^2)	Initial Conditions[b]			Peak Calculated Differential Pressure (psig)	Net Free Volume (ft^3)
				Temperature (°F)	Pressure (psia)	Humidity (%)		
9	Adjacent to node 8 and the next excore detector	14.1	15.7	120	14.4	25	4	229
10	Adjacent to nodes 9 and 5	14.1	13.3	120	14.4	25	4	198
11	Between shield plug and bottom of reactor cavity, below node 1	18.2	9.6	120	14.4	25	<2	159
12	Between shield plug and bottom of reactor cavity, below nodes 2 and 3	18.2	29.7	120	14.4	25	<2	500
13	Between shield plug and bottom of reactor cavity, below node 4	18.2	9.6	120	14.4	25	<2	159
14	Between shield plug and bottom of reactor cavity, below node 5	18.2	33.4	120	14.4	25	<2	571
15	Between shield plug and bottom of reactor cavity, below node 6	18.2	33.4	120	14.4	25	<2	571
16	Between shield plug and bottom of reactor cavity, below node 7	18.2	9.6	120	14.4	25	<2	159
17	Between shield plug and bottom of reactor cavity below nodes 8 and 9	18.2	29.7	120	14.4	25	<2	500
18	Between shield plug and bottom of reactor cavity below node 10	18.2	9.6	120	14.4	25	<2	159

6.2.1.2.3.2 Subcompartment Modeling. Subcompartment nodalization models are determined by physical flow restrictions within each compartment. These flow restrictions include consideration of concrete obstructions, doorways, vent shafts, grating, piping, the reactor cavity shield plug, and major equipment component. By choosing nodal boundaries at the various primary system components and physical flow restrictions, the calculated differential pressures and consequent vessel loads are maximized. A further increase in the number of subcompartment nodes modeled is not feasible unless additional physical flow restrictions are present. The subcompartment models, discussed below, take into account all physical flow restrictions present. Vent loss coefficients are categorized as either orifices or miscellaneous. Orifice coefficients are calculated by the COPDA computer code (see paragraph 6.2.1.2.3.1). For flow restrictions which cannot be adequately modeled as orifices, a miscellaneous flow coefficient is determined. References 3 and 4 are used in determining miscellaneous flow coefficients. The miscellaneous flow coefficients include friction losses; objects in flow paths; grating; and expansion, contraction, and turning losses.

A. Reactor Vessel Cavity

   There are no postulated breaks in the Reactor Vessel Cavity as a result of application of Leak Before Break Criteria.

Table 6.2.1-15
STEAM GENERATOR COMPARTMENT NODAL DESCRIPTION (Sheet 1 of 7)[a]

Volume No.[b]	Description	Height (ft)	Cross-Sectional Area (ft^2)	Initial Conditions Temperature (°F)	Initial Conditions Pressure (psia)	Initial Conditions Humidity (%)	Peak Calculated Differential Pressure (psid)	Net Free Volume (ft^3)
1	Adjacent to and east of hot leg east to reactor cavity cooling fan and south to primary shield wall, below 100.6'	13.6	47	120	16.7	0	(c)	283
2	Adjacent to and symmetric to 1	13.6	47	120	16.7	0	(c)	269
3	Between 1 and steam generator (S.G.)	13.6	40	120	16.7	0	(c)	108
4	Adjacent to and symmetric to 3	13.6	40	120	16.7	0	(c)	108
5	Between S.G. and reactor coolant pump (RCP) north to pump suction leg and south to cavity cooling fan	13.6	115	120	16.7	0	(c)	792
6	Same as 5 only west of steam generator	13.6	115	120	16.7	0	(c)	792

a. NRC Generic Letter 87-11 has been implemented.

b. Refer to figure 6.2.1-15.

c. Volume is not adjacent to shield wall.

STEAM GENERATOR NODAL SENSITIVITY STUDY

592-SQUARE INCH SUCTION LEG BREAK

	Sensitivity Study	Models	Present Model
Total number of nodes	41	47	55
Maximum primary wall pressure (psia)	38.4	38.8	38.8
Maximum secondary wall pressure (psia)	44.0	44.1	43.9
X-Axis moment (10^6 ft-lb)	2.80	2.79	2.79
Y-Axis moment (10^6 ft-lb)	-6.77	-6.93	-7.18
Lateral load (10^5 lb_f)	4.73	4.89	4.98
Uplift load (10^5 lb_f)	5.86	5.93	5.92

B. Steam Generator Compartments

For the steam generator compartment, the worst case break was determined to be the 129-square inch shutdown cooling line break. The pressure transient response is presented in figure 6.2.1-18. The peak differential pressures acting across the primary and secondary shield walls are summarized in table 6.2.1-15. Based on the results of nodal sensitivity studies performed for other plants, the nodalization of the steam generator compartment was increased from a maximum of 15 nodes at the construction permit stage to the current 55 nodes. These nodal boundaries were located radially and axially at all positions that could have significant pressure differentials or could contribute significantly to the loads on a piece of equipment. A nodal sensitivity study was performed on the present 55-node model. Pressure, force, and moment values from the 55-node model were compared to the values obtained from 41 and 47 node models. This study indicates negligible difference between the values in each model. The results are summarized in table 6.2.1-20. The inertial version of COPDA was used in the analysis.

C. Pressurizer Compartment

The response of the pressurizer compartment to postulated surge line break is presented in figure 6.2.1-19.

6.2.1.3 Mass and Energy Release Analysis for Postulated Loss-of-Coolant Accidents

A. The design basis LOCA is the double-ended discharge leg slot break. The mass/energy releases used in conjunction with the COPATTA computer code are as follows:

1. Decay heat (see table 6.2.1-21).
   4070 MWt analyzed core power:

   1979 ANS 5-1 decay heat with 2σ added for entire analyzed transient.

2. Metal water reaction included in blowdown containment P/T calculation. (See table 6.2.1-22)

3. Mass energy release data Table 6.2.1-4. (See table 6.2.1-23)

4. Spillage data (See table 6.2.1-24)

5. Miscellaneous energies (See table 6.2.1-25)

   (a) Energy stored in core

   (b) Energy stored in R.V. internals

   (c) Energy stored in R.V metal

   (d) Energy stored in pressurizer, primary piping, valves, and pumps

   (e) Energy stored in steam generator tubes

   (f) Energy stored in steam generator secondary walls

(g) Secondary coolant internal energy in Steam Generators No. 1 and No. 2

B. Additional energy releases:
Energy of steam in main steam line up to the MSIVs

4070 MWt analyzed core power:

= 9.8974×10^6 Btu (included in table 6.2.1-25).

6.2.1.4 Mass and Energy Release Analysis for Postulated Secondary System Pipe Ruptures Inside Containment

The MSLB methodology used for the PVNGS analysis is discussed in section 6.2.1.1.3.B.3 and 6.2.1.1.3.C.2 as follows. The PVNGS specific steam line arrangement was used for determining flow from the intact steam generator to the containment prior to isolation. The steam line model considered choking at the MSIV throat and cross-connect piping as well as at the venturi throat. The MSIV and MFIV closure times were 4.6 and 9.6 seconds, respectively.

The PVNGS specific mass and energy release data for the most severe MSLB containment pressure and temperature cases are given in table 6.2.1-4.

6.2.1.5 Minimum Containment Pressure Analysis for ECCS Performance Analysis

6.2.1.5.1 Introduction and Summary

Appendix K to 10 CFR 50[8] lists the required and acceptable features of Emergency Core Cooling System (ECCS) evaluation models. Included in the list is the requirement that the containment pressure used in the evaluation of ECCS performance not exceed a pressure calculated conservatively for that purpose. This section describes the analyses that determined the minimum containment pressure used in the Palo Verde 1, 2 and 3 ECCS performance analyses presented in subsection 6.3.3.

6.2.1.5.2 Method of Calculation

The calculations reported in this section used the NRC-approved 1999EM version of the Westinghouse Electric Company LLC large break LOCA evaluation model for Combustion Engineering designed PWRs[9, Supplement 4-P-A]. In the evaluation model, the CEFLASH-4A computer program[10] determines the mass and energy released to the containment during the blowdown phase of the postulated LOCA. The COMPERC-II computer program[11] determines both the mass and energy released to the containment during the refill/reflood phase of the LOCA and the minimum containment pressure response used in the ECCS performance analysis.

A minimum containment pressure analysis was completed to support an "ECCS break spectrum analysis" for implementation of replacement steam generators with 10% tube plugging and simplified head assembly for ZIRLO™ clad fuel rods for a

thermal power of 4070 MWt. This analysis bounds PVNGS units utilizing Zircaloy-4 clad material.

6.2.1.5.3 Input Parameters

The input for the minimum containment pressure analysis for Palo Verde 1, 2 and 3 presented herein is consistent with the input used in the ECCS performance analyses described in UFSAR section 6.3.3.

6.2.1.5.3.1 Mass and Energy Release Data. The mass and energy released to the containment for the limiting large break LOCA for peak clad temperature, the 0.6 DEG/PD break (Double Ended Guillotine break in Pump Discharge), are listed as a function of time in Table 6.2.1-26. The mass and energy released to the containment for the limiting large break LOCA for maximum clad oxidation and core-wide cladding oxidation, 0.8 DEG/PD, are similar in nature. The quantity of safety injection fluid that spills from the break is discussed in paragraph 6.2.1.5.3.5.

6.2.1.5.3.2 Initial Containment Internal Conditions. The initial containment internal conditions used in the "break spectrum" are:

Temperature	50°F (minimum)
Pressure	13.2 psia (minimum)[a]
Relative Humidity	100% (maximum)

For each parameter, the conservative direction with respect to minimizing the containment pressure appears in parentheses.

a. This pressure is less than Technical Specification minimum. Minimum pressure is conservative.

6.2.1.5.3.3 Containment Volume. The net free containment volume used in the analysis is 3,000,000 ft^3 which is the maximum value including all uncertainties.

6.2.1.5.3.4 Active Heat Sinks. In order to conservatively maximize the heat removal capacity of the containment active heat sinks, the containment sprays were modeled with a minimum actuation time following the LOCA and to operate at their maximum capacity.

The operating parameters used for the containment sprays in the "break spectrum analysis" are as follows:

Number of pumps	2
Flow rate	5250 gpm/pump
Actuation time	30 sec after LOCA
Temperature	60°F

6.2.1.5.3.5 Steam Water Mixing. The effect on containment pressure due to condensing containment steam with spilled ECCS water was calculated in the manner described in Section III.D.2 of reference 9 (CENPD-132P, Volumes I and II). The effective ECCS spillage rate is shown as a function of time in Figure 6.2.1-21 for the "break spectrum analysis." The spillage rate was conservatively determined using the maximum flow rate from two high pressure and two low pressure safety injection pumps and initiating the safety injection pump flow when the downcomer was refilled by the safety injection tanks.

6.2.1.5.3.6 Passive Heat Sinks. For the "break spectrum analysis," the surface areas and thickness of all exposed containment passive heat sinks are listed in Table 6.2.1-27. To maximize the heat transfer to the passive heat sinks, the surface areas were modeled at the maximum of their uncertainty ranges and their thermal properties (conductivity and heat capacity) were maximized. Table 6.2.1-27 also describes how they were modeled into ten equivalent walls for the COMPERC-II computer code.

6.2.1.5.3.7 Heat Transfer to Passive Heat Sinks. The condensing heat transfer coefficient between the containment atmosphere and the passive heat sinks was calculated in the manner described in Section III.D.2 and Figure III.D.2-2 of reference 9 (CENPD-132P, Volumes I and II). The variation of the condensing heat transfer coefficient is shown as a function of time in Figure 6.2.1-25, for the "break spectrum analysis."

6.2.1.5.3.8 Containment Purge System. The effects of the 8-inch power access purge system was evaluated in an earlier minimum containment analysis. The power access purge system was assumed to be operating at the time of the postulated LOCA. The purge system isolation valves are fully closed 8.0 seconds after a containment isolation actuation signal generated by high containment pressure (5.0 psig). It is assumed that only dry air is removed from the containment atmosphere through the purge system. This conservatively minimized the calculated containment pressure. Analysis has shown operation of containment purge system has negligible effect on results. This conclusion remains applicable to the latest analysis.

6.2.1.5.4 Results

For the limiting large break LOCA, the 0.6 DEG/PD break, the minimum containment pressure response for the ECCS "break spectrum" analysis is shown in Figure 6.2.1-22 and Figure 6.3.3.2-3F. The responses of the containment atmosphere and containment sump temperatures are shown in Figures 6.2.1-23 and 6.2.1-24 respectively, for the "break spectrum analysis" limiting break size.

The containment response is used in the ECCS performance analyses presented in Section 6.3.3.

6.2.1.6 Testing and Inspection

Testing and inspection requirements for the containment are discussed in subsection 6.2.6. No other testing of the containment structure is planned or required. Testing and inspection requirements for other engineered safety features that interface with the containment structure are discussed along with the applicable system descriptions.

6.2.1.7 Instrumentation Applications

The containment pressure is measured by independent pressure transmitters located at widely separated points outside the containment. Refer to section 7.3 for a discussion of pressure as an input to the engineered safety features actuation system (ESFAS). Refer to section 7.5 for a discussion of the display instrumentation associated with pressure.

The containment airborne radioactivity is monitored by the airborne radioactivity monitoring system, discussed in

section 11.5. Hydrogen concentration is monitored in the containment by the hydrogen monitoring system, discussed in subsection 6.2.5. Temperature sensors are positioned at appropriate locations throughout the containment. The temperature is displayed in the main control room along with high-temperature alarms.

6.2.1.8 Qualification Parameters for In-Containment, Safety-Related Equipment

In-containment, safety-related equipment required to operate post-MSLB is qualified to the main steam line break design basis accident environment as specified in Appendix A of the Equipment Qualification Program Manual. The results shown in Appendix A of the Equipment Qualification Program Manual are of a containment analysis for a 102% power, 7.16-square foot, slot-type main steam line break, with the loss of one containment spray train and no loss of offsite power. It differs from the analysis of the main steam line break of paragraph 6.2.1.1.3.1 in that the equipment qualification analysis utilizes 8% condensate reevaporation as allowed by Appendix B of NUREG-0588[5].

In-containment, safety-related equipment required to operate post-LOCA is qualified to the LOCA design basis accident environment as specified in Appendix A of the Equipment Qualification Program Manual. This environment bounds the calculated pressure-time and temperature-time response of figure 6.2.1-3 which shows the worst case LOCA transient as discussed in paragraph 6.2.1.1.3.1, listing D.

6.2.2 CONTAINMENT HEAT REMOVAL SYSTEMS

The functional performance objective of the containment spray system (CSS) as an engineered safety feature system is to reduce the containment temperature and pressure following a LOCA, MSLB accident, by removing thermal energy from the containment atmosphere. This cooling system also serves to limit offsite radiation levels by reducing the pressure differential between the containment atmosphere and the external environment, thereby diminishing the driving force for leakage of fission products from the containment to the environment.

6.2.2.1 Design Bases

The design bases for the containment spray system are:

A. The CSS shall be designed to rapidly reduce the containment pressure and temperature following a LOCA or MSLB, and maintain these parameters at acceptably low levels as required by NRC General Design Criterion 38. The sources and amounts of energy released to the containment that were used as the basis for the sizing of the containment spray system are given as functions of time in subsection 6.2.1.

B. The spray system shall consist of two redundant and independent trains each of which provides 100% of the required heat removal capability and 100% of the required iodine removal capability.

C. The heat removal capacity of the system shall be sufficient to keep the containment pressure and

temperature below design conditions for any size break in the reactor coolant system piping up to and including a double-ended break of the largest reactor coolant pipe. The system also is designed to mitigate the consequences of any size break in the main steam line piping, up to and including a double-ended break of the main steam line from a single steam generator. During recirculation, the system shall continue to reduce containment pressure and temperature and maintain them at acceptable levels. For the containment design basis accident, the containment spray system shall be designed to reduce containment pressure from peak value to one-half peak value in less than 24 hours.

D. The portions of the containment heat removal system located inside containment shall be designed to remain operable in the containment accident environment.

E. The CSS shall be designed such that a single failure of any active component will not degrade the system ability to fulfill design objectives.

Each train of the CSS shall receive power from a separate emergency diesel generator in the event that off-site power is unavailable during an accident. The two trains shall be physically separated from each other so that a failure in one train will not result in failure of the other train due to fire, flooding, jet impingement, or missiles.

Each train shall receive separate actuation signals. Critical plant parameters shall be monitored and the actuation signals shall be produced in the ESFAS.

F. The CSS shall be designed to Seismic Category I requirements.

G. The CSS shall be protected against dynamic effects associated with postulated rupture of piping as discussed in section 3.6.

H. The CSS is designed to permit the periodic inspection and testing as described in the plant Technical Specifications and Technical Requirements Manual.

I. The CSS shall be designed rapidly reduce fission product iodine concentration in the containment atmosphere.

J. System sizing shall be based on the long-term heat rejection function of the system. The CSS shall use the shutdown cooling heat exchangers to reject heat from the containment.

Protection of the CSS from wind and tornado effects is discussed in section 3.3. Flood design is discussed in section 3.4. Missile protection is discussed in section 3.5. Principal design codes and standards are given in table 3.2-1.

6.2.2.2 System Design

Piping and instrumentation diagrams and spray header arrangements of the CSS are provided in engineering drawings 01, 02, 03-M-SIP-001, -002, and –003 and 13-P-ZCG-114. A table of the design and performance data for the system is provided below.

CONTAINMENT SPRAY PUMPS

Quantity	2
Type	Centrifugal, vertical single stage
Safety Class	2
Code	ASME III, Class 2
Design Pressure, psig	650
Design Temperature, °F	400
Design Flow Rate, gpm	3890
Design Head, feet	505
Maximum Flow Rate, gpm	5200
Head at Maximum Flow Rate, feet	473 max/380 min
Shutoff Head, feet	690 max/640 min
NPSH Required, feet	20 at 5200 gal/min
Design Suction Pressure, psig	485
Maximum Suction Operating Pressure, psig	320
Material	Stainless Steel
Pumped Fluid	2.5% w/o boric acid (4400 ppmB)
Rated Motor Horsepower/Pump	800

Motor Voltage, volts	4000, 3 phase
SPRAY NOZZLES	(Reference Section 6.5.2.3)
Number (for two spray headers)	460 (primary) 80 (auxiliary)
Type	Non-clogging
Flow, per nozzle	15.2 gpm at 40 psid 3 gpm at 40 psid

Table 7.3-11A shows plant protection signals and setpoints that actuate the CSS.

The assumed delay times following postulated accidents are tabulated in Table 6.2.1-10. A discussion of the delay times following receipt of the actuation signals is provided in section 7.3.

A description of the qualification tests performed on system components is provided in CESSAR Sections 3.10 and 3.11. Environmental test conditions, as shown in CESSAR Figure 3.11A-1, are representative of post-accident conditions as described in subsection 6.2.1.

Fan systems for post-accident containment heat removal are not employed at PVNGS.

6.2.2.2.1 CONTAINMENT RECIRCULATION SUMP SCREENS

The general guidance of NEI 04-07, Pressurized Water Reactor Sump Performance Evaluation Methodology, is used to comply with requirements of GL 2004-02 for strainer sizing evaluations for

the replacement sump strainers installed under DMWO 2822654. The guidance document, NEI 04-07, has been reviewed by the NRC for use in sump strainer sizing evaluations for Pressurized Water Reactors, with the review documented in an SE dated December 6, 2004. The assumption of 50 percent blockage and approximate coolant velocity of 6cm/sec (0.2 ft/sec) described in Regulatory Guide 1.82 are no longer used for strainer sizing evaluations. The vertical and horizontal surfaces of the strainer is accounted for in the determination of total available surface area(this is an exception to Regulatory Guide 1.82). The design features of the recirculation intake structures (sumps) comply with Regulatory Guide 1.82, with the exceptions noted above, and include the following features:

A. Two independent sumps and screens are provided, one for each safety-related train.

B. Physically separated sumps preclude simultaneous damage to both strainers.

C. Sumps located in the lowest floor of the containment building, at elevation 80 feet 0 inch, are protected by cassette strainer assemblies with integral trash rack. The strainers are placed within a 3-inch high curb and atop a sub-floor covering the sump opening at elevation 80 feet 0 inch.

D. The floor level in the sump vicinity slopes toward local floor drains. In addition, to preclude surface waste from plugging the screens, a 3-inch curb is provided around the perimeter of the sub-floor.

E. The 3-inch curb around the sumps also provides protection from surface drains. No drains from upper regions impinge on the screen assemblies.

F. The strainer assemblies consist of horizontal cassette pockets made of perforated plate that provide the screen area. Each pocket is approximately 3 inches wide by 5 inches high, and the leading edge is solid plate, which acts as an integral trash rack to protect the perforated portion of the pocket from debris. See figure 6A-5

G. With the horizontal cassette pocket (specialty) design, the strainers consist of both vertical and horizontal flow paths through the screening elements. All pockets are submerged at the minimum post-LOCA flood level. Since the new strainers are approximately 3,142 ft^2 vs. the original 210 ft^2 screens, design coolant velocity at the new strainer is less than that for the original screens.

H. The top of the strainer assemblies is a solid (non-perforated) plate and will be submerged during the recirculation mode of operation at minimum water level conditions.

I. The strainer cassettes (with integral trash rack) are designed to withstand the vibrating motion of seismic events without loss of structural integrity.

J. The holes in the perforated plate of the strainers are 0.083 inches in diameter, which satisfies original C-E requirements on sump screen design (0.09 inches

maximum). No flow blockage will occur beyond the screen as all openings are larger than the minimum screen size.

K. The pump intake is designed to minimize vortexing and other degrading effects on pump inlets.

L. The strainer assemblies are fabricated from austenitic stainless steel and zinc-coated carbon steel. Both materials have a low sensitivity to spray-induced corrosion and will not be adversely affected by periods of inactivity.

M. A manhole is provided in the strainer assembly sub-floor to facilitate access into the sump and suction intake structures.

N. The manhole facilitates access for inspection of strainer parts accessible from below the sub-floor. Adequate space is provided around the strainers to facilitate unobstructed inspection of the outside strainers.

O. There are no high energy lines located in the vicinity of the emergency sumps which could interfere with the successful operation when required.

6.2.2.2.2 INSULATION IN CONTAINMENT

Identification of the reflective piping insulation and quantities used within the containment are listed in table 6.2.2-1.

The insulation is designed to be non-reactive under the following LOCA conditions:

Ambient temperature	140 to 350F
Relative humidity	Saturated steam/air mixture
Air velocity	0 to 300 ft/min
Radiation	3.3 x 107 rads integrated dosage
Chemical	Up to 4400 ppm boron, pH 4-10
Pressure	60 psig

Metallic, reflective-type insulation type 304, stainless steel is attached to the piping and components as two half-segments with quick release latches or by expansion-type metal bands. Mirror and reflective insulation is by Diamond Power Corporation and TRANSCO, respectively.

NUKON nonmetallic thermal insulation is used for the pressurizer. NUKON insulation is also installed on portions of the pressurizer spray line, the main feedwater line, and the blowdown line at pipe support locations. Table 6.2.2-2 indicates the location and quantity of NUKON insulation used in containment. NUKON insulation consists of high temperature fibrous glass insulation, enclosed in woven fibrous glass fabric. The fabric completely encloses the wool insulation, and its seams are sewn with fibrous glass thread. The blanket is enclosed in stainless steel wire mesh and the NUKON insulation is attached with heavy-duty Velcro fasteners. The uninsulated portion of piping at the support locations for the pressurizer spray line and selected uninsulated support locations for the blowdown line and main feedwater line are also wrapped with NUKON thermal insulation to avoid heat loss

at the junction of metallic insulation and the pipe supports. Due to this composition, density of the system varies with thickness. Therefore, a more accurate representation of density is in pounds per square foot. A 4-inch thick NUKON blanket will weigh an average of 1.8 to 2.2 pounds per square foot (with knitted wire mesh, add 0.2 to 0.3 pound per square foot). NUKON insulation is manufactured by Owens-Corning Fiberglass Corporation.

Table 6.2.2-1

REFLECTIVE PIPING INSULATION USED WITHIN CONTAINMENT IN UNITS WITH ORIGINAL STEAM GENERATORS

Nominal Pipe Dia (in.)	Length (ft)	Use	Attachment Method
28	710	Main Steam	Quick release latches or expansion type metal bands
24	290	Main Feedwater	Quick release latches or expansion type metal bands
14	60	Main Feedwater	Quick release latches or expansion type metal bands
6	280	Steam Generator Blowdown	Quick release latches or expansion-type metal bands
4[b]	130	Downcomer Blowdown	Quick release latches or expansion-type metal bands
4	60	Feedwater Recirculation	Quick release latches or expansive-type metal bands
12	540	Safety Injection	Quick release latches or expansive-type metal bands
14	160	Safety Injection	Quick release latches or expansive-type metal bands
16	290	Shutdown cooling	Quick release latches or expansive-type metal bands

a. 4-inch thick insulation is assumed for listed pipes.

b. Line size is 6-inch in Unit 2 only.

Table 6.2.2-2

NUKON INSULATION USED IN CONTAINMENT

Nominal Pipe Dia. (in.)	Quantity[(a)] (ft^3)	Use
NA	48	Top head area of the pressurizer
4	22	Pressurizer spray line
24	74	Main feedwater line
4[(c)]	24[(b)]	Blowdown lines

a. 4-inch thick insulation is assumed for all listed pipes.

b. Quantity includes NUKON installed on SG blowdown lines and Transco THERMAL-WRAPS® insulation system installed on downcomer blowdown lines. Unit 2 volume is 21ft^3.

c. Unit 2 only is 6-inch

The NUKON system will not be reduced to fine fiber because of the spray or radiation conditions of a LOCA. This has been demonstrated in the Owens-Corning Fiberglass Corporation Topical Report OCF-1: Nuclear Containment Insulation System (Final NRC Staff Evaluation, dated December 8, 1978).

Transco THERMAL-WRAP® insulation system consists of a lightweight fiberglass blanket. The THERMAL-WRAP® insulation system is designed for use in nuclear power plant containments

and uses materials that have been fully tested and qualified for use in nuclear power plants. It is similar in design and construction to the NUKON nonmetallic insulation systems and will not be reduced to fine fiber because of the spray or radiation conditions of a LOCA.

TEMP-MAT nonmetallic thermal insulation is used for the reactor vessel, and pressurizer as spacers between these components and their reflective insulation. The TEMP-MAT insulation is composed of needle-type, porous, fiberglass material that will not disintegrate to a powder form. As such, it is not expected that TEMP-MAT insulation material will form particles small enough to pass through the sump screens. TEMP-MAT is a type of fiberglass insulation enclosed in fiberglass cloth material and attached by pop rivets to the reflective insulation. The 1-1/2-inch thick TEMP-MAT insulation has a density of approximately 1.4 pounds per square foot. The TEMP-MAT insulation is manufactured by Pittsburgh-Corning Corporation. A total of 500 square foot of 1-1/2-inch thick TEMP-Mat insulation is installed on the reactor vessel and pressurizer in quantities of 200, and 300 square feet, respectively.

Nonmetallic insulation on nonreactor coolant pressure boundary components is limited to the normal chilled water system piping with a density of 4 pounds per cubic foot. Four hundred feet of fiberglass insulation is used on 10-inch, 8-inch, and 6-inch chilled water pipe. Nonmetallic insulation (fiberglass) is enclosed in stainless steel sheet and strapped to the component. The fiberglass insulation is manufactured by the CERTAINTEE Company.

6.2.2.3 Design Evaluation

A. The CSS is designed to rapidly reduce the containment pressure and temperature following a LOCA or MSLB. Figures 6.2.1-1 through 6.2.1-6 show the effect of containment spray in event of these accidents. Plan and elevation drawings of the containment showing expected spray coverage are provided in figures 6.5-1 through 6.5-6.

A discussion of containment sprayed volume and spray overlap is provided in paragraph 6.5.2.2. A discussion of the system's heat removal effectiveness is found in Section 3.1.34 Response.

Performance testing of the spray nozzles has verified that they will function as predicted, in terms of flow rate, spray angle, drop size spectrum, and mean drop size as a function of the pressure drop across the nozzles.

A detailed description of the SPRACO nozzle parameters was submitted earlier to the NRC for the Waterford Steam Electric Station, Unit No. 3, Docket No. 50-382.

Analysis of the NPSH of the recirculation pumps in accordance with Regulatory Guide 1.1 is provided in section 6.3 (the same analysis as for high-pressure safety injection (HPSI) pumps). Pump data are tabulated in UFSAR section 6.2.2.2.

B. The containment spray system consists of two redundant and independent trains, each of which is capable of

providing 100% of the required heat removal capability and 100% of the required iodine removal capability.

C. The heat removal capacity of the CSS is discussed in subsection 6.2.1.

D. The containment heat removal system is designed to remain operable in the containment accident environment as discussed in section 3.11.

E. The CSS is designed such that single failure of any active component will not degrade system abilities as shown in the failure modes and effects analyses Table 6.2.2-4 (for further discussion of system actuation, see section 7.3).

F. The entire CSS is designed to Seismic Category I requirements. System components as appropriate are designed to meet ASME Code, Section III, Class 2 requirements.

G. The CSS is protected against dynamic effects associated with postulated rupture of piping as discussed in section 3.6.

H. The CSS is designed to permit the periodic inspections and tests described in the Technical Specifications and the Technical Requirements Manual.

I. The CSS is designed to reduce fission product iodine concentration in the containment atmosphere as discussed in section 6.5.

J. The CSS is sized based on the long-term heat rejection function of the system. The shutdown cooling heat

exchangers used for rejecting heat from the containment are sized by the shutdown cooling function discussed in subsection 5.4.7.

PVNGS does not employ a fan system as part of the containment heat removal system during post-accident conditions.

Graphs of the integrated energy content of the containment atmosphere and recirculation water as functions of time are provided in figures 6.2.l-10, 6.2.1-11, and 6.2.1-12.

6.2.2.4 Test and Inspections

As part of the overall testing program, hydraulic model tests were performed in order to determine the effect of the sump design on vortex phenomena and on entrance and line losses relative to the required NPSH for ESF pumps. The hydraulic testing included taking suction from the original design model sump to verify vortex control and acceptable pressure drops across screening and suction lines and valves.

The preoperational testing of ESF pumps in accordance with Regulatory Guide 1.79 verified operability of the ESF pumps.

In evaluating the net positive suction head available (NPSHA) of safety-related pumps taking suction from the containment recirculation sumps, the head losses obtained from hydraulic model tests performed on the original recirculation sumps and suction piping were combined with conservative analytically calculated head losses of portions of pipe that were not modeled.

In evaluating the NPSHA of safety-related pumps taking suction from the refueling water tank (RWT), the data obtained during the preoperational pump tests was used in conjunction with analytical calculations.

The program for initial performance testing is covered in section 14.2 and CESSAR Appendix 6A, Section 9.0.

6.2.2.5 Instrumentation Requirements

6.2.2.5.1 ACTUATION SIGNALS

The Containment Spray System is automatically actuated by a Containment Spray Actuation Signal from the Engineered Safety Features Actuation System. The CSAS is initiated by a coincidence of two-out-of-four high-high containment pressure signals, or two remote manual signals from the control room, or by loss of power to two-out-of-four actuation logic channels.

The Containment Spray System’s supportive systems are automatically actuated by a Safety Injection Actuation Signal from the Engineered Safety Features Actuation System. The SIAS is generated prior to or coincident with the CSAS by a two-out-of-four high containment pressure signals, or remote manual signals from the control room, or by loss of power to two-out-of-four actuation logic channels. The SIAS is also actuated by low pressurizer pressure signals. Any SIAS will automatically start the containment spray pumps. The Containment Spray System’s suction is automatically changed from the Refueling Water Tank to the Containment Sump by a Recirculation Actuation Signal from the Engineered Safety Features Actuation System. The RAS is generated by two-out-of-four low Refueling Water

Tank level signals, or two remote manual signals in the control room, or by loss of power to two-out-of-four actuation logic channels. Following the RAS, timely operator action is required to isolate the RWT using valves CH-530 and CH-531 to prevent ingress of air in the ESF pump suction piping during switchover to recirculation.

The ESFAS trains are redundant, separate, and diverse. Details of the system are contained in Sections 7.3 and 7.4.

CSS ACTUATION

	SIAS Initiated CSAS Not Initiated	CSAS Initiated
CSP 1, 2	START / RUN	START / RUN
SI-671, 672	CLOSED	OPEN

A SIAS or CSAS starts the Containment Spray Pumps but only a CSAS opens the Spray Header Isolation Valves (SI-672, SI-671).

Separate ESFAS actuation devices are used for the CSP and Spray Header Isolation valve. The design is such that the pump actuation device may be tested separately from the valve actuation device.

The CSAS may be overridden on the component level.

Manual initiation of the CSAS is achieved by the actuation of two separate control switches. Similarly the RAS may be initiated manually by the actuation of two separate control switches. Manual initiation of containment spray actuation and recirculation actuation signals can be accomplished on a component level also.

Control room indications of pump operation and flow delivery are provided by pressure indicators and flow meter in the CSP discharge piping. Alignment of automatic valves is shown in the control room by open-closed indicator lights. Throttling valves are provided with continuous position indication.

6.2.2.5.2 INSTRUMENTATION

Display instrumentation which is available to the operator to allow him to adequately monitor conditions in the Containment Spray System and to perform any required manual safety functions. The information provided is sufficient to allow the operator to accurately assess the conditions within the Containment Spray System and in a timely manner perform those actions to maintain the system within the conditions assumed. In addition, the information allows cross-checking of the instrument channels to assure operational availability and positive indications that pumps and valves have actuated and that flows have been established.

6.2.2.6 System Operation

6.2.2.6.1 OPERATING MODE

6.2.2.6.1.1 Normal Operation

During normal plant operation the CSS is aligned for the injection mode, but does not operate.

6.2.2.6.1.2 Operation During Plant Accident Conditions

6.2.2.6.1.2.1 Injection Mode of Operation

The Containment Spray System is initiated by a containment spray actuation signal (CSAS) which occurs on a two out of four high-high containment pressure signal. The CSAS may also be initiated manually in the control room. The signal starts the containment spray pumps and opens the spray header isolation valves SI-671 and 672 to the containment.

The Safety Injection Actuation Signal (SIAS) automatically starts the containment spray pumps but does not open the spray header isolation valves SI-671 and SI-672.

The specific sequence of pump and valve actuation depends on which power source is available. If offsite power is available, then all equipment may receive power simultaneously. If offsite power is not available, the safeguards loads are divided between the two plant emergency diesel generators and are sequentially started after the diesel generators are running. During the injection mode, the minimum flow lines just downstream of each spray pump are kept open to prevent deadheaded operation. Water which passes through the minimum flow lines is returned to the refueling water tank (RWT).

Once the spray pumps are started and the valves are opened, the spray water flows into the containment spray headers. These headers contain spray nozzles which break the flow into small droplets, thus enhancing the water's cooling effect on the containment atmosphere. As these droplets fall to the containment floor they absorb heat until they reach thermal equilibrium with the containment. When the water reaches the

containment floor it drains to the containment ESF sump where it remains until the recirculation mode begins.

The Containment Spray System utilizes the RWT of the Chemical and Volume Control System. Whenever the CSS availability is required for containment heat removal the RWT contains sufficient borated water to supply both trains of the ESF pumps at their respective maximum flow rates until such time that the pump suction may be realigned to the containment ESF sumps and provide adequate cooling flow to maintain the core covered.

6.2.2.6.1.2.2 Recirculation Mode of Operation

When RWT inventory is reduced to approximately 10% level, a two out of four low RWT level signal will initiate a recirculation actuation signal (RAS). The RAS stops the LPSI pumps, closes e minimum flow line isolation valves (SI-664 and 665, SI-666 and 667, SI-668 and 669, SI-659 and 660), and opens the containment ESF sump isolation valves (SI-673, 674, 675, & 676). Upon indication that transfer to recirculation has occurred, the operator will verify that the LPSI pumps are stopped, and that the flow path from the sump to the suction of the injection pumps is open. Timely operator action is then required to isolate the RWT using valves CH-530 and CH-531 to prevent ingress of air in the ESF pump suction piping during switchover to recirculation. The operator will also check to see that the miniflow isolation valves are closed to prevent depletion of containment ESF sump inventory. The RAS may also be manually initiated at the component level.

6.2.2.6.1.3 Plant Shutdown

The CSS is aligned for injection until shutdown cooling is initiated.

Shutdown cooling is initiated when the Reactor Coolant System temperature and pressure drop below approximately 350°F and 400 psia. An interlock prevents opening of shutdown cooling suction isolation valves if RCS pressure is above 410 psia. The following steps are taken to align the system for shutdown cooling:

a. Unlocking and opening the valves bypassing containment spray flow around the shutdown cooling heat exchangers (SI-688, SI-693).

b. Unlocking and closing the valves isolating the Containment Spray System from the shutdown cooling heat exchangers (SI-684, SI-689, and SI-687, SI-695).

For a normal plant shutdown when Reactor Coolant System temperature is below 200°F (typically 170°F), and RCS pressure less than 250 psia the containment spray pumps can be realigned to provide additional flow through the shutdown cooling heat exchangers. This is done by opening the isolation valves (SI-689, 684) between the containment spray pumps and the shutdown cooling heat exchangers, closing the containment spray bypass valves (SI-688, 693) around the shutdown cooling heat exchangers, isolating the containment spray pumps from the refueling water tank (SI-104, 105) and unlocking and opening the valves (SI-184, 185) connecting the shutdown cooling suction lines to the containment spray pump suction lines.

Shutdown cooling is then continued using the low pressure and containment spray pumps until the refueling temperature of 135°F is attained.

6.2.2.6.1.4 Plant Startup

During cold shutdown, the CS pumps are used for their shutdown cooling function. Prior to commencing plant heatup, the CSS is lined up for emergency operation by closing the CS pump discharge valves (SI-684, 689) to the SDC heat exchangers and opening the CS/SDC heat exchangers bypass valves (SI-688. 693). The RCS is then warmed up to the maximum SDC temperature (approx. 350°F) at which time SDC is secured and the CS to SDC heat exchanger valves are opened and the SDC heat exchanger bypass valves are closed. The CSS is now aligned for the injection mode.

6.2.2.6.1.5 Maintenance

The system is designed to allow maintenance during both normal and post-accident conditions. CSS components are located to allow access for maintenance or manual system realignment of an intact train during recirculation.

TABLE 6.2.2-4

(Sheet 1 of 5)

CONTAINMENT SPRAY SYSTEM FMEA

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Remarks and Other Effects
1	Containment Spray Pump Suction Isolation Valve SI 104, SI 105	a) Fails closed	Corrosion, mechanical binding	Effective loss of one containment spray pump	Low flow indication F338, F348; Periodic testing	Parallel redundant containment spray path	Valves are normally locked open
		b) Fails open	Corrosion	No effect on safety operation	Periodic testing	None required	
2	Containment Spray Pump 1, 2	Fails to pump on CSAS	Mechanical failure, Electrical failure	Effective loss of one containment spray path	Low flow indication F 338, F 348; Periodic testing	Parallel redundant containment spray path	
3	Containment Spray Pump Flow Control Valve SI 678 SI 679	a) Fails closed	Corrosion, mechanical binding Electrical failure	Effective loss of one containment spray path	Low flow indication F 338, F 348; Valve position indicator; Periodic testing	Parallel redundant containment spray path	Valves are normally locked open; and design to fail as is; min. flow line will provide the min. flow required to protect the pump during injection phase.
		b) Fails open	Same as 3 a)	No effect on emergency operation	Valve position indicator; Periodic testing	Parallel redundant containment spray and shutdown cooling subsystem	

TABLE 6.2.2-4

11	Containment Spray Pump 1, 2	Fails to pump on CSAS	Mechanical failure, electrical failure	Effective loss of one containment spray pump	Low flow indication F 338, F 348; periodic testing	Parallel redundant containment spray path	
12	Containment Spray Header Isolation Valve SI 671, SI 672	a) Fails to open on CSAS	Corrosion, mechanical binding, electrical failure	Effective loss of one containment spray path	Valve position indicator; periodic testing	Parallel redundant containment spray path	
	After Recirculation Actuation Signal (RAS) is generated the following equipment is actuated / operated						
13	Containment Spray Min. Flow Isolation Valve SI 664, SI 665	Fails to close on RAS	Electrical malfunction, mechanical failure	None	Position indicator in the control room The operator is required by the the operating procedures to check that the valve is closed recirculation	Series redundant valve, SI 659 or SI 660 closes on RAS	
14	Min. Flow Line to RWT Isolation Valve SI660, SI659	Fails to close on RAS	Electrical malfunction, mechanical binding	None	Valve position indicator; periodic testing	Series isolation valves	
15	RWT Isolation Valve CH-530, CH-531	Fails to close (manual action)	Electrical malfunction, mechanical failure	Degraded performance of one train of containment spray (if air is entrained)	Valve position indicator; periodic testing	Parallel redundant containment spray path	Timely operator action required to close

6.2.3 SECONDARY CONTAINMENT FUNCTIONAL DESIGN

PVNGS does not utilize a secondary containment design.

This page intentionally left blank

6.2.4 CONTAINMENT ISOLATION SYSTEM

There is no particular system for complete containment isolation; isolation design is achieved by applying acceptable common criteria to the penetrations of fluid systems and by using the Containment Isolation Actuation Signal (CIAS) to automatically actuate the appropriate containment isolation valves. Also see subsection 18.II.E.4.2.

6.2.4.1 Design Basis

6.2.4.1.1 Criteria

Containment isolation is mandatory in the event of certain design basis accidents. A containment isolation actuation signal (CIAS) automatically initiates closure of containment isolation valves. Refer to paragraph 7.3.1.1.10.1 for a discussion of the generation of the CIAS.

Containment Isolation System design is based on the following criteria:

a) Two isolation valves are provided at each containment penetration: one inside the containment, and one outside the containment.

b) Systems which are not required to operate, or which only operate intermittently during normal plant power operation, are isolated at the containment penetration in accordance with General Design Criteria 55 and 56.

c) All containment penetration lines and their associated isolation valves are constructed to Safety Class 2, Seismic Category I standards.

d) The design temperature and pressure of the containment penetration lines and their associated isolation valves meet or exceed containment design conditions.

e) Containment isolation is required to minimize the release of fission products (which is postulated to occur within the Reactor Coolant System (RCS) and the containment) to the environment following a loss of Coolant Accident (LOCA). A CIAS is generated upon an indication that a LOCA has occurred to allow for automatic isolation of lines which are normally open during normal plant operation, and do not function in mitigating the effects of the accident. In particular, this includes lines which are part of the RCS pressure boundary, and through which flow normally leaves the containment. A detailed description of sensed parameters, setpoints, and signal generation, as applied to the CIAS is provided in Section 7.3.

f) The Safety Injection System (SIS) and the Shutdown Cooling System (SCS) are considered to be extensions of the containment pressure boundary following an accident. The portions of the SIS and SCS which are opened to the RCS or containment following an accident are constructed to Safety Class 2, Seismic Category I requirements. In addition, the design temperature and pressure of the subject portions of the SIS and SCS exceed containment design conditions. Details of SIS and SCS design and operation are provided in Sections 6.3 and 5.4.7 respectively.

   Containment isolation valves for these systems are identified in Table 6.2.4-1. Outside the containment isolation boundary, isolation valves are provided between

the portions of these systems handling RCS or containment sump fluid, and the environment. Double isolation is provided where active valves are used. Single isolation is allowable where passive valves (e.g., manual vent valves, manual drain valves, etc.) are used, since they are not subject to single failure criteria.

6.2.4.1.2 System Design Requirements

The containment isolation valves are located to minimize the length of piping between the containment and the valve. The actual piping and valve arrangements are indicated in tables 6.2.4-1 and 6.2.4-2. The test methods, including inservice valve testing, are discussed in paragraph 6.2.4.4.

The following is a summary of Containment Isolation System design features. Incorporation of these features into the Containment Isolation System results in a design where the design requirements for containment isolation barriers given above are met:

a) Containment isolation valves and interconnecting piping are designed and constructed to Safety Class 2 and Seismic Category I standards as defined in ANSI N18.2-1973 and Regulatory Guide 1.29 respectively.

b) Containment isolation valves and interconnecting piping are designed to withstand the effects of earthquakes.

c) Containment isolation valves and interconnecting piping are protected against missiles.

d) Containment isolation valves and interconnecting piping are protected against the effects of pipe whip and jet impingements.

e) The maximum allowable particle size entrained in water taken from the containment sump is limited. This ensures that the proper operation of ESF systems and CIS valves will not be inhibited by debris introduced into the containment following a LOCA.

f) Containment isolation valves are designed to operate under normal environmental conditions and to fulfill their safety related function under post-accident environmental conditions, consistent with the requirements of Section 3.11.

g) Containment isolation valves and associated penetration piping are qualified to Section III of the ASME Code, as Class 2 components, as described in Section 3.9.3.

h) Maximum allowable actuation times are imposed on containment isolation valves (see Table 6.2.4-1) consistent with their required safety function, as described in Table 6.2.4-1.

i) Valve operators and power sources are selected for containment isolation valves (see Table 6.2.4-2) consistent with their required safety function.

j) Valve controls for containment isolation valves are designed to allow valve actuation in accordance with the actuation modes given in Table 6.2.4-2.

k) Means of detecting leakage from the systems associated with containment isolation valves are provided as discussed in Section 5.4.7 for the Shutdown Cooling System, Section 6.3 for the Safety Injection System, and Section 9.3.4 for the Chemical and Volume Control System. Provisions for the detection of leakage in these systems allows the operator to determine when to isolate the affected system or train.

l) Provisions are made to allow the testing of containment isolation valves as described in Section 6.2.4.4.

6.2.4.2 System Design

6.2.4.2.1 General Description

Tables 18.II.E-2 and 18.II.E-3 list all essential and nonessential systems, respectively, penetrating the containment.

Table 6.2.4-1
CONTAINMENT ISOLATION SYSTEM[i] (Sheet 1 of 9)

Penetration Number[g]	Applicable GDC	System/Fluid	Essential System	Valve[a] Arrangement	Line[b] Size (in.)	Valve Number	Valve Location/[c] Distance from Containment (ft)	Type C[d] Leakage Test	Valve [e] Type
1,2,3,4	57	Main steam / steam	No	14	28	SGE-UV170 SGE-UV171 SGE-UV180 SGE-UV181	Outside/34	No	Gate
					6	SGE-PSV691 SGE-PSV692 SGE-PSV694 SGE-PSV695	Outside/8	No	Safety
					6	SGE-PSV575 SGE-PSV576 SGE-PSV557 SGE-PSV558	Outside/11	No	Safety

a. Valve arrangements are shown on figure 6.2.4-1.

b. Line size, inches, represent maximum ID of associated valves (except pressure sensing valves where it represents inlet size).

c. Distance from containment denotes maximum length of pipe from outside containment wall to associated valve.

d. Type C leakage tests are described in subsection 6.2.6.

e. A check valve inside the containment is considered to be an automatic valve for purposes of containment isolation.

f. These penetrations meet the exception clause of GDC 56 which allows for containment isolation acceptability on "some other defined basis" for a specific class of lines. Refer to paragraph 6.2.4.2.1 for a discussion of this basis.

g. Manual vent, drain, and test valves between the Containment Isolation Valves will be maintained locked closed under administrative controls or surveilled closed per Technical Specifications.

h. These penetrations were designed to the requirements of GDC 56 but may be isolated using a blind flange in plant operating modes 1-4. When blind flange is installed, only Type B testing of blind flange is required.

i. For application of the single failure rule to check valves, refer to Section 3.1.30.

j. In Units where DMWO 2529758 has been implemented, valve CHA-UV-715 is removed and valves HPA-UV-023 & HPA-UV-024 are de-terminated with upstream piping cut and capped as the new containment boundary.

k. Deleted

l. In units where DMWO 2778159 has been implemented, applicable valve(s) have been removed.

m. Applicable in those Units where DMWO 4345882 has been implemented.

n. Applicable in those Units where DMWO 4304156 has been implemented.

Symbols:

a. Position indications for remotely actuated valves are shown in the control room.
b. The parameters sensed and the values which generate actuation signals are given in Section 7.3.
c. Stroke Time is the time it takes for a valve to change positions, normally Open to Close. A time is given except in cases where the valve is only requried to change position (time independent). In these cases only the required stroke to position is given. See Table 7.3-1B for ESF Response Times.
d. Valves are essential. Operator actuation required to open valve.
e. The power supply to valve CHA-HV-524 is removed by locking open its breaker at MCC PHA-M3520. Restoration of power requires local operator action at the MCC. This has been done to prevent inadvertent closure of the valve when auxiliary spray or charging flow is required. This is an exception from CESSAR Section 6.2.4.
f. Failure mode for valves is open on loss of power and closed on loss of air.
g. Manual vent, drain, and test valves between the Containment Isolation Valves will be maintained locked closed under administrative controls or surveilled closed per Technical Specifications.
h. For application of the single failure rule to check valves, refer to Section 3.1.30.
i. In Units where DMWO 2529758 has been implemented, valve CHA-UV-715 is removed and valves HPA-UV-023 & HPA-UV-024 are de-terminated with upstream piping cut and capped as the new containment boundary.
j. Deleted
k. In units where DMWO 2778159 has been implemented, applicable valve(s) have been removed.
l. Applicable in those Units where DMWO 4345882 has been implemented.
m. Applicable in those Units where DMWO 4304156 has been implemented.

Symbols:

N.A	- not applicable	LO	- locked open
EA	- Class 1E bus A	LC	- locked closed
EB	- Class 1E bus B	FO	- fail open
EC	- Class 1E bus C	FC	- fail closed
ED	- Class 1E bus D	FAI	- fail-as-is
N	- normal power source	MSIS	- main steam isolation signal
O	- open	CSAS	- containment spray actuation signal
C	- closed	CPIAS	- containment purge isolation actuation signal
A	- automatic	AFAS	- auxiliary feedwater actuation signal
R	- remote operation	SIAS	- safety injection actuation signal
M	- manual local operation	RAS	- reciculation actuation signal
DU	-Data currently unavailable	CIAS	- containment isolation actuation signal
			- bracket indicates any one signal actuates each valve

In addition, figure 6.2.4-1 shows containment isolation valve arrangements. Containment isolation schemes comply with the requirements of GDC 54, 55, 56, and 57. Valves which receive an Engineered Safety Features Actuation Signal (ESFAS), or are actuated remotely by the operator, have actuation times consistent with the functional requirements of the systems they are associated with.

1) The CVCS charging line containment isolation valve (CHA-HV-524) has been locked in the open position by removing the power supply for the valve and the local handwheel has been chained and locked. This was done to prevent inadvertent closure of valve CHA-HV-524 during periods when charging or auxiliary spray flow is required.

2) The outside isolation valve associated with the CVCS reactor coolant pump seal injection line penetration is normally open, and does not receive a CIAS.

It is desirable to leave these two paths open to provide additional core protection after an accident in which offsite power is available by maintaining charging capability and reactor coolant pump seal injection capability. In addition, the charging pumps can be transferred to emergency power at the discretion of the operator in the event that offsite power is lost. Conversely, it is undesirable to lose charging or seal injection capability during normal operation due to an inadvertent CIAS.

The potential release of fission products through the two penetrations under discussion does not present a problem for the following reasons:

a) Flow through these penetrations is into the containment and the RCS.

b) Check valves inside the containment prevent backflow out of the containment if the charging pumps stop.

c) The connecting portions of the CVCS outside of containment are designed to Safety Class 2, Seismic Category I standards and have design pressures well in excess of containment design pressure.

d) The operator has the capability of isolating these lines if continued charging or seal injection proves to be unnecessary.

Table 6.2.4-2 lists all fluid penetrations and indicate ESF actuation signals that initiate closure of containment isolation valves. Refer to section 7.3 for a discussion of the generation of the signals.

The containment pressure instrumentation is located outside the containment. The containment pressure instrumentation lines are extensions of the containment boundary. These lines are critical to the functioning of the ESF systems. The design criteria for these lines are as follows:

A. Containment pressure instruments are located as close as practical to the containment and are installed using 3/8-inch stainless steel tubing.

B. All instrumentation provided is designed as a pressure-containing system.

C. One remote manually operated shutoff valve, meeting the requirements of Regulatory Guide 1.11, is provided outside the containment.

The instrument line, up to the instrument process connection, is Seismic Category I and ASME Section III, Class 2, and the instrument is Seismic Category I. The equipment is located in an area protected against physical damage due to pipe whip or missiles.

The parameters associated with containment isolation are high containment pressure or low pressurizer pressure. The parameters which actuate main steam and feedwater isolation are low steam generator pressure or high containment pressure or high steam generator water level. Channel separation is provided for automatic isolation valves. Automatic isolation valves are provided with position switches and position indicating lights in the control room to indicate valve positions.

The integrity of the isolation valve system and connecting lines under the dynamic forces resulting from inadvertent closure under operating conditions and seismic conditions is assured by performance of static and dynamic analyses on the piping, valves, and restraints. The static and dynamic analyses are discussed in subsection 3.9.2.

Piping isolation valves and actuators located outside containment are located as close as practical to the containment wall in accordance with General Design Criteria 55, 56, and 57.

Isolation valves inside the containment are located between the secondary shield and the inside containment wall. The secondary shield serves as the missile barrier. Isolation valves for the ECCS recirculation lines are located inside the recirculation sumps. Any necessary missile barriers for isolation valves and piping that provide one of the isolation barriers outside the containment consist of structural steel and concrete which forms walls and floors of adjacent buildings.

The effect of pipe whip and jet impingement forces on containment isolation valves and piping are considered in section 3.6.

The operability assurance of valve and valve operators under normal and accident conditions is discussed in section 3.9. Containment environmental conditions under normal and accident circumstances and qualification test conditions are described in section 3.11.

Containment isolation valves and piping are classified as Quality Group B, Seismic Category I.

Detection of leakage from systems that are required to function in the event of an accident is discussed in Section 6.2.4.1.

Valve stroke times are listed in table 6.2.4-2. Stroke times and valve leak tightness are specified to limit radiological effects from exceeding the guidelines established by 10CFR100.

Piping penetrations, except the containment pressure monitoring instrument lines and main steam lines, are furnished with two isolation valves to provide redundancy in the event that one valve fails to close.

The type of valve operators are indicated in table 6.2.4-2. Valve operators are supplied from the emergency, Class 1E power supplies as described in section 8.3.

6.2.4.2.2 Applicable Codes, Standards, and Regulatory Guides

The following list identifies the industry standards, NRC regulatory guides, and the general design criteria applicable to the design of the containment isolation system which were considered in system design:

A. General Design Criteria 54, 55, 56, and 57 of 10CFR50, Appendix A, and Appendix J of 10CFR50.

B. NRC Regulatory Guides 1.11, 1.26, 1.29, 1.73, and 1.141 (see section 1.8).

C. IEEE 382-1972, ANSI N18.2-1973, and Section III of the ASME Code.

Generic Letter 96-06, "Assurance of Equipment Operability and Containment Integrity During Design Basis Accident Conditions," was issued by the NRC on September 30, 1996. This letter required that addressees determine:

1. if containment air cooler cooling water systems are susceptible to either waterhammer or two-phase flow conditions during postulated accident conditions;

2. if piping systems that penetrate the containment are susceptible to thermal expansion of fluid so that overpressurization of piping could occur.

The PVNGS 120 day response to Generic Letter 96-06, was transmitted to the NRC under APS Letter 102-03855-JML/AKK/JRP

dated January 28, 1997. This response documented that the PVNGS containment cooling water systems are not susceptible to the development of waterhammer or two phase flow conditions as discussed in Generic Letter 96-06. No corrective actions were required, however, limited, defense in depth actions were taken to further enhance the system design with respect to these conditions. The response further stated that the as-built containment penetration configurations which do not have installed relief valves were evaluated and accepted by the NRC during initial PVNGS licensing and documented by reference in the PVNGS Safety Evaluation Report. This acceptance was based on a qualitative assessment which credits pipe deformation, valve leakage, and limiting heat transfer effects to preclude penetration failure due to overpressurization. PVNGS subsequently transmitted a supplemental response to the NRC under APS Letter 102-03943-JML/AKK/JRP dated May 30, 1997, wherein plant modifications were described which would accommodate a quantitative as well as a qualitative licensing basis.

These plant changes consisted of reducing fastener torque in the body to bonnet joint for containment isolation valves 13JRDBUV0024, 13JWCBUV0061, 13JWCAUV0062, 13PPCEV070, 13PPCEV076, 13PDWEV061 and 13DWEV062. The change in valve body to bonnet joint fastener torque for some of the containment isolation valves is to allow the body to bonnet gasket joint in the valves to leak at lower pressures and then reset. The use of ASME B&PV Code, Section III, Division I-1974 Edition with Winter 1975 Addenda, Appendix F-1000 in the evaluation of the containment penetration piping and valve components provides a

conservative limit in the amount of plastic strain allowed in the piping to be used to self relieve the pressure build-up inside the penetration. These inherent relief mechanisms in the valves and piping are in agreement with PVNGS' qualitative licensing basis. The referenced adjustment of bonnet joint fastener torque in conjunction with the use of ASME Code Appendix F-1000 stress criteria enables PVNGS to expand the current design criteria to encompass quantitative limits regarding thermally induced overpressurization of containment penetration isolation piping and valves due to a LOCA. PVNGS' response to a request for additional information from the NRC provided, under APS letter 102-04130-JML/SAB/RNW, dated June 4, 1998, detailed information on the methodology utilized to predict the response of the containment penetrations to thermally induced over-pressurization due to a LOCA. This response identified the use of ASME B&PV Code, Section II, Division I-1974 Edition with the Winter 1975 Addenda, Appendix F-1000 in the evaluation of the containment penetration piping and valve components as well as the reduction of fastener torque in the body to bonnet joint for some of the containment isolation valves.

6.2.4.2.3 Containment Purge Isolation Valves

A containment purge system consisting of a power access purge (2000 cubic feet per minute) and a refueling purge (30,000 cubic feet per minute) is provided as described in section 9.4. During preoperational flow balancing testing the 8-inch power access purge was unable to meet the design flow rates due to leaking seals, dampers, and higher than assumed pressure drops. An overall assessment confirmed that the as-built condition

(1100 cfm exhaust and 1200 cfm supply) is adequate to meet the design requirements as identified in NRC Inspection Report 87-15, Followup Item 50-529/85-43-01 Closure. The power access purge used during operation at power has 8-inch containment penetrations sized in accordance with the guidelines of Branch Technical Position CSB 6-4.

The 8-inch diameter valves (CPA-UV004A, 4B, CPB-UV005A, 5B) are capable of closing in less than 2 seconds after receipt of a CIAS or a CPIAS. This minimizes the amount of containment atmosphere mass released to the environment in the unlikely event that a LOCA should occur with the power access purge valves open.

The normally closed 42-inch diameter refueling purge valves (CPA-UV002A, 2B, CPB-UV003A, 3B) are designed to close in less than 12 seconds after the receipt of a CIAS or a CPIAS with offsite power available. The 42-inch diameter refueling purge valves are sealed closed during power operation. The 42-inch diameter refueling purge penetrations may be isolated using a blind flange in plant operating modes 1-4.

The setpoint for containment isolation is approximately 3 psig and purge isolation valve closure is initiated 0.9 second after the setpoint is reached.

In addition, the following valve characteristics are specified:

- Power access valves (8 inches) are ANSI rated 150 pounds. Refueling purge valves (42 inches) are ANSI rated 75 pounds.

- Power access valve bodies were hydrotested at 225 psi. Refueling purge valves were hydrotested at 112 psi.

- Power access valves seat leak test was at 150 psi differential. Refueling purge valves seat leak test was at 75 psi differential.
- Operability tests will be in conformance with the requirements of section 3.9.

6.2.4.2.4 Main Steam Line Penetrations

Valve arrangement 14, the main steam line penetration, contains relief valves which are connected to a closed system penetrating the containment. This arrangement complies with General Design Criterion 57 in that at least one remotely-operated, automatically-actuated isolation valve is provided in the piping outside of the containment. The relief valves shown in this arrangement are the main steam safety valves which are provided for protection of portions of the main steam system as described in subsections 5.2.2 and 5.4.13 and section 10.3. These safety valves, which are located outside containment, discharge directly to the atmosphere and are thus a potential release path. Their setpoints are such that they will normally only lift in the event a condition occurs that requires them to function to protect the integrity of the reactor coolant pressure boundary (RCPB) (see subsection 5.2.2) and that portion of the main steam supply system discussed in section 10.3 Sections 15.1, 15.2, and 15.6 discuss postulated accident transients in which these valves function to protect the system integrity. Section 15.2 discusses a potential incident that could be caused by the inadvertent operation of one of these valves.

6.2.4.2.5 Access Penetrations

The isolation arrangement of each equipment hatch, emergency personnel hatch, personnel lock, containment test connection, integrated leakage rate test (ILRT) verification, ILRT pressure measurement, and fuel transfer penetration shown in valve arrangements 20, 26, 27, and 9 consists of an access connection attached to and located inside the containment building. A blind flange or hatch encloses the inside end of the access connection. The 42-inch diameter refueling purge penetrations may be isolated with blind flanges located outside containment in plant operating modes 1 – 4 (shown in valve arrangements 22 and 30). The blind flange or hatch contains two 0-rings or gasket grooves and a pressure tap. The pressure tap is routed through the blind flange or hatch to the annulus between the two 0-rings or gaskets. When assembled preparatory to reactor operation, the blind flanges and hatches are secured to the access connection and the annulus between the 0-rings or gaskets is pressurized to ensure that both seals are functioning. The seal is further tested when test pressure is introduced into the containment.

The emergency personnel hatch, personnel lock, equipment hatch, ILRT verification, ILRT pressure measurement, containment test connection, refueling purge penetrations (when isolated with blind flanges in plant operating modes 1 – 4), and fuel transfer connection are considered to be part of the containment boundary and therefore General Design Criterion 56 does not apply to these penetrations and an isolation valve is not required.

6.2.4.3 Design Evaluation

A failure mode and effects analysis for components used for containment isolation is presented as part of the Chemical and Volume Control System failure mode and effects analysis (section 9.3.4), the Safety Injection System failure mode and effects analysis (section 6.3), and BOP ESFAS and NSSS ESFAS (section 7.3 and section 7.2). Single valve failure does not affect the integrity of the containment building due to redundancy of double isolation valve protection. There are two classes of exceptions to double isolation valve redundancy. Single isolation is provided for the main steam lines in accordance with the provisions of General Design Criterion 57. Containment pressure instrumentation has single isolation in accordance with Regulatory Guide 1.11. Operator action will be required to isolate a pressure instrument line rupture downstream of the isolation valve.

Proper functioning of the Containment Isolation System results from the following:

A) Environmental qualification of containment isolation valves to ensure that they fulfill their safety functions under post-accident conditions as described in section 6.2.4.2.1.

B) Protection of containment isolation components from the failures of other fluid systems following an accident, as described in section 6.2.4.2.1.

C) Preoperational and inservice testing of containment isolation components, as described in section 6.2.4.4.

D) The use of double isolation at the containment boundary as described in section 6.2.4.1.

E) Administrative control of the proper position of manual containment isolation valves, and automatic isolation valves whose use is not required subsequent to the design basis post accident conditions. All manual vent, drain, and test valves within a Containment Penetration (i.e., between the Containment Isolation valves) will be maintained locked closed per the locked valve administrative program or surveilled closed per Technical Specifications.

F) The use of ESFAS to actuate automatic containment isolation valves whose function is required in the short term to mitigate the effects of an accident.

G) Selection of isolation valve failure position consistent with the safety related function of the valve as shown in Table 6.2.4-2.

H) The use of redundant paths for systems required to be open to the containment following an accident.

I) The use of diverse means of powering the containment isolation valves required to be closed following an accident such that the required degree of containment isolation is assured despite a single active failure (see Table 6.2.4-2).

J) The design of normally open path to the containment after an accident to withstand containment design conditions and with double isolation between the system and the environment, as discussed in section 6.2.4.1.

K) Providing provisions for the detection and isolation of leakage in systems required to be open to the containment following an accident, as discussed in section 6.2.4.2.1.

As noted in paragraph 6.2.4.2, the equipment hatch, the emergency personnel hatch, the personnel lock, the containment test connection, ILRT verification, ILRT pressure measurement, refueling purge penetrations (when isolated with blind flanges in plant operating modes 1-4), and the fuel transfer penetration all have closures surrounding the access pipe with a blind flange fitted with double 0-rings or gaskets which serve as the primary containment seal. The respective access pipe closures and double 0-ringed blind flanges are designed to withstand the forces resulting from the safe shutdown earthquake. Prior to returning to operation after each refueling, the leaktightness of each foregoing mentioned closure is tested by the application of pressure between the O-rings. Therefore, the requirements of General Design Criterion 56 do not apply.

Also the containment pressure monitoring instrumentation is designed as an extension of the containment building and General Design Criterion 56 does not apply.

Piping penetrations which are connected to the RCS are provided with containment isolation valves in accordance with General Design Criterion 55.

Containment isolation of systems connected to the secondary side of the steam generators (SGs) are designed as extensions of the containment boundary. Such systems include main steam, feedwater, auxiliary feedwater, SG blowdown, and SG blowdown

samples and are shown in valve arrangements 14, 15, and 39. The systems are not connected to the RCS nor to the containment atmosphere. Piping inside the containment from the penetration to the steam generator is Seismic Category I, and thus a piping failure which would connect the penetration to the containment atmosphere is not postulated.

Valves HP-HV-007B (penetration 38) and HP-HV-008B (penetration 39) are the outlet valves to the hydrogen analyzers and valves HP-HV007A (penetration 35) and HP-HV008A (penetration 36) are the inlet valves to the hydrogen analyzers. These valves are used only for post-LOCA hydrogen analysis that may be required at elevated pressures, e.g., above the containment isolation signal setpoint. The valves are normally closed and fail closed. The hydrogen monitoring system is a closed system outside the containment and the piping and monitors are Seismic Category I and Safety Class 2. Therefore, a containment isolation actuation signal to close the valves is not required.

The containment purge penetrations, valve arrangements 22 and 30, are connected directly to the containment atmosphere. When the plant is in operating modes 1-4, the containment purge penetrations may be isolated using blind flanges and General Design Criteria 56 does not apply. When not isolated using the blind flanges in plant operating modes 1-6, containment isolation is provided by automatic containment isolation valves installed inside and outside the containment and General Design Criteria 56 does apply.

The remaining piping penetrations, other than described above, are not connected to the RCS nor to the containment atmosphere.

General Design Criterion 57, therefore, applies. However, as indicated in table 6.2.4-1, the more severe requirements of General Design Criterion 56 are used as the design basis. Each of these remaining penetrations is provided with an automatic isolation valve inside the containment, a check valve being used for this purpose when direction of fluid flow is into the containment.

An operating procedure will require that manual valves, such as those shown on valve arrangements 3, 5, 12, 28, and 35, be verified as closed prior to any operation requiring containment integrity.

An operating procedure will ensure that the charging flow valves are properly positioned following a CIAS and reactor coolant pump seal bleedoff valves are properly positioned following a CSAS.

6.2.4.4 Testing and Inspection

Leak testing of individual valves and penetrations may be accomplished by use of one of the following methods (refer to subsection 6.2.6):

A. Method 1, Pressure Decay

The test volume is established by closing the appropriate isolation valves. The volume to be tested is determined by either direct measurement of liquid drained from the system or by computation. The test volume is pressurized. The test volume pressure is recorded at 5-minute intervals for a minimum of

15 minutes. The leakage rate is computed using the rate of decay of pressure.

B. Method 2, Air Flow

The test volume is established by closing the appropriate isolation valves. This method does not require the determination of the volume to be tested. The test volume is maintained pressurized by a measurable air flow. No minimum test duration shall be required for an air flow test; however, test data shall be obtained during stable conditions.

C. Method 3, Water Flow

The test volume is established by closing the appropriate isolation valves. The test volume is filled with water and is vented by using the test vents and test connections provided on the containment penetrations. The test volume is pressurized and the leakage flow is measured from each valve.

Inservice testing of isolation valves in accordance with ASME OM Code is outlined in paragraph 3.9.6.2.

The initial test program is described in section 14.2.

This page intentionally left blank

6.2.5 COMBUSTIBLE GAS CONTROL IN CONTAINMENT

The containment hydrogen control system is classified as an engineered safety feature that serves as the combustible gas control system in the containment. Portions of the system, however, are nonsafety-related and non-Seismic Category I as described in this section and in table 3.2-1.

General Design Criterion 41 of Appendix A to 10CFR50 requires that systems be provided as necessary to control the concentrations of hydrogen, oxygen, and other substances, which may be released into the reactor containment following postulated accidents, to ensure containment integrity is maintained.

Following a LOCA, hydrogen gas is generated inside the containment as a result of the following:

A. Metal-water reaction involving the zirconium fuel cladding and the reactor coolant.

B. Radiolytic decomposition of the post-LOCA emergency cooling solutions (oxygen also evolves in this process).

C. Corrosion of metals and paints by solutions used for emergency cooling or containment spray.

The containment hydrogen control system is provided to ensure that the hydrogen concentration is maintained below the lower combustible limit (4 volume %) established by Regulatory Guide 1.7.

The hydrogen control system is composed of a hydrogen recombiner system, a hydrogen monitoring system, and a hydrogen purge system as described in the following sections.

6.2.5.1 Design Bases

Protection of the hydrogen control system from wind and tornado effects is discussed in section 3.3. Flood design is discussed in section 3.4. Missile protection is discussed in section 3.5. Protection against dynamic effects associated with postulated rupture of piping is discussed in section 3.6. Environmental design is discussed in section 3.11. Testing and inspection is discussed in paragraph 6.2.5.4. Additional design bases follow:

A. The hydrogen recombiner system is designed to maintain the containment hydrogen concentration below 4.0 volume %, the lower combustible limit of hydrogen in air as specified in Regulatory Guide 1.7. The design includes provisions to install the system, with all required services connected, within 72 hours of a LOCA, and to have the system functional within 100 hours of the same LOCA. Per the requirements of the Standard Review Plan, the manually installed system at PVNGS can be installed and functional before the hydrogen concentration in Containment reaches 3.5 volume percent.

B. Hydrogen mixing is provided by the containment spray system (described in paragraph 6.2.2.1), and the containment internal structure design, which permits convective mixing and prevents local entrapment of the hydrogen for as long as accident conditions require.

C. The redundant hydrogen monitoring system is designed to measure the hydrogen concentration inside the containment at two independent locations and to alert

the operator in the control room of the need to activate the hydrogen recombiners or hydrogen purge system. The monitors comply with Regulatory Guides 1.7 and 1.97.

D. The redundant hydrogen recombiner and hydrogen monitoring systems are designed so that a single failure of any component, assuming loss of offsite power, cannot impair the ability of the system to perform its designated function.

E. The Seismic Category I hydrogen recombiner system is designed to be functional after an SSE. The recombiner is designed to remain functional during and after an OBE.

System equipment located in the auxiliary building is arranged to preclude loss of hydrogen control capability due to failure of non-Seismic Category I systems or components.

F. Recombiner components are designed in accordance with the applicable safety classification of the ASME Boiler and Pressure Vessel Code, Section III.

G. In the event of offsite power loss, power to the hydrogen control system is supplied by the diesel generators.

H. The hydrogen control system is designed and qualified to remain functional in a non-HELB, harsh radiation environment, as described in the Equipment Qualification Program and UFSAR section 3.11.

I. Periodic tests and inspections are performed to ensure operability and are covered in paragraph 6.2.5.4.

J. Two hydrogen recombiners and their associated control cabinets are shared by all units on the site.

K. One hydrogen purge exhaust air filtration unit is shared by all units on the site.

L. Radiation protection for personnel during recombiner hookup is provided by a shield wall between the containment penetrations and the recombiner. Radiation protection for personnel during recombiner operation is provided by a shield wall between the recombiners and the control cabinets.

M. The hydrogen purge system provides the capability for a controlled purge of the containment atmosphere in order to maintain the hydrogen concentration below 4 volume % following a LOCA. The hydrogen purge system would be utilized in the unlikely event of the combined failure of the redundant hydrogen recombiners. With exception of the containment penetrations (which are common to the recombiner subsystem) the hydrogen purge system is non-Seismic Category I.

6.2.5.2 System Design

6.2.5.2.1 General Description

The total system for control of combustible hydrogen concentrations in the containment following a LOCA consists of a hydrogen monitoring system that measures the containment atmosphere hydrogen concentration, a hydrogen recombiner system

that provides the primary means of reducing containment hydrogen concentrations, and a hydrogen purge system that provides a backup capability for a controlled purge of the containment atmosphere.

These systems are shown schematically in engineering drawings 01, 02, 03-M-HPP-001. Design parameters for major components of each of these systems are given in table 6.2.5-1. Codes and standards applicable to the combustible gas control systems are listed in table 3.2-1. Design provisions for periodic tests and inspections are discussed in paragraph 6.2.5.4.

Following a LOCA, the containment spray system is automatically started. This system serves to minimize localized hydrogen buildup within the containment as well as remove fission products from the containment atmosphere and reduce containment pressure. Within 30 minutes after a LOCA, both redundant hydrogen analyzers are manually activated to monitor hydrogen levels, in accordance with UFSAR 18.II.F.1.6, and to alert the operator in the control room when operation of the hydrogen recombiners or hydrogen purge system is required.

The recombiners are manually started within 100 hours following a LOCA. A plot of post-LOCA containment hydrogen concentration vs. time with one recombiner train functioning for an analyzed core power of 4070 MWt is provided in Figure 6.2.5-2. The Hydrogen Recombiner System design includes two independent redundant trains. Accordingly, system function will not be lost as a result of a single failure (See Table 6.2.5-2). In the improbable event that both recombiner trains are unavailable, operation of the Hydrogen Purge System may be

manually initiated under the applicable Emergency Plan Implementing Procedures.

6.2.5.2.2 Hydrogen Mixing

Hydrogen mixing within the containment is accomplished by the containment spray system and the containment internal structure design, which permits convective mixing and prevents entrapment (Design Basis B).

Procedures to terminate system operation contain prerequisites to ensure that either adequate hydrogen mixing has been accomplished and further forced circulation by sprays is not required, or that forced air cooling is established in containment. This ensures that operation will not be terminated just because the system's heat removal function is completed.

The internal structures of the containment building were designed to provide vertical compartments, around each of the steam generators and the reactor vessel, which project upward from the containment basemat. (See engineering drawings 13-P-OOB-007 and -008.) Following a LOCA, the lower portions of the containment will be flooded (See section 6.2.1.1.2.4). This volume of water (long-term) and the steam generators, reactor vessel, and reactor coolant piping (short-term) represent heat sources that establish and maintain natural convective flows upward out of the lower containment volume through the steam generator compartments and reactor cavity.

Intermediate floors and other internal structures of the containment are designed to avoid stagnant accumulations of

containment atmosphere. The use of grating in appropriate areas also promotes the circulation of air.

The reactor drain tank (RDT) room is a closed-ended subcompartment within the containment. A review of possible hydrogen sources within the subcompartment indicated that the only credible mechanism for hydrogen evolution is radiolysis of the water entering the subcompartment as a result of the LOCA and subsequent ESF initiation. In order to eliminate potential ignition sources within the RDT room, permanent lighting have been removed from the room, thereby assuring that there are no ignition sources within the RDT room.

Analysis of hydrogen transport from the RDT room through the annular pipe opening for 30 days post-LOCA was conducted with the following results:

A. Convective transfer is sufficient to maintain the RDT room hydrogen concentration below the combustible limit. Convective transfer is brought about by a density differential between the gas mixture in the RDT room and the remainder of the containment. The density differential results from differences in the average molecular weights of the gas mixtures in the two regions (i.e., the RDT room versus the containment), or the temperature difference between the two regions, or both.

B. The temperature differential between the RDT room and the containment ambient atmospheres is expected to be positive (i.e., the RDT temperature being greater than the containment ambient) and, therefore, aids the establishment of convective flow. However, even under

assumptions which cause the temperature differential to be reduced to zero, the peak hydrogen concentration within the RDT room is 3.7% by volume. A sensitivity study using an extremely conservative -3F differential resulted in a nominal increase in hydrogen concentration over Regulatory Guide 1.7 limit, within the RDT room.

The hydrogen purge system (portion inside containment) is designed to remain intact following a LOCA.

Single failure analyses for the systems that provide containment atmosphere mixing are provided in subsection 6.2.2.

6.2.5.2.2.1 Hydrogen Recombiner System. The hydrogen recombiner system consists of the following components: Within the containment, each loop is comprised of a suction header (influent piping) with motor-operated valves and a discharge header (effluent piping) with check valves. Outside the containment, in the auxiliary building, each loop consists of influent piping, manual and motor-operated isolation valves, sample piping, a portable hydrogen recombiner skid, and effluent piping.

The hydrogen recombiner skid packages are thermal-type units and will be shared by all units. A single failure analysis is given in table 6.2.5-2.

The piping and instrumentation diagram for the system is given in engineering drawings 01, 02, 03-M-HPP-001. The hydrogen recombiner system is started manually. To put the hydrogen control system into operation, two recombiner skids are moved into the auxiliary building from onsite storage, aligned, and

Table 6.2.5-2

COMBUSTIBLE GAS CONTROL SYSTEM SINGLE FAILURE ANALYSIS

No.	Component	Failure Mode	Failure Mechanism	Effect on System	Method of Detection
1	Hydrogen recombine	Fails to start	Diesel generator failure: mechanical and/or electrical failure	None due to redundant recombiner train	Indication of lack of power at manual control station
2	Hydrogen analyzer	Signal failure	Sensing cell depletion	None due to redundant analyzer	Periodic testing and control room annunciation
		Electronic failure	Electrical component fails	None due to redundant analyzer	Periodic testing and control room annunciation
		Mechanical failure	Mechanical component fails	None due to redundant analyzer	Periodic testing and control room annunciation

connected to the influent and effluent piping in the auxiliary building. The recombiner control units are also moved into the auxiliary building, aligned, and connected to Class 1E power. All system services and isolation valves are opened and the recombiner units are manually started.

The containment atmosphere is drawn into the recombiner package through the suction header by means of a blower. Before entering the reaction chamber, the feed gas is electrically heated above 1150F, the hydrogen-oxygen reaction temperature. After recombination, the hot gas and water vapor leaving the reaction chamber enter a heat exchanger where they are cooled to approximately 150F. Air from outside the auxiliary building is used as cooling air and is returned to outside after cooling. The cooled air is at a low enough relative humidity and high enough temperature to prevent condensation of water vapor. The cooled gas and water vapor are then piped back to the containment.

Containment hydrogen concentration is measured by drawing recombiner influent through the gas analyzer. Provisions are also made for periodic checks of the hydrogen analyzer performance. A backup analyzer is available should a malfunction occur in the first analyzer.

Tests have verified that the hydrogen-oxygen recombination is not a catalytic surface effect associated with the heaters, but occurs due to the increased temperature of the process gases. As the phenomenon is not a catalytic effect, saturation of the unit is not predicted to occur. Results of testing a prototype electric hydrogen recombiner and production unit test results

are given in reference 1. There is no difference between the hydrogen recombiner units to be installed in PVNGS and the unit for which the tests were conducted.

6.2.5.2.2.2 Hydrogen Monitoring System. The hydrogen monitoring system for each unit consists of two completely redundant trains. Each train consists of a hydrogen sensor, an electronic subassembly, and local and remote readout/alarms. The electronic subassemblies for trains A and B are housed separately in cabinets located in the auxiliary building. A remote control panel mounted on the main control board provides control of each analyzer. Local indication and a control room high hydrogen alarm are provided to meet the guidance of Regulatory Guide 1.7. Redundant indication and recording for one channel are also provided in the control room per Regulatory Guide 1.97 (refer to Table 1.8-1). The heat trace used on the hydrogen monitoring sample piping is quality class QAG seismic Category IX.

A bottled nitrogen and hydrogen supply is used to calibrate the sensors at those intervals specified in the Technical Specifications.

Hydrogen measurement is accomplished by using a thermal conductivity cell and a catalytic reactor. The sample gas first flows through the sample section of the cell, then passes through the catalytic converter where hydrogen in the sample is catalytically combined with free oxygen to form water vapor, then passes through the reference section of the cell. The hydrogen content is indicated by the difference in thermal conductivity between the sample and reference sides of the

cell. Oxygen, in an amount sufficient to combine hydrogen at the highest range of the analyzer, is added to the sample gas, prior to passing through the sample section of the cell. The accuracy of the hydrogen analyzer components (e.g., the high level alarm) supporting compliance with Regulatory Guide 1.7 is given in Table 6.2.5-1.

The accuracy of the hydrogen analyzer components (e.g., control board recorder and indicator) supporting compliance with Regulatory Guide 1.97 is given in Table 7.5-1. These Table 7.5-1 values are descriptive of installed equipment, not prescriptive; the adequacy of the subject instruments is evaluated in applicable plant calculations and/or other design output documents.

A single failure analysis is given in table 6.2.5-2.

Refer to subsection 18.II.F.1.6 for TMI-related information pertaining to the containment hydrogen monitor.

6.2.5.2.2.3 Hydrogen Purge System. The hydrogen purge exhaust air filtration unit consists of a mist eliminator, an upstream and downstream high efficiency particulate air (HEPA) filter, charcoal adsorption filter, electric duct heater, and associated piping, valves, ductwork, dampers, instruments, and controls. The isolation valves are the only moving parts located inside the containment. The hydrogen purge system is designed to exhaust containment atmosphere at a rate of 50 standard cubic feet per minute and feed service air back to containment at the same rate. The driving head for the purge unit is developed from the differential pressure between the containment building and the plant stack. If the pressure

inside containment is insufficient to establish flow through the purge unit, the continual air flow into the containment from the service air system will serve to reduce the hydrogen concentration until the necessary differential pressure is achieved. The purge unit, like the recombiners, is mounted on a mobile skid package shared by all units.

The hydrogen purge supply and exhaust lines are located in missile-protected areas, and are designed to circulate air in a manner that prevents either containment spray or sump water from entering the ducts.

Should it be necessary to use the hydrogen purge system, operational considerations and site meteorology would determine the timing and duration of purges. In any case, sufficient purging would be performed to maintain the hydrogen concentration in the containment atmosphere below 4 volume %.

The hydrogen purge system was designed and constructed as a nonsafety system except for containment penetrations which are the same Seismic Category I penetrations used by the recombiners. A single failure analysis is not applicable to this system.

6.2.5.2.3 Plant Protection System Signals

The post-LOCA hydrogen monitoring and hydrogen recombiner systems are manually initiated. No plant protection signals are incorporated.

6.2.5.2.4 Environmental Qualification Tests

Environmental qualification tests are described in section 3.11.

6.2.5.3 Design Evaluation

A. Two completely separate and redundant recombiner systems are shared by all units at the site, each powered from a separate Class 1E electrical bus. Thus, a single failure will not prevent the recombiners from performing their safety function as shown in table 6.2.5-2.

Tests have verified that recombination is not a catalytic surface effect, but that it occurs due to the increased temperature of the process gases. Poisoning of the unit by fission products or containment spray solution will not occur. The heater-recombiner section consists of 15 electric heater elements each with a rating of 2.4 kW. Failure of up to one-third of the heaters will not significantly affect the efficiency of the recombiner.

During their operation, the recombiners and auxiliary equipment are located in the auxiliary building and are not exposed to the temperature and pressure transients, chemical, and radiation environment of the containment post-LOCA. Table 6.2.5-3 gives the plant parameters used to determine the amount of hydrogen evolved from the sources discussed below. For an analyzed core power of 4070 MWt, the hydrogen production from each of these sources is shown in figure 6.2.5-1.

The following paragraphs discuss the method used to evaluate the contribution of various sources.

1. Radiolytic Hydrogen Generation

   Water is decomposed into free hydrogen and oxygen by the absorption of energy emitted by fission products

contained in the fuel and fission products intimately mixed with the LOCA water. The quantity of hydrogen that is produced by radiolysis is a function of both the energy of ionizing radiation absorbed by the LOCA

Table 6.2.5-3

PARAMETERS USED TO DETERMINE HYDROGEN GENERATION

(Sheet 1 of 1)

Reactor power level, MWt (3990 +2% uncertainty)	4070
Containment net free volume (minimum), ft^3	2.6×10^6
Containment temperature before accident, °F	120
Weight zirconium, lb	83,000[(a)]
Corrodible metals	Aluminum, Zinc (galvanized steel), zinc-based paints

(a) The value listed for quantity of Zirconium is conservative following implementation of new top grid design for fuel assemblies. See Chapter 4 for details.

water and the net hydrogen radiolysis yield, $G(H_2)$, pertaining to the particular physical-chemical state of the irradiated water.

Evidence indicates that the net hydrogen yield from the radiolysis of pure water is 0.44-0.45 molecules per 100 eV of absorbed energy when the gaseous radiolysis products are continuously purged from the water. In the presence of reactive solutes in water, assuming the absence of gas purging of the solution, significant recombination of the products of radiolysis can occur, thereby reducing the net hydrogen yield. According to published data from ORNL, the net yield of hydrogen under conditions approximating those of the containment sump is 0.3 molecule/100 eV. In accordance with Standard Review Plan 6.2.5, a value of 0.5 molecule/100 eV was conservatively assumed for the net yield of hydrogen from radiolysis of all LOCA water.

The assumptions given in Regulatory Guide 1.7 were used to determine the fission product distribution after the accident. This distribution is assumed to occur instantaneously after the accident, and hydrogen production is assumed to begin immediately. Fifty percent of the halogens and 1% of the solids in the core are assumed to be released from the fuel and intimately mixed with the water in the sump. All noble gas activity is released from the fuel and is present in the containment atmosphere. Table 6.2.5-4 gives a summary of the assumptions made in the

analysis. The analysis was based on the equations given in Appendix A to NRC Standard Review Plan 6.2.5.

2. Zirconium-Water Reaction

As a result of a LOCA, fuel cladding temperatures begin to rise beginning after blowdown and continue until core refill. Zirconium reacts with steam according to the following reaction:

$$Zr + 2H_2O \rightarrow ZrO_2 + 2H_2$$

Thus, for each mole of zirconium that reacts, two moles of free hydrogen are produced. The extent of the metal-water reaction and associated hydrogen generated depends strongly on the course of events assumed for the accident and on the effectiveness of emergency cooling systems. Paragraph 6.3.3.1 indicates the peak core-wide oxidation of less than 0.86% for the design basis LOCA. The amount of hydrogen assumed to be generated by metal-water reaction in determining the performance requirements for combustible gas control systems is five times the maximum amount calculated.

The analysis conservatively assumes that hydrogen generation from the metal-water reaction goes to completion instantaneously. The hydrogen evolved is assumed to mix homogeneously with the containment atmosphere.

Table 6.2.5-4

SUMMARY OF ASSUMPTIONS USED FOR HYDROGEN GENERATION FROM RADIOLYSIS

1. Reactor power level is 4070 MWt (3990 + 2% uncertainty).
2. An insignificant quantity of hydrogen is generated due to the radiolysis from the noble gas isotopes.
3. The guidelines as set forth in Regulatory Guide 1.7 were followed:
   a. 100% of the noble gases are released to the atmosphere
   b. 50% of the halogens and 1% of the solids present in the core are intimately mixed with the coolant water
   c. $G(H_2)$ is 0.5 molecule/100 eV
   d. The following percentage of fission product radiation energy is absorbed by the coolant:

Percentage	Radiation Type	Location of Source
0	Beta	Fuel rods
100	Beta	Coolant
10	Gamma	Fuel rods
100	Gamma	Coolant

3. Corrosion of Metals and Paints in Containment

Hydrogen is formed by corrosion of metals in the containment. The significant portion of this source of hydrogen is from the corrosion of zinc (and, to a lesser extent, aluminum).

Zinc in the containment is in two forms: zinc-based paint and galvanized steel. Use of galvanized steel and zinc-rich primers in containment is limited as much as practical. The mass of zinc in containment is conservatively analyzed at 21,000 lb_m over a surface area of 230,000 ft^2. The mass of zinc-rich primer is conservatively analyzed at 32,000 lb_m over a surface area of 287,000 ft^2. During a LOCA, the containment is sprayed with a borated solution. During the long-term recirculation phase, the pH of the spray will be maintained in the range of 7 to 8.5 by the addition of trisodium phosphate (from baskets located near the containment sump). The hydrogen generation rates from zinc-based paint and galvanized steel in this environment are given in table 6.2.5-5. The hydrogen generation rate from corrosion of zinc is shown in figure 6.2.5-2. Use of aluminum inside the containment has been kept to a practical minimum. The mass of aluminum in containment is conservatively analyzed at 3,000 lb_m over a surface area of 1,096.9 ft^2. The hydrogen generation rate from corrosion of aluminum for an analyzed core power of 4070 MWt is shown in figure 6.2.5-2.

Table 6.2.5-5

HYDROGEN GENERATION RATES USED IN THE POST-ACCIDENT CONTAINMENT HYDROGEN GENERATION ANALYSIS(2) - ALL ANALYZED CORE POWER / STEAM GENERATOR CONFIGURATIONS

Temperature (°F)	Hydrogen Generation Rate (SCF/ft^2-h)	
	Galvanized Steel	Zinc-Based Paint
120	3.76E-05	6.65E-05
160	0.000162	2.87E-04
200	5.86E-04	0.00104
240	0.00183	3.24E-03
280	5.05E-03	8.94E-03

4. Miscellaneous Sources of Hydrogen

During normal operation of the plant, hydrogen is dissolved in the primary system water. The concentration of hydrogen in primary coolant ranges from 25 to 50 cubic centimeters per kilogram of coolant. The total amount of hydrogen in the primary system is considered to be insignificant (less than 10 pounds of H_2 total if the concentration is 50 cubic centimeters per kilogram of coolant).

B. In the extremely unlikely event that a LOCA occurs and the redundant recombiners fail to function properly, the hydrogen purge system may be utilized to control the hydrogen concentration inside the containment. Operation of the hydrogen purge system would be as directed from the TSC under applicable Emergency Plan Implementing Procedures.

The credible failures to the hydrogen recombiners and monitors involve mechanical failure, loss of power, missile impact, and flooding. Since both recombiners and monitors are completely redundant, no single mechanical failure could cause loss of function. The power supply to each redundant unit is from a separate Class 1E power source so that no single electrical failure could impair the operation of both safety trains. The components contained in each of the redundant systems are physically separated to ensure that missile impact due to a single failure would not impair the ability of the system to perform its designated safety function. The recombiners

and the hydrogen analyzers are located in the auxiliary building.

The suction points are above the post-LOCA water level (as specified in paragraph 6.2.1.1.2.4). The hydrogen recombiner system and hydrogen monitoring system are designed in accordance with Seismic Category I requirements as specified in section 3.2. (The hydrogen purge system and recombiners use the same Seismic Category I containment penetrations.) The components (and supporting structures) of any system, equipment, or structure, which are not Seismic Category I, and whose collapse could result in loss of a required function through either impact or flooding, are analytically checked to determine that they will not collapse when subjected to seismic loading.

C. The internal structures of the containment building are designed to provide vertical, open-ended compartments around each steam generator and pair of reactor coolant pumps and to rise from the lowest level of the containment to above the operating floor. Outside the secondary shield, the levels beneath the concrete operating floor are designed as open grating to preclude stagnant air pocketing. Auxiliary spray headers are located at elevation 120 and 140 feet to ensure adequate spray coverage of this sheltered volume. The interior of the containment above the operating floor is designed as one large, open compartment. With one of two redundant trains of four spray headers operating in conjunction with the auxiliary spray headers described above, the containment

spray system is designed to provide 94% coverage of the containment volume at a flowrate of 3890 gallons per minute with a maximum water temperature of 120F. These flows provide the mechanism for establishing convection air flows downward. Following a LOCA, the steam generators and reactor coolant system (short-term), and containment sump water (long-term) would provide the heat sources which establish and maintain upward natural convection flows within the containment. The water level in the containment post-LOCA has been calculated to be approximately 10 feet 6 inches above the floor and has a nominal temperature of 300F.

6.2.5.4 Test and Inspections

The analytical and test program for the hydrogen recombiners includes proof of principle tests and full-scale prototype tests on a production recombiner. The tests were completed and the results of these tests were submitted to the NRC in reference 1.

In the design of the equipment actually installed at PVNGS, all recombiner components can be inspected and are accessible for maintenance during normal plant operation.

Periodic testing of the containment hydrogen control system is described in the Technical Specifications.

Initial testing is described in section 14.2

6.2.5.5 Instrumentation Requirements

6.2.5.5.1 Hydrogen Recombiner System

A manual control station is provided for each train for starting and stopping the unit. The controller maintains the correct power input to bring the recombiner above the threshold temperature for the recombination process. The controller setting can be adjusted to accommodate variations in containment temperature and pressure in the post-LOCA environment. The system is designed to conform to the applicable portions of IEEE-279 and is powered from a Class 1E source. No automatic initiating signals or alarms are provided. The hydrogen recombiners are manually actuated based on containment atmospheric samples discussed in paragraph 6.2.5.2.2.2. The unit gas flow is monitored at various points on the unit control panel. Monitoring the recombiner system is provided in accordance with subsection 7.5.1 and table 7.5-1.

6.2.5.5.2 Hydrogen Purge System

Operation of the hydrogen purge system is manually initiated from the control room. No automatic initiating signals or alarms are provided. In the improbable event of loss of both recombiner trains, the hydrogen purge system may be manually actuated based on containment atmospheric samples discussed in paragraph 6.2.5.2.2.2.

6.2.6 CONTAINMENT LEAKAGE TESTING

This subsection presents the testing program for the reactor containment integrated leakage rate tests (Type A tests), containment penetration leakage rate tests (Type B tests), and containment isolation valve leakage rate tests (Type C tests) and complies with 10CFR50, Appendix A, General Design Criteria, and Appendix J, Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors, Option B – Performance-Based Requirements. Option B identifies the performance-based requirements and criteria for periodic leakage-rate testing. Specific guidance concerning a performance-based leakage-test program, acceptable leakage-rate test methods, procedures and analyses that may be used to implement these requirements and criteria that are provided in Regulatory Guide 1.163, "Performance-Based Containment Leak-Test Program." Regulatory Guide 1.163 endorses, with exceptions, NEI 94-01, "Industry Guideline for Implementing Performance-Based Option of 10CFR Part 50, Appendix J. The NEI 94-01 guideline in turn, endorses ANSI/ANS 56.8-1994, "Containment System Leakage Testing Requirements."

6.2.6.1 Reactor Containment Integrated Leakage Rate Test

After completion of construction of the reactor containment, including installation of all portions of mechanical, fluid, electrical, and instrumentation systems penetrating containment associated with containment integrity, and after satisfactory completion of the structural integrity tests as described in subsection 3.8.1, the preoperational containment integrated

leakage rate test is performed to verify that the actual containment leakage rate does not exceed the design limits.

After completion of the preoperational containment integrated leakage rate test, periodic Type A tests are conducted at intervals described in facility Technical Specifications.

In order to ensure a successful integrated leakage rate test, local leakage rate tests (Types B and C) are performed on penetration boundaries and on containment isolation valves. During the period between the completion of one Type A test and the initiation of the containment inspection for the subsequent Type A test, repairs are made, if necessary, to ensure that leakage through the containment isolation barriers does not exceed design limits. Repairs or adjustments are permitted prior to or during the Type A test provided that the change in leakage rate determined by local leakage rate testing is added to the Type A test result.

An integrated leakage rate test (Type A) is performed to determine that the total leakage from the containment does not exceed the maximum allowable leakage rate (La) at a calculated peak containment internal pressure of Pa, as defined in 10CFR50, Appendix J. Pertinent test data, including test pressures, test duration, and definitions of terms are presented in table 6.2.6-1. Acceptance criteria is given in facility Technical Specifications.

The Type A test may be conducted per ANSI/ANS 56.8-1994 or per BN-TOP-1, using the absolute method. Measurements of containment atmosphere drybulb temperature, dewpoint temperature (water vapor pressure), and pressure are taken to

calculate the leakage rate. A standard statistical analysis of the data is conducted using a linear least squares fit regression analysis to calculate the leakage rate and associated 95% confidence level (or maximum expected measurement system error). The calculated leakage rate and upper 95% confidence level are documented. Type B and C leakage rates not accounted for in the integrated leak rate test shall be added to the Type A test leakage rate UCL to determine an upper bound on the overall integrated leakage rate. The additions shall be based on minimum pathway leakage rates. Instrumentation meeting the requirements of ANSI/ANS 56.8-1994 may be used in lieu of the data acquisition system described in table 6.2.6-2.

Prior to commencement of any Type A test, the pretest requirements described in 10CFR50, Appendix J, are met.

Upon completion of the Type A test, a verification test is conducted to confirm the capability of the Type A data acquisition and reduction system to satisfactorily determine the calculated containment integrated leakage rate. The verification test is accomplished by imposing a known leak on the containment or by pumping back a known quantity of air into containment through a calibrated flow measurement device. Verification test acceptance criteria are in accordance with ANSI/ANS 56.8-1994 or BN-TOP-1, as applicable.

If, during a Type A test, including the verification test, excessive leakage paths are identified which interfere with satisfactory completion of the test, or which result in the Type A test not meeting the acceptance criteria of facility

Table 6.2.6-1

TYPE A TEST DATA (Sheet 1 of 2)

<u>4070 MWt</u>:	
Peak test pressure The calculated peak internal pressure related to the design basis loss-of-coolant accident.	Pa = 58 psig (see table 6.2.1-9)
Maximum allowable leakage rate The maximum allowable leakage from the containment building.	La = 0.1%/day (mass percent)
Measured leakage rate Overall measured leakage rate during Type A test.	Lam (%/day) (mass percent)
Imposed leakage rate The leakage rate imposed on the containment during the verification test. Li is 75% to 125% of La.	Lo
Verification test leakage The total containment leakage, including Lo, measured during the verification test.	Lc
Test duration A. After the containment atmosphere has stabilized, the integrated leakage rate test period begins. The duration of the test period must be sufficient to enable adequate data to be accumulated and statistically analyzed so that leakage rate and upper confidence limit can be accurately determined.	

Table 6.2.6-1

TYPE A TEST DATA (Sheet 2 of 2)

B. A Type A test shall last a minimum of 8 hours after a minimum 4-hour stabilization period and shall have a total of not less than 20 sets of data points at approximately equal time intervals.	
C. The Type A test cannot be successfully terminated until the acceptance criteria of facility Technical Specifications are met.	
Temperature limits during Type A test	40 to 120F
Free air volume	2.6×10^6 ft^3

Table 6.2.6-2

TYPICAL DATA ACQUISITION SYSTEM FOR PRIMARY CONTAINMENT INTEGRATED LEAKAGE RATE TEST (Sheet 1 of 2)

Item	No. Req'd	Description
UJN-1	1	Data acquisition system consisting basically of: multiplexer/ scanner/programmer/coupler capable of automatic, periodic scan mode
UI-1	1	Numeric display to read drybulb and dewpoint temperature in °F
KIT-1	1	Digital clock with binary coded decimal (BCD) output
UR-1	1	Digital printer with BCD 8421 code or pure binary 8421 code
PIT-1	1	Precision pressure gauge with BCD 8421 shaft encoder kit Range: 0 to 100 psia Accuracy: 0.010% of reading ±0.002% of full scale or better Repeatability: 0.005% of full scale
PE-1	1	Fused quartz bourdon capsules - for PI-1 Range: 0 to 100 psia
TE-1	10	Resistance temperature detectors Range: (system) 32 to 150F Accuracy: ±0.5F or better Repeatability: ±0.1F
ME-1	3	Dewpoint temperature detectors Range: (dewpoint temperature) 0 to 120F Accuracy: ±1.0F or better Repeatability: ±0.5F over the range of 40 to 120F

Table 6.2.6-2

TYPICAL DATA ACQUISITION SYSTEM FOR PRIMARY CONTAINMENT INTEGRATED LEAKAGE RATE TEST (Sheet 2 of 2)

Item	No. Req'd	Description
FT-1[(a)]	1	Flow transmitter Range: 0 to 10 standard ft^3/min Accuracy: ±1% full scale including linearity Repeatability: ±0.2% full scale
PT-1[(a)]	1	Pressure transducer Range: 0 to 75 psig Accuracy: Combined linearity and hysteresis within ±0.5% full scale
FI-1/PI-1[(a)]	2	Digital display FI-1: 0 to 10 standard ft^3/min PI-1: 0 to 75 psig

a. Used for imposed leakage verification test only.

Location	-		AB	CB	AB	CB		CB	AB
Type C tested	-		Yes	Yes	Yes	Yes		Yes	Yes
Test pressure on CB side[h]	-		Yes	Yes	Yes	Yes		Yes	Yes
Status during Type A test	-		C	C	C	-		C	C

a. Valves are in the secondary side of the steam generator (SG). These valves are not subject to Type C tests because they are not depended on in the LOCA dose calculations to keep the radiological consequences of a LOCA to within the 10 CFR 50, Appendix A General Design Criteria 19 and 10 CFR 100 limits. The LOCA dose calculations assume a single failure of a 10 CFR 50, Appendix A General Design Criteria 57 valve or a stuck open ADV.
b. Valves are opened in event of LOCA.
c. Instrumentation lines are considered an extension of CB boundary.
d. Inboard butterfly valves will be leakage tested in reverse direction.
e. Relief valves exhausting to containment sump or RDT are tested hydrostatically when piping is pressurized for Type C test of isolation valves. Pressure is under seat which provides a conservative test.
f. This system is used for decay heat removal after plant initial operation. Isolation valves are closed and system vented only for initial Type A test (prior to operation).
g. Pathways that are Type B or C tested within the previous 24 calendar months prior to the Type A test need not be vented or drained.
h. If test pressure is not applied during the Type A test, the Type A test results will be adjusted.
i. Position of valve is determined by Operations to maintain the plant in a safe shutdown condition.
j. Manual vent, drain, and test valves between the Containment Isolation Valves will be maintained locked closed under administrative controls or surveilled closed per Technical Specifications.
k. Penetrations may be isolated using blind flanges located outside containment in plant operating modes 1-4. Double o-ring blind flanges are Type B tested by pressurizing the interspace between o-rings.
l When blind flanges are installed, only Type B testing of the blind flanges is required.
m. For application of the single failure rule to check valves, refer to Section 3.1.30.
n. In Units where DMWO 2529758 has been implemented, valve CHA-UV-715 is removed and valves HPA-UV-023 & HPA-UV-024 are de-terminated with upstream piping cut and capped as the new containment boundary.
o. In units where DMWO 2778159 has been implemented, applicable valve(s) have been removed.
p. Applicable in those Units where DMWO 4304156 has been implemented.

Technical Specifications, the leakage path may be isolated and the Type A test completed. Subsequent to the Type A test, the leakage path is locally leak rate tested and the post repair minimum pathway leakage is added to the Type A test result.

If any Type A test fails to meet the acceptance criteria, the test schedule applicable to subsequent Type A tests is as described in facility Technical Specifications.

6.2.6.2 Primary Containment Penetration Leakage Rate Test

Containment penetrations whose design incorporates resilient seals, gaskets, or sealant compounds; air locks and lock door seals; equipment and access hatch seals; and electrical penetrations receive preoperational and periodic Type B leakage rate tests in accordance with 10CFR50, Appendix J. A list of all containment penetrations subject to Type B tests is provided in table 6.2.6-4.

Electrical penetrations are of a modular design and are provided with leak testing provisions meeting the requirements of IEEE 317.

Electrical penetrations are described in paragraph 3.8.1.1.3.4.

Expansion bellows are not utilized in the design of the mechanical penetrations. The bellows used on the fuel transfer tube penetration is to accommodate relative movement between the refueling canal liner and the containment building penetration and does not form part of the containment building pressure boundary.

Table 6.2.6-4

PENETRATIONS SUBJECT TO TYPE B TESTS

Penetration	Quantity	Test
Personnel lock L-1	1	Door seals interspace Electrical and mechanical penetrations interspace Air lock volume
Emergency lock L-3	1	
Equipment hatch L-2	1	Hatch seals
Fuel transfer tube 53	1	Flange seal interspace
Refueling purge (56, 57) (when blind flanges are installed)	2	
CB pressurization 58, 62B, 62C	1	
Electrical 24 in. nozzle	5	Interspace and seals
Electrical 18 in. nozzle	46	
Electrical 12 in nozzle	40	

The equipment hatch and air lock doors are fitted with double seals with an interspace test connection. Clamps are provided for restraining the air lock inner doors when the air lock chamber is pressurized. When multiple openings of the containment air locks occur, the air locks will be tested at least once every 7 days.

Electrical and mechanical penetrations on the air lock are provided with double seals and test connections.

Type B tests are conducted at containment peak accident pressure (Pa) as defined in table 6.2.6-1. The acceptance

criteria and leakage rate limits are given in the facility test specifications. Test methods are described in paragraph 6.2.6.3 below.

6.2.6.3 Containment Isolation Valve Leakage Rate Tests

Containment isolation valves are Type C tested in accordance with 10CFR50, Appendix J, as listed in table 6.2.6-3.

The process piping, instrumentation tubing, and personnel access penetrations are listed in table 6.2.4-1. Figure 6.2.4-1 shows the location of all test vent and drain connections and the direction in which the isolation valves will be tested.

The containment isolation valves for each piping penetration are tabulated in table 6.2.6-3, together with test method and test direction. The table also indicates the status of the valves during containment building, Type A test, and whether the system will be vented to the containment and drained during the Type A test.

Type C (and B) tests are performed by local pressurization utilizing either the pressure decay or flowmeter method. For the pressure decay method, the test volume is pressurized with air or nitrogen to at least Pa. The rate of decay of pressure of the known free air test volume is monitored to calculate leakage rate. For the flowmeter method, pressure is maintained in the test volume by makeup air, or nitrogen, through a calibrated flowmeter. The flowmeter fluid flowrate is the isolation valve leakage rate. Refer to paragraph 6.2.4.4.

Unless otherwise justified, the containment isolation valves are tested by measuring leakage across the valve seat in the direction out of the containment, in accordance with the requirements of 10CFR50, Appendix J, for Type C testing.

Systems connected to the secondary side of the steam generator, cooling water systems, and other closed systems are not vented to the containment building during Type A tests as indicated in table 6.2.6-3.

Where Type C tests can be performed on isolation valves in closed systems, the results of the Type C test will be added to the Type A test if the system is not vented during the Type A test.

Type C testing of the safety injection lines is not performed. Justification for this is on the basis that these valves will be opened in the event of a LOCA and, therefore, leakage across the isolation valves is not pertinent. If the valves are subsequently closed, the containment pressure will have dropped and reactor coolant will provide a water seal, thus eliminating any leakage across these valves. Reactor coolant will be replenished by the safety injection system, which meets the single failure criteria. A further consideration is that the addition of extra isolation valves in the injection lines for the sole purpose of performing Type C tests would impair the operability of these engineered safety features.

Inservice testing and inspection of these isolation valves, and also the associated piping system outside the containment, will be performed periodically under the ISI requirements of

ASME XI. During normal operation, the systems are water filled and degradation of valves or piping would be readily detected.

The 24-inch butterfly isolation valves on the safety injection system suction piping from the containment recirculation sumps are not Type C tested. These valves are normally closed, do not receive a CIAS and are opened post-accident on a recirculation actuation signal (RAS) to provide cooling and recirculation of safety injection and containment spray water. In addition, the recirculation sump piping penetrating containment connects to a Seismic Category I, Q Class, closed system outside containment that will effectively prevent direct communication between the atmosphere inside and outside containment through these valves. Post-accident, the sump suction lines and in-containment isolation valves will be water-flooded and submerged with a water seal providing additional protection against containment atmosphere leakage.

Isolation valves connected to the secondary side of the steam generator, such as main steam isolation valves, main steam relief valves, feedwater valves, vent valves, blowdown lines, and blowdown sample lines are considered containment isolation valves. These valves are not subjected to Type C tests because they are not depended on in the LOCA dose calculations to keep the radiological consequences of a LOCA to within GDC 19 and 10 CFR 100 limits. The LOCA dose calculations assume a single failure of a GDC 57 valve or a stuck open ADV.

Valves which are Type C tested are tested with the applied test pressure in the same direction as the pressure existing following an accident, except the butterfly and relief valves

listed in table 6.2.6-3. Due to the design of these valves, the test leakage will inherently be equal to or greater than the leakage following an accident.

Containment pressure monitoring lines are considered an extension of the containment boundary and, therefore, the isolation valves are not Type C tested.

Outboard motor operated containment isolation valves on the Containment Spray lines penetrating containment are not required to close on a containment isolation signal, are not required to operate intermittently during an accident, open on a containment spray actuation signal and are designed to fail as is. Therefore, these valves are not Type C tested.

The acceptance criteria for all penetrations and isolation valves subject to Types B and C tests will be given in the PVNGS Technical Specifications.

6.2.6.4 Scheduling and Reporting of Periodic Tests

The periodic leakage rate test schedules for Types A, B, and C tests will be given in the PVNGS Technical Specifications.

Type B and C tests may be conducted at any time during normal plant operations or during shutdown periods so long as the time interval between tests for any individual Type B or C test does not exceed the maximum allowable interval specified in the PVNGS Technical Specifications. Each time a Type B or C test is completed, the overall total leakage rate for all required Type B and C tests is corrected for any differences noted.

Provisions for reporting test results will be given in the PVNGS Technical Specifications.

6.3.1 DESIGN BASES

6.3.1.1 Summary Description

The Emergency Core Cooling System (ECCS) or Safety Injection System (SIS) is designed to provide core cooling in the unlikely event of a Loss-of-Coolant Accident (LOCA). The ECCS prevents significant alteration of core geometry, Precludes fuel melting, limits the cladding metal-water reaction, removes the energy generated in the core and maintains the core subcritical during the extended period of time following a LOCA.

The SIS accomplishes these functional requirements by use of redundant active and passive injection subsystems. The active portion of the SIS consists of high and low pressure Safety Injection pumps and associated valves. The passive portion consists of pressurized Safety Injection Tanks (SIT).

Events associated with ECCS and Safety Injection are described in Chapter 15 of the UFSAR.

6.3.1.2 Criteria

6.3.1.2.1 Functional Design Bases

a. The shutoff head and flowrates of the High Pressure Safety Injection Pump (HPSIP) and Low Pressure Safety Injection Pump (LPSIP) were selected to insure that adequate flow is delivered to the RCS to accomplish the functional requirements of Section 6.3.1.1.

b. Storage of fluid for the SIS is accomplished by the Refueling Water Tank (RWT) which contains a sufficient amount of borated fluid to accomplish the functional requirements of Section 6.3.1.1.

c. The SIS is designed such that equal flows are delivered to each injection point, regardless of break location.

6.3.1.2.2 Reliability Design Bases

a. The safety function defined in Section 6.3.1.1 can be accomplished assuming the failure of a single active component during the injection mode of operation or a single active or limited leakage passive failure of a component during the recirculation mode of operation (see 3.1.30 note "a"). For failure analysis, all necessary supporting systems including the onsite electrical power system are considered a part of the Safety Injection System. A Failure Modes and Effects Analysis is presented in Table 6.3.2-3.

b. Components of the Safety Injection System and instrumentation which must operate following a LOCA are designed to operate in the environment of Section 3.11.

c. The Safety Injection System is designed to perform the functions of Section 6.3.1.1 for the entire duration of a LOCA.

d. The Safety Injection System is designed to Seismic Category I requirements.

6.3.1.3 CESSAR Interface Requirements

Provided below are interface requirements repeated from CESSAR Section 6.3.1.3.

Below are detailed the interface requirements that the SIS places on certain aspects of the BOP, listed by categories. In addition, applicable GDC and Regulatory Guides, which C-E utilizes in its design of the SIS, are presented. These GDC and Regulatory Guides are listed only to show what C-E considers to be relevant, and are not imposed as interface requirements, unless specifically called out as such in a particular interface requirement.

Relevant GDC - 1, 2, 3, 4, 13, 18, 20, 21, 22, 23, 35, 36, 37, 54, 57

Relevant Reg. Guides - 1.1, 1.26, 1.28, 1.29, 1.31, 1.36, 1.38, 1.44, 1.46, 1.48, 1.53, 1.64, 1.68, 1.75, 1.79, 1.82

A. Power

1. The Safety Injection System pumps and valves shall be capable of being powered from the plant turbine generator (onsite power source), and/or plant startup power source (offsite power), and the emergency generators (emergency power).

2. Power connections shall be through a minimum of two independent buses so that in the event of a LOCA in conjunction with a single failure in the electrical supply, the flow from one high-pressure and one low-pressure safety injection train shall be available for core protection.

3. Each electrical bus of the above shall be connected to one high-pressure safety injection pump and associated valves and one low-pressure safety injection pump and associated valves.

4. Each emergency generator and the automatic sequencers necessary for generator loading shall be designed such that flow to the core is delivered to the RCS within a maximum of 29 seconds after SIAS is generated. The emergency generator interface requirements are described in Section 8.3.1 and shall be complied with.

5. Instrument power supplies shall be provided as stated in Chapter 8.

6. The SIS hot leg injection valves shall be powered such that a single electrical failure cannot cause spurious initiation of hot leg injection flow through either hot leg injection line, nor shall a single electrical failure prevent deliberate hot leg injection flow through at least one of the hot leg injection lines.

7. Air for all SIS pneumatic valve operators shall be clean, dry, and oil-free.

8. Provisions shall be made to remove power to the safety injection tank vent valves (SI-605, -606, -607, -608, -613, -623, -633 and -643) during plant operation. Provisions shall be made to allow restoration of power to these valves from

the control room and a remote shutdown location. The two safety injection tank vent valves on each SIT shall be powered from separate and independent emergency power sources.

B. Protection from Natural Phenomena

1. Design provisions shall be incorporated such that SIS components are capable of functioning in the event of the maximum probable flood or other natural phenomenon defined in General Design Criteria (GDC) 2 of 10CFR50.

C. Protection from Pipe Failure

1. Pipe Break Considerations - The maximum expected leakage from a moderate energy pipe rupture postulated during normal plant conditions in the Safety Injection System shall be as defined by the methods of Section 3.6. Isolation valves used to contain leakage shall be protected from the adverse effects of a high or moderate energy pipe rupture which might preclude their operation when required.

2. Pipe Leakage Considerations - No limited leakage passive failure or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, loss of NPSH, or loss of recirculation water inventory), in the SIS during the recirculation mode shall preclude the availability of minimum acceptable recirculation capability (minimum acceptable capability is

defined as that which is provided by the operation of one subsystem).

3. Design Requirements for Protection from Pipe Break - The Safety Injection System shall be protected from the effects of pipe rupture.

4. The Safety Injection System shall be protected from the effects of pipe whip.

D. Missiles

1. The Safety Injection System shall be protected from missiles in accordance with the Missile Barrier Design Interface Requirements.

E. Separation

1. Adequate physical separation shall be maintained between the redundant piping paths and containment penetrations of the SIS such that the SIS will meet its functional requirements even with the failure of a single active component during the injection mode, or with a single active failure or a limited leakage passive failure during the recirculation mode.

2. The cabling which is associated with redundant channels of vital Class 1E circuits for the SIS shall be physically separated to preserve redundancy and prevent a single event from causing multiple channel malfunctions or interactions between channels.

Associated circuit cabling from redundant channels shall either be separated, provided with isolation devices, or analyzed and/or tested to demonstrate that no credible single failure could adversely affect redundant channels of Class 1E circuits.

3. In the routing of SIS Class 1E circuits and location of equipment served by these Class 1E circuits, consideration shall be given to their exposure to potential hazards such as postulated ruptures of piping, flammable material, flooding, and non-flame retardant wiring. Adequate separation or protective measures shall be provided.

4. Failures of non-safety grade systems shall not compromise redundancy of the SIS.

F. Independence

1. Each SIS safeguards train shall be provided with an independent environmental control system.

2. Power connections for SIS components shall be from a minimum of two independent electrical buses. See A.2 above.

3. Two independent vital instrument power sources shall be provided for the SIS instrumentation. See A.5 above.

G. Thermal Limitations

Not Applicable

H. Monitoring

1. Provisions shall be made for the detection, containment, and isolation of the maximum expected leakage from a moderate energy pipe rupture, as discussed in C.1 above.

2. Process instrumentation shall be available to the operator in the control room to assist in assessing post-LOCA conditions. The type of instrument, parameter measured, and instrument range and accuracy are listed in Table 6.3.1.3-1.

I. Operational Controls

Not Applicable

J. Inspection and Testing

1. Inspection and testing requirements for the SIS are contained in Section 3/4.5 of the CESSAR Technical Specifications and shall be complied with.

2. Prior to initial plant startup, SIS flow tests shall be performed. An adequate supply of water and the necessary test connections at the containment sump shall be provided.

TABLE 6.3.1.3-1
(Sheet 1 of 2)

SAFETY RELATED PROCESS INSTRUMENTATION CESSAR TABLE 6.3.2-3
(Interface Requirements)

Instrument	Number of Channels	Range	Accuracy	Post-Accident Function
Primary System				
Pressurizer Pressure	4	0-3000 psia	± 1%	Initiate SIAS, monitor primary system pressure
Pressurizer Pressure	4	0-750 psia	± 1%	Monitor primary system pressure, provides interlocks on SCS suction valves and SIT isolation valves
Reactor Coolant Hot Leg Temperature Indicator/Recorder	1 per hot leg	375-675°F	± 1%	Monitor and record hot leg temperatures, used to determine when shutdown cooling can be initiated.
Safety Injection System				
HPSI Cold Leg Flow Rate	4	0-750 gpm	± 2.5%	Monitor HPSI cold leg injection flow
HPSI Hot Leg Flow Rate	2	0-750 gpm	± 2.5%	Monitor HPSI hot leg injection flow
Shutdown Cooling/LPSI Flow Rate	2	0-10000 gpm	±2.5%	Monitor Shutdown Cooling/LPSI flow rate. Used to set shutdown cooling flow
Shutdown Cooling Heat Exchanger Inlet and Outlet Temperature Indicator/Recorder	2	40-400°F	± 2.5%	Monitor and record shutdown cooling performance. Used to control RCS cooldown rate.
Shutdown Cooling Heat Exchanger Outlet Temperature	2	40-400°F	± 2.5%	Monitor Shutdown Cooling Heat Exchanger performance.

SAFETY RELATED PROCESS INSTRUMENTATION CESSAR TABLE 6.3.2-3
(Interface Requirements)

Instrument	Number of Channels	Range	Accuracy	Post-Accident Function
Safety Injection System				
Wide Range SIT Pressure	1 per tank	0-750 psig	± 2.5%	Monitor SIT pressure
RWT Level	4	0-100%	± 2%	Initiate RAS, monitor RWT level.
Wide Range SIT Level	1 per tank	0-100%	± 2.5%	Monitor SIT Level.
Containment				
Containment Pressure	4	-4-20 psig	± 1 psig	Initiate SIAS, monitor containment pressure

K. Chemistry/Sampling

1. The Sampling System shall provide a means of obtaining remote liquid samples from the SIS for chemical and radiochemical laboratory analysis.

2. The sample lines in contact with the reactor coolant shall be austenitic stainless steel or equivalent material compatible with the fluid chemistry.

L. Materials

1. Safety injection piping and fittings shall be Seismic Category 1.

2. Design and fabrication of the safety injection piping and fittings shall conform to ASME Boiler and Pressure Vessel Code (B&PV) Section III, Class 1 and 2.

3. Pipes and all parts in contact with the system fluid must be of austenitic stainless steel.

   Valve packings, gaskets, and valve diaphragm materials shall also be compatible with the chemistry of the water and the radioactive dose at that location.

4. Care shall be taken to prevent sensitization and to control the delta ferrite content of (1) the welds which join any system fabricated of austenitic stainless steel to the SIS, and (2) the field welds on the SIS.

5. Controls shall be exercised to assure that contaminants do not significantly contribute to stress corrosion of stainless steel.

6. Materials used for the containment and its internal structures shall withstand exposure to all post-accident conditions without causing deleterious or undesirable reactions, or significantly altering the existing recirculating water chemistry.

7. If the Containment Spray System utilizes a common suction with the SIS from the RWT or containment sump, then the materials used in this system shall be austenitic stainless steel or other compatible material and shall conform to the standards of Section III Class 2, ASME B&PV Code and applicable Code cases.

M. System/Component Arrangement

1. To assure that the Engineered Safety Features Systems flow requirements are met, the maximum and minimum acceptable head losses for the piping and fittings are as presented in Table 6.3.1.3-2. The NPSH requirements are shown in table 6.3.2-1.

2. For each safeguards train, the top of the piping junction between the RWT discharge and the containment sump must be located at a minimum of 16 feet below the minimum containment sump water level during recirculation. If containment pressure could go subatmospheric by values

greater than 3 psid, this must be accommodated for by increasing the distance of the piping junction top below the minimum containment sump water level during recirculation by 2.31 feet for each additional psid. The purpose of this requirement is to preclude the possibility of drawing air from the RWT to the safeguard pumps suction during recirculation should the RWT isolation valves remain open during recirculation.

Frictional losses in the safeguard pump suction piping between the containment sump and the junction with the RWT shall not exceed 7 feet, unless the elevation of the top of this junction is lowered an additional foot for each additional foot of head loss.

3. The high pressure safety injection pumps shall be located in the auxiliary building as close as practical to the containment structure.

   a. The elevation of these pumps shall be low enough such that adequate NPSH is available during the recirculation mode when the pumps take suction from the containment sump.

   b. The available NPSH shall be calculated at the pump suction, which may be assumed to be 2.5 ft. above its foundation elevation.

   c. The calculation shall consider concurrent low-pressure safety injection and containment

spray pump operation. Table 6.3.1.3-2 provides CESSAR, HPSI and LPSI pump head loss requirements. NPSH requirements are shown in table 6.3.2-1.

d. Credit shall not be taken for water that could be trapped above the containment floor.

4. The above requirements on location and elevation shall also be applied to the low-pressure safety injection pumps except the pump's suction is 14 inches below its supports. The NPSH required by these pumps is 18 feet at a runout flow rate of 5100 gpm per pump. This design calculation shall assume:

   a. Concurrent high-pressure safety injection and containment spray pump operation and flow.

   b. A refueling water tank temperature of 100F.

5. SIS components shall be properly supported such that pipe stresses and support reactions are within allowable limits. C-E will provide to each Applicant the design loads at the support/ structure interface locations for components that C-E supplies.

TABLE 6.3.1.3-2

SAFETY INJECTION SYSTEM HEAD LOSS REQUIREMENTS FROM CESSAR TABLE 6.3.2-5.b (Interface Requirements)

	Flow/Pump (gpm)	Required System Resistance (ft)
High Pressure Pumps		
a) Injection Mode	1130	1580(1)
b) Recirculation Mode	1130	1580(2)
c) Long Term Cooling Mode	1130	1580(3)
Low Pressure Pumps		
a) Injection Mode	5000	290(4)
b) Recirculation Mode	3500	370(5)
c) Ambient Temperature Recirculation Test	3500	370(6)

NOTES:

(1) Friction and elevation losses between the water level in the RWT at the start of recirculation and the outlet of the cold leg injection nozzle. One high pressure pump operating.

(2) Friction and elevation losses between the minimum water level in the containment sump and the outlet of the cold leg injection nozzle. One high pressure pump operating.

(3) Friction and elevation losses between the minimum water level in the containment sump and the outlet of the cold leg injection nozzles and the shutdown cooling nozzle on the hot leg. Required head losses include the flow balancing orifice. One high pressure pump operating.

(4) Friction and elevation losses between the water level in the RWT (at the start of recirculation) and the outlet of the cold leg injection nozzle. One low pressure pump operating.

(5) Friction and elevation losses between the minimum water level in the containment sump and the outlet of the cold leg injection nozzle. One low pressure pump operating.

(6) Friction and elevation losses through the entire flow path. One LPSI pump in operation taking suction from the containment sump and discharging to the RWT via the cross-connect lines normally used for inservice testing of the LPSI and CS pumps. Valves SI-306/307 and SI-657/658 must be set to the appropriate test position prior to starting this test in order to provide sufficient system resistance.

6. The loadings imposed by the SIS piping on the SIS/ RCS nozzles, or by the connecting system piping on SIS nozzles, shall be less than the design loads for these nozzles. C-E will provide to each Applicant the design loads for all nozzles on those SIS components that C-E supplies.

7. In the event of a limited leakage passive failure in one SIS train during recirculation, personnel access to the intact train shall be possible.

8. The two safety injection check valves in each of the six safety injection lines shall be located as follows: one as close as practicable to the Reactor Coolant System piping, the other as close as practicable to the containment penetration.

    a. Allowance shall be made for valve accessibility and maintenance.

    b. The total water volume in the piping from the Reactor Coolant System up to these valves shall be less than 30 cubic feet per line. This volume shall be kept to a minimum so that the delay time for injection of borated water will be a minimum.

    c. The check valve leakage lines shall be connected to the safety injection line immediately upstream of the safety injection check valve closest to the Reactor Coolant System piping. This is necessary to ensure

that all of the safety injection piping is borated to the refueling concentration at all times.

9. Each safety injection tank shall be located inside the containment, outside the biological shield, and as close as possible to the reactor coolant cold leg into which it injects.

   a. The piping run from each tank to the reactor coolant cold leg shall be as direct as possible with a minimum of bends and elbows.

   b. Long radius elbows or pipe bends shall be used.

   c. The piping run "K" factor shall not be less than 4.5 or greater than 7.0 including entrance and exit losses and valve resistance referenced to an area of 0.6827 ft^2.

   d. The bottom of the Safety Injection Tank shall be located above the centerline of the reactor coolant cold leg piping.

10. Manually-operated valves shall be provided with locking provisions as shown on P&ID, 01, 02, 03-M-SIP-001, -002 and -003.

11. Physical identification of safety related SIS equipment and cabling shall be provided to allow recognition of safety status by plant personnel.

12. In the routing of SIS Class 1E circuits and location of equipment served by these Class 1E

circuits, consideration shall be given to their exposure to potential hazards. See E.3 above.

13. All SIS ASME Boiler and Pressure Vessel Code Section III components shall be arranged to provide adequate clearances to permit inservice inspection.

14. Protection shall be provided from internally generated flooding that could prevent performance of safety-related functions.

N. Radiological Waste

1. Safety Injection System leakage to the safeguards room will normally drain to the room sump. Provisions shall be provided to accept the maximum leakage rates listed below:

   a. HPSI and LPSI pump seals: 100 cc/hr

   b. Valves

      backseat leakage: 10 cc/hr/inch seat diameter

      across the valve seat: 10 cc/hr/inch of nominal valve size

   All leakages shall be treated as radioactive waste with a low dissolved solids and organic content.

O. Overpressure Protection

Not Applicable

P. Related Services

1. Nitrogen gas shall be supplied to the safety injection tanks. This supply shall satisfy the following requirements:

Minimum Required Flow Rate	300 SCFM (at supply pressure)
Maximum Allowable Flow Rate	2490 SCFM (at supply pressure)
Minimum Supply Pressure	630 psig (for normal plant operations)
Maximum Supply Pressure	700 psig (all conditions)
Gas Volume Required for 4 Tank Blowdown	105,000 SCF
Design Criteria	ANSI B31.1
Nitrogen Supply	$\geq$ 99.99% N_2 $\leq$ 5 ppm O_2
Maximum Supply Free Stream Temperature	115F

No single failure shall allow the compressed nitrogen system delivery pressure to exceed 700 psig.

2. A containment sump shall be provided. Baffles and intake screens shall be installed to limit

the maximum particle size entering the recirculation piping to 0.09 in diameter in order to prevent flow blockage in the Engineered Safety Features components and piping and in the reactor.

3. The maximum particle size in the water exiting from the refueling water tank shall be 0.09 in diameter in order to preclude flow blockage in Engineered Safety Features components and piping and in the reactor.

4. A fire protection system shall be provided to protect the Safety Injection System consistent with the requirements of GDC 3, and shall include, as a minimum, the following features:

   a. Facilities for fire detection and alarming.

   b. Facilities or methods to minimize the probability of fire and its associated effects.

   c. Facilities for fire extinguishment.

   d. Methods of fire prevention such as use of fire resistant and non-combustible materials whenever practical, and minimizing exposure of combustible materials to fire hazards.

   e. Assurance that fire protection systems do not adversely affect the functional and structural integrity of safety related structures, systems, and components.

f. Care should be exercised to ensure fire protection systems are designed to assure that their rupture or inadvertent operation does not significantly impair the capability of safety related structures, systems, and components.

5. The SIS containment penetrations shall not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of equipment or piping inside or outside the containment.

6. Where required, bellows shall be provided between piping and the containment wall to prevent excessive forces on the piping.

Q. Environmental

1. Each SIS safeguards train shall be provided with an independent environmental control system such that the safety-related equipment in each train operates within the environmental design limits specified in Section 3.11.

6.3.1.4 CESSAR Interface Evaluations

The CESSAR interface requirements are met by the PVNGS design as follows:

A. Power

1. The SIS pumps and valves can be connected to the offsite (preferred) power supply, and the diesel generator (standby) power supply.

2. The connections are through two independent buses so that in the event of a LOCA in conjunction with a single failure in the electrical supply, the flow from one high-pressure safety injection (HPSI) train and one low-pressure safety injection (LPSI) train is available for core protection.

3. One HPSI pump and associated valves and one LPSI pump and associated valves are connected to each Class 1E load group.

4. The diesel generator and the automatic sequencers necessary for diesel loading are designed such that flow to the core is attained within a maximum of 30 seconds of reaching SIAS setpoint. Upon receipt of start signal, the diesel generator starts, achieves or exceeds minimum acceptable speed and voltage and the diesel generator output breaker closes, all within 10 seconds. Refer to section 8.3 for a detailed description of the electrical supply system.

CESSAR interface requirements in CESSAR Section 8.3.1, items 1 and 2, and the safety injection system (SIS) equipment electrical power requirements in CESSAR Table 8.3.1-1 are addressed in subsections 8.3.4 and 8.3.5.

5. Refer to subsection 8.3.1 for a discussion covering the instrument power sources.

6. The SIS hot leg injection valves are powered such that a single electrical failure will not cause a spurious initiation of hot leg injection flow, nor prevent deliberate hot leg injection flow through at least one of the hot leg injection lines. Each valve is powered from a separate power supply and is controlled by a keylocked switch in the control room. The design meets the single failure criterion to prevent premature hot leg injection.

7. Instrument air supplied to all SIS pneumatic valve operators is clean, dry, and oil-free as described in subsection 9.3.1.

8. Provisions are made to remove power to the safety injection tank vent valves (SI-605, -606, -607, -608, -613, -623, -633, and -643) during plant operation. Provisions are made to allow restoration of power to these valves from the control room and a remote shutdown location. The two safety injection tank vent valves on each SIT are powered from separate and independent

emergency power sources. Engineering drawings 01, 02, 03-M-SIP-001, -002 and -003 reflects these design provisions.

In addition the following valves require power lockout:

Safety Injection Tank (SIT) Isolation Valves

Valve No.

J-SIA-UV-634
J-SIA-UV-644
J-SIB-UV-614
J-SIB-UV-624

The SIT isolation valve motor power feeder breakers are locked open before RCS pressure exceeds 430 psia.

Electrical power cannot be restored to the valves from the control room. The safety injection tanks can be depressurized for cold shutdown by venting rather than performing tank isolation in the event the motor centers are not accessible during an emergency shutdown.

Testing is performed by manually opening the breaker and verifying breaker position, with indication provided in the control room.

Valve position indication is provided by indicating lights driven from valve limit switches and by a redundant and independent position indicator.

For the safety injection tank vent valves, power is disconnected from the solenoid valves by a switch in the control room. One switch disconnects power for the train A valves, and one switch disconnects power for the train B valves.

Electrical power can be restored to the valves by the control room switches.

Testing is performed by disconnecting power and verifying proper operation by indication provided in the control room.

One set of valve position indicating lights driven from proximity type limit switches on each solenoid valve is provided in the control room. Due to the small size of the solenoid valve, a second means of direct valve position indication cannot be provided. Indication of valve position can, however, be derived from safety injection tank pressure.

B. Protection from Natural Phenomena

1. Design provisions for maintaining functional capability of safety-related systems during the maximum probable flood or other natural phenomena defined in GDC 2 are discussed in subsection 3.1.2. All safety-related pumps and components are located in Seismic Category I structures. The protection of Seismic Category I structures against natural phenomena is presented in sections 3.3 and 3.4.

C. Protection from Pipe Failure

1. Pipe Break Considerations

Maximum expected leakage from a moderate energy pipe rupture is defined by the methods of subsection 3.6.2 and CESSAR Sections 3.6.1 and 3.6.2. The piping rupture is postulated (as defined in CESSAR Section 3.6.2.1) in the LPSI system dual-purpose piping outside containment which operates during normal as well as emergency plant conditions.

The above-mentioned leakage could be from RWT inventory and will occur when the LPSI system is idle or from the RCS when the LPSI system is operating. Provisions are made for detection, containment, and isolation of such leakage. Reactor coolant leakage from the HPSI, LPSI or CS pumps pipe breaks, considered as moderate energy line breaks, are bounded by the SCS line break postulated in UFSAR Section 5.4.7.3.C.1, dealing with the shutdown cooling system.

2. Provisions are incorporated to assure the required minimum acceptable capability of the emergency core cooling system (ECCS) and containment spray system (CSS) due to a limited leakage passive failure. Each HPSI, LPSI, and containment spray pump and shutdown cooling heat exchanger is located in a separate room (refer to engineering drawing 13-P-OOB-002). The

Containment Spray System components and supportive systems are powered through two independent engineered safety features (ESF) electrical power trains so that in the event of postulated accident conditions, in conjunction with loss of the preferred plant electrical power source and a single failure in the emergency electrical power sources, one containment spray train will be available to perform the system safety functions. Each electrical power train is connected to one containment spray pump and its associated valves and instrumentation. Emergency electrical power source loads are given in Table 8.3-1.

3. Design Requirements for Protection from Pipe Break

The ECCS, both inside and outside containment, is protected from the effects of postulated high and moderate energy pipe ruptures. Appropriate design procedures are employed to ensure that postulated failures do not result in loss of ECCS function. The ECCS design includes the following features:

a. Protection from the consequences of a postulated pipe failure by: (1) separation via physical plant layout, (2) pipe restraints, (3) protective structures, (4) isolation capability, (5) drain check valves or (6) other suitable means (see UFSAR Table 3.6-3).

b. Isolation valves (system and/or containment) used to contain leakage are protected from the adverse effects of a pipe failure which might preclude their operation when required.

These design features protect the redundant ECCS train and other plant equipment from the effects of a pipe break (pressurization, pipe whip, impingement, and flooding). The design basis flood for specific rooms and compartments is based on the line break with the largest spillage per Section 3.6.2.1.

Flood protection for the ECCS pumps is provided by train separation and drainage system design. Each HPSI, LPSI, and CS pump is located in a separate compartment. The compartment walls serve as flood barriers so that flooding within or outside of the ESF pump room of one train will not jeopardize the operation of the pump of the redundant train. Water in the ECCS compartments is routed to the Radioactive Waste Drain System, which includes two ESF drain subsystems, one serving Train A equipment and the other serving Train B equipment. A drain header from each ECCS pump room is routed directly to the appropriate ESF sump and is equipped with a check valve to prevent backflow. These check valves are included in the ISI and IST Programs. The two ESF drain Subsystems are included in the Maintenance Rule, and the two ESF drain subsystems are physically separate from drains serving the non-ESF equipment rooms (reference engineering

drawings 01, 02, 03-M-RDP-002). Thus, the worst case (design basis) flooding of one ESF pump room, will not affect the operation of redundant safety-related equipment that is required to perform protective actions to mitigate the consequences of the postulated break or place the plant in a safe shutdown condition.

The level instrumentation is mounted in each safety injection pump room sump. This provides a high water level alarm in the control room after an accumulation of 3.5 gallons of water in the sump. Each safety injection pump room sump high water level alarm is a 1E annunciation in the control room. This level is sufficient to provide isolation of the leak by appropriate operator action within 30 minutes. This action will consist in part of shutting suitable isolation valves to stop the leak. This action will also include steps to isolate the leaking train. The safety injection leak detection system consists of individual level switches in each train pump room. Individual control room 1E annunciation windows enable identification of the leaking train.

Fuel building exhaust radiation monitors 13-J-SQB-RU-145 and -146 will monitor noble gas releases from the essential filtration units that serve areas subject to leakage from ESF recirculation components and piping. Monitor sensitivities are described in section 11.5 and are adequate to provide early detection of recirculation loop leakage.

The safety injection leak detection system consists of a 1E (safety grade) switch in each pump room for each train of the high-pressure safety injection pump, low-pressure safety injection pump, and containment spray pump.

Each level switch actuates a 1E annunciation in the control room. The train A pump rooms are monitored by channel A instrumentation powered by train A, Class 1E power. The train B pump rooms are monitored by channel B instrumentation powered by train B, Class 1E power. The system complies with IEEE Standard 279-1971 except for single failure requirements. These level switches are not required to be environmentally qualified since flooding of these pump rooms will not occur as a result of an initiating event considered by the PVNGS EQ program.

4. The safety injection system components are located such that any missiles from pipe breaks, pipe whip, and/or any of the associated dynamic effects originating in one train would not affect performance of the other safety-related train, as discussed in sections 3.5 and 3.6.

D. Missiles

The SIS is protected from missiles as discussed in subsection 3.5.2

E. Separation

1. Physical separation is provided and maintained between redundant piping paths and containment

penetrations of the SIS and containment spray system such that the SIS and containment spray system will meet their functional requirement even with the failure of a single active component during the injection mode, or with a single active failure, or a limited leakage passive failure during the recirculation mode.

2. Separation of cabling associated with redundant channels is provided as discussed in subsection 8.3.1.

3. In the routing of Class 1E circuits and in locating equipment served by these Class 1E circuits, consideration is given to their exposure to potential hazards such as postulated ruptures of piping, flammable material, flooding, and nonflame-retardant wiring. Adequate separation or protective measures commensurate with the damage potential of the hazard is provided. In addition, discussion of separation or protective measures against the effects of possible missile generation and pipe whip is provided in sections 3.5 and 3.6, respectively.

4. Single active failures of nonsafety grade systems will not compromise redundancy of the SIS.

F. Independence

1. Each subsystem of the ECCS and CSS is provided with a separate environmental control system such that the system operates within the environmental

design limits (refer to subsection 9.4.2). Each pump room is provided with a separate self-contained essential cooling system (refer to subsection 9.4.2.).

2. Refer to sublisting A.2.

3. Refer to sublisting A.5.

G. Thermal Limitation

Not applicable

H. Monitoring

1. Refer to sublisting C.1.

2. Process instrumentation as described in Table 1.8-1 is available to operators in the control room to assist in assessing post-LOCA conditions.

I. Operational Controls

Following a LOCA in which the CSS is actuated, the operator will be able to secure the CSS when the containment vapor temperature falls within the qualification envelope described in Appendix A of the Equipment Qualification Program Manual. An indirect method of determining containment mixing will be by comparing the temperature displays of the ten sensing elements (TE-37 through TE-42E, as shown in engineering drawings 01, 02, 03-M-HCP-001) distributed about the containment shell. Temperature stratification would be indicated by significant local temperature differentials. Additionally, temperatures

approaching the qualification temperatures of Appendix A of the Equipment Qualification Program Manual will independently direct the operator to manually reinitiate CSS for a short period.

For MSLB only the temperature concerns of containment mixing are applicable. (Since MSLB will not generate hydrogen, hydrogen pocketing is not a concern.)

The PVNGS procedures will provide sufficient information so that the operator can take the proper action to restore the plant to a safe condition. An SIAS will not be reset unless the operator has determined that conditions warrant this action.

Additionally, procedures will be provided to cover operation of the diesel generators. These procedures will ensure that the diesels are correctly loaded, including the event of loss of offsite power following an SIAS reset.

Plant procedures will ensure timely operator action to isolate the RWT after a RAS to prevent ingress of air in the ESF pump suction piping during switchover to recirculation.

Plant procedures will also require an operator to check at least once per shift ECCS performance during long-term recirculation cooling using the ECCS. These procedures will provide specific guidance on recognition and mitigation of ECCS performance degradation during recirculation operation. They will

also include guidance to alert the operator to the symptoms of inadequate core cooling.

J. Inspection and Testing

1. The inspection and testing are described in the Technical Specifications.

2. Prior to initial plant startup, SIS flow tests will be performed in accordance with the C-E position on Regulatory Guide 1.79. In addition, full scale hydraulic model testing will be performed as described in subsection 6.2.2.

   A preoperational test was performed at PVNGS to demonstrate that the ECCS pump runout flows are lower than those assumed in the NPSH calculations.

K. Chemistry/Sampling

1. Sample points are provided at the following locations:

   - Shutdown cooling suction lines
   - Minimum flow bypass lines
   - Recirculation line back to refueling water tank
   - Each shutdown cooling heat exchanger outlet
   - Safety injection tanks
   - Refueling water tank

   Refer to subsection 9.3.2.

2. The sample lines in contact with the reactor coolant are austenitic stainless steel or

equivalent material compatible with the fluid chemistry.

L. Materials

1. Safety injection piping and fittings are Seismic Category I (refer to section 3.2).

2. Design and fabrication of the safety injection piping and fittings conform to ASME Boiler and Pressure Vessel Code, Section III, Class 1 and 2 (refer to section 3.2).

3. Piping and components in contact with the system fluid are of austenitic stainless steel (type 316, type 304, or C-E-approved alternate) compatible with the chemistry of the injection and recirculation fluid. Valve packings, gaskets, and valve diaphragm materials are also compatible with the chemistry of the water and the radioactive dose at that location.

4. Using the guidance of Regulatory Guides 1.44 and 1.31, as discussed in section 1.8, care is taken in preventing sensitization and in controlling the delta ferrite content of:

   a. Welds that join any system fabricated of austenitic stainless steel in the ECCS

   b. Field welds on the ECCS (refer to subsection 5.2.3)

5. Cleaning and contamination protection procedures are discussed in subsection 6.1.1. The

insulation used on the austenitic stainless steel is discussed in subsection 5.2.3. Conformance to Regulatory Guides 1.36 and 1.37 is discussed in section 1.8.

6. The materials used for the containment and its internal structures are compatible with both the normal operating environment and the most severe thermal, chemical, and radiation environment expected during post-accident conditions. Appendix A of the Equipment Qualification Program Manual lists the environmental conditions. Containment materials were selected to be compatible with the spray water chemistry and existing recirculating water chemistry to ensure that containment materials will withstand this exposure without causing deleterious or undesirable reactions, or significantly altering the water chemistry.

7. The containment spray system is designed and constructed in conformance with ASME III, Class 2, requirements. The material used in this system is austenitic stainless steel type 316 or 304 or other C-E-approved compatible material.

M. System/Component Arrangement

It is noted that some of the Interface Requirements described in this section were provided for original piping and component design/selection to ensure that the as-built system would support required design

functions. For the operating plant, the adequacy of the design to support required design functions is maintained and demonstrated by current design basis calculations and surveillance tests that evaluate the as-built systems, and the values specified by the original interface requirements are no longer relevant. The specific interface requirement in this section for which this applies and that provides historical information is: M.1.

1. The piping arrangement is such that the head loss requirements presented in Table 6.3.1.3-2 were met for the initial design. For the as-built systems, the total system losses provide the required ECCS flow to support design functions.

2. The piping for each safeguards train is designed such that the top of the piping junction of the pipe runs to the refueling water tank and the containment recirculation sump is located at least 16 feet below the top of the recirculation containment sump, which is 4 feet below the minimum water level in the containment during recirculation. This provides adequate margin for the containment minimum pressure of –3.5 psig, as described in subsection 6.2.1, to preclude the water level in the RWT suction line from dropping below the piping junction. To preclude the possibility of drawing air from the RWT into the safeguards pump suction during recirculation,

timely operator action is required to isolate the RWT after the RAS has occurred.

Frictional losses in the safeguard pump suction piping between the containment sump and the junction with the RWT are less than 5 feet.

3. The location and elevation of the HPSI pumps are indicated in engineering drawing 13-P-OOB-002. The HPSI pumps are located in the auxiliary building as close as practical to the containment.

   a. The elevation of the HPSI pumps is such that the available NPSH is at least 25 feet during the recirculation mode when the pumps take suction from the containment sump. In determining this elevation, no credit was taken for subcooled water in the containment sump following a LOCA.

   b. The available NPSH was calculated at the pump suction inlet that is 4.5 feet above its foundation elevation.

   c. The available NPSH was calculated taking into consideration the concurrent operation of the low-pressure safety injection and containment spray pumps. The available NPSH of each pump is summarized below to demonstrate that an adequate margin exists:

Pump	Required NPSH	Available NPSH	Margin
HPSI	25 feet	28.8 feet	3.8 feet
LPSI	20 feet	26.1 feet	6.1 feet
CS	22 feet	24.8 feet	2.8 feet

These margins are calculated for concurrent operation of HPSI and LPSI pumps at their respective recirculation mode flow rates (Table 6.3.2-1) and the CS pump at maximum flow (Section 6.2.2.2), which is conservative for the NPSH calculation. The required NPSH values are revised from original CESSAR Interface requirements to reflect the required NPSH at these flow rates.

d. Credit was not taken for water trapped above the containment floor.

4. The requirements on location and elevation applied to the HPSI are applied to the location and elevation of the LPSI pumps except that the pump's suction is located at the impeller eye, which is at the lower surface of the pump support mounting feet. This reference point was changed by CE from the originally specified reference point of 14 inches below the pump supports. Each LPSI pump is located so that the NPSH requirements listed in table 6.3.2-1 are satisfied. For the injection mode, the design calculation assumes:

a. Concurrent HPSI, LPSI, and containment spray pump operation.

b. A refueling water tank temperature of 120F.

5. Safety injection system components are properly supported such that pipe stresses and support reactions are within the allowable limits as defined in subsection 3.9.3.

6. The PVNGS design of the SIS piping and any connecting system piping is such that the loadings imposed on the SIS/RCS nozzles or SIS nozzles are less than the C-E-furnished nozzle design loadings for the C-E-supplied SIS components.

7. In the event of a limited leakage passive failure in one SIS train during recirculation, personnel access to the intact train will not be precluded due to flooding.

8. Two safety injection check valves in each of the six safety injection lines are located as follows: one as close as practical to the RCS cold leg piping and the other as close as practical to the containment penetration. Additionally, a third check valve is located in each of the four cold leg injection lines upstream of the safety injection tank branch connection in order to minimize high energy piping runs.

a. Space is provided to permit valve accessibility and maintenance.

b. The total unborated water volume for all four cold leg injection SI lines from the RCS to the first SI valve is less than 120 cubic feet. Specifically, the total (four leg) calculated volume is less than 33 cubic feet and the safety analysis described in Section 15.1.5.3.2.2 uses a total sweepout volume of 60.6 cubic feet. The total unborated water volume in each of the two long term recirculation lines between the RCS and the first SI valve is less than 16 cubic feet for A train for all three units and less than 44 cubic feet for B train for all three units. Refer to UFSAR Section 1.9.2.4.7. The total volume of safety injection water that must be swept out of the piping before borated water reaches the core is 67 cubic feet.

c. Each check valve leakage line is connected to the safety injection line immediately upstream of the safety injection check valve.

9. The safety injection tanks are located inside the containment and outside the biological shield. Each safety injection tank is located as close as practical to the reactor coolant cold leg to which it injects.

a. The piping run from each tank to the reactor coolant cold leg is as direct as possible with a minimum of bends and elbows.

b. Long-radius elbows or pipe bends are used.

c. The piping run "K" factor or resistance is between 2.0 and 7.0, including entrance and exit losses and valve resistance, referenced to an area of 0.6827 square foot. The ECCS small and large break LOCAs were evaluated to expand the K-factor range from the original range of 4.5 to 5. It was determined that the original analysis remains valid and compliance with the ECCS performance criteria of 10CFR50.46 is assured with a range of K-factors from 2.0 to 7.0 with a reference area of 0.6827 square feet.[1]

d. The bottom of the safety injection tank is located above the centerline of the reactor coolant cold leg piping.

10. See Response to Question 6A.35 (NRC Question 440.14) The six manual valves identified during inspection of the CESSAR-F design, which if improperly aligned, could prevent flow from the associated train are: SI-435 and SI-447 located downstream of the LPSI pumps; SI-402 and SI-470, located upstream of the HPSI pumps; and valves SI-476 and SI-478, located downstream of the HPSI pumps. These valves are

locked open and administrative procedures are used to assure their proper position (the locked position designation has been removed from plant drawings.)

11. Physical identification of safety-related equipment is provided as discussed in subsection 7.1.1 and section 8.3.

12. Refer to sublisting E.3 above.

13. All SIS ASME Boiler and Pressure Vessel Code, Section III, components are arranged to provide adequate clearances to permit inservice inspection.

14. Protection is provided from internally generated flooding that could prevent performance of safety-related functions. Refer also to section 3.6 and subsection 9.3.3.

N. Radiological Waste

1. Safety injection system leakage to the safeguards room will normally drain to the room sump, from where it drains into the safety-related ESF pump rooms drain sump. Provisions are provided to accept the maximum leakage rates listed below:

    a. HPSI and LPSI pump seals: 100 cc/h

       The pump seal leakage is piped to the radioactive drain system.

b. Valves

Backseat leakage:	10 cc/h/inch seat diameter
Across the valve seat:	10 cc/h/inch of nominal valve size

All leakages are treated as radioactive waste with a low dissolved solids and organic content.

O. Overpressure Protection

Not applicable

P. Related Services

1. A supply of nitrogen meets the requirements of subsection 6.3.1.3.P.1.

2. The containment sump design meets the guidance of Regulatory Guide 1.82 requirements as discussed in Section 1.8 and paragraph 6.2.2.2.1.

   Baffles and intake screens are installed as required to prevent the introduction into the recirculation piping of particles which are over 0.09 inch in diameter.

3. The maximum particle size in water exiting from the refueling water tank will be 0.09 inch in diameter.

4. The fire protection system meets the interface requirements listed in subsection 6.3.1.3.P.4. The detailed description of the fire protection

system provided to protect the SIS components is discussed in subsection 9.5.1.

5. The SIS containment penetrations will not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of equipment or piping inside or outside the containment. This is accomplished by physical separation and the use of shielding barriers.

6. Not applicable

Q. Environmental

1. The SIS is provided with an environmental control system such that the safety-related equipment operates within the environmental design limits specified in Appendix A of the Equipment Qualification Program Manual.

6.3.2 SYSTEM DESIGN

6.3.2.1 System Schematic

The Safety Injection System Piping and Instrumentation Diagram is shown in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003. The major components of this system are high pressure safety injection pumps, low-pressure safety injection pumps, safety injection tanks, high-pressure injection valves, and low-pressure injection valves. The major components are described in the following section. In addition, the system uses the refueling water tank of the Chemical and Volume Control System, Section 9.3.4. PVNGS has an additional

pressure boundary isolation check valve (SI-540, -541, -542, -543) in each of the HPSI/LPSI combined headers to the RCS cold legs.

Connections for the refueling water level indication system are shown in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003.

Engineering drawings 01, 02, 03-M-SIP-001, -002 and –003 shows PVNGS tag numbers and vent/drain valves.

6.3.2.2 Component Description

A summary of design parameters and codes for major components are given in Table 6.3.2-2.

6.3.2.2.1 Safety Injection Tanks

The four safety injection tanks discharge their contents to the Reactor Coolant System following depressurization as a result of a Loss-of-Coolant Accident. Each tank is piped into a cold leg of the Reactor Coolant System (RCS) via a safety injection nozzle located on the RCS piping near the reactor vessel inlet. During normal plant operation each safety injection tank is isolated from the Reactor Coolant System by two check valves in series. The safety injection tanks automatically discharge into the RCS if RCS pressure decreases below safety injection tank pressure during reactor operation.

The motor-operated isolation valves on the safety injection tank discharge are interlocked with the pressurizer pressure measurements channels, to automatically open these valves, when RCS pressure is above the setpoint value shown in Table 7.6-1,

and to prevent inadvertent closure prior to or during an accident. After the valve is opened, it will be locked open in the Control Room, and power to the motor will be removed (See Section 7.6).

During normal power operation, the valve, although locked open, receives a confirmatory SIAS "Open" signal, if the Reactor Coolant System pressure should inadvertently drop below 1837 psia. During startup and shutdown operations, a variable setpoint is used as described in Section 7.2.1.1.1.6. During plant cooldowns, safety injection tank pressure will be lowered to 300 psig by the operator when Reactor Coolant System pressure (nominal) reaches 750 psia. An interlock with pressurizer pressure will prevent the safety injection tank valves from being closed until RCS pressure drops below the setpoint value shown in Table 7.6-1; and if the valves are closed, a SIAS will cause them to open. Inadvertent repressurization of the safety injection tanks during this mode of operation due to a leaky nitrogen supply valve or by accidental tripping of a nitrogen supply valve switch is prevented by having two fail-closed valves in series with separate hand switches on each safety injection tank nitrogen supply line. The air supply actuating the nitrogen supply valves is controlled by solenoid valves. The two nitrogen supply valve solenoids on each safety injection tank are connected to separate electrical buses via redundant and physically separated electrical trains. This is to ensure that a fault in one of the trains will not cause a spurious opening of both nitrogen supply valves.

If Reactor Coolant pressure is above the setpoint value shown in Table 7.6-1, an interlock with pressurizer pressure will automatically open the safety injection tank isolation valves. The operator will repressurize the safety injection tanks when pressurizer pressure exceeds SIT operating pressure, but before pressurizer pressure reaches the SIT-RCS 1E differential pressure alarm condition described in Table 7.6-1.

The tank gas/water fractions, gas pressure, and outlet pipe size are selected to allow three of the four tanks to recover the core before significant clad melting or zirconium-water reaction can occur following a LOCA. The volume of water in the tanks is conservatively calculated assuming that all water injection prior to the end of the RCS blowdown is lost.

The tanks contain borated water and are pressurized with nitrogen as specified in the Technical Specifications.

Redundant level and pressure instrumentation (described in more detail in Section 6.3.5.3 and Table 7.5-2) is provided to monitor the condition of the tanks. Sufficient visual and audible indication has been made available to the operator such that maintaining the safety injection tanks within the required technical specifications during various modes of plant operation is readily accomplished from the control room. Provisions have been made for sampling, filling, draining, and correcting boron concentration. Atmospheric vent valves are provided for tank venting. They are locked closed and the power to each valve is removed during normal operation. This prevents inadvertent tank venting during normal plant operation. Safety Injection Tank Data is summarized in Table 6.3.2-2.

6.3.2.2.2 Low-Pressure Safety Injection Pumps

The Low-Pressure Safety Injection (LPSI) pumps serve two functions. One of these is to inject large quantities of borated water into the Reactor Coolant System in the event of a large pipe rupture. Sufficient flow is delivered under these conditions to satisfy functional requirements described in Section 6.3.1.1. The other function of the low-pressure safety injection pumps is to provide shutdown cooling flow through the reactor core and shutdown cooling heat exchangers for normal plant shutdown cooling operation or as required for long term core cooling. A typical pump characteristic curve is presented in Figure 6.3.2-2.

During normal operation the low-pressure safety injection pumps are isolated from the RCS by motor-operated valves. During safety injection the LPSI pumps deliver water from the refueling water tank to the RCS via the RCS safety injection nozzles whenever system pressure is below pump shutoff head.

Sizing of the low-pressure safety injection pump is governed by the shutdown cooling function. The flow available with a single low pressure safety injection pump is sufficient to maintain a core ΔT at an acceptable level at the initiation of shutdown cooling (3.5 hours after shutdown).

The design temperature for the low-pressure safety injection pumps is based upon the temperature of the reactor coolant at the initiation of shutdown cooling, about 350°F nominal, plus a design tolerance, resulting in a temperature of 400°F. The design pressure for the low pressure pumps is based upon the sum of the maximum pump suction pressure, which occurs at the

initiation of shutdown cooling, and the pump shutoff head. (See Section 5.4.7 also).

The low-pressure safety injection pumps are vertical, single stage centrifugal units equipped with mechanical face seals backed up by a bushing, with a leakoff to collect the leakage past the seals. The seals are designed for operation with a pumped fluid temperature of 400°F. The pump motors are specified to have the capability of starting and accelerating the driven equipment, under load, to design point running speed within 5 seconds, based upon an initial voltage of 75% of rated voltage at the motor terminals, and increasing linearly with time to 90% voltage in the first 2 seconds, and increasing to 100% voltage in the next 2 seconds.

The pumps are provided with drain and flushing connections to permit reduction of radiation levels before maintenance. The pressure containing parts are fabricated from stainless steel; the internals are selected for compatibility with boric acid solutions. The pumps are provided with minimum flow protection to prevent damage when starting against a closed system. The low-pressure pump data is summarized in Table 6.3.2-2. The shutdown cooling function of the pump is described in Section 5.4.7.

6.3.2.2.3 High-Pressure Safety Injection Pumps

The primary function of a High-Pressure Safety Injection (HPSI) pump is to inject borated water into the RCS if a break occurs in the RCS boundary. For small breaks, the RCS pressure remains high for a long period of time following the accident,

and the high-pressure safety injection pumps ensure that the injected flow is sufficient to meet the criteria given in Section 6.3.1. The high-pressure safety injection pumps are also used during the recirculation mode to maintain a borated water cover over the core for extended periods of time following a Loss Of Coolant Accident. For long term core cooling, the HPSI pumps are manually realigned for simultaneous hot and cold leg injection. This insures flushing and ultimate subcooling of the core independent of break location. For small breaks, the HPSI pumps continue injecting into the RCS to provide makeup for spillage out the break while a normal cooldown is implemented.

During normal operation the high pressure safety injection pumps are isolated from the RCS by motor operated valves. During safety injection the HPSI pumps deliver water from the refueling water storage tank to the RCS via the cold leg safety injection nozzles whenever RCS pressure falls below pump shutoff head. During the recirculation mode of operation, the pumps take suction from the containment sump.

The high-pressure safety injection pumps are sized such that one HPSI pump (after consideration of spillage directly out the break) will supply adequate water to the core to match decay heat boiloff rates soon enough to minimize core uncovery and allow small break LOCA’s to meet the performance criteria of 10CFR50.46. A typical pump characteristic curve is shown in Figure 6.3.2-3. The effectiveness of the pump during a steam line break is also analyzed to assure that the pumps are adequately sized. Mechanical shaft seals are used and are provided with leakoffs which collect any leakage past the

seals. The seals are designed for operation with a pumped fluid temperature of 350°F.

The pump motors are specified to have the capability of starting and accelerating the driven equipment, under load, to design point running speed within 5 seconds based on an initial voltage of 75% of the rated voltage at the motor terminals, increasing linearly with time to 90% voltage in the first 2 seconds, and increasing to 100% voltage in the next 2 seconds.

The pumps are provided with drain and flushing connections to permit reduction of radiation before maintenance. The pressure containing parts of the pump are stainless steel with internals selected for compatibility with boric acid solutions. The materials selected are analyzed to ensure that differential expansion during design transients can be accommodated.

The pumps are provided with minimum flow protection to prevent damage resulting from operation against a close discharge. Also, individual HPSI pump ultrasonic flow meters provide low flow alarming.

The design temperature is based on the saturation temperature of the reactor coolant at the containment design pressure plus a design tolerance. The design pressure for the high pressure pumps is based on the shutoff head plus maximum containment pressure plus a design tolerance. The High-Pressure Pump Data is summarized in Table 6.3.2-2.

6.3.2.2.4 Piping

Piping is specified to deliver borated safety injection water from the safety injection tanks and from the refueling water tank via the safety injection pumps, to the safety injection nozzles in the RCS. The major piping sections are (refer to engineering drawings 01, 02, 03-M-SIP-001, -002 and -003):

a. From each safety injection tank to its respective RCS cold leg safety injection nozzle;

b. Redundant piping from the refueling water tank and containment sump to the suction of the high- and low-pressure safety injection pumps;

c. Redundant piping from the high-pressure safety injection pumps discharge to redundant high-pressure injection headers each of which serves the four safety injection nozzles on the cold legs and one nozzle on each shutdown cooling suction line;

d. Redundant piping from the low-pressure safety injection pump discharge to each low-pressure injection header which serves two of the four safety injection nozzles.

The Safety Injection System piping is fabricated of austenitic stainless steel and is designed to ASME Code Section III. Flexibility and seismic loading analyses are performed by each Applicant to confirm the structural adequacy of the system piping. In addition, the flexibility and seismic loading analyses of piping are presented in section 3.9.

6.3.2.2.5 Valves

The location, type and size, type of operator, position (during the normal operating mode of the plant) and failure position of the SIS valves, is shown in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003. Pressure design rating and code design classification are also shown.

a. Relief Valves

Protection against overpressure of components within the Safety Injection System is provided by conservative design of the system piping, appropriate valving between high-pressure sources and low-pressure piping, and by relief valves. All lines within the high- and low-pressure systems from the RCS up to and including the safety injection valves are designed for full Reactor Coolant System pressure. In addition, the high-pressure header to which the charging pumps discharge is designed for full Reactor Coolant System pressure up to and including the header check valve. Relief valves are provided as required by applicable codes. All relief valves are of the totally enclosed, pressure tight-type with suitable provisions for gagging.

A tabulation of Safety Injection System relief valves is provided below.

1. SI-211, 221, 231, and 241, Safety Injection Tank relief valves.

The relief valves on the safety injection tanks are sized to protect the tanks against the maximum fill rate of liquid or gas into the safety injection tanks. They discharge into the

containment. The set pressure is 700 psig with a capacity of 6000 SCFM of gas or 230 gpm of liquid.

2. SI-473, Check Valve Leakage Relief Valve.

A relief valve is provided on the safety injection test and leakage return line.

This relief valve is sized to protect against overpressure of the line when relieving injection line pressure following check valve testing or during normal operation. It discharges into the reactor drain tank. The set pressure is 2050 psig with a capacity of 35 gpm.

3. SI-474 and SI-407, Safety Injection Tank Fill Line Relief Valves.

Relief valves are located on the Safety Injection Tank fill line to protect against overpressure due to a temperature increase. SI-474 discharges to the Reactor Drain Tank and SI-407 discharges to the Equipment Drain Tank. They are set at 2050 psig with a capacity of 10 gpm.

4. SI-439 and SI-449 Low Pressure Safety Injection Relief Valves.

These valves protect each isolated low-pressure safety injection line against the pressure developed due to a temperature increase. They discharge into the equipment drain tank. The set pressure is 650 psig with a capacity of 10 gpm per valve.

5. SI-409 and SI-468 High Pressure Safety Injection Relief Valves.

These valves are sized to protect the isolated high pressure headers against the pressure due to a temperature increase. They discharge into the equipment drain tank. SI-409 is set at 2050 psig and SI-468 is set at 2485 psig. Each has a capacity of 10 gpm.

6. SI-166 and SI-417, High Pressure Safety Injection Relief Valves.

The high pressure safety injection headers to which the charging pumps discharge are protected from the charging pumps discharge pressure by these valves. They discharge into the equipment drain tank. The set pressure is 2485 psig with a capacity of 145 gpm each.

7. SI-288, Low Pressure Safety Injection Relief Valve.

This valve is sized to protect the isolated low pressure safety injection test line from pressure due to a temperature increase. It discharges into the equipment drain tank. The set pressure is 650 psig with a capacity of 10 gpm.

8. SI-140 and SI-151, Containment Sump Suction Relief Valves.

These valves are sized to protect a normally isolated section of piping from pressure due to a temperature increase. They discharge to the non-ESF sump. The set pressure is 100 psig with a capacity of 10 gpm.

9. SI-141 and SI-150, Pool Cooling and Purification to Shutdown Cooling System Cross Connect Relief Valves.

These valves are sized to protect a normally isolated section of pipe in the cross-connect line against pressure due to temperature increase. They discharge to the Equipment Drain Tank. The set pressure is 485 psig with a capacity of 10 gpm.

10. SI-192 and SI-162, Pool Cooling and Purification to Shutdown Cooling System Cross Connect Relief Valves.

These valves are sized to protect a normally isolated section of pipe in the cross-connect line against pressure due to temperature increase. They discharge to the Equipment Drain Tank. The set pressure is 650 psig with a capacity of 10 gpm.

11. SI-285 and SI-286, Safety Injection Relief Valves.

These valves are sized to protect the Safety Injection pump bypass flow lines against pressure due to a temperature increase. They discharge to the Equipment Drain Tank. The set pressure is 2050 psig with a capacity of 10 gpm.

12. SI-475 and SI-476, Alternate RC Makeup Connection Relief Valves

For Units where DMWO 4304156 has been implemented, these valves are sized to protect a normally isolated section of pipe in the alternate RC makeup connection piping against pressure due to temperature increase. They discharge to a local floor drain in the mechanical penetration rooms. The set pressure is 2050 psig with capacity of 10 gpm.

b. Actuator-Operated Throttling and Stop Valves

The position of each valve on loss of actuating signal or power supply (failure position) is selected to ensure safe operation. System redundancy is considered when defining the failure position of any given valve. Valve position indication is provided at the main control panel as indicated in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003. A locking-type control switch on the main control panel and/or manual override handwheel is provided where necessary for efficient and safe plant operation. All actuator-operated valves were supplied with a double packing with a lantern ring leakoff connection. During original plant design, an evaluation determined that leakoffs piped to the equipment drain tank present a greater ALARA concern than capping the valve leakoff. The cap has been designed as part of the SIS pressure boundary.

The high pressure and low pressure safety injection valves are trimmed during pre-operational flow tests to prevent the safety injection pumps from exceeding runout flow and for flow balancing during emergency operation. Following the determination of the required valve stem position for proper functioning of the system, each of the safety injection valves will be fitted with stops or limit switches to ensure that is will open to the position necessary to fulfill its safety function.

HPSI hotleg injection valves SI-321,-331 are manually throttled for proper flow balance during long term coding initiation.

Following the determination of the required valve stem position for proper functioning of the system, each of the safety

injection valves will be fitted with stops or limit switches to ensure that it will open to the position necessary to fulfill its safety function. For PVNGS, HPSI hotleg injection valves SI-321 and SI-331 are manually positioned for proper flow balance. The limit switches are positioned such that they will allow the valves to achieve their required position but do not determine that final position.

c. Check Valves

All check valves are the totally enclosed type. Check valves in pump suction lines are of a low pressure drop type with flow resistance characteristics equal to or less than a swing check valve of the same size as the connecting pipe.

6.3.2.2.6 Containment Sump

For interfaces see UFSAR Section 6.3.1.3. The design of the containment recirculation sump is described in subsection 6.2.2.

6.3.2.3 <u>Applicable Codes and Classification</u>

Refer to Section 6.3.2.2 and Table 6.3.2-2

6.3.2.4 <u>Material Specification and Compatibility</u>

The materials used in the construction of the Safety Injection System components are presented along with the components parameters in Table 6.3.2-2. Basically, all materials in contact with reactor coolant are austenitic stainless steel with stellite or equivalent material being used for valve seats. The materials of construction used in both the active

and passive components have been evaluated and in each case it has been concluded that the materials selected are both compatible with the most severe environmental condition they will be exposed to and in accordance with all code requirements.

6.3.2.5 System Reliability

Refer to section 8.3 for a discussion of power sources.

6.3.2.5.1 Safety Injection Tanks

The safety injection tanks containing borated water pressurized by a nitrogen cover constitute a passive injection system because no operator action or electrical signal is required for operation. Each tank is connected to its associated reactor coolant cold leg by a separate line containing two check valves which isolate the tank from the Reactor Coolant System during normal operation. When the reactor coolant pressure falls below the tank pressure, the check valves open discharging the contents of the tank into the Reactor Coolant System.

The evaluation in Section 6.3.3 demonstrates the adequacy of the quantity of coolant supplied. In order to prevent accidental overpressurization of the Shutdown Cooling System, safety injection tank pressure is controlled by facility procedures when reactor coolant pressure is being reduced as discussed in section 6.3.2.2.1. An interlock with pressurizer pressure prevents these valves from being closed if pressurizer pressure is above the setpoint value shown in Table 7.6-1. In the unlikely event of a LOCA during shutdown cooling, an SIAS will automatically open the SI tank isolation valves.

Inadvertent repressurization of the safety injection tanks during shutdown cooling due to a leaky nitrogen supply valve or the accidental tripping of a valve switch is prevented by having two such fail-closed supply valves in a series with separate hand switches. The air supply actuating the nitrogen supply valves is controlled by solenoid valves. The two nitrogen supply valve solenoids on each safety injection tank are connected to separate electrical buses via redundant and physically separated electrical trains. This is to ensure that a fault in one of the trains will not cause a spurious opening of both nitrogen supply valves.

The motor-operated isolation valves on the safety injection tank discharge are interlocked with the pressurizer pressure, to automatically open the valves when RCS pressure is above the setpoint value shown in Table 7.6-1. The operator will repressurize the safety injection tanks when pressurizer pressure exceeds SIT operating pressure, but before pressurizer pressure reaches the SIT-RCS 1E differential pressure alarm condition described in Table 7.6-1. Further details of valve control are provided in Section 7.6.

The atmospheric vents on the safety injection tank are locked closed, fail closed and power to their solenoid valve is interrupted during operation with the RCS pressure greater than 700 psig. This ensures that the tank will not be vented during RCS power operation.

6.3.2.5.2 High Pressure and Low Pressure Safety Injection Subsystems

Two redundant high pressure safety injection subsystem trains are provided. One pump and the associated injection valves operate from one emergency power supply, the other pump and injection valves from a second independent source of emergency power. This provides the automatic operation of one complete, full capacity subsystem in the unlikely event of concurrent loss of offsite power and the failure of an active component, including a standby generator.

Two redundant low pressure safety injection subsystems trains are provided. One pump and the associated valves operate from one load group, the other pump and injection valves from the other load group. This provides automatic operation of one complete, full capacity subsystem in the unlikely event of a simultaneous loss of both offsite (preferred) power supplies and the failure of an active component, including an emergency diesel generator.

All valves in the injection paths not receiving a SIAS signal are maintained locked in position by administrative controls.

Prevention of flow blockage in small diameter pipes, including the above piping, is accomplished by control of particle size and specific weight in the injection water through containment sump and RWT exit design.

6.3.2.5.3 Power Source

Independent electrical buses supply power to the Safety Injection System equipment. Each bus may receive power from:

a. Offsite (preferred) power supply

b. Diesel generator (standby) power supply

The safeguards initiation sensors, electrical controls, and electrical indication equipment normally receive power from four 120-volt ac buses. Four 125-volt station batteries with inverters are provided as a backup upon loss of all other sources of power.

System reliability is achieved with the following:

a. Two electrical buses, with each bus supplying power to a 100% capacity low-pressure pump, a 100% capacity high-pressure pump, associated valves and associated support systems. (Each support system contains two full capacity subsystems, one connected to each bus and one subsystem servicing each independent injection train).

b. Two sources of power, normal and standby to both buses, with automatic backup from the emergency generators.

c. Two emergency generators, each capable of supplying power for the minimum safeguards loads.

d. The system is designed such that a single electrical failure can neither spuriously initiate unnecessary injection flow, not prevent initiation of required injection flow.

A detailed description of the power sources is given in Section 8.3.

6.3.2.5.4 Capacity to Maintain Cooling Following a Single Failure.

The Safety Injection System is designed to meet its functional requirements even with the failure of a single active component during the injection mode of operation or with the single active or limited leakage passive failure of a component during the recirculation mode of operation. By providing proper redundancy of equipment, even with the single failure noted above, the minimum required safety injection equipment is always available.

A failure modes and effects analysis demonstrating this is given in table 6.3.2-3. The analysis is based on the following assumptions:

A. One Active Failure is assumed to occur in the system.

B. Relief and check valve failures are not considered credible failures.

C. Failure to respond to an external signal is considered an active failure.

Minimum operability requirements for components of the ECCS are as delineated in PVNGS Technical Specifications, Section 3.5. Consistent with these operability requirements and system failure modes, the minimum ECCS equipment that will operate during postulated accidents is as discussed in Section 6.3.3. This complement of equipment is required to mitigate the consequences of a LOCA initiated when the reactor is anywhere from hot shutdown to full power operation, and this complement will result in conservative results for other incidents where ECCS is required.

The following design features are provided in the system in order to meet the single failure criterion.

a. Redundant high and low pressure safety injection pumps.

b. Redundant piping and valving between refueling water tank and safety injection pump suction.

c. Redundant piping between containment sump and safety injection pump suction.

d. Redundant high-pressure and low-pressure safety injection headers.

e. Four injection discharge points into the Reactor Coolant System cold legs and redundant injection discharge points into the RCS hot legs.

f. Separation of the redundant subsystems of the ECCS. No limited leakage passive failure, as defined in Section 3.1.31, or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, loss of NPSH, or loss of recirculation water inventory) during them recirculation mode precludes the availability of minimum acceptable recirculation capability (minimum acceptable capability is defined as that which is provided by the operation of one subsystem).

g. Those portions of the Safety Injection System required for safe plant shutdown and cooldown are required to be protected from the effects of high and moderate energy pipe ruptures as described in Section 3.6.5.1.

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
	When pressurizer pressure drops below 1750 psia or containment pressure rise above 5 psig during plant operation a Safety Injection Actuation Signal (SIAS) will be generated and this SIS automatically goes into operation. The following equipment are actuated: (Item 1 to 16).						
1	LPSI Pump to Shutdown Cooling Valve Isolation Valve SI656, SI690, SI654, SI655, SI691, SI653, SI652, SI651	a) Fails closed	Mech. binding, corrosion,	None	Periodic testing; Valve position indicator	None required	
		b) Fails open	Mech. binding, elect. malf.	None	Same as 1 (a)	Series redundant valve	Valve is normally closed
2	Safeguard Pump Test Line Isolation Valve SI460, SI464	a) Fails closed	Mech. binding, corrosion	None	Periodic testing	None required	
		b) Fails open	Mech. binding,	None	Periodic testing	Series redundant valve	Valve is normally closed
3	HPSI Pump 1, 2	a) Fails to start on SIAS	Elect. malf., bearing failure	Reduce flow to high pressure header	Low pressure indication P308 or P309; Periodic testing	Redundant HPSI pump	
4	LPSI Pump 1, 2	a) Fails to start on SIAS	Elect. malf., bearing failure	Reduce flow to low pressure header	Low pressure indication P306 or P307; Periodic testing	Redundant LPSI pump	
5	HP Header Isolation Valve SI616, SI617, SI626, SI627, SI636, SI637, SI646, SI647	a) Fails to open on SIAS	Elect. malf., mech. binding	Decrease in ability to inject high pressure water in RCS	Period testing	Parallel redundant cold leg injection lines

9	SI Cold Leg Check Valve Test Isolation Valve SI618, SI628, SI638	a) Fails to close on SIAS	Elect. malf., seat failure, contamination	None	Periodic testing; valve position indicator	Redundant stop valve in series SI682 prevent SI cold leg being drained	Valve is designed to fail closed and is normally closed
	SI648	b) Fails closed	Mech. binding, air line separates from operator	Cannot perform test on the cold leg check valve	Same as 9(a)	None required	Plant must be shut down and valve repaired
		c) Fails open	Seat failure, contamination	None series stop valves prevent cold leg being drained	Same as 9(a)	Same as 9(a)	Valve is normally closed and failed closed
10	Hot Leg Check Valve Test Isolation Valve SI322, SI332	a) Fails to close on SIAS	Elect. malf., seat failure, contamination	None	Periodic testing valve position indicator	Redundant stop valve in series SI682 prevent SI Hot leg being drained	Valve is designed to fail closed
		b) Fails closed	Mech. binding, air line separates from operator	Cannot perform test on the hot leg injection line check valve	Same as 10(a)	Repair	
		c) Fails open	Seat failure, contamination	None	Same as 10(a)	Redundant stop valve in series SI6852 prevent SI Hot leg being drained	Valve is normally closed and failed closed
11	SI Tank Drain & Fill Line to FWT Isolation Valve SI682, SI463	a) Fails to close on SIAS	Elect. malf seat failure, contamination	None	Periodic testing Valve Position indicator	Redundant stop valve in series	Valve is normally to fail closed
		b) Fails closed	Mech. binding, or air line separate from operator	Cannot adjust the SI tank water level when required	Same as 11(a) SI tank level indicator	None required	
		c) Fails open	Seat failure, contamination	None	Periodic testing; valve position indicator; low SI tank level alarm & indicator	Series isolation valves	Valve designed to fail closed

Table 6.3.2-3 (Sheet 4 of 10)

SAFETY INJECTION SYSTEM FMEA CESSAR Table 6.3.2-2

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
12	LP Pump Min. Flow Line Isolation Valve SI669, Si668	a) Fails closed	Elec. malf., mech. binding	Possible damage to one LPSI pump	None, unless pump overheats and fails; valve position indicator; periodic testing	Redundant pump	Valve is normally locked open
13	Min. Flow Line to RWT Isolation Valve SI660, SI659	a) Fails closed	Elect. malf., mech. binding	Possible damage to associated pump	Same as 12(a)	Redundant train	Valve is normally locked open
14	HP Pump Min. Flow Line Isolation Valve SI666, SI667	a) Fails closed	Elect. malf., mech binding	Possible damage to one HPSI pump	Same as 12(a)	Redundant pump	Valve is normally locked open
15	LPSI Line to Shutdown Cooling Heat Exchanger (SDCHX) Discharge and Isolation Valves SI685, SI657, SI686, SI694, SI658, SI696	a) Fails open	Mech. binding, elect. malf.	Potential diversion of LPSI flow to Containment Spray System	Same as 1(a)	Series isolation valves for SI657, SI686, SI658, SI696	Valve is normally locked closed
	When RWT inventory is down to approximately 10% of the inventory required to be available for safety injection mode operation, a Recirculation Actuation Signal (RAS) is generated. The following equipment are actuated/operated. (Item 16 to 21)						
16	LPSI Pump 1, 2	a) Fails to stop on RAS	Elect. malf.	LPSI pump dead headed, or possible damage due to insufficient NPSH or air entrainment from RWT.	Pump run light; Periodic testing	Timely operator action to isolate RWT after RAS. Ensures vortex breaker is not uncovered.	RWT transfer volume is sized assuming this failure, crediting timely operator action.**
17	Sump Line Isolation Valve SI673, SI674 SI675, SI676	a) Fails to open on RAS	Elec. malf., mech. binding	Effective loss of one safety injection train (HPSI and CS) during recirculation.	SESS alarms. Valve position indicators.	Redundant sump line and pumps. LPSI not required after RAS.	For some break sizes, this could mean a faster drain down of the RWT, which would ultimately be terminated by operator action to isolate the RWT.

**In initially establishing reliance on timely operator action as the licensing basis for this failure, APS performed analyses to quantify the likelihood of the single failure and obtained a license amendment based upon that analysis. Subsequent to NRC approval and implementation of the license amendment, the NRC staff concluded that exclusion of the LPSI pump single failure on probabilistic grounds was inappropriate. Rather, the NRC staff concluded that the LOCA-related design requirement related to RWT transfer volume sizing should be established using solely deterministic methods. In response to this, the design and licensing bases were revised to deterministically evaluate the LPSI pump single failure (Ref. 16-21).

17	Sump Line Isolation Valve (Continued)						
		b) Fails open	Elect. malf., mech. binding, contamination	None, redundant isolation valve, and check valve	Same as 17(a)	Redundant Isolation valve and check valve	
18	LP Pump to Min. Flow Line Isolation Valve SI669, SI668	a) Fails to close on RAS	Elect. malf., mech. binding, contamination	None	Valve position indicator; Periodic testing	Series isolation valve SI660, SI659	
19	Min. Flow Line to RWT Isolation Valve SI660, SI659	a) Fails to close on RAS	Elect. malf., mech. binding contamination	None	Valve position indicator; periodic testing	Series isolation valves	
20	HP Pump to Min. Flow line Isolation Valve SI666, SI667	a) Fails to close on RAS	Elect. malf., mech. binding contamination	None	Valve position indicator; Periodic testing	Series isolation valve SI660, SI659	
21	RWT Isolation Valve CH-530, CH-531	a) Fails to close (manual action)	Electrical malfunction, mechanical failure	Degraded performance of one train of HPSI (if air is entrained)	Valve position indicator; periodic testing	Parallel redundant HPSI path from sump. LPSI not required after RAS.	Timely operator action required to close

At one hour after the Loss of Coolant Accident (LOCA), the operator initiates cooldown with the Steam Generators (S.G.). Steam is relieved through the turbine bypass system if AC power is available or through the atmospheric dump system if power is unavailable. Then at two hours after the LOCA, the High Pressure Safety Injection (HPSI) pump discharge lines are realigned so that the total injection flow is divided equally between the hot and the cold legs. The following equipment are actuated: (Item 22 to 23)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
22	HPSI Pump Discharge Isolation Valve SI698, SI699, SI476, SI478	a) Fails open during hot and cold legs injection	Elect. malf., mech. failure	Flow to the affected hot leg will be less than 50% of total flow. HPSI pump may exceed run out flow	Periodic testing; valve position indicator	Redundant HPSI train	
		b) Fails closed	Mech. binding	Effective loss of one HPSI pump if SI476 or SI478 fails closed. None for SI698, SI699	Low pressure indication P308, P309; same as 22(a)	Redundant HPSI train	Valve is normally locked open

23	Hot Leg Injection Line Isolation Valve SI604, SI321, SI609, SI331	a) Fails closed during hot and cold legs injection	Elect. malf., mech. failure	Loss of one Hot leg Safety injection flow path	Periodic testing; valve position indicator	Redundant HPSI train	
		b) Fails open	Mech. binding, elect. malf.	None	Valve position indicator; periodic testing	Series Isolation Valve	Valve is normally locked closed

At eight hours after the LOCA, if RCS pressure has fallen (or remained) below 300 psia, the break may be too large for absolute assurance that proper suction is available for the shutdown cooling mode; however, in this event there is assurance that simultaneous hot leg/cold leg injection alone will both cool the core and flush the reactor vessel indefinitely.

At eight hours after the LOCA, if RCS pressure has remained above 300 psia, this indicates that there is sufficient fluid in the RCS to allow the LPSI pumps to operate in their shutdown cooling mode. The Operator will realign the LPSI pumps for this service, thus inducing a subcooled flushing flow through the core. In the shutdown cooling mode, the LPSI pumps take suction from the hot legs of the RCS through the shutdown cooling lines, discharge through the shutdown cooling heat exchangers, and return flow to the RCS through the injection lines. Prior to the initiation of this mode of operation, RCS pressure must be reduced to 400 psia to allow opening of the shutdown cooling suction line isolation valves. This is done by dumping steam and throttling HPSI flow with the HPSI valves. To accomplish depressurization of RCS to below 400 psia in a reasonable time period, it may also be necessary to reduce the pressure in the SIT’s. This is done by opening at least one of the two solenoid operated vent valves on each SIT from the control room. The HPSI pumps continue to make up for spillage. The following equipments are actuated: (Item 24 to 31)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
24	LPSI Pump Suction Isolation Valve SI683, SI692	a) Fails to close during shutdown cooling phase	Elect. malf., mech. failure	None	Valve position indicator; periodic testing	Cooldown can be achieved by using one shutdown path; Series check valves provide required isolation	
		b) Fails closed	Mech. binding, elect. malf.	None	Same as 24(a)	None required	Valve is required to be closed during this mode

SAFETY INJECTION SYSTEM FMEA CESSAR Table 6.3.2-2

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
40	SI Tank Vent Valve, SI605, SI613, SI606, SI623, SI607, SI633, SI608, SI643	a) Fails closed	Mech. binding, elect. malf.	Degradation of redundancy to vent the tank for refill or to relieve pressure	No change in tank pressure when valve is opened; periodic testing; valve position indicator	Redundant parallel valve	
		b) Fails open	Elect. malf., mech. binding, contamination	None, power removed when operation not required	Low SI tank pressure alarm		Power removed from valve until tanks are required to be vented
41	LPSI Line to Pool Cooling & Purif. System Isolation Valve SI453, SI450, SI455, SI454	a) Fails closed	Mech. binding, corrosion	No impact on safety injection	Operator	None required	Redundant train available
		b) Fails open	Mech. binding	None	Operator, or SFP level	Series Isolation Valve	Valve is normally locked closed
42	Pool Cooling & Purif. System (PCPS) to LP Pump Suction Isolation Valve SI443, SI256, SI442, SI204	a) Fails closed	Mech. binding, corrosion	No impact on safety injection	Operator	None required	
		b) Fails open	Mech. binding	Potential diversion of PCPS inventory to LPSI system	Spent Fuel Pool level indicator	Series redundant valve	Valve is normally closed
43	Shutdown Purif. To LP Pump Suction Isola-tion Valve CH397, SI418, CH419	a) Fails closed	Mech. binding, corrosion	No impact on safety injection	Operator	Not required	
		b) Fails open	Mech. binding	None	Operator	Series redundant valve	Valve is normally closed
44	RC Makeup Isolation Valves SI1024 and SI1027 (Effective for Units where DMWO 4304156 has been implemented.)	a) Fails closed	Mech. Binding, corrosion	No impact on safety injection	Operator	Not required	
		b) Fails open	Mech. Binding	None	Operator	Series redundant valve	Valve is normally closed

* The Method of Detection column is used to show that it is possible to detect the failure, during or before the accident.

6.3.2.6 Protection Provisions

The Safety Injection System is provided with protection from damage that could result from a LOCA by: (a) designing components to withstand the Design Bases Event environment including coolant chemistry, radiation, temperature and pressure resulting from the accident, (b) a seismic design that will withstand the stress imposed by a Safe Shutdown Earthquake occurring simultaneously with a LOCA, and (c) protection from missiles in accordance with Section 3.5.4.1.

To minimize the potential for water hammer and degraded pump performance, the safety injection suction and discharge piping will be maintained filled with water in accordance with Technical Specification and Technical Requirements Manual surveillance requirements. All piping is provided with high point vents and low point drains. The centrifugal pumps are vented through their discharge pipes. All SI pumps use a casing drain for draining and are tested quarterly to satisfy the requirements of ASME XI.

6.3.2.6.1 Capability to Withstand Design Bases Environment

Components located in the containment, such as remote-operated valves and instrumentation and control equipment, required for initiation of Safety Injection System are designed to withstand the LOCA conditions of temperature, pressure, humidity, chemistry and radiation for the extended period of time required as detailed in Section 3.11. These valves include the two sump isolation valves, and the valves associated with fill, drain, and pressure control of the safety injection tanks which receive SIAS or are required to operate following an accident.

The instrumentation includes the wide range level and pressure instrumentation associated with the safety injection tanks.

Insofar as practical, safety injection components required to maintain a functional status have been located outside containment to eliminate exposure of this equipment to the post-LOCA conditions. The equipment outside containment is designed in consideration of the chemical and radiation effects associated with operation following a LOCA. (Engineering drawings 01, 02, 03-M-SIP-001, -002 and -003 indicates location of equipment inside or outside of containment).

The design life of the safety injection pumps is 40 years, corresponding to the life of the plant. Design pressures and temperatures are in excess of the maximum pressures and temperatures seen by the respective component during the worst or normal operating and design bases conditions. Materials of construction for the pumps are compatible with the expected water-chemistry under normal and LOCA conditions. A radiation resistance requirement has been placed on the pumps consistent with Section 3.11.

6.3.2.6.2 Missile Protection

Protection from possible Reactor Coolant System generated missiles is afforded by locating all components outside the containment except for the safety injection tanks. These tanks are located outside the biological shield such that protection from possible Reactor Coolant System generated missiles is provided.

6.3.2.6.3 Seismic Design

Since operation of the Safety Injection System is essential following a Loss-of-Coolant Accident, it is considered Category 1 for seismic design. The general design basis for Category I equipment is that it must be able to withstand the appropriate seismic loads plus other applicable loads without loss of design functions which are required to protect the public.

For the safety injection system this means that the components must be able to withstand the stresses resulting from emergency operation following a LOCA, simultaneous with the stresses resulting from the Safe Shutdown Earthquake (SSE) without loss of function.

Refer to Section 3.7 for details on seismic design and analysis methods.

6.3.2.7 Required Manual Actions

The two modes of operation, injection and recirculation, are automatically initiated by a Safety Injection Actuation Signal (SIAS) and a Recirculation Actuation Signal (RAS) respectively. Timely Operator action is required to close the RWT discharge valves after verifying the sump discharge valves have opened after receiving a RAS to prevent ingress of air in the ESF pump suction piping during switchover to recirculation.

Long term core cooling is manually initiated at approximately 2 hours post-LOCA at which time the hot leg injection valves are opened to provide simultaneous hot and cold leg high pressure safety injection, which results in a circulation flow

through the core. For small pipe breaks, the HPSI pumps provide makeup for spillage, while the Reactor Coolant System is cooled down and depressurized to shutdown cooling initiation conditions utilizing the steam generator atmospheric dump valves and Auxiliary Feedwater System. For small LOCA's the SIT's must be vented to allow RCS depressurization. This is followed by manual SDC operation.

6.3.3 PERFORMANCE EVALUATION

6.3.3.1 Introduction and Summary

10 CFR 50.46 provides acceptance criteria for Emergency Core Cooling Systems (ECCS) for light-water nuclear power reactors [Reference 1]. The ECCS performance analyses described in this section demonstrate that the PVNGS ECCS design satisfies these criteria.

The PVNGS ECCS performance analyses encompass a wide range of Reactor Coolant System (RCS) break locations and sizes, including both large and small break Loss-of-Coolant Accident (LOCAs). The limiting break, which results in the closest approach to 10 CFR 50.46 acceptance criteria for peak clad temperature, is a 0.6 DEG/PD (Double-Ended Guillotine in the Reactor Coolant Pump Discharge leg) as noted in UFSAR Section 6.3.3.2. The limiting break, which results in the closest approach to 10 CFR 50.46 acceptance criterion maximum clad oxidation (or local clad oxidation), and maximum core-wide cladding oxidation is a 0.8 DEG/PD as noted in UFSAR Section 6.3.3.2. For these limiting breaks, the PVNGS ECCS design meets the acceptance criteria of 10 CFR 50.46 as follows:

Criterion 1: Peak Cladding Temperature. ". . .The calculated maximum fuel element cladding temperature shall not exceed 2200°F. . . ."

For the limiting break, the PVNGS ECCS performance analysis yielded a peak cladding temperature of 2106°F.

Criterion 2: Maximum Cladding Oxidation.". . . The calculated total oxidation of the cladding shall nowhere exceed 0.17 times the total cladding thickness before oxidation. . . ."

For the limiting break, the PVNGS ECCS performance analysis yielded a maximum cladding oxidation of 0.119 times the total cladding thickness before oxidation.

Criterion 3: Maximum Hydrogen Generation. ". . . The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam shall not exceed 0.01 times the hypothetical amount that would be generated if all of the metal in the cladding cylinders surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react. . ."

For the limiting break, the PVNGS ECCS performance analysis yielded a maximum core-wide oxidation of less than 0.0099 times the hypothetical amount that would be generated if all of the metal in the cladding cylinders

surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react.

Criterion 4: Coolable Geometry. ". . . Calculated changes in core geometry shall be such that the core remains amenable to cooling. . . ."

For the limiting breaks, the PVNGS ECCS performance analysis utilized the NRC-approved 1999 EM version of the Westinghouse Electric Company LLC large break LOCA evaluation model for Combustion Engineering designed PWRs, which is described in UFSAR Section 6.3.3.2.2. This evaluation model includes a cladding swelling and rupture model that accounts for the effects of changes in core geometry, if such changes are predicted to occur [Reference 2]. The ECCS performance analysis demonstrated adequate core cooling even with core geometry changes. The ECCS performance analysis was performed to a point in time where cladding temperatures were decreasing and the RCS was depressurized, thereby precluding any further cladding deformation. Therefore, a coolable core geometry has been demonstrated.

Criterion 5: Long-Term Cooling. ". . . After any calculated successful initial operation of the ECCS, the calculated core temperature shall be maintained at an acceptably low

value and decay heat shall be removed for the extended period of time required by the long-lived radioactivity remaining in the core. . . ."

For the limiting breaks, the ECCS performance analysis showed that the rapid insertion of borated water from the Safety Injection Tanks (SITs) and the safety injection pumps limits the peak cladding temperature and cools the core within a short period of time. Subsequently, the safety injection pumps will continue to supply cooling water from the Refueling Water Tank (RWT) or the containment sump. See UFSAR Section 6.3.3.4 for additional information on post-LOCA long-term cooling.

6.3.3.2 Large Break LOCA Analysis

6.3.3.2.1 Historical Background and Analyses of Record

Early large break LOCA analyses were performed to support NRC approval of the CE Nuclear Power LLC large break LOCA evaluation model [Reference 3]; to obtain a Final Design Approval (FDA) from the NRC for the standard System 80 plant design described in the Combustion Engineering Standard Safety Analysis Report (CESSAR) [Reference 4]; and to support NRC issuance of operating licenses for PVNGS Units 1, 2, and 3. These early large break LOCA analyses considered a wide spectrum of breaks including slot breaks and guillotine breaks, ranging in size from 0.5 ft^2 up to the full double-ended break

area. Postulated break locations included the Reactor Coolant Pump (RCP) suction and discharge legs, as well as the hot leg. These analyses demonstrated that large breaks in the RCP discharge leg were the most limiting, because both the core flow rate during blowdown and the core reflood rate were minimized for this location.

Additional large break LOCA analyses were subsequently performed to support NRC approval of PVNGS operating license amendments; to support core reload design efforts; and to correct miscellaneous errors that were discovered either in the evaluation model itself, or in the plant design data that was used as input to the evaluation model.

PVNGS conformance to the acceptance criteria of 10 CFR 50.46 is established by the following large break LOCA analysis of record:

A. A "break spectrum analysis" was performed to support implementation of replacement steam generators with 10% tube plugging and simplified head assembly for ZIRLO™ clad fuel rods. The results of this analysis are applicable to the PVNGS units with or without Simplified Head Assembly (SHA) implementation. The impact of SHA or ECCS performance has been determined to be insignificant and any differences in the containment configuration due to SHA would be covered by using contingency in the passive heat sink accounting. This analysis bounds PVNGS units utilizing Zircaloy-4 clad material.

This analysis of record serves to establish the limiting break size in the RCP discharge leg (i.e., a 0.6 DEG/PD), which produces the closest approach to the 10 CFR 50.46 acceptance criterion for peak clad temperature. This analysis also identifies a separate limiting break size of 0.8 DEG/PD for the maximum clad oxidation and core-wide cladding oxidation criteria.

Table 6.3.3.2-1 identifies the break sizes that were examined in this analysis of record. This analysis was conducted with the 1999 EM version of the Westinghouse Electric Company LLC large break LOCA evaluation model for Combustion Engineering designed PWRs, which is described in UFSAR Section 6.3.3.2.2.

6.3.3.2.2 1999 EM Large Break LOCA Evaluation Model

The current PVNGS large break LOCA break spectrum analysis of record, was performed using the NRC-approved 1999 EM version of the Westinghouse Electric Company LLC large break LOCA evaluation model for Combustion Engineering designed PWRs [Reference 5]. This evaluation model utilizes the CEFLASH-4A computer code [Reference 6] to determine the behavior of the RCS during the blowdown phase of a LOCA, and the COMPERC-II computer code [Reference 7] to determine the behavior of the RCS during the refill and reflood phases of a LOCA. Core flow and thermodynamic parameters from these two computer codes are input to the STRIKIN-II computer code [Reference 8] to calculate the hot rod cladding temperature transient. STRIKIN-II also utilizes steam cooling heat transfer

Table 6.3.3.2-1

TIMES OF INTEREST

(Seconds after Break Occurs)

Break Spectrum Analysis

Break Size (DEG/PD)	SI Tanks On	End of Blowdown	Start of Reflood(5)	SI Tanks Empty	SI Pumps On	Hot Rod Rupture
Spectrum Results for Peak Cladding Temperature(2)						
1.0	14.12	18.42	23.17	40.77	38.38	27.48
0.8	15.25	19.64	24.38	41.99	38.47	29.07
0.6	17.30	21.76	26.48	44.18	38.65	41.83
0.4	22.55	27.08	31.76	49.67	38.98	57.81
Case Results for Peak Local Oxidation(3)						
0.8	15.25	19.64	24.38	41.99	38.47	54.42
Case Results for Maximum Core-Wide Oxidation(4)						
0.8	15.83	24.11	32.37	84.3	38.48	55.06

(1) Break type is Double-Ended Guillotine (DEG), located in the Reactor Coolant Pump Discharge (PD) leg (i.e., RCS cold leg). The effective break area for the 1.0 DEG/PD is 9.8174 ft^2, corresponding to twice the pump discharge leg cross-sectional flow area. The limiting break for PCT (i.e., a 0.6 DEG/PD) has a break area that is 60% of this value.

(2) Results are for Erbia fuel type at a burnup of 34 GWD/MTU (corresponding to FATES3B Cycle 28)

(3) Results are for Erbia fuel type at a burnup of 0.5 GWD/MTU (corresponding to FATES3B Cycle 4)

(4) Results are for Erbia fuel type at a burnup of 0.5 GWD/MTU (corresponding to FATES3B Cycle 4)

(5) Start of reflood is defined by the Contact Time.

coefficients that are calculated with the HCROSS [Reference 2] and PARCH [References 2 and 9] computer codes.

Peak cladding temperature and maximum cladding oxidation are obtained from the STRIKIN-II computer code. The maximum core-wide cladding oxidation is obtained from the results of both the STRIKIN-II and COMZIRC [Reference 7] computer codes. Initial steady-state fuel rod conditions used in STRIKIN-II are determined with the FATES computer code [Reference 10].

6.3.3.2.3 Large Break LOCA "Break Spectrum Analysis"

The PVNGS large break LOCA break spectrum analysis of record evaluated four double-ended guillotine (DEG) breaks located on the RCP discharge. Slot breaks were not included in the analysis because they are known to be less limiting than guillotine breaks on a pump discharge line. Table 6.3.3.2-2 summarizes important results of the analysis.

The analysis of record demonstrated that the limiting break size for peak cladding temperature was 0.6 DEG/PD and for both maximum cladding oxidation and maximum core-wide cladding oxidation was 0.8 DEG/PD. It should be noted that the RCP discharge leg has an inside diameter of 30 inches and consequently a cross-sectional flow area of 4.9087 ft^2. Therefore, the effective break area for the 1.0 DEG/PD is approximately 9.8174 ft^2, and the limiting breaks have break areas of 60% and 80% of this value, or approximately 5.89 ft^2 and 7.857 ft^2 respectively.

Table 6.3.3.2-2

(3)Results are for Erbia fuel type at a burnup of 0.5 GWD/MTU (corresponding to FATES3B Cycle 4)

6.3.3.2.4 Safety Injection System Parameters

The Safety Injection (SI) system consists of four SITs, two High Pressure Safety Injection (HPSI) pumps, and two Low Pressure Safety Injection (LPSI) pumps. The SITs automatically discharge when RCS pressure decreases below the SIT pressure. Each SIT injects to a single cold leg. The HPSI and LPSI pumps are automatically actuated by a Safety Injection Actuation Signal (SIAS) that is generated by either low pressurizer pressure or high containment pressure. Each HPSI pump injects to one of two high pressure injection headers, each of which feeds four cold legs. Each LPSI pump injects to one of two low pressure injection headers, each of which feeds two cold legs.

The large break LOCA analyses of record conservatively represent the spillage of safety injection flow. All of the safety injection flow to the broken RCP discharge leg (i.e., cold leg) is assumed to spill out through the break and into the containment building.

The large break LOCA analyses of record considered several single failures i.e., failure of one LPSI pump, failure of one HPSI pump, failure of one diesel generator and no failure. No failure was determined to be the most limiting condition for the following two reasons. First, any equipment failure results in essentially the same liquid level in the downcomer during reflood as the case of no failure. Therefore, both cases are equivalent in terms of maintaining the downcomer head which drives core reflooding. Secondly, the no failure case results in more spillage of ECCS flow to the containment. This results in a lower containment pressure, which impedes the

reflood process. Specifically, as pressure is reduced, steam density decreases, thereby making it more difficult for steam to flow from the core to the break, and for water to reflood the core. Consequently, no failure is more limiting because it has an adverse impact on the core reflood rate, and because it does not have a beneficial impact on the downcomer level relative to any equipment failure.

Based on the PVNGS ECCS design, spillage considerations, and no failure of the ECCS, the following SI flows into the RCS were used for the large break LOCA analyses of record for RCP discharge leg breaks:

A. 100% of the flow from three SITs;

B. 75% of the flow from two HPSI pumps; and

C. 100% of the flow from one LPSI pump and 50% of the flow from the other LPSI pump.

Consistent with the fact that no ECCS failure is the worst condition, maximum HPSI and LPSI pump flow rates were used in the large break LOCA analyses of record. The pumps were modeled to start injection after the downcomer was refilled by the SITs, as noted in UFSAR Section 6.2.1.5.3.5.

6.3.3.2.5 Core and System Parameters

Pertinent input parameters and initial conditions used in the large break LOCA break spectrum analysis are listed in Table 6.3.3.2-3. In this analysis the initial reactor power level is 4070 MW_t, or 102% of a rated thermal power of 3990 MW_t.

Table 6.3.3.2-3

SYSTEM PARAMETERS AND INITIAL CONDITIONS FOR THE LARGE BREAK LOCA ECCS PERFORMANCE BREAK SPECTRUM ANALYSIS

Parameter	Units	Value
Reactor Power Level (102% of 3990)	Mwt	4070
Peak Linear Heat Generation Rate (PLHGR) of the Hot Rod	kW/ft	13.1
PLHGR of the Average Rod in the Assembly with the Hot Rod	kW/ft	12.35
Gap Conductance at the PLHGR	Btu/hr-ft^2-°F	2143[a]
Fuel Centerline Temperature at the PLHGR	°F	3260[a]
Fuel Average Temperature at the PLHGR	°F	2020[a]
Hot Rod Gas Pressure	psia	2408[a]
Moderator Temperature Coefficient at Initial Density	$\Delta\rho$/°F	0.5×10^{-4}
RCS Flow Rate	lbm/hr	147.6×10^6
Core Flow Rate	lbm/hr	143.2×10^6
RCS Pressure	psia	2250
Cold Leg Temperature	°F	541
Hot Leg Temperature	°F	611
Safety Injection Tank Pressure (Minimum/Maximum)	psia	602/652
Safety Injection Tank Water Volume (Minimum/Maximum)	ft^3	1750/1950
Containment Temperature (Minimum)	°F	50

NOTE:

(a) These values correspond to the rod average burnup of the hot rod that yielded the highest peak cladding temperature.

The limiting break reanalysis accounts for up to 2516 plugged steam generator tubes (total for both replacement steam generators). Because the overall steam venting loss coefficient in COMPERC-II is not significantly impacted by asymmetric tube plugging, the limiting break reanalysis does not impose any asymmetric steam generator tube plugging limits.

6.3.3.2.6 Containment Parameters

Section 6.2.1.5 describes the minimum containment pressure analyses that were performed as part of the large break LOCA analyses of record, including pertinent input parameters and initial conditions. For the "break spectrum analysis," passive heat sink inputs to the COMPERC-II code were based on data contained in UFSAR Table 6.2.1-27,B Detailed Listing.

The containment pressure response predicted by the "break spectrum analysis" for the limiting break size is shown in Figure 6.3.3.2-3F.

6.3.3.2.7 Results and Conclusions

Table 6.3.3.2-1 lists times of interest for the large break LOCAs that were analyzed for the "break spectrum analysis”. Likewise, Table 6.3.3.2-2 summarizes the peak cladding temperatures, maximum cladding oxidation percentages, and maximum core-wide oxidation percentages for each of the breaks that were analyzed.

As noted in Table 6.3.3.2-4, the results for each break are presented in Figures 6.3.3.2-1 through 6.3.3.2-4. For each break size, the results of eight parameters (e.g., cladding

temperature) are plotted as a function of time as indicated by Table 6.3.3.2-5. For the limiting break size, thirteen additional parameters are plotted as a function of time as indicated by Table 6.3.3.2-6.

As shown in Table 6.3.3.2-2, analysis of the limiting large break LOCA for peak clad temperature (i.e., the 0.6 DEG/PD break resulted in a peak clad temperature of 2106°F, a maximum clad oxidation percentage of 11.9% for the limiting large break LOCA (i.e., the 0.8 DEG/PD), and a maximum core-wide oxidation percentage of less than 0.99% (chosen to bound all the values in Table 6.3.3.2-2). These results meet the acceptance criteria of 10 CFR 50.46.

6.3.3.3 Small Break Analysis

6.3.3.3.1 Evaluation Model

The analysis reported in this section was performed using the C-E small break LOCA evaluation model which is described in reference 11 and was approved by the NRC in reference 12. This particular version is the Supplement 2 Model (S2M) of the Westinghouse Electric Company LLC for Combustion Engineering designed PWRs. In the C-E model, the CEFLASH-4AS[Reference 13] computer program is used to determine the RCS behavior during the blowdown phase, and the COMPERC-II[Reference 7] computer program is used to determine the RCS behavior during the reflood phase. Fuel rod temperatures and cladding oxidation percentages are calculated using the STRIKIN-II[Reference 8] and PARCH[Reference 9] computer programs. The interfacing between these programs is discussed in detail in reference 11.

a. Refer to Table 6.3.3.2-4 for the figure numbers associated with the limiting break size.

6.3.3.3.2 Safety Injection System Assumptions

The safety injection system (SIS) includes two high pressure pumps, two low pressure pumps, and four safety injection tanks. It is conservatively assumed that offsite power is lost upon reactor trip and, therefore, all safety injection pumps must await diesel startup and load sequencing before they can start. The total time delay assumed is 30 seconds from the time that the pressurizer pressure reaches the SIAS setpoint to the time that the SI flow is delivered to the RCS. For breaks in the reactor coolant pump discharge leg, it is also assumed that all safety injection flow delivered to the broken leg spills out the break.

An analysis of the possible single failures that can occur within the SIS has shown that the worst single failure for the small break LOCA analysis is the failure of one of the emergency diesels to start.[Reference 11] This failure causes a loss of both a high pressure pump and a low pressure pump, and results in a minimum of safety injection water being available to cool the core. Therefore, based on the above assumptions, the following safety injection flows are credited for the small break analysis.

A. Since each high pressure safety injection pump (HPSIP) is piped so that it can feed all four cold leg injection points:

   1. For a break in the pump discharge leg, the HPSIP flow credited is 75% of the flow from one HPSIP. The remaining 25% is assumed to spill out the break.

2. For breaks in other locations, the HPSIP flow credited is 100% of one HPSIP.

B. Since each low pressure safety injection pump (LPSIP) is piped so that it feeds two of the cold leg injection points:

1. For a break in the pump discharge leg, the LPSIP flow credited is 50% of the flow from one LPSIP. The remaining 50% is assumed to spill out the break.

2. For breaks in other locations, the LPSIP flow credited is 100% of one LPSIP.

C. The four safety injection tanks (SITs) are piped so that each SIT feeds a single cold leg injection point. Thus:

1. For a break in the pump discharge leg, the SIT flow credited is 100% of the flow from three SITs. The remaining SIT is assumed to spill out the break.

2. For breaks in other locations, the SIT flow credited is 100% of four SITs.

6.3.3.3.3 Core and System Parameters

The significant core and system parameters and initial conditions used in the Unit 2 Cycle 11 small break LOCA analysis, hereafter referred to as the SBLOCA reference cycle, are presented in Table 6.3.3.3-2. The peak linear heat generation rate (PLHGR) of 13.5 kw/ft was assumed to occur 15% from the top of the active core. A conservative beginning-of-

life moderator temperature coefficient of 0.0 $\Delta\rho/°F$ was used in the analysis.

The analysis accounts for up to 2,750 plugged tubes per steam generator.

The initial steady state fuel rod conditions were obtained from the FATES3B(Reference 17) computer program. The small break LOCA analysis employed a hot rod average burnup which maximized the amount of stored energy in the fuel.

Table 6.3.3.3-1 presents the high and low pressure safety injection pump flow rates used in the PVNGS small break LOCA analysis.

6.3.3.3.4 Containment Parameters

The small break LOCA analysis does not use a detailed containment model. Therefore, other than the initial containment pressure and the containment volume, which are assumed to be 14.7 psia and 3.0 x 10^6 ft^3, respectively, no containment parameters are employed for this analysis.

6.3.3.3.5 Break Spectrum

Seven breaks were analyzed to characterize the small break spectrum. Six breaks, ranging in size from 0.01 ft^2 to 0.07 ft^2, were postulated to occur in the pump discharge leg. The break size range of 0.01 ft^2 to 0.07 ft^2 encompasses the breaks sizes for which hot rod cladding heatup is terminated solely by injection from the HPSIP. It is within this range that the limiting SBLOCA, the 0.05 ft^2 break, resides. Breaks

Table 6.3.3.3-2

SYSTEM PARAMETERS AND INITIAL CONDITIONS

FOR THE SMALL BREAK LOCA ECCS PERFORMANCE ANALYSIS

Parameter	Value	Units
Reactor power level (102% of 3990)	4070	MWt
Average linear heat generation Rate	5.9	kW/ft
Peak linear heat generation rate (PLHGR)	13.5	kW/ft
Gap conductance at PLHGR	1839	BTU-hr-ft^2-°F
Fuel centerline temperature at PLHGR	3243	°F
Fuel average temperature at PLHGR	2045	°F
Hot rod gas pressure	1,058	psia
Moderator temperature coefficient at initial density	0.0	$\Delta\rho$/°F
RCS flow rate	147.6×10^6	lbm/hr
Core flow rate	143.2×10^6	lbm/hr
RCS pressure	2,250	psia
Core inlet temperature	541[a]	°F
Core outlet temperature	612	°F
Low pressurizer pressure reactor trip setpoint	1,600	psia
Low pressurizer pressure SIAS setpoint	1,600	psia
Safety injection tank pressure	200[b]	psia

a. This is below Technical Specification minimum cold leg temperature, but is conservative for LOCA analysis.

b. This pressure arbitrarily set at the low value to prevent SIT water injection during a SBLOCA transient. This is a conservative approach by not taking any SIT credit.

outside this range are either too small to experience any core uncovery or are sufficiently large such that injection from the SITs will recover the core and the terminate cladding heatup before the cladding temperature approaches the PCT calculated for the limiting SBLOCA. The PVNGS Cycle 1 SBLOCA break spectrum analysis demonstrated that breaks larger than 0.07 ft^2 had peak cladding temperatures that were less than the limiting SBLOCA. One break, equal in area to a fully open pressurizer safety valve (0.03 ft^2), was postulated to occur in the top of the pressurizer. Each break size was evaluated for different combinations of the cladding material of Zircaloy-4 and ZIRLO™ and fuel of $U0_2$ and Erbia. Table 6.3.3.3-3 lists the various break sizes and locations.

6.3.3.3.6 Results

The analysis found the combination of ZIRLO™ clad and $U0_2$ fuel resulted in the highest PCTs, 0.05 ft^2/PD being the limiting break size. For different break sizes the results were less sensitive to the combination of clad and fuel.

The transient behavior of important NSSS parameters is shown in the figures listed in table 6.3.3.3-4. Table 6.3.3.3-5 summarizes the important results of this analysis. Times of interest for the various breaks analyzed are presented in table 6.3.3.3-6. A plot of peak cladding temperatures (PCT) versus break size is presented in figure 6.3.3.3-8. The 0.05 ft^2 break results in the highest PCT (1618F) of the small breaks analyzed. The PCT is approximately 490F lower than that reported in paragraph 6.3.3.1 for the limiting large break.

The break resulting in the next highest PCT of the small break spectrum is the 0.06 ft^2 break with a PCT of 1485F.

b. SIT pressure was set at 200 psia to prevent SIT injection.
c. Time includes the 30 second delay from the time the pressurizer pressure reaches the low pressure SIAS setpoint to the time the pump powered and at full speed.
d. Blowdown peak clad temperature.

6.3.3.3.7 Instrument Tube Rupture

In addition to the seven small breaks discussed above, the rupture of an in-core instrument tube was considered. A break, equal in size to a completely severed instrument tube (0.003 ft^2), was postulated to occur in the reactor vessel bottom head.

Following rupture, the primary system depressurizes until a reactor scram signal and safety injection actuation signal (SIAS) are generated due to low pressurizer pressure. The assumed loss of offsite power causes the primary coolant pump and the feedwater pumps to coast down. After the delay required to start the emergency diesel and the high pressure safety injection pump following SIAS, safety injection flow is initiated to the RCS. At this time an auxiliary feedwater pump is also started, providing a source of cooling to the steam generators. Due to the assumed failure of one diesel, only one high pressure safety injection pump and one auxiliary feedwater pump are available. (Four SITs and one low pressure safety injection pump are also available but do not inject due to the high reactor coolant system (RCS) pressure.) The steam generator secondary sides also become isolated at this time.

The primary side depressurization continues accompanied by a rise in secondary side pressure until the secondary side pressure reaches the lowest setpoint of the steam generator safety relief valves. The primary system pressure continues to fall until it is just slightly greater than the secondary side pressure. At this point, the flow from the one operating HPSIP exceeds the leak flow. Therefore the RCS will fill. The decay

heat generated in the core is removed in the steam generators by steam flow through the automatic secondary side safety relief valves. Thus, the core will remain covered and cooled in this condition. The post-LOCA long term procedures described in paragraph 6.3.3.4 are initiated at 1 hour to provide long term cooling.

6.3.3.4 Post-LOCA Long-Term Cooling

6.3.3.4.1 General Plan

Long Term Cooling (LTC) is initiated when the core is quenched after a LOCA and is continued until the plant is secured. The objectives of LTC are to maintain the core at safe temperature levels and to avoid the precipitation of boric acid in the core region. To accomplish these objectives, a LTC analysis for PVNGS was performed using the computer codes and methods documented in Reference 14.

The LTC plan for PVNGS uses one of two procedures, depending on the break size. Shutdown cooling is initiated if the break is sufficiently small that successful operation of the shutdown cooling system (SCS) is assured. Otherwise, simultaneous hot and cold side injection is used to maintain core cooling and boric acid flushing. The appropriate procedure is selected on the basis of the indicated reactor coolant system (RCS) pressure.

Figure 6.3.3.4-1 shows the basic sequence of events and the time schedule for operator actions in the PVNGS LTC plan. The time schedule gives a time interval in which the action is to

be accomplished. It is assumed that the specified functional requirement is met within the specified time interval.

The operator's first action is to initiate cooldown within 1 hour post-LOCA by releasing steam from the steam generators. The steam is released either through the turbine bypass system, if it is available, or through the atmospheric dump valves. Between 1 and 3 hours post-LOCA, the Safety Injection Tanks (SITs) are isolated or vented to avoid injecting nitrogen, a non-condensable gas, into the RCS. Between 1 and 4 hours post-LOCA, pressurizer cooldown is initiated. Between 2 and 3 hours post-LOCA, the high pressure safety injection (HPSI) pump discharge is realigned so that the injection flow is divided between the hot and cold sides of the RCS.

If the indicated RCS pressure is above 440 psia between 8 and 9 hours after the LOCA, the RCS is filled which assures that proper suction is available for initiating shutdown cooling. Cooling the RCS continues until the indicated RCS temperature is lower than the maximum SCS entry temperature including instrument uncertainty. The HPSI pumps are then throttled until RCS pressure is reduced to below the SCS entry pressure including instrument uncertainty. All HPSI pump flow is then shifted back to the cold legs and shutdown cooling is initiated.

A prerequisite for throttling or terminating HPSI pump flow is that the RCS must be in a subcooled condition for the indicated RCS pressure. Therefore, while reducing RCS pressure to initiate shutdown cooling, it is essential to maintain subcooling of the RCS consistent with Emergency Operating Guidelines.

For EOP purposes, an alternative method for decay heat removal is the continued use of the steam generators. This requires the continued availability of auxiliary feedwater and the atmospheric dump valves or the turbine bypass system. If the SCS becomes operable at a later time, it is put into operation. This path is indicated by the dashed lines in Figure 6.3.3.4-1.

If the indicated RCS pressure is below 440 psia between 8 and 9 hours, the break is too large for absolute assurance that proper suction is available for initiating shutdown cooling. In this event, simultaneous hot and cold side injection of HPSI pump flow is used to both cool the core and flush the reactor vessel.

6.3.3.4.2 Assumptions Used in the Short Term LTC Analysis

The major assumptions used in performing the LTC analysis are listed below:

1. No offsite power is available.
2. The worst single failure is the failure of an emergency diesel generator. Therefore:
    a. One HPSI pump is operable. (No LPSI pumps are used during the recirculation mode.)
    b. One auxiliary feedwater pump is operable.
3. One atmospheric dump valve on each steam generator is operable.
4. RCS cooldown begins at one hour post-LOCA.
5. The SITs are vented or isolated in establishing SCS entry conditions for the small break LTC procedure.

6. The pressurizer is cooled down in establishing SCS entry conditions for the small break LTC procedure.

7. RCS cooldown is terminated when the hot leg temperature is below the maximum SCS entry temperature including instrument uncertainty.

8. Pump flow rates and initial water source inventories used in the large break LOCA boric acid precipitation analysis are selected to maximize the boric acid concentration in the core.

9. A boric acid precipitation limit of 30 wt% is used in the large break LOCA boric acid precipitation analysis. This is the precipitation limit in saturated water at 17 psia. The value of 17 psia was calculated using a conservative model for containment pressure.

6.3.3.4.3 Parameters Used in the LTC Analysis

The significant core and system parameters and initial conditions used in the Unit 2 Cycle 7 LTC analysis, hereafter referred to as the LTC reference cycle, are presented in Table 6.3.3.4-1.

6.3.3.4.4 Results of the LTC Analysis

The double-ended (9.8 ft^2) cold leg break is the limiting break for long term boric acid accumulation in the reactor vessel. For a cold leg break, the core flushing flow is the difference between the hot side HPSI pump flow rate and the core boiloff flow rate. The initiation of a simultaneous hot and cold side HPSI pump flow rate of at least 380 gpm to each side between 2

and 3 hours post-LOCA provides a substantial and time-increasing core flushing flow as shown in Figure 6.3.3.4-2. Figure 6.3.3.4-3 shows that with no core flushing flow, boric acid would begin to precipitate at approximately 3.5 hours post-LOCA. However, with a hot side injection flow rate of 380 gpm, initiated at 3 hours post-LOCA, the maximum boric acid concentration in the core is 28.5 wt% as compared to the precipitation limit of 30 wt%. The margin provided for the prevention of boric acid precipitation by a constant core flushing flow of 30 gpm is also shown in Figure 6.3.3.4-3.

The time at which all hot leg steam entrainment of injection water is terminated was calculated to be less than 2 hours post-LOCA. Therefore, the initiation of simultaneous hot and cold side injection between 2 and 3 hours is after the potential for hot leg entrainment has been terminated.

Figure 6.3.3.4-1 shows the two procedures for long term cooling. The small break procedure (left branch) applies to those break sizes for which the RCS refills before all auxiliary feedwater is exhausted. The LTC analysis determined that more than 13 hours is required to exhaust all auxiliary feedwater during the cooldown of the RCS. The analysis predicts the RCS to refill at various times depending on the break area as shown in Figure 6.3.3.4-4. To allow a substantial time margin to avoid exhausting the auxiliary feedwater, a time of 8 to 9 hours post-LOCA was selected for the operator to decide if the small break procedure is appropriate. As shown in Figure 6.3.3.4-4, a break area as large as 0.03 ft^2 refills within 8 hours. By 13 hours the RCS will refill for even larger break areas. Therefore, the

analysis demonstrates that breaks as large as 0.03 ft^2 will be able to use SCS for the long term cooling and flushing of the core.

The LTC analysis determined that the large break procedure (right branch) can flush the core for break areas as small as 0.006 ft^2. The overlap in break areas for which either the large or small break procedure can be used is illustrated in Figure 6.3.3.4-5.

The operator chooses the appropriate procedure on the basis of indicated RCS pressure between 8 and 9 hours. Figure 6.3.3.4-5 lists the RCS pressure at 8 hours for a wide range of break sizes and Figure 6.3.3.4-6 presents this information graphically. The decision pressure is selected as 440 psia, such that, for the pressurizer pressure measurement uncertainty of +77/-100 psi (Table 6.3.3.4-1), the operator is assured of selecting the proper procedure for any break size.

The emergency operating procedures (EOPs) do not require the operator to wait for 8 to 9 hours before choosing the long term cooling mode. The EOPs direct the operator to place shutdown cooling into service when the RCS pressure and temperature are within the design limits of the shutdown cooling system, and when pressure and inventory control have been established (as indicated by the RCS being subcooled and the pressurizer level being above the minimum to allow heater operation). The objective of the UFSAR assumption is to assure that the RCS is refilled. The EOP step implements this strategy by using other indications to assure the RCS is refilled.

Table 6.3.3.4-1

Core and System Parameters Used in the LTC Analysis

Parameter	Value
Reactor power level	4070 MWt (102% of 3990 MWt)
Number of plugged tubes per SG	2750
SCS entry temperature	350°F[a]
SCS entry pressure	385 psia[a]
Pressurizer pressure measurement uncertainty for determining entry into shutdown cooling	+77/-100 psi
Atmospheric dump valve capacity at 1000 psia	950,000 lbm/hr/valve (minimum)
Condensate storage tank inventory	300,000 gallons (minimum)
Initial boric acid concentration	
RCS	2100 ppm (1.20 wt%) (maximum)
RWT	4400 ppm (2.52 wt%) (maximum)
SIT	4400 ppm (2.52 wt%) (maximum)
Initial inventory used in boric acid precipitation analysis	
RCS	670,000 lbm (maximum)
RWT	760,000 gal (maximum)
SIT	1950 ft^3/tank (maximum)
Pump flow rates used in boric acid precipitation analysis	
HPSI pump	900 gpm (minimum)
LPSI pump	3000 gpm (minimum)
Containment spray pump	3000 gpm (minimum)

(a) Maximum indicated value for entry into shutdown cooling.

Table 6.3.3.5-1
SEQUENCE OF EVENTS FOR REPRESENTATIVE LARGE AND SMALL BREAK LOCAS
(Sheet 1 of 2)

Event	Large Break (0.8 DEG/PD)[a] Setpoint or Value	Large Break (0.8 DEG/PD)[a] Time (sec)	Small Break (0.02 Ft^2)[b] Setpoint or Value	Small Break (0.02 Ft^2)[b] Time (sec)	Success Path
Break occurs		0.0		0.0	
Core peak power	117%	0.15	105%	96.0	
Pressurizer pressure reaches reactor trip and SIAS analysis setpoint	1,600 psia	9.43	1,600 psia	456.0	Reactivity control
Reactor trip and safety injection actuation signals generated		10.43		457.0	Reactivity control
SIT discharge begins	607.7 psia	16.2	607.7 psia	7,500	Reactivity control
Reflood begins		37.7		NA	
Main steam safety valves begin to open		NA	1,295 psia[c]	456.0	Secondary system integrity
Maximum secondary pressure	1,239 psia		1,340 psia	184.0	
HPSI pump flow delivered to RCS		68.2		492.0	Reactivity control
SITs empty		68.2		NA	
LPSI pump flow delivered to RCS		68.2		NA	Reactivity control

a. For the large break, loss of ac power and start of the diesel generators occurs at initiation of event (t = 0.0).

b. For the small break, loss of ac power and start of the diesel generator occurs at time of P_pL trip (t = 456.0).

c. Current MSSV (1303 psia) opening pressures used in the analyses have been justified based upon the tolerance changes (+/- 1% to +/-3%) but the sequence of event does not reflect the minor change in time.

Table 6.3.3.5-1

SEQUENCE OF EVENTS FOR REPRESENTATIVE LARGE AND SMALL BREAK LOCAS

(Sheet 2 of 2)

Event	Large Break (0.8 DEG/PD)[(a)]		Small Break (0.02 Ft^2)[(b)]		Success Path
	Setpoint or Value	Time (sec)	Setpoint or Value	Time (sec)	
Main steam safety valves closed			1,295 psia[(c)]	2,600	
Recirculation actuation signal	15% range	1,200-7,200	15% range	1,200-7,200	Reactivity control
Initiate cooldown		3,600		3,600	Secondary system integrity
Enter hot and cold leg injection mode		7,200		7,200	Reactor heat removal
Decision point for entry into shutdown cooling or continuation of hot and cold leg injection mode		28,800		28,800	Reactor heat removal

c. New PSV (2575 psia for Units 1 and 3, and 2550 psia for Unit 2) and MSSV (1303 psia) opening pressures used in the analyses have been justified based on the tolerance changes (+/-1% to +3/-1% and +/-1% to +/-3%, respectively), but the sequence of event does not reflect the minor changes in time.

6.3.3.5 Sequence of Events and Systems Operation

Table 6.3.3.5-1 presents a chronological list of events which occur during two representative LOCAs, a small break of 0.02 ft^2 and a large break, the 0.8 x double-ended guillotine break in pump discharge leg (DEG/PD). Table 6.3.3.5-1 extends from the occurrence of the break to the decision point at 8 hours about whether or not to enter the shutdown cooling mode.
Figure 15.0-1 contains a glossary of symbols and acronyms which may be used with the sequence of events diagram, figure 6.3.3.5-1, to trace the actuation and interaction of systems which mitigate the consequences of these events.
Table 6.3.3.5-2 contains a matrix which describes the extent to which normally operating plant systems are assumed to function during the event. An explanation of the interpretation of the sequence of events diagram may be found in paragraph 15.0.1.6.
The inadvertent opening of the primary safety valve is considered as a special case in the small break spectrum.

The success paths in the sequence of events diagram (figure 6.3.3.5-1) are as follows:

A. Reactivity Control

Following the break, the RCS pressure drops rapidly. For both breaks, this results in the generation of a low pressurizer pressure trip signal and the CEAs drop into the core. In the case of the large break, the insertion of negative reactivity via the scram will probably also occur but is not required, as the amount of voiding which occurs in the moderator introduces sufficient negative reactivity to make the reactor

subcritical. At the low pressurizer pressure trip setpoint a safety injection actuation signal (SIAS) is generated and additional negative reactivity is added to the system, in the form of borated water from the refueling water tank (RWT). In the case of the large break, the RCS pressure drops low enough to allow discharge of the SITs and LPSIs and additional borated water is added. For the small break only the SITs discharge. For all breaks, the water level in the RWT will eventually drop sufficiently to result in the generation of a recirculation actuation signal (RAS). Upon generation of the RAS, the containment sump isolation valves open to supply the HPSI pumps during the recirculation phase. For some small breaks, relatively small amounts of borated water are added during the ECC injection phase and additional boron must be added to bring the system to the cold shutdown concentration. To accomplish this the operator may use the HPSI pumps to add boron by replacing the volume shrinkage which occurs during cooldown.

B. Reactor Heat Removal

Following the loss of power to the non-engineered safety feature (ESF) loads as a result of the turbine trip and the subsequent grid collapse, the reactor coolant pumps coast down. For the small break, reactor heat removal takes place by means of natural circulation and the additional cooling capability of the relatively low enthalpy RWT water, introduced by the safety injection system. For the large break,

reactor heat removal is initially accomplished by the safety injection system, since the conditions which exist within the RCS during the early phase of the accident will prevent the establishment of natural circulation flow. Following the generation of the RAS, reactor heat removal continues through the use of the safety injection system, in the recirculation mode.

Two hours after the LOCA the operator manually aligns the HPSI pump discharge lines for simultaneous hot and cold leg injection. Eight hours after the LOCA, the operator may initiate shutdown cooling provided that the RCS pressure has remained above 440 psia. If RCS pressure is less than 440 psia, hot and cold leg injection is sufficient to cool the core and is continued.

C. Primary System Integrity

For small break LOCAs in which the RCS pressure can be maintained at or above 440 psia, the RCS pressure is controlled by throttling the HPSI discharge valves or the SIT vent valves. If the indicated RCS pressure is above 440 psia between 8 and 9 hours after the LOCA, the RCS is filled which assures that proper suction is available for initiating plant cooldown. Cooling the RCS continues until the indicated RCS temperature is lower than the maximum SCS entry temperature including instrument uncertainty. The HPSI pumps are then throttled until RCS pressure is reduced to below the SCS entry pressure including instrument uncertainty.

D. Secondary System Integrity

For all break sizes, the reactor trip will result in a turbine trip and the subsequent loss of offsite power will result in the loss of main feedwater flow. Since the steam bypass control system is not available due to loss of condenser vacuum on loss of offsite power, the secondary system pressure will increase and for some small breaks will reach the opening pressure of the main steam safety valves (MSSVs). In the cases where the MSSVs open, the lack of main feedwater will eventually result in the generation of auxiliary feedwater actuation signals and the delivery of auxiliary feedwater to both steam generators. The operator will initiate cooldown at one hour after the LOCA, using the atmospheric dump valves if non-emergency ac power has not been reestablished or using the steam bypass system if it has. Along with the dump or bypass valves, the operator will utilize one feedwater pump designated as "auxiliary" and intended for normal startup or shutdown of the plant. During the cooldown, the operator will reduce the $P_{sg}L$ setpoint to prevent the inadvertent generation of a main steam isolation signal (MSIS).

E. Containment Integrity

A containment spray actuation signal is generated on a high-high containment pressure signal. The containment spray (CS) pumps spray water from the RWT into the containment to reduce the temperature and pressure of

the containment atmosphere. On the generation of an RAS, the containment sump isolation valves open to supply water to the CS pumps.

F. Combustible Gas Control

The containment sprays act to mix the containment atmosphere and prevent the formation of hydrogen gas pockets, and the operator actuates balance of plant (BOP) systems to control the hydrogen concentration in the containment atmosphere.

G. Radioactive Effluent Control

When the pressurizer pressure reaches the low pressure setpoint, a containment isolation actuation signal (CIAS) is generated. The CIAS results in the isolation of various containment, primary, and secondary systems to limit radioactive releases. In addition, the containment spray system functions to remove radioactive iodine from the containment atmosphere.

H. Control Room Habitability

SIAS or BOP signals may actuate control room habitability systems. See section 6.4 for a description of control room habitability systems.

I. Fuel Handling Building Habitability

SIAS or BOP signals may actuate fuel handling building habitability systems. See subsection 9.4.5 for a description of fuel building HVAC systems.

J. Restoration of AC Power

The standby generators are automatically started when an undervoltage condition is sensed on the associated ESF bus. For large break LOCAs ac power is assumed to be lost at t = 0 seconds. For small break LOCAs ac power is assumed to be lost following the reactor trip and the failure of one standby generator is assumed. All required ESF loads are loaded onto the standby generators within 30 seconds after generator breaker closure and re-energization of the ESF buses. The standby generators and automatic sequencers necessary for generator loading are also designed such that flow to the core is attained within 30 seconds of reaching a SIAS setpoint, as described in UFSAR Section 6.3.1.4.A.4.

K. Spent Fuel Heat Removal

Spent fuel pool (SFP) cooling is terminated on the loss of normal power to the ESF loads. Spent fuel heat removal is continuously accomplished utilizing the heat capacity of the SFP water. Pool cooling is restored by manually loading the SFP cooling pumps onto the standby generators and by aligning the SFP heat exchangers to receive essential cooling water.

Tables 6.3.3.5-3 and 6.3.3.5-4 contain matrices which summarize the utilization of safety systems as they appear in the LOCA analyses.

6.3.3.6 Radiological Consequences

Following a postulated double-ended rupture of a reactor coolant pipe with subsequent blowdown, the ECCS limits the clad temperature to well below the melting point and ensures that the reactor core remains intact and in a coolable geometry, minimizing the release of fission products to the containment.

a. Balance of plant systems.

b. See assumptions in paragraph 6.3.3.2.2.

c. Break is too large to use shutdown cooling.

d. Containment sprays are assumed to be actuated at 0.0 seconds.

However, a hypothetical accident involving a significant release of fission products to the containment is evaluated.

It is assumed that 100% of the noble gas and 50% of the iodine equilibrium core saturation fission product inventory are immediately released to the containment atmosphere (Source Tem is calculated using US-AEC-TID14844, Methodology(Reference 15)). Of the iodine released to the containment, 50% is assumed to plate out onto the internal surfaces of the containment or adhere to internal components per guidelines of Regulatory Guide 1.4. The remaining iodine and the noble gas activity are assumed to be immediately available for leakage from the containment.

The source terms and associated assumptions are itemized in table 6.3.3.6-1. The following specific assumptions were used in the analysis.

A. The reactor core equilibrium noble gas and iodine inventories are based on long-term operation at the ultimate core power level (102% of Licensed Power).

B. One hundred percent of the core equilibrium radioactive noble gas inventory is immediately available for leakage from the containment.

C. Fifty percent of the core equilibrium radioactive iodine inventory is immediately released to the containment atmosphere. Half is plated out onto the internal surfaces of the containment and the other half is available for leakage from the containment.

D. Of the iodine fission product inventory released to the containment, 91% is in the form of particulate iodine, and 4% is in the form of organic iodine.

The radioactive doses associated with these source terms are described in section 15.6.

6.3.3.7 Reload Cycle Evaluations

ECCS performance analyses of the limiting break size are performed for subsequent cycles on an as needed basis and verified as acceptable prior to unit operations. For future reloads the acceptability will be based upon the successful completion of the Reload Process Improvement (RPI) LOCA checklist.

6.3.4 TESTS AND INSPECTIONS

During fabrication of the safety injection system (SIS) components, tests and inspections are performed and documented in accordance with code requirements to assure high quality construction. As necessary, performance tests of components are performed in the vendor's facility. The SIS is designed and installed to permit inservice inspections and tests in accordance with ASME Code Section XI.

6.3.4.1 ECCS Performance Tests

Prior to initial plant startup, a comprehensive series of system flow tests, as detailed in section 14.2, were performed to verify that the design performance of the system and individual components is attained.

6.3.4.2 Reliability Tests and Inspections

6.3.4.2.1 System Level Tests

After the plant is brought into operation, periodic tests and inspections of the SIS components and subsystems are performed to ensure proper operation in the event of an accident. The

scheduled tests and inspections are necessary to verify system operability, since during normal plant operation, SIS components are aligned for emergency operation and serve no other function. The tests defined permit a complete checkout at the subsystem and component level during normal plant operation. Satisfactory operability of the complete system can be verified during normal scheduled refueling shutdown. The complete schedule of tests and inspections of the SIS is detailed in the Technical Specifications.

6.3.4.2.2 Component Testing

In addition to the system level tests described in paragraph 6.3.4.1, tests to verify proper operation of the SIS components are also conducted. These tests supplement the system level tests by verifying acceptable performance of each active component in the SIS. Pumps and automatic valves will be tested in accordance with ASME OM Code.

6.3.5 INSTRUMENT REQUIREMENTS

6.3.5.1 Design Criteria

The instruments and controls for the safety injection system (SIS) are designed in accordance with the applicable portions of IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations." The controls are interlocked to automatically provide the sequence of operations required to initiate SIS operation. The instrumentation and controls which actuate and control the SIS are designed on the following bases.

A. Redundant instruments are provided for initiation of SIS actions. Four sensors are used for each of the critical parameters. A trip from any two of these four sensors initiates the appropriate SIS action. Circuits are run in separate wiring raceways to assure the availability of safety injection actuation signals.

B. Electric power required for SIS controls and instruments is supplied via two preferred ac buses. Emergency generators provide an alternate source of power.

Actuator-operated valves are provided with key-operated control switches where considered necessary to prevent unintentional misalignment of safety injection flow paths during power operation.

All valves that are not required to operate on initiation of safety injection or recirculation in the safety injection flow path are locked in the safety injection position during operation. Administrative controls ensure that the valves are locked in the correct position.

A further discussion of the instrumentation and associated analog and logic channels employed for safety injection initiation is given in section 7.3.

6.3.5.2 System Actuation Signals

Operation of the safety injection system is controlled by two actuation signals. The first of these, the safety injection action signal (SIAS), initiates operation of the SIS in the event of low pressurizer pressure or high containment pressure. Both of these parameters provide an indication of a LOCA which

requires operation of the SIS. SIAS may be manually initiated from the control room. The second control signal is the recirculation actuation signal (RAS). This signal changes the operation mode of the SIS from injection with suction from the refueling water tank to recirculation with suction from the containment sump. The RAS is initiated by low refueling water tank level. RAS occurs automatically, whether SIAS is initiated manually or automatically. Following the RAS, timely operator action is required to close the RWT isolation valves to prevent ingress of air in the ESF pump suction piping during switchover to recirculation. Changing from the injection mode of operation to recirculation permits continuous flow to the core when the RWT water supply is depleted.

6.3.5.2.1 Safety Injection Actuation Signal (SIAS)

Initiation of safety injection is derived from four independent pressurizer pressure sensors and four independent containment pressure sensors. Coincidence trip signals from two-out-of-four sensors for either parameter will automatically initiate safety injection. Automatic SIS operation is actuated at a pressurizer pressure of 1837 psia during power operation or a containment pressure of 3 psig. During startup and shutdown operations, a variable setpoint on the low pressurizer pressure is used. A further discussion of the SIAS is given in Section 7.3.

6.3.5.3 Instrumentation During Operation

The instrumentation provided for monitoring safety injection system components during SIS operation is discussed in this

section. See engineering drawings 01, 02, 03-M-SIP-001, -002 and -003 for instrumentation readout locations, and Figures 6.3-2A through 2J for component usage during the various modes.

The flows identified on Figures 6.3-2A through 6.3-2J are typical expected flows. See Section 6.3.5.3.5 for a description of the differences in HPSI hot leg injection orifices, Section 6.2.2.2 for Containment Spray pump flow and NPSH parameters, Table 6.3.2-1 for ECCS pump NPSH requirements and Section 6.3.3 for flow performance characteristics under typical accident conditions.

6.3.5.3.1 Temperature

A. Shutdown Cooling Suction and Injection Temperature

RTDs and a recorder on each low-pressure injection header are used to measure and record shutdown cooling water temperature as it enters and leaves the safety injection system. This readout is used to provide a measure of the overall system performance and provides information allowing the operator to adjust cooldown rate. The recorder is located for easy access in the control room on the operator's console. Indication is provided in the control room and the remote shutdown panel. See subsection 5.4.7.

6.3.5.3.2 Pressure

A. Safety Injection Tank Pressure

A wide range pressure transmitter mounted on each safety injection tank permits readings of each tank pressure in the control room.

6.3.5.3.3 Valve Position

A. Safety Injection Tank Isolation Valve Position

Valve position is indicated in the control room by redundant and diverse indicators. Indicator lights verify either the fully open or fully closed position, with an alarm if the valve is not fully open. In addition, continuous valve position monitoring indicates partially opened or partially closed valve position.

B. Shutdown Cooling System Valve Position

Valves that must be repositioned and valves used to control cooldown have position indication both inside the control room and at a location outside the control room.

C. Hot Leg Injection Valve Position

Hot leg injection valve position is indicated in the control room. Indicator lights verify either open or closed position. In addition, continuous valve position monitoring indicates partially opened or partially closed position.

D. LPSI Header Isolation Valve Position

Valve position is indicated both inside the control room and at a location outside the control room.

E. HPSI Header Isolation Valve Position

Valve position is indicated inside the control room.

6.3.5.3.4 Level

A. Safety Injection Tank Level

Water level for each safety injection tank is indicated in the control room throughout the complete tank volume, except for water above the upper level or below the lower level instruments taps. The instrument taps are 5 inches nominal below the upper tank tangent and 5 inches nominal above the lower tank tangent. Signal input for this indication is provided by a differential pressure transmitter.

6.3.5.3.5 Flow

A. Shutdown Cooling/LPSI Flow

A shutdown cooling/LPSI flow indicator indicates total shutdown cooling flow.

The flowmeter may also be used for backup flow rate data during safety injection and for testing the performance of the low pressure safety injection pumps. The flow rate is indicated in the control room and at the remote shutdown panel.

B. High Pressure Safety Injection Flow

These flow channels indicate the flow rate in each of the four high pressure safety injection lines to the cold legs and each of the two lines to the hot legs. The flow elements for the flowmeters are located in such a manner that they serve both high pressure manifolds. The flowmeters are used to balance the high pressure safety injection flow rates in each of the lines. Readout is provided in the control room.

Note: On October 20, 1989, an error in the original installation of the flow measuring orifices in the "A" train HPSI pump hot leg injection lines and the use of inappropriate flow calibration curves during system testing was discovered.

The orifices installed in the "A" train HPSI pump hot leg injection line for each of the three Palo Verde units were larger in diameter than specified in the instrument data sheet. This resulted in the HPSI hot leg injection flow indication reading less than the actual flow during the performance of the simultaneous hot leg and cold leg injection testing required by Technical Specifications. Since the test was performed with the hot leg flow indicators reading lower than actual flow, the actual hot leg flows after correcting for the misinstalled orifices, were approximately 30 gpm higher than the indicated flow, thus exceeding the TS limit. A TS Change was submitted and approved in

Amendment 47 to Facility Operating License No. NPF-41 Safety Evaluation Report.

These orifices only provide flow indication and do not provide a flow control function.

6.3.5.4 Post-Accident Instrumentation

The instrumentation available for evaluation of post-accident performance is identified in subsection 6.3.2 and paragraph 7.5.1.1.5.

6.4 HABITABILITY SYSTEMS

The control room habitability systems include missile protection, radiation shielding, radiation monitoring, air filtration, and heating, ventilation, and air conditioning (HVAC) systems, lighting, personnel support, and fire protection equipment. (Refer also to section 3.1 for a discussion on conformance with NRC General Design Criterion 19.)

The HVAC equipment discussed in this section is also discussed in section 7.3 and subsection 9.4.1. This section addresses essential service requirements and the response and operation of control room HVAC equipment under emergency conditions. Other equipment and systems are described only as necessary to define their connection with control room habitability.

6.4.1 DESIGN BASES

Safety design bases for the habitability systems are:

A. Design Basis One

   The habitability systems shall provide coverage for the control room envelope defined in paragraph 6.4.2.1.

B. Design Basis Two

   The control room essential system shall be capable of maintaining the control room atmosphere within conditions suitable for prolonged occupancy throughout the duration of any of the postulated accidents discussed in chapter 15.

C. Design Basis Three

The control room essential ventilation and air conditioning system shall be capable of maintaining an environment suitable for sustained occupancy by six persons.

D. Design Basis Four

Food, water, medical supplies, and sanitary facilities shall be provided for sustained control room occupancy by six persons for 7 days.

E. Design Basis Five

The radiation exposure of control room personnel, through the duration of any of the postulated limiting faults discussed in chapter 15, shall not exceed the limits set by 10CFR50, Appendix A, General Design Criterion 19.

F. Design Basis Six

The habitability systems shall provide the capability to detect and protect control room personnel from smoke and airborne radioactivity.

G. Design Basis Seven

Respiratory, eye, and skin protection shall be provided for emergency use within areas of the control room envelope.

H. Design Basis Eight

The control room essential HVAC system shall be capable of automatic and manual transfer from its normal operating mode to the emergency or isolation modes.

I. Design Basis Nine

A single active failure of a component of the control room essential HVAC system, assuming a loss of offsite power, shall not impair the ability of the system to comply with the other design bases of this section.

J. Design Basis Ten

The control room essential HVAC system shall be designed to remain functional during and after a safe shutdown earthquake (SSE).

Air ducts and their supports shall be Seismic Category I.

The control room normal HVAC system is described in subsection 9.4.1.

Protection of the habitability systems in the control room from wind and tornado effects is discussed in section 3.3. Flood design is discussed in section 3.4. Missile protection is discussed in section 3.5. Protection against dynamic effects associated with the postulated rupture of piping is discussed in section 3.6. Environmental design is discussed in section 3.11. The fire protection system is discussed in subsection 9.5.1.

Codes and standards applicable to the control room emergency ventilation system are listed in table 3.2-1. The system is

consistent with the recommendations of Air Moving and Conditioning Association (AMCA) standards and NRC Regulatory Guide 1.52, except as noted in section 1.8.

6.4.2 SYSTEM DESIGN

6.4.2.1 Definition of the Control Room Envelope

The areas, equipment, and materials to which the control room operator could require access during an emergency are shown in figure 7.5-1. Those spaces requiring continuous or frequent operator occupancy are also shown in figure 7.5-1. Functional areas included on the control building's elevation 140 feet are: the satellite technical support center (STSC), the control room, the kitchen, and the sanitary facilities. A layout drawing and a description of shielding required to maintain habitability of the control room during the course of postulated accidents is provided in section 12.3.

Refer to subsection 18.III.D.3.4 for TMI-related information pertaining to "Control Room Habitability Requirements".

6.4.2.2 Ventilation System Design

6.4.2.2.1 General Description

Subsection 9.4.1 contains an overall description of the control room HVAC system. The system is shown schematically in engineering drawings 01, 02, 03-M-HJP-001, -002 and -003. Figure 6.4-1 shows the plant layout, including the location of potential radiological release points with respect to the control room air intakes. The closest distance between the containment and the air intakes is approximately 150 feet.

Elevation and plan drawings with descriptions providing building dimensions and locations are located in section 1.2. Potential sources of toxic gas releases are discussed in subsection 2.2.3.

The volume of the habitability zone served by the HVAC system in the emergency mode or the isolation mode is approximately 1.6×10^5 cubic feet.

Environmental design criteria for the air purification system are based on the most limiting conditions resulting from any of the postulated design basis accidents (DBAs) and on their duration in accordance with Regulatory Guide 1.52, as discussed in section 1.8. Two identical, physically separated high efficiency filtration trains with charcoal adsorbers are provided to process intake air flow and recirculated air flow in the control room. Components are listed in table 6.4-1. Section 1.8 presents the system design conformance to each position in Regulatory Guide 1.52. The seismic classifications of components, instrumentation, and ducting are given in table 3.2-1.

Table 6.4-1

ESSENTIAL CONTROL ROOM AIR HANDLING UNIT

COMPONENT DESCRIPTION

(Two Units Per Control Building)

High Efficiency Filter	
Flowrate, standard ft^3/min	28,600

Quantity	1
Fan	
Flowrate, standard ft^3/min	28,600
Quantity	1

Refer to subsection 18.III.D.3.4 for TMI-related information pertaining to "Control Room Habitability Requirements".

6.4.2.2.2 Component Description

The essential air handling unit contains a fan, a prefilter, a HEPA prefilter, an activated charcoal filter, a HEPA after-filter, and a cooling coil. Pneumatic-operated dampers are provided for system isolation purposes. Fans are located upstream of the HEPA filters and carbon adsorbers to ensure that air leakage is out of the essential supply system.

A. Filter Unit Housings

The filter unit housings are Seismic Category I and are made of carbon steel. Each housing is provided with a service access door, explosion-proof light, filter test connections, connections for pressure gauges, and drains. The housings are of all-welded construction.

B. Prefilter

A prefilter of the fiberglass pad type at the inlet to each filter train removes larger particulates from the air stream in order to limit the loading of the downstream HEPA filters.

C. HEPA Filters

HEPA filter elements are of pleated fiberglass with aluminum separator design, measure 24 x 24 x 11.5 inches, and are capable of handling a nominal flow-rate of 1000 cubic feet per minute each. The filter medium is cased in stainless steel, has face guards on both sides, and is water- and fire-resistant. HEPA filter elements are manufactured and tested prior to installation in accordance with MIL-F-51068, as

modified by NRC Health and Safety Information Issue 306. The filter element minimum acceptance criterion is removal of 99.97% of 0.3-micron, thermally generated monodisperse dioctylphthalate (DOP) particles.

D. Carbon Adsorbers

The carbon adsorbers for the essential air handling units are of the bulk type, 2 inches deep, and have an all-welded design.

Minimum air residence time in the carbon is 0.25 second at a nominal face velocity of 40 feet per minute. Approximately 4350 pounds of an 8 x 16 mesh impregnated-activated charcoal is used in each filter. This amount of carbon exceeds the amount needed to accommodate the iodine potentially released from the containment. The acceptance criteria for the carbon adsorbers include a requirement for greater than 95% removal of all particulates and iodines, respectively, at a controlled relative humidity of 70%. Carbon adsorbers are of rechargeable type.

E. Cooling Coil

The cooling coils are of nonferrous construction with copper fins mechanically bonded to seamless copper tubing. Coils are arranged for counter-flow operation using chilled water. The tube bundle is enclosed in a steel frame. Coils are arranged for horizontal air flow and are provided with inlet and outlet piping,

vent, and drain connections. The chilled water system is discussed in subsection 9.2.9.

F. Emergency Recirculation Train Fans

The emergency recirculation train fans are Seismic Category I and are capable of delivering 28,600 cubic feet per minute flowrate with all filters at their maximum anticipated pressure drop. Fans are chosen with a steeply rising pressure-flow characteristic to maintain a reasonably constant air flow over the full filter train life. Fan and motor materials are suitable for operation under the environmental conditions associated with the postulated DBA.

Refer to subsection 18.III.D.3.4 for TMI-related information pertaining to "Control Room Habitability Requirements".

G. Ductwork

The system ductwork and dampers are Seismic Category I. Ductwork is redundant where required to provide functional support to active components in meeting the single active failure criteria. Leaktight ductwork and isolation dampers are provided where required to isolate the system from unfiltered outside air.

In general conformance with Position C.4 of Regulatory Guide 1.52, accessibility and adequate working space for maintenance and testing operations are provided in the design and layout of the air purification system equipment.

H. Control Access Doors

To minimize inleakage, the control access doors are equipped with self-closing devices that shut the doors automatically following the passage of personnel. Two sets of doors with a corridor between, acting as an air lock, are provided at each of the two entrances to the control room and associated spaces.

I. Isolation Dampers

System isolation dampers are capable of automatically closing within approximately 50 seconds after receipt of an actuation signal, as verified by testing.

The isolation dampers, with a maximum area of approximately 12.2 square feet per damper are tested as bubble-tight dampers for zero leakage, as part of the manufacturer's test program.

Refer to subsection 18.III.D.3.4 for TMI-related information pertaining to "Control Room Habitability Requirements".

J. Radiation Detectors

Redundant radiation detectors are installed in the control room normal supply air duct. Each unit is responsive to gaseous activity at concentrations as low as 10^{-6} $\mu Ci/cm^3$ of Xe-133. The monitors are described in sections 7.3, 11.5.2.1.3.11, and table 11.5-1.

K. Breathing Apparatus

Self-contained portable breathing equipment sufficient for six individuals is stored within the habitability area of the control room, and provides at least 6 hours of breathable air. At least two spare units are provided to allow for equipment failures. The equipment selected shall be capable of being donned in 2 minutes or less. Operator training and equipment testing and maintenance shall be covered in the PVNGS Respiratory Protection Program which complies with Occupational Safety and Health Administration (OSHA) Regulations 29CFR1910.134.

L. Smoke detectors are provided to alert the control room operator to manually isolate the control room.

The remainder of the system; i.e., supply/recirculation fans, exhaust fans, ducting, and dampers are components that function during normal operation and are described in section 9.4.

6.4.2.3 Leaktightness

The exfiltration and infiltration analyses were performed using the methods and assumptions given in ASHRAE Handbook of Fundamentals-1977 Edition(1), Regulatory Guide 1.78, and ANSI N509-1976.

The leakage paths considered were ducting, piping, electrical penetrations, dampers, and doors.

Table 6.4-2 provides a listing of leakage data and total leakage rates for all leak paths. For analysis of exfiltration

from the pressurized control room envelope, a 1/4-inch water gauge (WG) pressure differential was considered for all leak paths resulting in a total outleakage of 1000 cubic feet per minute. The outside air supply is designed to pressurize the control room and is sized to deliver 1000 cubic feet per minute flowrate into the control room. Based on the rate of outleakage, this flowrate is adequate to maintain a 1/4-inch positive pressure in the control room envelope.

The sealing of doors, dampers, ducting, and penetrations was designed to be more effective in inhibiting inleakage to the control room envelope than outleakage.

6.4.2.4 Interaction With Other Zones and Pressure Contained Equipment

The outside air intake ducts are located such that:

- They are protected from the effects of a main steam line break.
- They minimize the introduction of airborne radioactive material from unit release points.
- They minimize the introduction of diesel generator exhaust and other noxious gases.

Table 6.4-2

CONTROL ROOM LEAKAGE RATES

Leak Path	Outleakage Rate At 1/4-inch WG. ft^3/min
Duct-piping: filter housing, and electrical penetrations	330
Dampers[a]	0
Doors	670
Total	1000

a. Considered bubbletight dampers at zero leakage.

The possibility of radioactive material, noxious gases, or steam to be transferred directly into the control room from adjacent areas and buildings other than through the outside air duct is improbable due to the following design arrangements and considerations:

A. The control room is at the 140-foot elevation. There are no piping penetrations into the building above the 140-foot elevation. The control room is maintained at 1/8 inch WG pressure above atmospheric to prevent infiltration of air. The volume of the control room and other space protected by the habitability system is 1.6×10^5 cubic feet. The outside air supply of 1000 cubic feet per minute will ensure pressurization of the area in excess of 1/8 inch WG so that all flow

of air through the potential leakage paths, doors, ductwork and filtration units, and cable penetrations is outwards and not inwards. The outside air intake is through the plenum system shown in engineering drawing 13-P-OOB-003. The inlet to the plenum is through louvered openings at the upper part of the building under the roof. The plenum system is designed as a Seismic Category I structure, which is an integral part of the building structure. The diesel building exhaust stack is situated such that effluent gases will not enter the control building outside air intake.

The essential HVAC system is inactive during normal operation and thus is not exposed to atmospheric dust.

The outside air supplied during emergency operation may carry airborne dust. The outside air intake filters are designed for an average dust loading of 1.78 mg/m^3 with an average maximum dust concentration period of 30 days. This dust loading is based on reference 4.

The two air intakes are located at the southeast and southwest corners of the control building.

B. The adjacent buildings to the control building are the radwaste, diesel generator, and auxiliary buildings. These buildings are maintained at a pressure slightly below atmospheric to prevent exfiltration of air. All normal releases from these buildings are exhausted

through an elevated stack. This precludes any direct transfer of contaminants to the control room intake.

C. The control room consists of two air spaces separated by a false ceiling. The upper air space contains cable penetrations (sealed) from the upper cable spreading room above, Seismic Category I duct hangers, Seismic Category I ceiling hangers, recessed light fixture enclosures (with power connections), and the Seismic Category I HVAC air ducts. There is no leakage path from any of these attachments or penetrations in the 8-inch floor slab of the cable spreading room above the control room. The suspended ceiling is not sealed from the lower air space containing the computer and control room equipment.

D. The floor of the control room contains sealed cable penetrations from the cable spreading area below the control room. There is, therefore, no leakage path from the lower cable spreading room through the control room floor into the control room.

E. There are two doorway entrances into the control room: from the corridor outside the control room or from the stairway running the full height of the building. Entrance to the corridor building is through the main entrance located between the turbine building and the diesel generator building. Outside entrance to the stairway is by a door located at ground level at the southeast corner of the control building. The door from the corridor into the control room and the door

from the alternate stairs into the control room are capable of being sealed from the external environment. The two entrances to the control room are each provided with two sets of doors acting as an air lock. The doors are provided with seals to reduce out-leakage and to secure the pressurization.

The path for entrance of radioactive material, noxious gases, or steam is so devious from the sources of such contamination to the access doors of the control room that this path is not credible. Even in the event of such potential entrance by this path, the control room doors would be sealed and the leakage past the seals would be insignificant.

F. The ductwork for the essential HVAC system for the control room under accident conditions is separated from connections to other areas or to the normal operating HVAC air handling or supply units by two Seismic Category I leaktight dampers independently actuated and powered by the two ESF trains. Air filters conforming to Regulatory Guide 1.52 are used for the makeup air supply to the essential HVAC system.

G. This section intentionally left blank.

H. Halon 1301 tanks are located at elevation 120 feet in the control building. These tanks provide fire protection capability for the communications and computer areas. A discussion of the design of the Halon fire protection systems relative to maintaining

the habitability of the control room is provided in subsection 9.5.1.

6.4.2.5 Shielding Design

The design basis loss-of-coolant accident (LOCA) dictates the shielding requirements for the control room. Control room shielding design bases are discussed in paragraph 12.3.2.2.7. Descriptions of the design basis LOCA source terms and control room shielding parameters, and evaluation of design basis accident doses to control room personnel are presented in section 15.6.

Drawings of the control room and its location in the plant, identifying distances and shielding with respect to each radiation source discussed in section 15.6. are shown in the radiation zone drawings in section 12.3.

6.4.3 SYSTEM OPERATIONAL PROCEDURES

6.4.3.1 Normal Mode

Control room HVAC system operation in the normal mode is described in subsection 9.4.1.

6.4.3.2 Essential Operation

In the event of a specified emergency signal such as a control room ventilation isolation actuation signal (CRVIAS), control room essential filtration actuation signal (CREFAS), safety injection actuation signal (SIAS), loss of offsite power (LOP), there will be automatic transfer to operation of the essential air handling units (AHUs). The tabulation below

shows the system response upon receipt of the indicated signals:

Signal	System Response
SIAS, LOP:	Receipt of either one of these signals will actuate both trains of the control room essential AHUs, ESF switchgear essential AHUs, and the battery room essential exhaust fans. Simultaneously, normal AHUs and battery room normal exhaust fans will automatically stop and isolation dampers will close. Bubbletight dampers will remain open to permit routing of the outside air chase to the control room essential AHUs.
CREFAS:	Receipt of this signal will activate the control room essential AHUs. Simultaneously, the control room normal AHU will automatically stop and isolation dampers will close. Bubbletight dampers will remain open to permit routing of the outside air from the outside air chase through the control room essential AHUs to the control room for pressurization to prevent infiltration of untreated air. However, these dampers will close in the event a CRVIAS signal is received subsequent to the CREFAS signal.
CRVIAS:	Receipt of this signal will activate the control room essential AHUs. Simultaneously, the control room normal AHU will automatically

stop and isolation dampers will close. Bubbletight dampers will close to isolate the control room and habitability areas at elevation 140 feet from the outside air.

After automatic actuation of both trains to emergency operation, one train may be manually stopped from the control room, while the other train continues to operate in the emergency mode. In the event of low-flow in the operating air conditioning train, low differential switches across the fans and air handling units will alarm the condition in the control room, so the other train can be manually actuated.

6.4.3.3 Isolation Mode

Isolation operation only applies to the control room complex when a CRVIAS signal is initiated. An alarm would sound in the control room upon detection of smoke in the outside air intake plenum from an external source. The control room essential air conditioning system may be placed into recirculation operation by manual actuation from the control room.

In recirculation operation, the control room air is continuously recirculated through one of the control room essential AHUs for cooling and filtration of radioactive particulates and radioiodine if present in the airstream. In this operating mode, when a CRVIAS signal is initiated, no outside air is introduced in the control room.

This operating mode is identical to emergency operation with the exception that the control room essential AHU is supplied with the air recirculated from the control room and no outside

air is introduced. This is accomplished by closing the normally open outside air intake dampers HJA-M02, HJA-M03, HJB-M02, and HJB-M03, shown in engineering drawings 01, 02, 03-M-HJP-001, -002 and -003.

6.4.3.4 Smoke Removal Mode

The smoke removal from the control building will be performed by use of portable smoke removal equipment which will exhaust smoke to the outside. For the portable smoke removal equipment, fresh air will be obtained by opening outside doors in the stairwells, opening missile doors or opening doors of the corridor building. The existing smoke removal system in the control building can be used to remove the smoke. Only portable equipment, however, is relied upon for smoke removal capability. This smoke removal mode of the installed equipment can remove smoke from the individual floors of the control building by exhausting 21,000 cubic feet per minute of air directly to the atmosphere, while introducing outside air as makeup. This is accomplished by opening dampers between the floor and the smoke exhaust chase with a smoke-exhaust fan exhausting to the atmosphere. Purge air makeup dampers between the smoke purge outside air intake chase and the respective floor space are opened. Dampers are simultaneously closed in the supply and return ducts, isolating the floor from the rest of the air conditioning system. All dampers for smoke purging are operated from the control room.

6.4.4 DESIGN EVALUATIONS

6.4.4.1 Radiological Protection

The effects of potential radiological accidents are analyzed in chapter 15. The radiological protection afforded operators in the event of an accident is described in subsections 6.4.2, 12.3.2, 12.3.3, and 12.3.4, and in section 11.5.

6.4.4.2 Toxic Gas Protection

Chlorine is generated in electrolytic cells in the water reclamation facility. However, chlorine gas and other toxic gases are not stored or used onsite in quantities sufficient to necessitate control room protection, as required by Regulatory Guide 1.78. The analysis of potential offsite sources for toxic gases is presented in subsection 2.2.3.

6.4.4.3 Implementation of Design Bases

These evaluations are listed to correspond with the design bases of subsection 6.4.1.

A. Safety Evaluation One

   Control room habitability system components discussed in paragraph 6.4.2.2.2 are arranged in redundant safety-related ventilation trains, as shown in engineering drawings 01, 02, 03-M-HJP-001, -002 and -003. The location of components and ducting within the control room envelope ensures an adequate supply of filtered air to all areas requiring access.

B. Safety Evaluation Two

By using chilled water cooling coils and duct heaters, the control room essential air conditioning system maintains the temperature between 70F and 80F for the Control Room and other essential occupancy areas and the relative humidity below 50%. The control room pressure is maintained at least 1/8 inch WG above atmospheric pressure during emergency operation. The control room essential ventilation system maintains the same temperature and humidity conditions when operating in the isolation mode.

C. Safety Evaluation Three

The control room ventilation system is capable of removing sensible and latent heat loads of 957,528 Btu/h and 49,872 Btu/h, respectively, which includes consideration of equipment heat loads and minimum personnel occupancy requirements. Table 9.4-3 shows the installed HVAC equipment performance data and design details.

The transfer to essential or isolation operation mode does not create a hazard for CO^2 buildup. In case of emergency operation, there is a supply of outside air at a maximum of 1000 cubic feet per minute and the long-term equilibrium for CO^2 will remain below one part per thousand for up to 50-person occupancy. In case of isolation mode operation, where the control room is sealed, the critical level of 3% would be

reached at the following times for the various occupancies:

6 persons	26.2 days
12 persons	13.1 days
30 persons	5.2 days

There is no specific design capacity limit on the number of personnel permitted in the control room under normal operation.

D. Safety Evaluation Four

Food, water, medical supplies (including a potassium iodide drug supply), and sanitary facilities are provided for a minimum occupancy of six persons for 7 days. Storage locations provided ensure that the above supplies will not be contaminated as a result of postulated accidents.

The supply of food and water is sufficient for a prolonged occupancy since outside supplies can be provided within the 7-day interval.

Refer to subsection 18.III.D.3.4 for TMI-related information pertaining to "Control Room Habitability Requirements".

E. Safety Evaluation Five

The control room air purification system and shielding designs are based on the most limiting design basis assumptions contained in NRC Regulatory Guide 1.4.

Automatic transfer of the control room normal ventilation system to the essential system is accomplished upon receipt of a high radiation signal from the outside air intake duct detectors, receipt of LOP signal, receipt of a safety injection actuation signal, or receipt of a fuel building high radiation signal from the ESF actuation system. Transfer to the essential system also may be manually initiated from the control room. Refer to section 7.3 for a discussion of the actuation logic.

The airborne fission product source term in the reactor containment following the postulated LOCA is assumed to leak from the containment at a rate of 0.1% per day for the first 24 hours after the accident, and 0.05% per day thereafter. Mixing in the building wake, in which the control room and its ventilation intake are presumed to be immersed for the duration of the post-accident phase, is also assumed.

The concentration of radioactivity, which is postulated to surround the control room after the postulated accident, is evaluated as a function of the fission product decay constants, the containment spray system effectiveness, the containment leak rate, and the meteorology conditions in effect. The assessment of the amount of radioactivity within the control room takes into consideration the flowrate through the control room outside air intake, the effectiveness of the control room air purification system, the

radiological decay of fission products, and the exfiltration rate from the control room.

Air within the control room is recirculated continuously through the emergency air conditioning units, which contain high efficiency filters, HEPA prefilters, charcoal adsorbers, HEPA after filters, cooling coil, and fan, to control room temperature and airborne radioactivity. The outside air required for pressurization is mixed with the return air before it enters the filtration unit.

During the emergency mode of operation, the control room HVAC is designed to pressurize the control room to 1/4 inch WG pressure to prevent unfiltered in leakage.

The calculated doses as a result of a postulated LOCA are given in section 15.6.

Control room shielding design, based on the most limiting design basis LOCA fission product release, is discussed in section 12.3 and is evaluated in chapter 15. The evaluations in chapter 15 demonstrate that the radiation exposures to control room personnel originate from containment direct radiation, external cloud direct radiation, and containment airborne radioactivity sources. Total exposures resulting from DBAs are below the dose limits specified by General Design Criterion 19. The portion contributed by containment direct radiation and external cloud direct radiation is reduced to a small fraction of the total

by means of shielding. The potential for radiation streaming through the control room structure boundary penetrations was also considered in the above analysis.

F. Safety Evaluation Six

As discussed and evaluated in subsection 9.5.1, the use of noncombustible construction and heat and flame-resistant materials throughout the plant minimizes the likelihood of fire and consequential fouling of the control room atmosphere. Smoke detectors in the control building air intake header alarm in the control room. The air intake to the control room can then be manually isolated.

Emergency portable breathing apparatus is also provided for the control room operators, in accordance with Regulatory Guide 1.78, Position C13.

G. Safety Evaluation Seven

A supply of protective clothing, respirators, and self-contained breathing apparatus adequate for at least six persons is stored at specified locations within the control room envelope.

H. Safety Evaluation Eight

To protect against high airborne radioactivity inside the control room, the control room HVAC system is automatically transferred from the normal mode to the emergency mode of operation upon receipt of a CREFAS due to outside air intake high radiation signal.

Transfer of the system to emergency or isolation modes may also be initiated manually from the control room. Controls and instrumentation requirements are discussed in subsection 6.4.6.

I. Safety Evaluation Nine

The filtration and cooling functions of the control room HVAC system may be performed fully even if the capability of the system is reduced by a single active component failure within the system or its supporting systems. Should one recirculation air handling unit fail, the redundant train will provide the required cooling. Redundant supply and recirculation trains provide the required filtration should an excessive pressure drop develop across the other filter train. Normally open isolation dampers are arranged in series pairs so that the failure of one damper to shut upon transfer to the emergency mode will not result in a breach of isolation. There are two emergency diesel generators for each unit. If one of the emergency diesel generators fails to start and assume its load, the control room emergency ventilation system equipment powered by the other diesel will provide the required service.

A single failure analysis is provided in table 6.4-3.

J. Safety Evaluation Ten

The control room essential ventilation system and isolation dampers are designed in accordance with Seismic Category I requirements as specified in

section 3.2. The components (and supporting structures) of any system, equipment, or structure that is not Seismic Category I, and whose collapse could result in loss of a required function of the control room HVAC system through either impact or flooding, are analytically checked to determine that they will not collapse when subjected to seismic loading. The control room essential ventilation system is designed to function during and after an SSE.

Table 6.4-3

CONTROL ROOM ESSENTIAL HVAC SYSTEM SINGLE FAILURE ANALYSIS

Component	Failure Mode/Cause	Effects on System	Method of Detection	Inherent Compensating Provision
Fan	Fails to operate/ mechanical or electrical failure	Loss of one of the two redundant filter-cooling trains	Annunciated in control room	Two redundant loops provided. Either loop is capable of providing 100% of requirement.
Filter	Plugged/mechanical failure	Loss of one of the two redundant filter-cooling trains	Annunciated in control room	Two redundant loops provided. Either loop is capable of providing 100% of requirement.
Cooling Coil	Ruptured or plugged/ mechanical failure	Loss of cooling for one of the two redundant filter-cooling trains	Annunciated in control room	Two redundant loops provided. Either loop is capable of providing 100% of requirement.
Isolation damper	Fails to close/ mechanical or electrical failure	None	Indicated in control room	Redundant in series isolation dampers provided.
Radiation monitor	Fails to operate	None	Abnormal control room indication	Redundant monitor provided
Intake damper	Fails to open/ mechanical or electrical failure	Loss of one of the two redundant filter cooling trains	Indicated in control room	Two redundant loops provided. Either loop is capable of providing 100% of requirement.
One Class IE bus	Loss of power/ electrical failure	Loss of one of the two redundant filter cooling trains	Annunciated in control room	Two redundant loops provided. Either loop is capable of providing 100% of requirement.

6.4.5 TESTING AND INSPECTION

A detailed program of preoperational and postoperational testing requirements to assure continued system capability will be implemented prior to station operation as described in section 14.2. Emphasis is placed on tests and inspections essential to a determination that performance criteria and operational capability are achieved and maintained.

The control room isolation capability and the ability to process outside air through one of the two high efficiency filter trains will be tested periodically. The filtration trains will be tested periodically by standard methods in general conformance with Regulatory Guide 1.52, as noted in section 1.8.

High efficiency particulate air (HEPA) filter elements are tested individually prior to installation to verify an efficiency of 99.97% with a thermally generated monodisperse 0.3-micron DOP aerosol. HEPA filter banks are tested in-place prior to operation and periodically thereafter in conformance with ANSI N510, and complies with Position C.5.b of Regulatory Guide 1.52.

Impregnated, activated carbon is batch tested prior to loading into the adsorber section. Acceptance criteria are those described in Table 5.1 of ANSI N509-1980 version. The carbon adsorber section is filled with carbon in a manner to ensure a uniform packing density and to minimize dusting. The adsorber section is leak tested in conformance with ANSI N510 with a gaseous fluorocarbon prior to operation and periodically thereafter to verify less than 0.05% bypass. In addition, a

periodic laboratory test of a representative sample of the impregnated activated carbon is performed to verify iodine removal efficiencies in accordance with Position C.6 and Table 2 of Regulatory Guide 1.52 for the assigned decontamination efficiency and bed depth (refer to section 1.8).

Design and testing of filtration systems is consistent with the recommendations of NRC Regulatory Guide 1.52, Design, Testing, and Maintenance Criteria for Atmosphere Cleanup System Air Filtration and Adsorption Units of Light Water-Cooled Nuclear Power Plants, except as discussed in section 1.8.

Inservice testing of the control room essential HVAC system is conducted in accordance with the surveillance requirements specified in the Technical Specifications

Portable equipment such as air samplers, personnel dosimeters, and other radiation analysis equipment applicable to control room habitability is tested and inspected periodically as noted in section 12.5.

6.4.6 INSTRUMENTATION REQUIREMENT

The following indications are displayed in the control room: fan status, damper positions, room temperatures, and outside air intake radioactivity. Alarms indicate low fan differential pressure and outside air intake airborne radioactivity greater than 10^{-6} mCi/cm^3 (Xe-133). (Refer also to sections 7.3 and 7.5.)

Instrumentation required for actuation of the control room essential HVAC system is discussed in paragraph 6.4.2.2.2 and

section 7.3. System control logic diagram is shown in figure 7.3-5.

Details of the radiation monitors used to initiate CREFAS are given in sections 7.3 and 11.5. Information, including detector locations, type of radiation detected, detector type, range, and sensitivity, is given in table 11.5-1.

The instrumentation is designed as Seismic Category I. A description of initiating circuits logic interlocks and periodic testing requirements and redundancy of instrumentation relating to control room habitability appears in section 7.3.

6.4.7 BOUNDING SYSTEM UNFILTERED AIR INLEAKAGE FOR RADIOLOGICAL DESIGN

6.4.7.1 Design

The Palo Verde Nuclear Generating Station (PVNGS) Control Room (CR) is designed to meet GDC 19 of 10 CFR 50, Appendix A during all design basis events. This design basis complies with Regulatory Guide 1.4 and 10 CFR 50.34 (a)(1)(ii)(D) guidance for source term, release, and mitigation of consequences. This section of 10 CFR 50.34 supports 10 CFR 100, which regulates offsite dose.

Bounding radiological Leakage, as described here, includes all known and unknown sources of air leaking into the positively pressurized habitability boundary. This leakage includes, but is not limited to, ingress-egress, essential and normal HVAC system component leakage, habitability boundary "wall" leakage, and other system leakage into the pressurized envelope such as instrument air and nitrogen.

Key Essential System parameters used in radiological analysis: The following Essential HVAC (HJ) Parameters are critical to the determination of an integrated inleakage rate:

1. Maximum outside air supplied by essential system and filtered by a 2 inch (minimum depth) charcoal bed is 1000 SCFM.
2. Minimum air recirculation rate for the essential HVAC system is 25740 SCFM, filtered by 2 inch (minimum depth) charcoal filter beds.
3. The filtration units meet or exceed the Regulatory Guide 1.52 requirements with exceptions as stated in Section 1.8 of the PVNGS UFSAR.
4. Minimum pressure differential for the Control Room radiological boundary is 1/8 inch (gauge) of water.
5. Maximum (net) control room volume not to exceed 1.61E+5 ft^3.
6. 10 SCFM inleakage into the habitability envelope is a result of personnel ingress-egress (Standard Review Plan section 6.4).

6.4.7.2 Single Failure Applied to Control Room Habitability Analysis

For control room habitability analysis only, it has been assumed that both essential HJ trains would be actuated and one would be immediately turned off by control room operators. This is a conservative assumption since doubling the outside air supply would pressurize the control room envelope beyond

the minimum design delta P, thereby reducing inleakage into the envelope. For this reason, the single failure assumed that for this analysis is the same as is assumed for the postulated event. No credit has been taken in this analysis for the normal HVAC system. It is assumed that the normal HVAC system would perform in a manner that would not challenge the essential HVAC. If a DBE assumes a loss of power, it is assumed that components in nonessential systems would fail in "As Is" positions, with the exception of components that are designed to fail in safe positions.

6.4.7.3 Control Room Radiological Assessment

The control room dose for bounding unfiltered inleakage is evaluated for the following four limiting accidents:

1) LOCA, as described in section 15.6.5 and Appendix 15B.
2) CEA Ejection's, as discussion in section 15.4.8 and Appendix 15B.
3) RCP sheared shaft with pre-existing iodine spike in the reactor and a stuck open ADV, as discussed in section 15.3.4 and Appendix 15B.
4) A SGTR with a stuck open ADV and a pre-existing iodine spike to the secondary side, as described in section 15.6.3 and Appendix 15B. It has been determined that the Pre-accident Iodine Spike (PIS) dominates the Generated Iodine Spike (GIS).

Table 6.4.7-1[8]

Summary of Control Room Radiological Assessment

at 51[1] SCFM Inleakage

Event	Condition of fuel during the accident	Time, Event Start to Control Room Isolation (Damper Closed)[7] (Sec.)	Limiting organ (Thyroid) dose[2] in rem
LOCA[3]	100% fuel melt (Reg Guide 1.4 model)	52	18
CEA Ejection[4]	17% fuel experiences DNBR. Failed fuel peaking factor 1.77 (Reg Guide 1.77 model)	119	27
RCP Sheared Shaft with Stuck open ADV[5]	17% fuel experiences DNBR. Failed fuel peaking factor 1.72 (Reg Guide 1.77 model)	340	13
SGTR with Stuck open ADV[6]	Preaccident iodine spike; assume no failed fuel; RCS conc. 60 μCi/cc	300	18

1. 51 SCFM is the allowable inleakage and it applies to all events. This value is in addition to a 10 SCFM in leakage requirement for ingress-egress.
2. Whole body and Beta skin doses are within GDC 19 requirements and are not bounding for the inleakage calculation.
3. Bounds all Small Break LOCAs larger than 0.05 ft^2.
4. Bounds all Small Break LOCAs smaller than 0.05 ft^2 and Fuel Handling Accident.
5. This assessment bounds all events in which fuel would experience DNBR and the primary system maintains its integrity.
6. Bounds all events that would result in PIS or GIS such as Letdown line break. This event also bound GRS / LRS events as described in section 15.7.
7. Time from initiation of event to generation of either ESFAS or BOP ESFAS signal and closure of the Control Room damper.
8. Information is applicable for Control Room dose evaluations only and is not intended to reflect Chapter 15 Offsite Dose Analyses.

As can be seen in the table 6.4.7-1, the controlling accident is the CEA Ejection with stuck open ADV. This accident sets the upper bound on the unfiltered inleakage for the control room habitability system. These analyses assume 10-scfm inleakage for ingress–egress and 51-scfm inleakage from all other sources that may penetrate control room habitability boundary. In conclusion, radiological consequences to control room operators are within the limits of 10 CFR 50, Appendix A GDC 19 for all design bases events.

6.5 FISSION PRODUCT REMOVAL AND CONTROL SYSTEMS

6.5.1 ENGINEERED SAFETY FEATURE FILTER SYSTEMS

The engineered safety feature (ESF) filter systems consist of the control room ventilation filters and the fuel building filters. The effectiveness of these systems under postulated accident conditions is discussed in sections 15.6 and 15.7, respectively.

Non-ESF filter systems include the containment power access purge filters, the hydrogen purge filters, the auxiliary building exhaust filters, the waste gas decay tank filter, and the radwaste building exhaust filters. These systems are discussed in sections 9.4 and 11.3.

6.5.1.1 Design Bases

Engineered safety feature air handling units and filters for the control room and the fuel building are designed to accomplish the following:

A. (Control room system only)

   Ensure that the radiation exposures to operating personnel in the control room resulting from the hypothetical accidents discussed in chapter 15 are within the guideline values of 10CFR50, Appendix A, General Design Criterion 19.

B. (Fuel building system only)

   Ensure that the offsite radiation exposures and exposures to operating personnel in the control room are within the guideline values of 10CFR100 and

10CFR50, Appendix A, General Design Criterion 19, respectively. These exposures could result from either the postulated fuel handling accident discussed in subsections 15.7.1 and 15.7.2 or from equipment leakage due to post-LOCA coolant recirculation in the auxiliary building.

C. Ensure that failure of any component of any ESF train, assuming loss of offsite power, cannot impair the ability of either system to perform its safety function.

D. Remain intact and functional in the event of a safe shutdown earthquake (SSE).

E. Are consistent with the recommendations of Regulatory Guide 1.52 as discussed in sections 1.8 and 6.4.

The design bases employed for sizing the filters, fans, and associated ductwork are discussed in sections 6.4 and 9.4.

The design, equipment, and materials conform to the applicable requirements and recommendations of the guides, codes, and standards listed in section 3.2.

6.5.1.2 System Design

6.5.1.2.1 General System Description

The control room essential HVAC system is described in section 6.4. The fuel building essential HVAC, normal HVAC, and control room normal HVAC systems are described in section 9.4. Flow diagrams for all systems are provided in section 9.4.

6.5.1.2.2 Component Description

Each ESF filter train consists of a prefilter, a high efficiency particulate air (HEPA) filter, a charcoal adsorber, and a downstream HEPA filter. The filtration trains are connected to heating coils, axial fans with direct drive motors, associated ductwork, and controls. Specific component design parameters are provided in table 6.5-1. The design meets the recommendations of Regulatory Guide 1.52 to the extent described in section 1.8.

The filter housing design provides adequate space for filter maintenance and inspection. The housing is fitted with the necessary ports for testing. Pipe, cable, and conduit penetrations are sealed to minimize leakage. Access doors are marine-type bulkhead doors with gastight seals and double-pin hinges.

The charcoal adsorber portion of each filter train is provided with a fire detection system and a water spray system to allow flooding of the charcoal bed in the event of bed ignition.

6.5.1.3 Design Evaluation

The following design evaluations are written to correspond to the design bases of paragraph 6.5.1.1.

A. The performance capability of the control room essential filtration is discussed in section 6.4. The design of individual components, which ensure the capability to perform the safety function, is also discussed in section 6.4. Control room doses

resulting from postulated radiological accidents are given in section 15.6. These doses are within the guideline values of 10CFR50, Appendix A, General Design Criterion 19.

B. Component descriptions and safety evaluation for the fuel building essential filtration units are provided in section 9.4. Dose analyses of postulated fuel handling accidents are discussed in subsection 15.7.2. Dose analyses of the exposure to recirculation leakage post-LOCA are discussed in section 15.6. Offsite radiation exposures and control room doses resulting from these accidents are shown to be within the guideline values of 10CFR100 and 10CFR50, Appendix A, General Design Criterion 19, respectively.

C. The control room ventilation system and the fuel building ventilation system each have two independent and redundant filtration trains. Should any component in one train fail, filtration can be performed by the other train which is powered from a separate Class 1E electrical bus. Failure modes and effects analyses are provided in paragraphs 6.4.4.3, 9.4.2.2, and 9.4.5.2.

D. The ESF filter systems are designed to Seismic Category I requirements, as specified in section 3.2.

E. The ESF filter systems were designed and constructed to be consistent with the recommendations of Regulatory Guide 1.52, as discussed in section 1.8.

Table 6.5-1
ESF FILTER SYSTEM DESIGN PARAMETERS

Component	Units Installed	Units Required for Operation	Unit Capacity
Control room essential ventilation system			
Essential air handling units	2	1	
Fans per unit	1	1	
Capacity, ft^3/min			28,600
Allowed pressure drop across filters, in. WG			4.8
Motor, hp			125
Prefilter banks per unit	1	1	
Capacity, ft^3/min			28,600
HEPA filter banks per unit	2	2	
Capacity, ft^3/min			28,600
Charcoal filter backs per unit	1	1	
Capacity, ft^3/min			28,600
Fuel building essential ventilation system			
Essential air handling units	2	1	
Fans per unit	1	1	
Capacity, ft^3/min			6,000
Allowed pressure drop across filters, in. WG			5.2
Motor, hp			40
Prefilter banks per unit	1	1	
Capacity, ft^3/min			6,000
HEPA filter banks per unit	2	2	
Capacity, ft^3/min			6,000
Charcoal filter banks per unit	1	1	
Capacity, ft^3/min			6,000

6.5.1.4 Tests and Inspections

6.5.1.4.1 Preoperational Testing

High efficiency particulate air filters are manufactured and tested prior to installation in accordance with MIL-F-51068C as modified by NRC Health and Safety Information Issue 306. High efficiency particulate air filter banks are tested in-place prior to operation to verify efficiency of at least 99.95% with a cold generated polydisperse 0.7 micron DOP aerosol.

Impregnated, activated carbon is batch tested prior to loading into the adsorber bed. Acceptance criteria are those described in ANSI N509-1980, "Nuclear Power Plant Air Cleaning Units and Components." Tests include particle size distribution, hardness, density, moisture content, pH of water extract, ash content, ignition temperature, and elemental iodine and methyl iodine removal efficiencies at postulated accident conditions.

The charcoal adsorber is Freon leak tested prior to operation to verify less than 0.05% bypass. In addition, a laboratory test of a representative sample of the impregnated activated charcoal is performed to verify iodine removal efficiencies. Pre-operational testing is performed on systems in accordance with the test descriptions in section 14.2.

6.5.1.4.2 Inservice Testing

Inservice testing of the ESF filtration systems is conducted in accordance with the surveillance requirements of the Technical Specifications.

6.5.1.4.3 General Testing

Design and testing of ESF filtration systems is consistent with the recommendations of NRC Regulatory Guide 1.52, Design, Testing and Maintenance Criteria for Atmosphere Cleanup System Air Filtration and Adsorption Units of Light Water-Cooled Nuclear Power Plants, as discussed in section 1.8.

6.5.1.5 Instrumentation Requirements

Controls and instrumentation for the control room and for the fuel building systems are discussed in section 7.3. Each system is designed to function automatically upon receipt of an ESF actuation system signal. Fans can also be controlled from the control room.

The status of the essential ventilation equipment is displayed in the control room during both normal and accident operations.

Section 1.8 addresses the extent to which the recommendations of NRC Regulatory Guide 1.52 are followed with respect to instrumentation.

6.5.1.6 Materials

The materials of construction used in or on the filter systems are given in paragraphs 6.4.2.2 and 9.4.5.2. Each of the materials is compatible with the normal and accident environments postulated in the control room and the fuel building.

Accident environments (i.e., extreme temperature or radiation) that could potentially produce radiolytic or pyrolytic decomposition of filter materials are not applicable to the control room or fuel building. Thus, filter system decomposition products will not be present.

6.5.2 CONTAINMENT SPRAY SYSTEMS

6.5.2.1 Design Bases

Credit for the iodine removal capability is discussed in paragraph 6.5.2.3. This credit, due to system performance, is used to meet the requirements of 10CFR100 for the design basis accidents presented in chapter 15.

6.5.2.2 System Design (for Fission Product Removal)

The spray header arrangement is shown in engineering drawings 13-P-ZCG-114, -118 and -120.

Regions within the containment can be shielded from direct spray by flooring, missile shielding, and equipment. The PVNGS containment design limits these unsprayed regions to approximately 6% of the containment volume. Most of the containment volume receives direct spray coverage from the primary spray headers (located above the operating floor), although some of the containment volume receives direct spray coverage from auxiliary headers (located below the 120-foot and 140-foot levels under concrete slabs on the eastern end of the refueling pool). These volumes that are sprayed by the auxiliary headers receive at least the same spray flowrate per

unit volume of gas space (gallons per minute per cubic foot) as the volumes which are sprayed by the primary spray headers. Detailed plans and sections of the containment which illustrate the unsprayed regions are given in figures 6.5-1 through 6.5-6. Table 6.5-2 lists the unsprayed regions by volume above elevation 100 feet. Except for the steam generator compartment, areas below elevation 100 feet are not sprayed. The gross containment volume above elevation 100 feet is 2.72×10^6 cubic feet. Therefore, the sprayed containment volume above elevation 100 feet is 2.45×10^6 cubic feet. The sprayed volume below elevation 100 feet of the steam generator compartment is 2.05×10^4 cubic feet. Thus, the total containment sprayed volume is 2.47×10^6 cubic feet. As the containment net free volume is 2.62×10^6 cubic feet, only 6% of the net free volume is unsprayed.

The containment spray nozzles are attached to and become part of the spray headers. The spray nozzles serve to disperse the spray solution throughout the containment in droplets to increase the heat transfer surface. The nozzles and headers are oriented to ensure maximum effective coverage of the containment volume. The spray nozzles are of the non-clogging type. The nozzles attached to the primary headers in the upper portion of containment are designed to pass 3/8 inch diameter particles. The nozzles attached to the auxiliary headers in the lower portion of containment are designed to pass 3/16 inch diameter particles. The design of the spray nozzles is sufficient to prevent clogging from debris entering the recirculation system through the sump screens since the spray

nozzle openings are larger than the containment sump screen openings.

6.5.2.3 Design Evaluation

The effectiveness of the containment spray system in removing radio-iodine is evaluated separately for the two sprayed regions described in paragraph 6.5.2.2. The containment spray system with no chemical additive is considered to be effective in removing only elemental and particulate forms of iodine. The elemental and particulate iodine removal coefficients are listed in Table 15.6.5-2.

In addition to the iodine removal mechanism provided by the containment spray system, iodine is also removed from the containment atmosphere as a result of plateout on containment surfaces. This phenomenon is not a function of containment spray system performance and therefore occurs in the unsprayed region as well as in the sprayed region. The significant difference in the surface area/volume ratio between the upper and lower containment regions was accounted for in the plateout model. Plateout removal coefficients are listed in Table 15.6.5-2.

Although the spray removal mechanism is not effective in the unsprayed region, iodine removal from the unsprayed region is enhanced by mixing of the sprayed and unsprayed region air volumes. This occurs as a result of diffusion as well as general bulk transfer between regions due to such factors as break location, natural convection, and steam condensation by

containment spray. Of these mechanisms, only the bulk mass transfer between the sprayed and unsprayed regions due to steam concentration is used in the evaluation of the reduction of iodine concentration within the unsprayed region.

For a containment with the majority of the mass and energy releases occurring below the operating level and the majority of the steam condensation occurring in the sprayed region above the operating level, flow is induced from below to above the operating level at a rate equivalent to the steam condensation rate. The mean volumetric exchange rate of the region below the operating level is calculated as follows:

The heat removal capacity of one spray train is related to a condensed mass of steam in the sprayed volume. The volume contraction of this condensing steam mass will induce an equivalent volume of steam from available mass sources which can be identified as being below the operating level. It is seen that the minimum volume contraction occurs at the highest temperatures in spite of the maximum mass condensation which is experienced at that time. This is due to the effect of containment pressure on the specific volume of steam.

Accordingly, a very conservative containment temperature of 300F is chosen. Makeup sources are assumed to be concentrated in the lower 25% of the containment volume for the purpose of fixing the induced makeup rate.

This approach predicts approximately 3.3 unsprayed volume changes per hour. This mixing rate is then applied to the unsprayed volumes and is used in conjunction with the spray λ

to determine doses. In summary, the assumptions underlying the calculation of mixing rates are as follows:

A. Of the several mechanisms causing containment mixing, credit is taken only for a volume contraction in the sprayed region due to the condensation of steam in that region.

B. One spray train is in operation.

C. Maximum RWT temperature of 120F is used to calculate heat removal.

D. Steam condensed in the sprayed volume is replaced by an equal volume of steam from available mass/energy sources.

E. Pressure differentials between compartments are insignificant.

F. Loss-of-coolant accident mass/energy sources are identified as being below the operating floor, or approximately the lower 25% of the containment volume.

G. Sprayed and unsprayed volumes each are homogeneous in terms of concentrations and distribution of mass/energy sources.

Table 6.5-2

UNSPRAYED REGIONS INSIDE CONTAINMENT ABOVE ELEVATION 100 FEET

Region	Unsprayed Volume (cubic feet)
Pressurizer compartment	2.87×10^4
Pressurizer valve gallery	7.34×10^3
Safety injection tanks (4)	1.22×10^4
Steam generators (2)	3.06×10^4
Reactor coolant pumps (4)	9.6×10^3
HVAC ducting	2.30×10^4
Elevator and regenerative HX compartments	1.16×10^4
Miscellaneous equipment	1.81×10^4
Steam line support	5.28×10^3
Primary and secondary shield walls	7.83×10^4
Refueling pool walls	3.19×10^4
Refueling canal floor	1.23×10^4
Total	2.50×10^5

The PVNGS design utilizes 230 Spraco 17071417 (15.2 gallons per minute) spray nozzles in each train of the primary spray headers. Spraco 17071417 spray nozzle performance data are provided in appendix 6A, figures 6A-1, 6A-2, and 6A-3 (see appendix 6A, Question 6A.11). It also uses 80 Spraco 17651308 (3 gallons per minute) nozzles in each train of the auxiliary spray headers.

6.5.2.4 Tests and Inspection

Preoperational testing is performed on the system in accordance with the test description in section 14.2. Periodic testing is performed in accordance with the requirements of the Technical Specifications.

6.5.2.5 Instrumentation Requirements

The containment spray system is provided with instrumentation and controls as described in section 6.2.2.5.

6.5.2.6 Materials

Refer to section 6.2 for a description of the material of the containment spray system and their compatibility with the containment sump solution.

6.5.2.7 CESSAR Interface Requirements

A. CONTAINMENT SPRAY SYSTEM

The following interface criteria are repeated from Section 7.0 of CESSAR Appendix 6A.

(A)7.0 INTERFACE REQUIREMENTS

(A)7.1 POWER

(A)7.1.1 The containment spray system pumps, valves, and instrumentation shall be capable of being powered from the plant turbine generator (onsite power source), plant startup power source (offsite

power), and the emergency generators (emergency power).

(A)7.1.2 Power connections shall be through a minimum of two independent buses so that in the event of a LOCA in conjunction with a single failure in the electrical supply, the flow from one containment spray train shall be available for containment heat removal.

(A)7.1.3 Each electrical bus of the above shall be connected to one containment spray pump and associated valves and instrumentation.

(A)7.1.4 Each emergency generator and the automatic sequencers necessary for generator loading shall be designed such that flow to the containment atmosphere is attained within a maximum of 58 seconds after a CSAS, as described in Section 6.3.

(A)7.1.5 Instrument power supplies shall be provided as stated in CESSAR Section 8.3.1.

(A)7.2 PROTECTION FROM NATURAL PHENOMENA

Design provisions shall be incorporated such that CSS components are capable of functioning in the event of the maximum probable flood or other natural phenomenon defined in GDC 2.

(A)7.3 PROTECTION FROM PIPE FAILURE

(A)7.3.1 The maximum expected leakage from a moderate energy pipe rupture postulated during normal plant conditions in the containment spray system shall be as defined by the methods of CESSAR Section 3.6.1.

Isolation valves used to contain leakage shall be protected from the adverse effects of a high or moderate energy pipe rupture which might preclude their operation when required.

(A)7.3.2 No limited leakage passive failure or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, loss of NPSH, or loss of recirculation water inventory), in the CSS during the recirculation mode shall preclude the availability of minimum acceptable recirculation

capability (minimum acceptable capability is defined as that which is provided by the operation of one subsystem).

(A)7.3.3 The containment spray system shall be protected from the effects of pipe rupture.

(A)7.3.4 The containment spray system shall be protected from the effects of pipe whip.

(A)7.4 MISSILES

The containment spray system shall be protected from missiles.

(A)7.5 SEPARATION

(A)7.5.1 Adequate physical separation shall be maintained between the redundant piping paths and containment penetrations of the CSS such that the CSS will meet its functional requirements even with the failure of a single active component during the injection mode, or with a single active failure or a limited leakage passive failure during the recirculation mode.

(A)7.5.2 The cabling which is associated with redundant channels of vital Class 1E circuits for the CSS shall be physically

separated to preserve redundancy and prevent a single event from causing multiple channel malfunctions or interactions between channels. Associated circuit cabling from redundant channels shall either be separated, provided with isolation devices, or analyzed and/or tested to demonstrate that no credible single failure could adversely affect redundant channels of Class 1E circuits.

(A)7.5.3 In the routing of CSS Class 1E circuits and location of equipment served by these Class 1E circuits, consideration shall be given to their exposure to potential hazards such as postulated ruptures of piping, flammable material, flooding, and non-flame retardant wiring. Adequate separation or protective measures shall be provided.

(A)7.5.4 Failures of non-safety grade systems shall not compromise redundancy of the CSS.

(A)7.6 INDEPENDENCE

(A)7.6.1 Each CSS train shall be provided with an independent environmental control system.

(A)7.6.2 Power connections for CSS components shall be from a minimum of two independent electrical buses. See 7.1.2 above.

(A)7.6.3 Two independent vital instrument power sources shall be provided for the CSS instrumentation. See 7.1.5 above.

(A)7.6.4 Mechanical See 7.3, 7.4, and 7.5 above.

(A)7.7 <u>THERMAL LIMITATIONS</u>

Each CSS train shall be provided with an independent environmental control system such that the safety related equipment in each train operates within the environmental design limits specified in CESSAR Section 3.11.

(A)7.8 <u>MONITORING</u>

Provisions shall be made for the detection, containment, and isolation of the maximum expected leakage from a moderate energy pipe rupture in one train, as discussed in 7.3.1 above.

Process instrumentation shall be available to the operator in the control room to assist in assessing post-LOCA conditions. The type of instrument, parameter measured, instrument range and

accuracy are listed in Sections 6.1 and 6.2.

(A)7.9 OPERATIONAL AND CONTROLS

Refer to Section 7.1.

(A)7.10 INSPECTION AND TESTING

Inspection and testing requirements for the CSS are contained in Section 8.0 and in CESSAR Section 16. Prior to initial plant startup, CSS flow tests which comply with Section 9.0 shall be performed. An adequate supply of water and the necessary test connections at the containment sump and containment spray header piping penetrations shall be provided.

(A)7.11 CHEMISTRY AND SAMPLING

(A)7.11.1 The CSS shall be designed for the following fluid conditions:

Basic Fluid	Water
with: H_3B0_3	3.5 w/o

phosphate controlled pH of 10 max.

(A)7.11.2 SAMPLING

(A)7.11.2.1 The sampling system shall provide a means of obtaining remote liquid samples

from the CSS for chemical and radiochemical laboratory analysis.

(A)7.11.2.2 The sample lines in contact with the reactor coolant shall be austenitic stainless steel or equivalent, such that the material is compatible with the fluid chemistry.

(A)7.11.2.3 The fluid velocity in the sample lines should be selected to obtain representative samples. The purge flowrate should be high enough to remove crud from lines.

(A)7.11.2.4 Sample taps should be located on vertical runs of pipe whenever possible. Where this cannot be done, it is permissible to take samples from the top of horizontal pipe runs.

(A)7.12 MATERIALS

(A)7.12.1 CSS piping and fittings shall be Seismic Category I.

(A)7.12.2 Design and fabrication of the CSS piping and fittings shall conform to ASME Boiler and Pressure Vessel Code (B&PV) Section III, Class 2 as identified on CESSAR Section 6.3.1.

(A)7.12.3 Pipes and all parts in contact with the system fluid shall be of austenitic stainless steel. The stainless steel shall be type 316, type 304, or CE approved alternate. Selection of the type of stainless steel shall be on the basis of compatibility with design pressure and temperature considerations and with the chemistry of the fluid.

Valve packings, gaskets, and valve diaphragm materials shall also be compatible with the chemistry of the fluid and the radioactive dose at that location.

(A)7.12.4 Care shall be taken to prevent sensitization and to control the delta ferrite content of: (1) the welds which join any system fabricated of austenitic stainless steel to the CSS, and (2) the field welds on the CSS. The guidance of Regulatory Guides 1.44, "Control of the Use of Sensitized Stainless Steel" and 1.31, "Control of Ferrite Content in Stainless Steel Weld Metal" is relevant at these weld locations.

(A)7.12.5 Controls shall be exercised to assure that contaminants do not significantly

contribute to stress corrosion of stainless steel. Regulatory Guides 1.36, "Nonmetallic Thermal Insulation for Austenitic Stainless Steel", and 1.37, "Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water Cooled Nuclear Power Plants" are relevant for CSS components, and for all CSS field welds, including welds at the CSS boundaries.

(A)7.12.6 Materials used for the containment and its internal structures shall withstand exposure to all post-accident conditions without causing deleterious or undesirable reactions, or significantly altering the recirculating water chemistry.

(A)7.12.7 If the containment spray system utilizes a common suction with the SIS from the RWT or containment sump, then the materials used in this system shall be austenitic stainless steel, type 316 or 304, or other compatible material subject to approval by C-E, and shall conform to Section III Class 2, ASME B&PV Code.

(A)7.13 PHYSICAL ARRANGEMENT

(A)7.13.1 To assure that containment spray system flow requirements are met, the maximum and minimum acceptable head losses for the piping and fittings are presented in CESSAR Appendix 6A, Table 7.13. The required NPSH for the CS pumps are presented in UFSAR section 6.2.2.2.

(A)7.13.2 Flow measurement devices are provided on the containment spray pump discharge lines. The piping runs upstream and downstream of the flow measurement devices shall meet the recommendations of "ASME Fluid Meters: Their Theory and Application, Parts 1 and 2".

(A)7.13.3 For each spray train, the top of the piping junction between the RWT discharge and the containment sump must be located at a minimum of 16 feet below the minimum containment sump water level during recirculation. If containment pressure could be sub-atmospheric by values greater than 3 psig, this must be accommodated for by increasing the distance of the piping junction top below the minimum containment sump water

level during recirculation by 2.31 feet for each additional psig.

(A)7.13.4 Frictional losses in the CSS pump suction piping between the containment sump and the junction with the RWT shall not exceed 7 feet, unless the elevation of the top of this junction is lowered an additional foot for each additional foot of head loss.

(A)7.13.5 The CSS pumps shall be located in the auxiliary building as close as practicable to the containment structure.

(A)7.13.5.1 The elevation of these pumps shall be low enough such that adequate NPSH is available during the recirculation mode when the pumps take suction from the containment sump.

(A)7.13.5.2 The available NPSH shall be calculated at the pump impeller eye.

(A)7.13.5.3 The calculation of NPSH shall consider concurrent high pressure safety injection, low pressure safety injection and containment spray pump operation. Table 6.3.1.3-2 provides HPSI and LPSI pump head loss requirements. The

corresponding NPSH requirements are presented in UFSAR table 6.3.2-1. CS pump NPSH requirements are identified in UFSAR section 6.2.2.2. No credit shall be taken for sub-cooled water in the sump.

(A)7.13.5.4 Credit shall not be taken for water that could be trapped above the containment floor.

(A)7.13.6 In the event of a limited leakage passive failure in one CSS train during recirculation, personnel access to the intact train shall be possible.

(A)7.13.7 The two CSS check valves in each of the spray header lines shall be located as close as practicable to the containment penetration:

a. Allowance shall be made for valve accessibility and maintenance.

b. The total water volume in the spray header piping shall be kept to a minimum so that the delay time for spray of borated water will be a minimum.

(A)7.13.8 Manually-operated valves shall be provided with locking provisions as shown on P&ID's CESSAR Section 6.3.

(A)7.13.9 Physical identification of safety-related CSS equipment and cabling shall be provided to allow recognition of safety status by plant personnel.

(A)7.13.10 In the routing of CSS Class 1E circuits and location of equipment served by these Class 1E circuits, consideration shall be given to their exposure to potential hazards. See 7.5 above.

(A)7.13.11 The CSS containment penetrations shall not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of equipment or piping inside or outside the containment.

(A)7.13.12 Where required, bellows shall be provided between piping and the containment wall to prevent excessive forces on the piping.

(A)7.13.13 Each CS pump bypass flow line shall be capable of passing 150 gpm with its CS

pump operating at design operating conditions.

Note: This original interface requirement was prescribed to satisfy recirculation line allowable head loss and line sizing requirements at design operating conditions. This particular interface requirement does not establish the minimum (or maximum) recirculation flow rate. Minimum recirculation flow rates have been established by the CS pump vendor to provide adequate pump cooling at or near shut-off conditions and these requirements are documented in the respective Containment Spray pump vendor technical manual.

(A)7.13.14 The design of the CSS piping and spray headers shall consider the effects of water hammer. Fill and drain connections together with associated valves and instrumentation shall be provided if filling of the riser piping inside the containment is required to preclude the effects of water hammer.

The maximum spray header elevation above the RWT outlet nozzles shall not exceed 185 feet.

(A)7.13.15 The resistance of the RWT return lines shall be established so as to permit periodic testing of each spray pump at conditions as near to design (see Table 1) as practicable. For pre-operational testing, provisions should be made to provide full flow. For this test, the RWT return line or an alternate may be used.

(A)7.13.16 All CSS ASME, Section III components shall be arranged to provide adequate clearances to permit inservice inspection. The design of the arrangement should conform to the guidelines of Section XI of the ASME Code. Manually-operated valves which contain reactor coolant or other potentially radioactive liquids during normal plant operations, shall be provided with hand wheel extensions and shielding, to allow periodic actuation as per ASME Section XI, Subsection IWV. Appropriate ALARA practices shall be followed during the periodic pressure tests and nondestructive examinations of the containment spray system.

Access to system components not designed to ASME, Section III should be provided for periodic visual inspection for leak age, structural distress and corrosion.

(A)7.13.17 Protection shall be provided from internally generated flooding that could prevent performance of safety-related functions.

(A)7.14 RADIOLOGICAL WASTE COLLECTION

Containment spray system leakage to the safeguards room will normally drain to the room sump. Provisions shall be provided to accept the maximum leakage rates listed below:

a. CSS pump seals: 100 cc/hr/pump

b. Valves

backseat leakage:	10 cc/hr/inch seat diameter/valve
across the valve seat:	10 cc/hr/inch of nominal valve size/valve

All leakages shall be treated as radioactive waste with a low dissolved solids and organic content.

(A)7.15 OVERPRESSURE PROTECTION

Relief valves shall be provided for overpressure protection.

(A)7.16 RELATED SERVICES

(A)7.16.1 REFUELING WATER TANK

The RWT will have 100% of the capacity required to operate the CSS pumps at a flow of 4,400 gpm/pump for the required minimum injection period of 20 minutes in addition to the requirements of other systems.

The maximum particle size in the water exiting from the RWT shall be 0.09 inch in diameter in order to preclude flow blockage in engineered safety features components and piping and in the reactor.

The contents of both the RWT and piping associated with the CSS must be maintained at a minimum temperature of 60F to preclude possible boron precipitation.

(A)7.16.2 CONTAINMENT SPRAY SUMP

The containment sump shall be designed to comply with Regulatory Guide 1.82, "Sumps for Emergency Core Cooling and

Containment Spray Systems" requirements. Baffles and intake screens shall be installed to limit the maximum particle size entering the recirculation piping to 0.09 in diameter in order to prevent flow blockage in the engineered safety features components and piping and in the reactor. The sump intakes shall be designed so as to preclude the entrainment of air and/or steam into the sump suction lines. The pressure drop across the baffles and intake screens shall be sufficiently low to provide the NPSH required by the containment spray pumps. The post-LOCA sump pH shall be raised to a minimum of 7.0 within 4 hours post-accident. The maximum long-term pH shall not exceed 8.5.

(A)7.16.3 SHUTDOWN COOLING HEAT EXCHANGER

Cooling water shall be provided to each shutdown cooling heat exchanger to transfer heat from the sump fluid during the recirculation mode.

The cooling water supplied to each shutdown cooling heat exchanger shall be provided at a flowrate of 11,000 gpm.

Cooling water flow shall be established to the shutdown cooling heat exchanger prior to or simultaneously with the start of recirculation.

The cooling water temperature to the inlet of the heat exchangers shall be within the limits of 65-120F during a LOCA.

(A)7.16.4 FIRE PROTECTION

A fire protection system shall be provided to protect the containment spray system consistent with the requirements of GDC 3, and shall include, as a minimum, the following features:

a. Facilities for fire detection and alarming.

b. Facilities or methods to minimize the probability of fire and its associated effects.

c. Facilities for fire extinguishment.

d. Methods of fire prevention such as use of fire resistant and noncombustible materials whenever practical, and minimizing exposure

of combustible materials to fire hazards.

e. Assurance that fire protection systems do not adversely affect the functional and structural integrity of safety-related structures, systems, and components.

f. Care should be exercised to ensure fire protection systems are designed to assure that their rupture or inadvertent operation does not significantly impair the capability of safety-related structures, systems, and components.

(A)7.17 ENVIRONMENTAL

See Section 7.7 for environmental interfaces.

(A)7.18 MECHANICAL INTERACTION

(A)7.18.1 CSS components shall be properly supported such that pipe stresses and support reactions are within allowable limits, as defined in CESSAR Section 3.9.2. C-E provides the applicant with the loads at the support/structure

interface locations for components that C-E supplies, under normal, upset, emergency, faulted, and test conditions.

(A)7.18.2 CSS piping and fittings shall be Seismic Category I.

B. IODINE REMOVAL SYSTEM (Abandoned in Place)

6.5.2.8 CESSAR Interface Evaluations

The numbering of this interface section corresponds to that used for the presentation of interface requirements in CESSAR Appendices 6A and 6B. An R prefaces the numbering to denote that these are the responses to paragraph 6.5.2.7. Refer to appendix 6A, Question 6A.42, for additional discussion.

A. INTERFACE EVALUATION FOR CONTAINMENT SPRAY SYSTEM

(RA)7.1 POWER

(RA)7.1.1 The containment spray pumps, valves, and associated instrumentation can be powered from two power sources: preferred offsite power or the emergency diesel generators. For more details, see chapter 8.

(RA)7.1.2 Two independent power trains are provided, one for each train of containment spray pump, valves, and associated instrumentation.

(RA)7.1.3 See (RA)7.1.2.

(RA)7.1.4 The full containment spray flow can be attained within 90 seconds after a CSAS. Refer to section 1.9.

(RA)7.1.5 Instrument power supplies are provided as stated in Section 8.3.1.

(RA)7.2 PROTECTION FROM NATURAL PHENOMENA

Design provisions for maintaining functional capability of the safety—related systems during a flood, earthquake, tornado, or high winds as defined in GDC 2 are discussed in subsection 3.1.2.

The containment spray system is located within Seismic Category I structures. The protection of Seismic Category I structures against natural phenomena is presented in sections 3.3 and 3.4.

(RA)7.3.1 PROTECTION FROM PIPE FAILURE

The maximum leakage from a moderate energy pipe rupture of the containment spray system postulated during normal plant conditions is as defined by the methods of subsection 3.6.2.

Isolation valves (system and/or containment) used to contain leakage will be protected from the adverse effects of a

pipe failure which might preclude their operation when required.

(RA)7.3.2 No limited leakage passive failure or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, loss of NPSH, or loss of recirculation water inventory), in the CSS during the recirculation mode will preclude the availability of minimum acceptable recirculation capability. Minimum acceptable capability is defined as that which is provided by the operation of one train.

(RA)7.3.3 The containment spray system, both inside and outside containment, will be protected from the effects of pipe rupture whenever the spray system is required to mitigate the effect of the break.

(RA)7.3.4 The containment spray system will be protected from the effects of pipe whip whenever the spray system is required to mitigate the effect of the break.

(RA)7.4 <u>MISSILES</u>

Design provisions for protecting the CSS from missiles inside the containment are discussed in section 3.5.

Design provisions for protecting the CSS from missiles outside the containment are discussed in section 3.5.

Appropriate design procedures which ensure that the impact of any potential missile does not prevent the conduct or maintenance of a safe plant shutdown are discussed in section 3.5.

(RA)7.5 SEPARATION

(RA)7.5.1 Adequate physical separation is maintained between the redundant piping paths and containment penetrations of the CSS such that the CSS will meet its functional requirements even with the failure of a single active component during the injection mode, or with a single active failure or a limited leakage passive failure during the recirculation mode.

The protection of safety systems inside and outside containment is discussed in section 3.6.

(RA)7.5.2 The cabling that is associated with redundant channels of vital Class 1E circuits for the CSS is physically separated to preserve redundancy and prevent a single event from causing

multiple channel malfunctions or interactions between channels. Associated circuit cabling from redundant channels is either separated, provided with isolation devices, or analyzed and/or tested to demonstrate that no credible single failure could adversely affect redundant channels of Class 1E circuits.

(RA)7.5.3 In the routing of CSS Class 1E circuits and location of equipment served by these Class 1E circuits, consideration is given to their exposure to potential hazards such as postulated ruptures of piping, flammable material, flooding, and non-flame retardant wiring. Adequate separation or protective measures are provided.

(RA)7.5.4 Failure of non-safety grade systems does not compromise redundancy of the CSS.

(RA)7.6 <u>INDEPENDENCE</u>

(RA)7.6.1 Each CSS train is provided with an independent environmental control system.

(RA)7.6.2 Power connections to each CSS train are from independent electrical buses.

(RA)7.6.3 Instrumentation in each train of CSS is powered by an independent power source.

(RA)7.6.4 For mechanical independence, see (RA)7.3, (RA)7.4, and (RA)7.5.

(RA)7.7 THERMAL LIMITATIONS

Each CSS train is provided with an independent environmental control system, such that the safety-related equipment in each train operates within the environmental design limits specified in Section 3.11.

(RA)7.8 MONITORING

Provisions are made for detection, containment, and isolation of the maximum expected leakage from a moderate energy pipe rupture in each train.

Redundant pressure, temperature, and flow instrumentation as described in Table 1.8-1 is available to the operator in the control room to assist in assessing post-LOCA conditions.

(RA)7.9 OPERATIONAL AND CONTROLS

See (RA)7.1.

(RA)7.10 INSPECTION AND TESTING

For inspection and testing, see the Technical Specifications.

In addition, prior to initial plant startup, the CSS system will be tested in accordance with section 14.2.

(RA)7.11 CHEMISTRY AND SAMPLING

(RA)7.11.1 The CSS is designed for the following fluid conditions:

Basic fluid:	Water
with H_3BO_3:	3.5 w/o

Trisodium phosphate controlled pH of 7 to 8.5 maximum.

(RA)7.11.2 SAMPLING

(RA)7.11.2.1 The nuclear sampling system (NSS) is designed to provide a means of obtaining remote liquid samples from the CSS for chemical and radiochemical laboratory analysis.

(RA)7.11.2.2 The sample lines in contact with the reactor coolant are fabricated of austenitic stainless steel.

(RA)7.11.2.3 The fluid velocity in the sample lines is designed to obtain representative samples. The purge flowrate is high enough to remove crud from lines.

(RA)7.11.2.4 Sample taps are located on vertical runs of pipe whenever possible. Where this cannot

be done, the samples are taken from the top of horizontal pipe runs.

(RA)7.12 MATERIALS

(RA)7.12.1 Containment spray system piping and fittings are Seismic Category I.

(RA)7.12.2 Design and fabrication of the CSS piping and fittings conform to ASME Boiler and Pressure Vessel (B&PV) Code, Section III, Class 2, as identified in Section 6.3.1.

(RA)7.12.3 Materials in contact with the system fluid are fabricated of austenitic stainless steel of type 316, type 304, or C-E approved alternate. Selection of the type of stainless steel is based on compatibility with design pressure and temperature considerations and with the chemistry of the fluid.

Valve packings, gaskets, and valve diaphragm materials are also compatible with the chemistry of the fluid and the radiation dose at that location.

(RA)7.12.4 Care is taken to prevent sensitization and to control the delta ferrite content of (1) the welds which join any system fabricated of austenitic stainless steel to the CSS, and (2) the field welds on the CSS. The

guidance of Regulatory Guides 1.44, Control of the Use of Sensitized Stainless Steel, and 1.31, Control of Ferrite Content in Stainless Steel Weld Metal, is relevant at these weld locations (refer to section 1.8).

(RA)7.12.5 Controls are exercised to assure that contaminants do not significantly contribute to stress corrosion of stainless steel. Regulatory Guides 1.36, Nonmetallic Thermal Insulation for Austenitic Stainless Steel, and 1.37, Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water Cooled Nuclear Power Plants, are relevant for CSS components and for all CSS field welds, including welds at the CSS boundaries (refer to section 1.8).

(RA)7.12.6 Materials used for the containment and its internal structures can withstand exposure to all post-accident conditions without causing deleterious or undesirable reactions, or significantly altering the recirculating water chemistry.

(RA)7.12.7 The material of common suction piping with the SIS from the RWT and containment recirculation sump is austenitic stainless

steel type 304 and conforms to ASME Section III, Class 2, requirements.

(RA)7.13 PHYSICAL ARRANGEMENT

It is noted that some of the Interface Requirements described in this section were provided for original piping and component design/selection to ensure that the as-built system would support required design functions. For the operating plant, the adequacy of the design to support required design functions is maintained and demonstrated by current design basis calculations and surveillance tests that evaluate the as-built systems, and the values specified by the original interface requirements are not longer relevant. The specific interface requirements in this section for which this applies and that provide historical information are: (RA)7.13.1 relative to piping head losses, (RA)7.13.14 relative to maximum spray header elevation.

(RA)7.13.1 The CSS is designed to meet the maximum and minimum piping head losses as presented in CESSAR Appendix 6A, Table 7.13. The system is also designed to meet the NPSH

requirements indicated in UFSAR section 6.2.2.2.

It is noted that the piping head losses as presented in CESSAR Appendix 6A, Table 7.13 reflect the original CE System 80 values. These requirements were subsequently changed by CE for PVNGS. The CSS was originally designed to meet the PVNGS-specific head loss of 505 ft. maximum at a pump flow rate of 3,890 gpm. For the as-built system, the total system losses provide the required CS flow to support design functions.

(RA)7.13.2 Flow measurement devices (SIA-FT338, SIB-FT348) are provided on the containment spray pumps discharge lines. The piping runs upstream and downstream of the flow measurement devices meet the recommendations of "ASME Fluid Meters: Their Theory and Application, Parts 1 and 2."

(RA)7.13.3 For each spray train, the top of the piping junction between the RWT discharge and the containment sump is located at a minimum of 38 feet below the minimum containment sump water level during recirculation. To preclude the possibility of drawing air

from the RWT into the safeguards pump suction during recirculation, timely operator action is required to isolate the RWT after the RAS has occurred.

(RA)7.13.4 Frictional losses in the CSS pump suction piping between the containment sump and the junction with the RWT do not exceed 10 feet, which exceeds the requirement by 3 feet. The junction point is, however, located 22 feet lower than C-E required minimum of 16 feet; the head loss is thus acceptable. To preclude the possibility of drawing air from the RWT into the safeguards pump suction during recirculation, timely operator action is required to isolate the RWT after the RAS has occurred.

It is noted that the frictional losses in the CSS pump suction between the containment sump and the junction with the RWT do not exceed 5 feet for the as-built design.

(RA)7.13.5 The CSS pumps are located in the auxiliary building as close as practicable to the containment structure.

(RA)7.13.5.1 The elevation of these pumps is low enough such that adequate NPSH is available during

the recirculation mode when the pumps take suction from the containment sump.

(R)7.13.5.2 The available NPSH is calculated at the pump impeller eye.

(RA)7.13.5.3 The calculation of NPSH considers concurrent high-pressure safety injection, low-pressure safety injection, and containment spray pump operation. No credit is taken for sub-cooled water in the sump. The calculated NPSH is greater than the required NPSH presented in section 6.2.2.2.

(RA)7.13.5.4 Credit is not taken for water that could be trapped above the containment floor.

(RA)7.13.6 In the event of a limited leakage passive failure in one CSS train during recirculation, personnel access to the intact train is not precluded by flooding.

(RA)7.13.7 The two CSS check valves in each of the spray header lines are located as close as practicable to the containment penetration:

A. Allowance is made for valve accessibility and maintenance.

B. To minimize delay time for spray initiation, total water volume in the spray header piping is kept to a

minimum and the spray headers are maintained full of water up to 13-foot indicated elevation. Fresh water may be used instead of borated water to fill portions of the spray headers inside containment. Refer to section 1.9.

(RA)7.13.8 Manually-operated valves are provided with locking provisions as shown in Section 6.3.

(RA)7.13.9 Physical identification of safety-related CSS equipment and cabling is provided to allow recognition of safety status by plant personnel.

(RA)7.13.10 In the routing of CSS Class 1E circuits and location of equipment served by these Class 1E circuits, consideration is given to their exposure to potential hazards. See (RA)7.5.

(RA)7.13.11 The CSS containment penetrations will not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of equipment or piping inside or outside the containment.

(RA)7.13.12 Where required, bellows will be provided between piping and the containment wall to prevent excessive forces on the piping.

(RA)7.13.13 Each CS pump bypass flow line is capable of passing 150 gallons per minute with its CS pump operating at design operating conditions.

Note: This original interface requirement was prescribed to satisfy recirculation line allowable head loss and line sizing requirements at design operating conditions. This particular interface requirement does not establish the minimum (or maximum) recirculation flow rate. Minimum recirculation flow rates have been established by the CS pump vendor to provide adequate pump cooling at or near shut-off conditions and these requirements are documented in the respective Containment Spray pump vendor technical manual.

(RA)7.13.14 The design of the CSS piping and spray headers considers the effects of water hammer. Hydraulic Systems Transient Analysis (HSTA), Bechtel Standard Computer Program NE820, is used to develop time history forcing function input for water

hammer stress analysis. HSTA is a generalized finite difference code based on the characteristics method for analyzing water hammer effects in the complex piping systems of a power plant. HSTA predictions of pressure and velocity are in good agreement with other experimental and theoretical/numerical data for similar situations published in the literature.

The maximum spray header elevation above the RWT outlet nozzles does not exceed 192 feet. Refer to section 1.9.

It is noted that this maximum spray header elevation discussion is relative to the original design. For the as-built system, the total system losses provide the required CS spray flow to support design functions.

(RA)7.13.15 The resistance of the RWT return lines is established so as to permit periodic testing of each spray pump at conditions as near to design as practicable (the pumps will be flow-tested at approximately half-full flow).

(RA)7.13.16 All CSS ASME Section III components are arranged to provide adequate clearances to permit inservice inspection. The design of

the arrangement conforms to the guidelines of Section XI of the ASME Code. Manually operated valves that contain reactor coolant or other potentially radioactive liquids during normal plant operations, are provided with hand wheel extensions and shielding to allow periodic actuation as per ASME Section XI, Subsection IWV. Appropriate ALARA practices shall be followed during the periodic pressure tests and nondestructive examinations of the containment spray system.

Access to system components not designed to ASME Section III is provided for periodic visual inspection for leakage, structural distress, and corrosion.

(RA)7.13.17 Protection is provided from internally generated flooding that could prevent performance of safety-related functions. Also refer to section 3.6 and subsection 9.3.3.

(RA)7.14 RADIOLOGICAL WASTE COLLECTION

Containment spray system leakage to the engineered safety features room will normally drain to the room sump. Provisions are provided to accept the maximum leakage rates listed below:

a. CSS pump seals: 100 cc/h/pump

b. Valves

backseat leakage:	10 cc/h/in. seat diameter/valve
across the valve seat:	10 cc/h/in. of nominal valve size/valve

Leakages will be treated as radioactive waste with a low dissolved solids and organic content.

(RA)7.15 OVERPRESSURE PROTECTION

Relief valves are provided for overpressure protection.

(RA)7.16 RELATED SERVICES

(RA)7.16.1 Refueling Water Tank

The RWT has been sized to ensure that a sufficient volume of water will be available to sustain ESF pump flow, including the CSS pumps at run-out flow rates (5200 gpm), for the duration of the injection period as assumed in the safety analyses. Sufficient inventory is maintained to satisfy the requirements of other systems.

The RWT has been sized to also ensure that a sufficient volume of water will be

available to sustain ESF pump flow during the transfer from ECCS injection to the ECCS recirculation phase of operation. The transfer volume was sized assuming single failure of a LPSI pump to trip on a RAS and a conservative CS pump flow rate. To preclude air entrainment, timely operator action to isolate the RWT after a RAS ensures the tank is isolated before the vortex breaker is uncovered.

The maximum particle size in the water exiting from the RWT is 0.09 inch in diameter in order to preclude flow blockage in engineered safety features components and piping and in the reactor. In addition, vortexing tendencies within the tank are precluded by a suction cage inside the tank, similar in design to the cage installed in the containment emergency sump. The minimum required RWT level and volume are the useful level and volume above the volume that is unusable due to vortex considerations.

The contents of both the RWT and piping associated with the CSS is maintained at or above a minimum temperature of 60F to preclude possible boron precipitation.

The RWT is provided with two vent lines in parallel: One is an 8-inch vent at the peak of the RWT roof that is connected to a 10-inch header. The other is a 16-inch vent line connected to the manway hatch on the roof of the RWT. Both vent lines are routed to the Fuel Building normal exhaust duct system. The vent pipes are routed without piping pockets that could cause the accumulation of moisture.

(RA)7.16.2 Containment Spray Sump

The containment sump and screen are designed to comply with Regulatory Guide 1.82, Sumps for Emergency Core Cooling and Containment Spray Systems, as described in Section 1.8. The original sumps' hydraulic performance was tested on a one-to-one model in a hydraulic laboratory. As a result of the tests, a special vortex breaking cage was installed to the safety injection sump suction line inside each sump. The tests showed that the hydraulic performance of the sump is satisfactory with the vortex breaking cage installed. Further information on the model study is contained in the transcript to the containment systems independent design

review submitted under PVNGS transmittal letter ANPP-18147, dated June 4, 1981. The vortex breakers remain installed at the ECCS pump suction piping inside the sumps with the new strainers installed by DMWO 2822654. In addition, testing and evaluation has determined that the minimum submergence above the top of the new strainer cartridges (non-perforated) is sufficient and vortexing is not a concern. Intake screening elements are installed to limit the maximum particle size entering the recirculation piping in order to prevent flow blockage in the engineered safety features components and piping and in the reactor. The sump intakes are designed so as to preclude the entrainment of air and/or steam into the sump suction lines. The pressure drop across the intake screening elements is sufficiently low to provide the NPSH required by the containment spray pumps. The post-LOCA sump pH will be raised to a minimum of 7.0 within 4 hours post-accident. The maximum long-term pH will not exceed 8.5.

Containment level instrumentation is provided to ensure there is sufficient NPSH for the safety injection pumps and to

verify that essential equipment is not flooded. The range provided is from approximately 6 inches above the sumps (approximate elevation 80.5 feet) to approximately 18 inches above the maximum flood level (approximate elevation 92.5 feet). This range is above the minimum level for NPSH requirements (elevation 84.5 feet). A total range of 12 feet is provided in the control room. This safety grade instrumentation is redundant, physically separated, environmentally qualified to post-LOCA environment, seismically qualified to function during and following an SSE and powered from redundant Class 1E sources.

(RA)7.16.3 Shutdown Cooling Heat Exchanger Cooling water will be provided to each shutdown cooling heat exchanger to transfer heat from the sump fluid during the recirculation mode.

The minimum required flow of cooling water supplied to each shut-down cooling heat exchanger is a flowrate of 12,600 gallons per minute.

Cooling water flow will be established to the shutdown cooling heat exchanger prior

to or simultaneously with the start of recirculation.

The cooling water temperature to the inlet of the heat exchangers will not exceed 135°F.

(RA)7.16.4 Fire Protection

The fire protection system provided to protect the CSS is discussed in subsection 9.5.1.

(RA)7.17 ENVIRONMENTAL

For environmental interfaces, see (RA)7.7.

(RA)7.18 MECHANICAL INTERACTION

(RA)7.18.1 Containment spray system components are properly supported such that pipe stresses and support reactions are within allowable limits, as defined in CESSAR Section 3.9.2.

(RA)7.18.2 Containment spray system piping and fittings are Seismic Category I.

B. INTERFACE EVALUATION FOR IODINE REMOVAL SYSTEM (Abandoned in place)

6.5.3 FISSION PRODUCT CONTROL SYSTEMS

6.5.3.1 Primary Containment

The primary containment structure consists of a reinforced concrete cylinder and hemispherical dome, lined with welded

¼ inch steel plates, forming a continuous, leaktight pressure boundary. Details of the containment structural design are discussed in section 3.8. Layout drawings of the containment structure and the hydrogen purge system are given in the general arrangement drawings of section 1.2 (hydrogen purge equipment is located in the auxiliary building at elevation 100 feet).

The containment walls, liner plate, mechanical penetrations, isolation valves, hatches, and locks function to limit release of radioactive materials, subsequent to postulated accidents, such that the resulting offsite doses are less than the guideline values of 10CFR100. Containment parameters affecting fission product release accident analyses are given in table 6.5-3.

Long-term containment pressure responses to the design basis accidents are discussed in subsection 6.2.1. Relative to this time period, the CSS is operated to reduce iodine concentrations and containment atmospheric temperature and pressure from the time commencing with system initiation, at approximately 90 seconds, until containment pressure has returned to normal.

For the purpose of post-LOCA dose calculations discussed in chapter 15, spray iodine removal, credit is taken only during the 0 to 2 hour time frame.

Table 6.5-3

PRIMARY CONTAINMENT OPERATION

FOLLOWING A DESIGN BASIS ACCIDENT

General		
Type of Structure	Steel-lined, reinforced cylinder and base with hemispherical dome	
Internal fission product removal systems	Redundant containment water spray systems	
Free volume of containment	2.62×10^6 ft^3	
Hydrogen purge system operation assumptions	See paragraph 6.2.5.3	
Time Dependent Parameters	Anticipated	Conservative
Containment leakage rate		
0 to 24 hours	<0.1 vol%/d	0.1 vol%/d
1 to 30 days	<0.05 vol%/d	0.05 vol %/d
Iodine spray removal coefficient (spray λ, elemental)	See paragraph 6.2.5.3	

The containment power access purge system may be operated for personnel access to the containment when the reactor is at power. Even though the purge frequency is a small percentage of the total annual operating period, operation of the power access purge system at the time of occurrence of a design basis accident is assumed in the analyses of radiological releases. The power access purge will terminate and the containment will isolate within 12 seconds after initiation of large break LOCA.

Redundant, safety-related hydrogen recombiners are provided for the containment atmosphere as the primary means of controlling post-accident hydrogen concentrations. A hydrogen purge system is provided for backup hydrogen control.

6.5.3.2 Secondary Containments

This paragraph is not applicable to PVNGS.

6.5.4 ICE CONDENSER AS A FISSION PRODUCT CLEANUP SYSTEM

This subsection is not applicable to PVNGS.

6.6 INSERVICE INSPECTION OF CLASS 2 AND 3 COMPONENTS

Design of and provision for access to ASME Code, Class 2 and 3, components is in accordance with the requirements of the 1974 Edition of ASME Section XI through the Summer 1975 Addenda. The preservice inspection will be conducted in accordance with 10CFR50.55a(g). The inservice inspection (ISI) program will be updated to a more recent code during each inspection interval as determined to be practical in accordance with the procedures of 10CFR50.55a(g)(4).

6.6.1 AUGMENTED INSERVICE INSPECTION TO PROTECT AGAINST POSTULATED PIPING FAILURES.

6.6.1.1 The EPRI Risk-Informed Inservice Inspection (RI-ISI) Methodology to Break Exclusion Region (BER) Program is being implemented in all three units. For those portions of systems located between the containment penetration and the main steam support structure wall that are identified in paragraph 3.6.2.1.1.2, listing C, an augmented inservice inspection will be performed. This augmented program will include the piping welds selected and examined using the methodology defined by EPRI Report 1006937 “Extension of the EPRI Risk-Informed Inservice Inspection (RI-ISI) Methodology to Break Exclusion Region (BER) Programs”. The specific areas subject to examination, the extent, the method and the frequency of examinations will be provided on a schedule consistent with the ISI program.

Page 6.2.2-4 missing

RESPONSE: A spot check of 60 complete FSARs revealed that page 6.2.2-4 is present as the back side of page 6.2.2-3 in all cases. It is concluded that reviewer's copy was an inadvertent result of a printing error. Pages 6.2.2-3 and 6.2.2-4 have been transmitted to the PVNGS Licensing Project Manager.

<u>QUESTION 6A.2</u> (NRC comment on subsection 6.3.4) (6/18/80) (6.3.4)

Not included

RESPONSE: The response is given in amended subsection 6.3.4.

<u>QUESTION 6A.3</u> (NRC comment on subsection 6.3.5) (6/18/80) (6.3.5)

Not included

RESPONSE: The response is given in amended subsection 6.3.5.

<u>QUESTION 6A.4</u> (NRC Question 281.1) (6.5.2)

In the FSAR you indicated that, following an accident which requires operation of the containment spray system, hydrazine will be used in the spray water for short-term injection and trisodium phosphate will be added to the sump water for long-term recirculation. In view of the fact that trisodium

phosphate has a tendency to cake, it may not be readily dissolved in the sump water following the accident. Provide design basis information and a proposed surveillance program to ensure that, by commencement of the recirculation of sump water, sufficient trisodium phosphate will be dissolved in the sump water to achieve a pH value of at least 8.5.

RESPONSE: Refer to paragraph 6.1.1.2 for a discussion on trisodium phosphate dodecahydrate.

QUESTION 6A.5 (NRC Question 281.4) (6.2)

Indicate the total amount of protective coatings, paints, and organic materials (including uncovered cable insulation) used inside the containment that do not meet ANSI N101.2 (1972) and Regulatory Guide 1.54.

RESPONSE: Refer to section 1.8 for a discussion on conformance to Regulatory Guide 1.54.

QUESTION 6A.6 (NRC Question 460.3) (1.8 and 6.5)

In section 1.8 of the FSAR which deals with "Conformance to NRC Regulatory Guides", reference is made to Regulatory Guide 1.52, Revision 0 (June 1973) and Revision 1 (July 1976) versions. Since Regulatory Guide 1.52, Revision 2 (March 1978), "Design, Testing and Maintenance Criteria for Post-Accident Engineered-Safety-Feature Atmosphere Cleanup System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants" has replaced the earlier versions, comparison should be made of the design features and fission product removal capability of each ESF filter system to applicable positions detailed in

Regulatory Guide 1.52, Revision 2. For each item for which an exception is taken, the acceptability of the proposed design should be justified. For example, if, as stated under section 1.8, demisters are not provided for the fuel building ESF ventilation system, explain how relative humidity will be controlled so as not to exceed 70%. Likewise, if, as stated under section 1.8, 1E alarms or recorders for pressure drops or flowrates for the ESF ventilation systems are not provided, describe the form in which this information is available in the control room, e.g., digital readout of pressure drop and/or flow rate, type of alarm, such as high or low, visual or audible, etc.

RESPONSE: See section 1.8, response to Regulatory Guide 1.52.

QUESTION 6A.7 (NRC Question 450.3) (6.4)

In your description of the control room's protective features, provide the time interval between the time the chlorine concentration exceeds 5 ppm at the isolation dampers and the time the dampers are completely closed.

RESPONSE: Refer to the response to NUREG-0737, Section 18.III.D.3.4.(2).(j).

QUESTION 6A.8 (NRC Question 450.4) (6.4)

List the areas, equipment, and materials to which the control room operator has access during emergency operation; i.e., during the time the control room is serviced by the emergency ventilation system.

RESPONSE: The response is given in amended paragraph 6.4.2.1.

QUESTION 6A.9 (NRC Question 450.5) (6.4)

In your analysis of toxic gas protection for control room personnel, provide the number and type of respiratory devices, the type of operator training for respiratory use, the estimated time for donning or deploying the equipment, the length of time the equipment can be used, and the equipment testing and maintenance procedures.

RESPONSE: The response is given in amended paragraph 6.4.2.2.2, listing K.

QUESTION 6A.10 (NRC Question 450.6) (6.5.2)

On page 6.5-27 of the PVNGS FSAR, it is stated that the post-LOC sump pH shall be raised to a minimum of 7.0. It is not clear that the pH, by itself, is high enough to prevent iodine evolu-tion from the sump. Explain how evolution of iodine from the post-LOCA sump will be prevented, or kept to a very low level.

RESPONSE: See the responses to Questions 6A.4, 6A.28 and 6A.30.

QUESTION 6A.11 (NRC Question 450.7) (6.5.2)

Please provide spray nozzle performance data (spray droplet pattern, drop size distribution) for Spraco 17071417 and 17651308 nozzles.

RESPONSE: Spray nozzle performance data are given in figures 6A-1, 6A-2, and 6A-3.

<u>QUESTION 6A.12</u> (NRC Question 450.8) (6.5.2)

The discussion on pages 6.5-8 and 6.5-9 implies that 100% of the containment net free volume (above 100-foot elevation) is sprayed. State whether this implication is true and provide justification for the spray coverages assumed in your analysis.

RESPONSE: This statement is true as auxiliary sprays are located under concrete floors at the 120-foot and 140-foot elevations.

<u>QUESTION 6A.13</u> (NRC Question 480.1) (6.2.1.1)

State whether containment leakage was assumed as part of the containment peak pressure calculations. If so, provide and justify the leak rate used.

RESPONSE: The response is given in amended paragraph 6.2.1.1.1.1.

<u>QUESTION 6A.14</u> (NRC Question 480.2) (6.2.1.1)

Instrumentation capable of operating in the post-accident environment will be required to monitor containment atmosphere pressure and temperature and sump water temperature. Provide additional information on how this requirement will be met including the instrument range, accuracy, and response times and compliance with Regulatory Guide 1.97. (Note: See also NUREG-0737, Clarification of TMI Action Plan Requirements, II.F.1, Attachment 4, Containment Pressure Monitor.)

RESPONSE: The response was provided in PVNGS Balance of Plant Instrumentation and Control Systems Review Board, Section 2.C.3.B, Exhibits 2C3-8 and 2C3-15.

QUESTION 6A.15 (NRC Question 480.3) (6.2.1.2)

The following pertain to subcompartment nodalization:

a. It is stated in section 6.2.1.2 that the steam generator subcompartment nodalization is based on nodalization sensitivity studies of other plants. Justify this basis by specifically describing the steam generator compartments of these other plants and their dimensional similarities to the Palo Verde plant. Also provide a discussion of the results of the sensitivity studies showing that increasing the number of nodes chosen does not affect the analysis results.

b. The number of nodes used for the reactor cavity (RC) and steam generator (SG) subcompartment analyses is unclear. The FSAR text indicates 18 nodes were used for the RC analysis (table 6.2.1-19) and 54 nodes for the SG analysis, whereas the graphs of resultant pressures (figures 6.2.1-17 and 6.2.1-18) indicated 37 nodes for the RC analysis and 55 nodes for the SG analysis. Explain or correct this apparent discrepancy.

RESPONSE:

a. The response is provided in paragraph 6.2.1.2.3.2, listing B and table 6.2.1-20.

b. The response is provided in paragraph 6.2.1.2.3.2, listing B and table 6.2.1-19.

QUESTION 6A.16 (NRC Question 480.4) (6.2.1.2)

Peak calculated differential pressures do not appear in tables 6.2.1-14 and 6.2.1-15 as referenced on FSAR pages 6.2.1-94 and 6.2.1-95. Revise these tables or create new tables to include these results for all subcompartment analyses.

RESPONSE: The response is provided in paragraph 6.2.1.2.3.2, listings A and B, and tables 6.2.1-13, 6.2.1-15, and 6.2.1-17.

QUESTION 6A.17 (NRC Question 480.5) (6.2.1.2)

Justify the selected subcompartment analysis initial conditions of 14.4 psia pressure and 25% relative humidity. The initial atmospheric conditions within a subcompartment should be selected to maximize the resultant differential pressure (Reference SRP Section 6.2.1.2 II.1).

RESPONSE: Refer to table 6.2.1-13.

QUESTION 6A.18 (NRC Question 480.6) (6.2.1.3)

FSAR paragraph 6.2.1.3 simply states, "Refer to CESSAR Section 6.2.1.3." But CESSAR Section 6.2.1.3 states, "The long-term energy release, being containment design dependent, is detailed in each applicant's SAR." Therefore, provide long-term mass and energy release data for the design basis LOCA. Tabulate the data showing mass release rate in lbm/hr and energy release rate in Btu/hr. Extend the table through 10^6 seconds after shutdown. Ensure that the long-term energy

release rate accounts for the dominant mechanisms, which include decay heat and the cooling of all NSSS metal.

RESPONSE: The response is provided in amended paragraph 6.2.1.3.

<u>QUESTION 6A.19</u> (NRC Question 480.7) (6.2.4)

Valves SG-UV134 (penetration No. 2) and SG-UV138 (penetration No. 3) are listed in FSAR tables 6.2.4-1 and 6.2.4-2 as being <u>not</u> essential and yet they are automatically opened by an auxiliary feedwater actuation signal (AFAS). Either correct table 6.2.4-1 to show these valves are essential or provide justification why they do not meet the containment isolation requirements for nonessential systems.

RESPONSE: The response is provided in table 6.2.4-1.

<u>QUESTION 6A.20</u> (NRC Question 480.8) (6.2.4)

Table 6.2.4-2 does not differentiate between valves which are closed and "locked" closed. Since this distinction is important in evaluating the acceptability of the containment isolation design, modify table 6.2.4-2 to indicate when valves will be "locked" closed in accordance with the SRP Section 6.2.4.II.6.f definition of a sealed closed barrier. Based on the FSAR P&IDs this should include DW-V061, DW-V062 (penetration No. 6); SI-UV654, SI-UV656, SI-HV690 (penetration No. 26); SI-UV653, SI-UV655, SI-HV691 (penetration No. 27); SJ-V463 (penetration No. 28); CH-V854 (penetration No. 41); PC-V071, PC-V070 (penetration No. 50); PC-V075, PC-V076

(penetration No. 51); IA-V072 (penetration No. 59); SI-HV331 (penetration No. 67); and SI-HV321 (penetration No. 77).

RESPONSE: The response is provided in table 6.2.4-2.

QUESTION 6A.21 (NRC Question 480.9) (6.2.4)

Provide in table 6.2.4-1 the distance from containment for valves HC-UV045 (penetration No. 25A) and HC-UV046 (penetration No. 25B).

RESPONSE: The response is provided in table 6.2.4-1.

QUESTION 6A.22 (NRC Question 480.10) (6.2.4)

Confirm that penetration Nos. 5, 32B, 32C, 54B, 54C, 55B, 55C, 64, 65, 66, 68, 69, 70, 71, 73, 74, 80, and 81 are not used.

RESPONSE: The response is provided in amended tables 6.2.4-1 and 6.2.4-2.

QUESTION 6A.23 (NRC Question 480.11) (6.2.4)

Add valves SG-HV200 and SG-HV201 (penetration No. 11 and No. 12) to tables 6.2.4-1 and 6.2.4-2.

RESPONSE: The response is provided in tables 6.2.4-1 and 6.2.4-2.

QUESTION 6A.24 (NRC Question 480.12) (6.2.4)

Explain why valves HP-HV007B and HP-HV008B (penetration No. 35 and No. 36, respectively) will not be automatically closed by a containment isolation signal (see also open item No. 24 from May 21, 1981 IDR transcript).

RESPONSE: The response is given in amended paragraph 6.2.4.3.

QUESTION 6A.25 (NRC Question 480.13) (6.2.4)

Provide an analysis of the effect of the containment purge system; i.e., an open purge line, on the minimum containment pressure analysis for performance capability studies on the ECCS (reference CSB BTP 6-4 B.5.c). (Note: The CESSAR Section 6.2.1.5 analysis referenced from FSAR paragraph 6.2.1.5 assumes complete containment isolation.)

RESPONSE: The response is given in amended paragraph 6.2.1.5.

QUESTION 6A.26 (NRC Question 480.14) (6.2.5)

Provide the design justification for not including a fan or blower in the containment hydrogen purge exhaust unit to ensure a purge rate of 50 scfm (see also open item No. 28 from the May 21, 1981 IDR transcript).

RESPONSE: The response is given in amended paragraph 6.2.5.2.2.3.

QUESTION 6A.27 (NRC Question 480.15) (6.2.5)

Describe the guidelines that will be provided the operators following a LOCA or MSLB in which the CSS is actuated that will tell them when they can terminate and/or periodically shut down the CSS. The concern is that the CSS is needed to ensure adequate containment mixing to prevent stratification or pocketing of hydrogen.

RESPONSE: The response is given in amended paragraph 6.3.1.4 listing I.

QUESTION 6A.28 (NRC Question 450.12) (6.5.2)

The NRC staff evaluates the long-term effectiveness of containment spray systems by determining the long-term decontamination factor, which is based on possible iodine evolution from the containment sump after the injection phase of containment spray. To make this determination, the long-term (post-injection) pH range of the sump water is needed. The range of 7.0 to 8.5 for sump pH stated in the PVNGS FSAR is not sufficiently detailed for our evaluation. State the amount of TSP used for sump chemistry control, in kg or moles, and the location of the TSP baskets. Calculate the post-injection sump pH. Preliminary staff calculations indicate that the long-term pH should be at least 8.0 to meet 10CFR100 dose guidelines for the DBA LOCA.

RESPONSE: The response will be provided on the CESSAR docket. See CESSAR FSAR responses to NRC Questions (NRC Question 450.3). Also refer to the response to Question 6A.30 (NRC Question 281.5).

QUESTION 6A.29 (NRC Question 450.18) (6.4)

Provide the following information required for the control room habitability evaluation:

(1) control room shielding including radiation streaming from penetrations, doors, ducts, stairways, etc.

(2) self-contained breathing apparatus availability (number)

(3) bottled air supply (hours supply)

(4) control room personnel capacity (normal and emergency)

(5) potassium iodide drug supply

(6) control room emergency filtration system including the capability to maintain the control room pressurization at 1/8 inch water gauge, verification of isolation by test signals and damper closure times, and filter testing requirements.

RESPONSE:

1) The required information is provided in paragraphs 6.4.2.5 and 12.3.2.2.7.

2) The required information is provided in listing K of paragraph 6.4.2.2.2.

3) The required information is provided in listing K of paragraph 6.4.2.2.2.

4) The required information is provided in subsection 6.4.1 and paragraph 6.4.4.3, for the designed personnel capacity of the control room in emergencies. Refer to the PVNGS security plan for additional details of control room access restrictions.

5) The response is given in amended paragraph 6.4.4.3.

6) The required information is provided in paragraphs 6.4.2.2, 6.4.2.3, 6.4.2.4, 6.4.3.2, and 6.4.4.3 and in subsection 6.4.5.

QUESTION 6A.30 (NRC Question 281.5) (6.1.1,6.5.2)

In your response to our request for information 281.1, you stated that no surveillance of the trisodium phosphate (TSP) baskets will be conducted other than to assure that the baskets are full. It is our position, as stated in CE-PWR Standard Technical Specification (3/4.5.2), that this ECCS subsystem shall be demonstrated operable at least once per 18 months by (1) verifying that a minimum total volume of solid granular TSP dodecahydrate is contained within the TSP baskets, and (2) verifying that when a representative sample of TSP from a TSP basket is submerged, without agitation, in borated water from the refueling water tank, the pH of the mixed solution is raised to an acceptable level within 4 hours. Indicate that these surveillance requirements will be met.

Also, provide the minimum total volume of TSP to be stored in the TSP basket and state the basis for the stored quantity.

RESPONSE: The response is given in amended paragraph 6.1.1.2.

QUESTION 6A.31 (NRC Question 281.6) (6.1.2)

In table 6.1-4 of the FSAR, you indicate that there are 259,560 pounds of cable insulation inside the containment building. Indicate what fraction of this weight consists of organic materials. We also need the following additional information

for estimating the generation rate of combustible gases from organic materials in cable insulation under DBA conditions: (1) The quantity (weight and volume) of uncovered cable and cable is closed metal conduit or closed cable trays. We will give credit for beta radiation shielding for that portion of cable that is indicated to be in closed conduit or trays, (2) A breakdown of cable diameters and associated conductor cross-section, or an equivalent cable diameter and conductor cross-section that is representative of total cable surface area associated with the quantity of cable identified in 1) above, and (3) The major organic polymer or plastic material in the cables. If this information is not provided, we will assume the cable insulation to be polyethylene and assume a G value for combustible gas of 3.

RESPONSE: Refer to revised table 6.1-4.

(1) The quantity of covered/uncovered cable is not readily available. Therefore, all cable is assumed exposed.

(2) A breakdown of cable diameters and conductor cross-section was provided to the NRC under separate cover.

(3) Organic polymers in various insulation types are listed in table 6.1-4.

<u>QUESTION 6A.32</u> (NRC Question 440.11) (6.3)

Discuss the provisions and precautions for assuring proper system filling and venting of ECCS to minimize the potential for water hammer and air binding. Address piping and pump casing venting provisions and surveillance frequencies.

RESPONSE: Refer to paragraphs 6.3.2.6, 6.5.2.8 (listing A) [(RA) 7.13.7.B], and PVNGS Technical Specifications for discussions on fill and vent requirements.

<u>QUESTION 6A.33</u> (NRC Question 440.12) (6.3.3)

Paragraph 6.3.3.2.2 states that the worst single failure for the large break LOCA is the failure of one of the low pressure pumps to start which will result in a minimum amount of safety injection water available to the core. Explain why the single failure of a diesel generator, which results in loss of one HPSI train and one LPSI train, is not the worst single failure for the large break LOCA with respect to the amount of safety injection water available to the core in post LOCA operation.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

<u>QUESTION 6A.34</u> (NRC Question 440.13) (6.3)

Identify all ECCS valves that are required to have power locked out and confirm they are included under the appropriate Technical Specifications, with surveillance requirements listed.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

<u>QUESTION 6A.35</u> (NRC Question 440.14) (6.3)

Consideration should be given to the possibility that local manual valves (handwheel), could go undetected in the wrong position until a postulated accident occurs. Appropriate

administrative controls or valve position indication are examples of methods to be considered to minimize this possibility. Provide a list of all critical manual valves and address the actions that will be implemented to assure all critical valves are properly positioned.

Identify all manual valves which have locking provisions.

It is our position that limit switches which enable valve position to be indicated in the control room should be installed on all manually operated and normally locked ECCS valves.

In addition a recent event (Docket 50-320, LER 78-20/3L, 4/21/78) has brought to our attention that the automatic operation of some motor operated valves can be disabled when the manual handwheel pins are engaged. Identify all critical motor-operated valves associated with the CESSAR 80 design that have this design feature and describe the controls and procedures utilized to prevent the inadvertent disablement of the automatic operation of these valves.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

<u>QUESTION 6A.36</u> (NRC Question 440.15) (6.3)

Identify the plant operating conditions under which certain automatic safety injection signals are blocked to preclude unwanted actuation of these systems. Describe the alarms available to alert the operator to a failure in the primary or secondary system during this phase of operation and the time available to mitigate the consequences of such an accident.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

<u>QUESTION 6A.37</u> (NRC Question 440.16) (6.3)

The information in the CESSAR 80 FSAR regarding post-LOCA passive failures is not complete. It is the reactor systems branch position that detection and alarms be provided to alert the operator to passive ECCS failures during long-term cooling which allow sufficient time to identify and isolate the faulted ECCS line. The leak detection system should meet the following requirements:

1. Identification and justification of maximum leak rate should be provided.

2. Maximum allowable time for operator action should be provided and justified.

3. Demonstration should be provided that the leak detection system will be sensitive enough to initiate (by alarm) operator action, permit identification of the faulted line, and isolation of the line prior to the leak creating undesirable consequences such as flooding of redundant equipment or excessive radioactive fluid. The minimum time to be considered is 30 minutes.

4. It should be shown that the leak detection system can identify the faulted ECCS train and that the leak is isolatable.

5. The leak detection system must meet the following standards:

a. Control room alarm

b. IEEE 279-1971, except single failure requirements

RESPONSE: The response to items 1 and 2 is provided in the response to Question 5A.19 (NRC Question 440.8), items 1 and 2. Additional ECCS pump room flooding considerations are discussed in the response to Question 3A.30 (NRC Question 410.4). In addition, refer to section 6A.37.

<u>QUESTION 6A.38</u> (NRC Question 440.17) (6.3)

The acceptance criteria in the Standard Review Plan for Section 6.3 states the ECCS should retain its capability to cool the core in the event of a single active or passive failure during the long-term recirculation cooling phase following an accident. Demonstrate that CESSAR 80 ECCS design has this capability.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

<u>QUESTION 6A.39</u> (NRC Question 440.18) (6.3)

A reported event has raised a question related to the conservatism of NPSH calculations with respect to whether the absolute minimum available NPSH has been considered. In the past, the required NPSH has been taken by the staff as a fixed number supplied through the applicant by either the architect engineer or the pump manufacturer. Since a number of methods exist and the method used can affect the suitability or unsuitability of a particular pump, it is requested that the

basis on which the required NPSH was determined be branded (i.e., test, Hydraulic Institute standards) for all the ECCS pumps and the estimated NPSH variability between similar pumps including the testing inaccuracies be provided.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

QUESTION 6A.40 (NRC Question 440.19) (6.3)

Provide the basis for ECCS lag times. Are these times calculated or verified by test. If calculated, are they verified during preoperational tests, and periodically reverified?

RESPONSE: The response was provided on the CESSAR docket. In addition, PVNGS will verify ECCS lag times during the preoperational testing phase. See CESSAR responses to NRC Questions.

QUESTION 6A.41 (NRC Question 440.20) (6.3)

Provide in the Technical Specifications (1) the range of nitrogen cover gas pressure for the SIT, and (2) the ECCS pump discharge pressures.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

QUESTION 6A.42 (NRC Question 440.21) (6.3)

Provide a time reference for each action in the sequence of action included in the changeover from injection to recirculation. Indicate the time required to complete each

action and what other duties the operator would be responsible for at this point in the accident. How much time does the operator have to assure that the system is realigned to the recirculation mode before RWST water is exhausted if the RWSP isolation valves are not closed? Consider the required pump NPSH in your response.

If the operator fails to close the RWST isolation valves, demonstrate that the HPSI will continue to adequately cool the core during the recirculation mode.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR responses to NRC Questions. Additional information is provided as follows:

The changeover from the safety injection mode to the recirculation mode occurs automatically upon recirculation actuation signal. For the opening time of the containment isolation valves for ECCS recirculation refer to subsection 6.2.4. After opening of these valves, the operator may close the RWT isolation valves manually (full closure takes 30 seconds) from the control room. It should be noted that the closure of these valves is not mandatory for proper ECCS performance due to the fact that physical arrangement of the RWT, as described in paragraph 6.5.2.8, PVNGS emergency procedures describe operator guidelines.

PVNGS has performed a walk through of the emergency procedures on its simulator and verified the operator has enough time to complete all required actions.

APPENDIX 6A

QUESTION 6A.43 (NRC Question 440.22) (6.3)

Recently, another plant has indicated that a design error existed in the sizing of their RWST. This error was discovered during a design review of the net positive suction head requirements for the containment spray and residual heat removal pumps. The review showed that there did not appear to be sufficient water in the RWST to complete the transfer of pump suctions from the tank to the containment sump, before the tank was drained and ECCS pump damage occurred.

It was reported that in addition to the water volume required for injection following a LOCA, an additional volume of water is required in the RWST to account for:

1. Instrument error in RWST level measurements.

2. Working allowance to assure that normal tank level is sufficiently above the minimum allowable level to assure satisfaction of technical specifications.

3. Transfer allowance so that sufficient water volume is available to supply safety pumps during the time needed to complete the transfer process from injection to recirculation.

4. Single failure of the ECCS system which would result in larger volumes of water being needed for the transfer process. In this situation, the worst single failure appears to be failure of a single ECCS train to realign to the containment sump upon low RWST signal. This result in the continuation of large RWST outflows and reduces the time available for the manual recirculation switchover,

before the tank is drawn dry and the operating ECCS pumps are damaged.

5. Unusable volume in the tank is present because once the tank suction pipes are reached, the pumps lose suction and any remaining water is unusable. Additionally, some amount of water above the suction pipes may also be unusable due to NPSH considerations and vortexing tendencies with the tank.

Preliminary indications are that approximately an additional 100,000 gallons of RWST capacity were needed to account for these considerations. It is our understanding that the design parameters for instrument error, transfer allowance and single failure have changed since the original sizing of the tank.

In light of the above information, discuss the adequacy of your RWST. Provide a discussion of the necessary water volumes to accommodate each of the five considerations indicated above. Justify your choice of volumes necessary to account for each consideration. Provide drawings of your RWST, showing placement and elevation of tank suction lines, and level sensors. Also, provide operator switchover procedures for aligning to the recirculation mode, with estimates of the time required for each action.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR responses to NRC Questions. The PVNGS design meets the CESSAR interface requirements identified in the CESSAR response.

Refer to paragraph 6.5.2.8 for a discussion on vortexing tendencies of the RWT.

Refer to paragraphs 7.5.1.1.6 and 7.5.2.6 for a discussion of the SESS panel alarms.

QUESTION 6A.44 (NRC Question 440.23) (6.3)

Provide a discussion on specific methods of detecting, alarming and isolating passive ECCS failures during long-term cooling to include valve leakage. Show that there is sufficient time for the operator to take corrective action and maintain an acceptable water inventory for recirculation. [1] Justify the basis for the assumed leak rates. [2] Describe how the contaminated water would be handled if one ECCS train must continue to operate with a leak.

RESPONSE:

1. The response will be provided on the CESSAR docket. Additional discussion is provided in amended paragraph 6.3.1.4. Normal valve leakage is considered insignificant when compared to the passive ECCS failure identified in the same response.

2. The leakage from the valves within the auxiliary building is collected in ESF sumps at the lowest building elevation of 40 feet. From this point, the waste can be pumped to the liquid radwaste system (LRS) for processing.

QUESTION 6A.45 (NRC Question 440.24) (6.3)

Assume a maximum passive failure flowrate of 50 gpm in each ECCS pump room and discuss the effects of the passive failure

to each ECCS pump operation, and demonstrate that adequate protection is provided for ECCS pumps from possible flooding.

RESPONSE: The response is given in amended paragraph 6.3.1.4.

QUESTION 6A.46 (NRC Question 440.25) (6.3)

In the event of early manual reset of the safety injection actuation signal (SIAS) followed by a loss of offsite power during the injection phase, operator action may be required to reposition ECCS valves and restart some pumps. The staff requires that operating procedures specify SIAS manual reset not be permitted for a minimum of 10 minutes after a LOCA. Provide the administrative procedures to ensure correct load application to the diesel generators in the event of loss of offsite power following an SIAS reset.

RESPONSE: The SIAS can only be reset when the initiating parameters have cleared. If SIAS were reset, then the conditions would have been restored to normal and the safety injection system would not be in the injection mode but the safety injection pumps would continue to operate until individually shut off by the operator. Refer to amended paragraph 6.3.1.4, listing I, for a discussion on procedure requirements.

QUESTION 6A.47 (NRC Question 440.26) (6.3)

Describe the instrumentation for level indication in the containment emergency sump. Also, provide detailed design drawings of the containment emergency sump including the design

provisions which preclude the formation of air entraining vortices during recirculation cooling. Confirm that the containment emergency sump design meets the requirements of Regulatory Guide 1.82.

RESPONSE: Refer to section 1.8 that describes PVNGS compliance with NRC Regulatory Guide 1.82, Revision 0.

Refer to paragraph 6.5.2.8 for discussion on the sumps vortexing breaking cage and level instrumentation.

QUESTION 6A.48 (NRC Question 440.27) (6.3)

Recent plant experience has identified a potential problem regarding the operability of the pumps used for long-term cooling (normal and post-LOCA) for the time period required to fulfill that function. Provide the pump design lifetime (including operational testing) and compare to the continuous pump operational time required during the short- and long-term of a LOCA. Submit information in the form of tests or operating experience to verify that these pumps will satisfy long-term requirements.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

QUESTION 6A.49 (NRC Question 440.28) (6.3)

Describe the means provided for ECCS pump protection including instrumentation and alarms available to indicate degradation of ECCS pump performance. Our position is that suitable means should be provided to alert the operator to possible degradation of ECCS pump performance. All instrumentation

associated with monitoring the ECCS pump performance should be operable without offsite power, and should be able to detect conditions of low discharge flow.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC Questions.

QUESTION 6A.50 (NRC Question 440.29) (6.3)

Describe the instrumentation available for monitoring ECCS performance during post-LOCA operation (injection mode and recirculation mode).

RESPONSE: The response was provided on the CESSAR docket. See CESSAR responses to NRC questions.

QUESTION 6A.51 (NRC Question 440.30) (6.3)

Provide a commitment that Palo Verde will perform preoperational and startup tests to meet the requirements of Regulatory Guide 1.68 and 1.79.

RESPONSE: PVNGS will perform preoperational and startup tests to meet the requirements of Regulatory Guides 1.68 and 1.79 as outlined in CESSAR Chapter 14 for tests in CESSAR scope and PVNGS FSAR chapter 14 for tests outside of CESSAR scope. See section 1.8, responses to Regulatory Guides 1.68 and 1.79.

QUESTION 6A.52 (NRC Question 440.31) (6.3)

Provide a commitment that Palo Verde will perform tests of ECCS as installed to confirm that the actual ECCS flowrates are greater than the values assumed in the LOCA analyses.

RESPONSE: During the preoperational phase, PVNGS will perform tests of ECCS (as described in CESSAR Chapter 14) to confirm that the actual ECCS flowrates are greater than the values assumed in the LOCA analyses.

<u>QUESTION 6A.53</u> (NRC Question 440.56) (6.3)

The LOCA break spectrum analyses presented are stipulated to be applicable to any System 80 plant that conforms to the interface requirements specified within subsection 6.3.3. The submittal for the LOCA analyses does not address the effects of steam generator tube plugging. The effect of a decrease in steam generator tube flow area is an increase in the peak cladding temperature (when the peak occurs during the reflood portion of the transient). If the analyses provided are considered to support generators with plugged tubes, describe the intent of the plugging the analyses support and the method used to account for the plugging. If steam generator tube plugging was not considered, the applicant will be required to perform additional ECCS analyses prior to operation with plugged generator tubes. In either case, the applicant is required to include an interface requirement on the validity of the LOCA analysis (acceptance criteria of 10CFR50.46) and the Technical Specification limit for the number (or percentage) of allowable plugged steam generator tubes.

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 6A.54 (NRC Question 440.77) (6.3)

List all ECCS valve operators and controls that are located below the maximum flood level following a postulated LOCA or main steam line break. If any are flooded, evaluate the potential consequences of this flooding both for short and long-term ECCS functions and containment isolation. List all control room instrumentation lost following these accidents.

RESPONSE: Air-operated drain valves SIB-UV322 and 332 are used for relieving piping header pressure to the reactor drain tank after the RCS check valve test, but are not used during emergency operation.

An air-operated containment isolation valve CHA-UV560 is used to isolate the reactor drain tank discharge header. A second isolation valve is located outside containment.

Pressure instruments SIA-PT390 and SIB-PT391 are used in conjunction with RCS check valve testing and can also be used for indication of check valve leakage.

No control room instrumentation is lost. There are no harmful effects on the safety injection system from long- or short-term flooding of the above items.

QUESTION 6A.55 (NRC Question 440.78) (6.3)

Because of freezing weather conditions, blocking of the vent line on the refueling water tank (RWT) has occurred on at least one operating plant. Describe design bases and features that preclude this condition from occurring in the Palo Verde plant.

RESPONSE: The response is given in amended paragraph 6.5.2.8. As the winter ambient temperature at PVNGS has never been recorded below 32F for 24 consecutive hours, plugging of the RWT vent lines is considered very improbable.

QUESTION 6A.56 (NRC Question 440.79) (6.3)

It is our position that the SIS hotleg injection valves should be locked closed with power removed during normal plant operation in order to prevent premature hot leg injection following a LOCA.

RESPONSE: The response is given in amended paragraph 6.3.1.4.

QUESTION 6A.57 (NRC Question 440.80) (6.3)

Your sump test program described in subsection 6.2.2 is not in sufficient detail. The experimental program just demonstrate that sufficient margin in available NPSH over that required for each pump with all pumps at runout or maximum post-LOCA flow.

The test must demonstrate that the design precludes conditions adverse to safety system operation. Test parameters must include: (1) minimum to maximum containment water level, (2) minimum to maximum safety system flow range in various combinations (this includes transients associated with startup, shutdown, or throttling of a train or pump), (3) random blockage of up to 50 percent of the screens and grids, (4) approach flow for each dominant direction and combinations thereof, and (5) simulation of break flow or drain flow

impinging or originating within line of sight of the sump and its approaches.

If adverse conditions are encountered, the model configuration must be revised until an acceptable configuration is developed and demonstrated to perform over the full range of variables.

Since you choose to conduct a model test, provide details of the test program. Include information on the model size, scaling principles utilized, comparison of model parameters to expected post-LOCA conditions, and a discussion on how all possible flow conditions and screen blockages will be considered in the model tests. Whenever a reduced scale model is tested, all tendencies for vortex formation must be suppressed. Rota-tional flow patterns and surface dimples which might be acceptable in full scale tests, probably would not be accepted in a model program. Model testing must include some in-plant testing to demonstrate experimentally that NPSH margin exists for each pump.

RESPONSE: The response is given in amended paragraphs 6.2.2.2 and 6.3.1.4.

QUESTION 6A.58 (NRC Question 440.81) (6.3)

During our reviews of license applications we have identified concerns related to the containment sump design and its effect on long-term cooling following a LOCA.

These concerns are related to (1) creation of debris which could potentially block the sump screens and flow passages in the ECCS and the core, (2) inadequate NPSH of the pumps taking suction from the containment sump, (3) air entrainment from

streams of water or steam which can cause loss of adequate NPSH, (4) formation of vortices which can cause loss of adequate NPSH, air entrainment and suction of floating debris into the ECCS, and (5) inadequate emergency procedures and operator training to enable a correct response to these problems. Pre-operational recirculation tests performed by utilities have consistently identified the need for plant modifications.

The NRC has begun a generic program to resolve this issue. However, more immediate actions are required to assume greater reliability of safety system operation. We therefore require you take the following actions to provide additional assurance that long-term cooling of the reactor core can be achieved and maintained following a postulated LOCA.

1. Establish a procedure to perform an inspection of the containment, and the containment sump area in particular, to identify any materials which have the potential for becoming debris capable of blocking the containment sump when required for recirculation of coolant water. Typically, these mate-rials consist of: plastic bags, step-off pads, health physics instrumentation, welding equipment, scaffolding, metal chips and screws, portable inspection lights, unsecured wood, construction materials and tools as well as other miscellaneous loose equipment. "As licensed" cleanliness should be assured prior to each startup.

This inspection shall be performed at the end of each shut-down as soon as practical before containment isolation.

2. Institute an inspection program according to the requirements of Regulatory Guide 1.82, Item 14. This item addresses inspection of the containment sump components including screens and intake structures.

3. Develop and implement procedures for the operator which address both a possible vortexing problem (with consequent pump cavitation) and sump blockage due to debris. These procedures should address all likely scenarios and should list all instrumentation available to the operator (and its location) to aid in detecting problems which may arise, indications the operator should look for, and operator actions to mitigate these problems.

4. Pipe breaks, drain flow, and channeling of spray flow released below or impinging on the containment water surface in the area of the sump can cause a variety of problems; for example, air entrainment, cavitation, and vortex formation.

   Describe any changes you plan to make to reduce vortical flow in the neighborhood of the sump. Ideally, flow should approach uniformly from all directions.

5. Evaluate the extent to which the containment sump(s) in your plant meet the requirements for each of the items previously identified; namely debris, inadequate NPSH, air entrainment, vortex formation, and operator actions.

The following additional guidance is provided for performing this evaluation.

5.1 Refer to the recommendations in Regulatory Guide 1.82 (Section C) which may be of assistance in performing this evaluation.

5.2 Provide a drawing showing the location of the drain sump relative to containment sumps.

5.3 Provide the following information with your evaluation of debris:

a. Provide the size of openings in the fine screens and compare this with the minimum dimensions in the pumps which take suction from the sump (or torus), the minimum dimension in any spray nozzles and in the fuel assemblies in the reactor core or any other line in the recirculation flow path whose size is comparable to or smaller than the sump screen mesh size in order to show that no flow blockage will occur at any point past the screen.

b. Estimate the extent to which debris could block the trash rack or screens (50%). If a blockage problem is identified, describe the corrective actions you plan to take (replace insulation, enlarge cages, etc.).

c. For each type of thermal insulation used in the containment, provide the following information:

(1) type of material including composition and density,

(2) manufacturer and brand name,

(3) method of attachment,

(4) location and quantity in containment of each type,

(5) an estimate of the tendency of each type to form particles small enough to pass through the fine screen in the suction lines.

d. Estimate what the effect of these insulation particles would be on the operability and performance of all pumps used for recirculation cooling. Address effects on pump seals and bearings.

RESPONSE:

1. The Technical Requirements Manual (TRM) commits to inspection of the containment prior to establishing containment integrity.

2. Technical Specifications implement the inspection required by Regulatory Guide 1.82 (Revision 0), Item 14.

3. The response is given in amended paragraph 6.3.1.4 listing I. Amended paragraph 6.3.1.4, sublisting H.2 refers to CESSAR Table 6.3.2-3, which provides a list of the instrumentation available to the operator to monitor ECCS performance.

4. The response is given in amended paragraph 6.2.2.2.

5.1 Refer to section 1.8 for the PVNGS design requirements that meet NRC Regulatory Guide 1.82, Revision 0.

5.2 Figure 6A-4 shows the location of the drain sump relative to the containment sump.

5.3.a Figure 6A-5 provides the general arrangement and size of openings on the strainer assemblies. The response is given in amended paragraph 6.2.2.2.

5.3.b The response is given in amended paragraph 6.2.2.2.

5.3.c(1) The response is given in amended paragraph 6.2.2.2.

5.3.c(2) The response is given in amended paragraph 6.2.2.2.

5.3.c(3) The response is given in amended paragraph 6.2.2.2.

5.3.c(4) The response is given in amended paragraph 6.2.2.2.

5.3.c(5) The response is given in amended paragraph 6.2.2.2.

The only portion of the system that needs to be considered in this regard is that which is destroyed by the "blast" effects near the postulated breakpoint. In NUREG-0897, currently under review and revision, this area has been conservatively defined as all material within a right angle cone, extending seven diameters in line with the pipe. In this area, the material is "shredded" into fibers which will collect on the sump strainers. The volume of debris that is small enough to "pass through the fine screen in the suction lines" would, therefore, be much smaller than this volume. Although there exists no empirical data on which to base an analysis, it is thought that only a small percentage (less than 10%) would actually pass through the sump strainers.

This opinion is based on the fact that the majority of fibrous debris has been shown to transport along the floor and build up on the bottom of the strainers. Turbulent water is needed to disperse the fibers across a screen. Very fine fibers would tend to be trapped in large clumps

of fibers and would also be more susceptible to being "caught" in various gratings, crevices, and "crud traps".

5.3.d he stainless steel jacketed fiberglass insulation is not located near any postulated high energy line breaks (HELBs) that will require the use of the emergency sumps. Therefore, the fiberglass insulation will not be subject to the resulting affects of a HELB (i.e., pipe whip or jet impingement).

The fiberglass debris from the NUKON system does not pose a threat to the operability and performance of the pumps used for recirculation cooling. The glass fibers used in NUKON are typically less abrasive than the mineral fiber considered in Section 3.2.2.4 of NUREG-0897, Revision 1. The key conclusion of that section is that "...complete pump degradation or failure is not likely..." because the bearings are not subject to failure.

Since the TEMP-MAT insulation material will not disintegrate into a powder form, the insulation will not infiltrate the recirculating cooling water system to affect either the pump seals or bearings.

<u>QUESTION 6A.59</u> (NRC Question 440.84) (6.3)

Your response to Item II.K.3.17 of NUREG-0737 is not complete. Provide a commitment that you will establish a program prior to fuel loading for data collection on information regarding ECCS outages. The information will contain: (1) outage dates and duration of outages; (2) cause of the outages; (3) ECCS systems or components involved in the outage; and (4) collective action taken.

RESPONSE: The response is provided in amended Section 18.II.K.3.17.

QUESTION 6A.60 (NRC Question 440.86) (6.3)

Expand your interface requirements in paragraph 6.3.1.3 to include the requirement of power locked out on the SIS hot leg injection valves in order to prevent premature hot leg injection following a LOCA.

RESPONSE: The response is provided on the CESSAR docket. Refer to engineering drawings 01, 02, 03-M-SIP-001, -002 and -003.

See CESSAR FSAR responses to NRC Questions (NRC Question 440.77).

QUESTION 6A.61 (NRC Request for Additional Information, Containment System Branch)

Under postulated LOCA conditions, the reactor coolant drain tank (RCDT) room would become an essentially closed room, with only an annular pipe opening in the RCDT room ceiling available for the venting of any hydrogen evolved to the bulk containment volume. Furthermore, your present analysis of hydrogen production and accumulation following a LOCA indicates that the hydrogen concentration in the RCDT room would reach combustible levels relatively quickly. It is acknowledged that your hydrogen production analysis is conservatively based on staff licensing models for calculating hydrogen evolution for radiolysis of water, and assumptions of hydrogen transport from the RCDT room. Nevertheless, we have the following concerns which should be addressed:

(a) As a result of your Independent Design Review, you have identified the presence of the lights in the RCDT room as a potential ignition source if combustible levels of hydrogen are present. Therefore, describe the design features and/or administrative controls (normal and emergency operating procedures) that will assure the unavailability of electrical power to these lights under LOCA conditions.

(b) Provide an analysis of hydrogen transport from the RCDT room through the annular pipe opening into the adjacent containment region. For the postulated accident condition, the open containment volume, as opposed to the RCDT room, would contain a noncombustible hydrogen-air mixture. Therefore, the purpose of the calculation should be to determine if a combustible mixture exiting the RCDT room is adequately mixed to become nonflammable before it reaches a potential ignition source. Identify any potential ignition sources in the vicinity of the annular opening that could come in contact with a plume of a combustible hydrogen mixture.

(c) If the potential exists for a combustible plume of hydrogen emerging with the annular opening to come in contact with a potential ignition source, provide an analysis of the pressure response of the RCDT room assuming combustion under the most adverse conditions. Compare the calculated results to the structural capability of the RCDT room and discuss the response of any safety-related equipment located either inside or in the vicinity of the RCDT room.

RESPONSE:

(a) The response is given in paragraph 6.2.5.2.2.

(b) The response is given in paragraph 6.2.5.2.2.

(c) As noted in paragraph 6.2.5.2.2, there is no potential for a combustible plume of hydrogen emerging from the annular opening to come in contact with an ignition source.

7. INSTRUMENTATION AND CONTROLS

7.1 INTRODUCTION

Instrumentation and control systems that monitor and perform safety-related functions are discussed in this chapter. Complete descriptions and analyses of these systems are provided in sections 7.2 through 7.6. Systems that are not required for safety are discussed in section 7.7.

7.1.1 IDENTIFICATION OF SAFETY-RELATED SYSTEMS

The safety-related instrumentation and controls, including supporting systems, are identified below. The responsibility for the design of each system is identified as follows:

Combustion Engineering (C-E)/Westinghouse Electric Company LLC

Bechtel (Bechtel)

Identification of supplier/builder not identified below can be found in table 1.9-1.

7.1.1.1 Protection System

The PPS includes the electrical and mechanical devices and circuitry required to perform the protective functions defined below.

A. Reactor Protective System (RPS)

   The RPS is the portion of the PPS that acts to trip the reactor when required. The RPS is described in section 7.2.

B. Engineered Safety Features Actuation System (ESFAS)

The ESFAS is the portion of the PPS which activates the Engineered Safety Features Systems listed in section 7.1.1.3 and described in section 7.3.

C Supplementary Protection System (SPS)

The Supplementary Protection System (SPS) augments reactor protection by utilizing a separate and diverse trip logic from the Reactor Protective System for initiation of reactor trip. The addition of the SPS provides a simple, reliable, yet diverse mechanism to initiate a reactor trip. The SPS will initiate a reactor trip when pressurizer pressure exceeds a predetermined value.

The SPS is provided with sensors and circuitry which are diverse from those of the RPS. A selective two-out-of-four logic to interrupt the power supplied to the CEDM's and thereby cause the CEA's to drop into the core by gravity is used. The system is independent and separate from all control systems.

7.1.1.2 Reactor Trip System

The RTS includes the RPS portion of the PPS, Reactor Trip Switchgear System (RTSS) and the arrangement of components that perform a reactor trip after receiving a signal from the RPS or SPS automatically or manually by the operator. The RTS initiates a reactor trip based on the signals from the sensors which monitor various NSSS parameters and the containment pressure.

7.1.1.3 Engineered Safety Feature Systems

The ESF Systems include the NSSS and BOP ESFAS and the arrangement of components that perform protective actions after receiving a signal from the NSSS or BOP ESFAS or the operator. The instrumentation and controls for ESF Systems are described in section 7.3.

The NSSS ESF Systems are:

A.	Containment Isolation System;	(C-E)/(Bechtel)
B.	Main Steam Isolation System;	(Bechtel)
C.	Safety Injection System;	(C-E)
D.	Auxiliary Feedwater System;	(Bechtel)
E.	Containment Spray System;	(C-E)
F.	Supporting Systems.	(Bechtel)

The BOP ESF Systems are:

A. Fuel building essential ventilation system

B. Containment purge isolation system

C. Control room essential filtration system

D. Control room essential ventilation system

E. Containment combustible gas control system (manual)

7.1.1.4 Systems Required for Safe Shutdown

Systems required for safe shutdown are defined as those essential for pressure and reactivity control, coolant inventory makeup, and removal of residual heat once the reactor

has been brought to a subcritical condition. These systems are categorized according to the following shutdown modes:

A. Hot Shutdown

Systems required for maintenance of the primary system at, or near, operating temperature and pressure.

B. Cold Shutdown

Systems required to cool down and maintain the primary system at or near ambient conditions.

The systems required for safe shutdown are listed below and described in section 7.4.

The safe shutdown systems required to place the reactor in hot shutdown include:

1. Diesel Generator; (Bechtel)
2. Diesel Generator Fuel Storage and Transfer System; (Bechtel)
3. Class 1E AC System; (Bechtel)
4. Emergency Power Distribution System; (Bechtel)
5. Auxiliary Feedwater System; (Bechtel)
6. Atmospheric Steam Dump System; (Bechtel)
7. Chemical and Volume Control System (portions only, see section 9.3.4) (C-E)
8. Essential Spray Pond System; and (Bechtel)
9. Condensate Storage System (Bechtel)

In addition, equipment and systems are provided to allow emergency shutdown from outside the control room.

The safe shutdown systems or portions of systems required to place the reactor in cold shutdown include those in 1. through 9. above, plus the following:

10. Nuclear Cooling Water System; (Bechtel)
11. Essential Cooling Water System; (Bechtel)
12. Shutdown Cooling System. (C-E)

7.1.1.5 Safety-Related Display Instrumentation

The Safety-Related Display Instrumentation provides information to the operator to allow him to adequately monitor plant operating conditions and to perform any required manual safety functions. Safety-Related Display Instrumentation is described in section 7.5.

Safety-related displays are provided for:

A. Safety-Related Plant Process Display Instrumentation; (C-E)/(Bechtel)

B. Reactor Trip System Monitoring; (C-E)

C. Engineered Safety Features Systems Monitoring; (C-E)/(Bechtel)

D. CEA Position Indication; (C-E)/(Bechtel)

E. Post-Accident Monitoring; and (C-E)/(Bechtel)

F. Automatic Bypass Indication. (Bechtel)

7.1.1.6 All Other Systems Required for Safety

Other systems required for safety include the interlocks required to prevent overpressurization of the Shutdown Cooling System and to ensure safety injection availability. These are provided as listed below and described in section 7.6.

A. Shutdown Cooling System Suction Line Isolation Valve Interlocks; and (C-E)

B. Safety Injection Tank Isolation Valve Interlocks. (C-E)

7.1.1.7 Design Comparison

The Reactor Protective System (RPS) is designed by Combustion Engineering. The system will be functionally identical to the system provided for the Arkansas Nuclear One - Unit 2 (ANO-2) plant (NRC Docket No. 50-368) with the following exceptions:

A. High Linear Power Level Trip is replaced by a Variable Overpower Trip. The Variable Overpower Trip provides protection to the NSSS for rapid power changes from low initial power levels.

B. The Reactor Trip Switchgear (RTSG), which had consisted of nine trip circuit breakers on ANO-2, is now four circuit breakers in a Reactor Trip Switchgear System (RTSS). The change to the RTSS was performed to implement the SPS requirements.

C. The Supplementary Protection System (SPS) is new to the CESSAR licensing scope. This system is

specifically designed to increase the reliability of reactor trip initiation.

D. A low reactor coolant flow trip has been added to provide protection in the event of a reactor coolant pump sheared shaft.

The Engineered Safety Features Actuation System (ESFAS) is designed by Combustion Engineering. Each initiation system logic, including testing features, is similar to the logic for the RPS and is contained in the same physical enclosure. The actuation logic and devices are contained in the ESFAS Auxiliary Relay Cabinets. The design of this system is described in section 7.3. The following changes from ANO-2 make the ESFAS more diverse and responsive to the situation requiring its actuation:

A. CIAS initiation logic now includes low pressurizer pressure;

B. MSIS initiation logic now includes high steam generator level and high containment pressure;

C. RAS has had manual initiation added;

D. AFAS initiation logic is modified by removing a steam generator low pressure permissive and by adding interlocks between AFAS-1 and AFAS-2.

Balance of Plant engineered safety features actuation systems (BOP ESFASs) designed to actuate ESF systems presented in paragraph 7.1.1.3 F, A through E employ one-out-of-two logic, described in section 7.3, as opposed to the two-out-of-four logic for this NSSS ESFAS.

7.1.2 IDENTIFICATION OF SAFETY CRITERIA

Comparison of the design with applicable Regulatory Guide recommendations and the degree of compliance with the appropriate design bases, General Design Criteria, standards, and other documents used in the design of the systems listed in Section 7.1.1 are described in Sections 7.1.2.1 through 7.1.2.35, and in each of the sections describing the system. (Refer to sections 7.2 through 7.6.)

7.1.2.1 Design Bases

The design bases for the safety-related instrumentation and control of each safety-related system are presented in the section of this chapter that discusses the system to which the information applies.

Consideration has been given to instrument error in the selection of all safety system setpoints. Where setpoints are listed in Chapter 7, it is understood that these are nominal values. The actual setpoint may vary within prescribed accuracies which have been considered in selection of the values.

7.1.2.1.1 Systems Required for Plant Protection

The instrumentation and controls for the Reactor Protective System and Engineered Safety Features Systems conform to the following:

A. The PPS and the ESF Systems conform to IEEE Standard 279-1971. Detailed discussion of conformance for these and other safety-related system instrumentation

and controls is provided in the applicable section of this chapter. Conformance to the other IEEE Standards is discussed in sections 7.1.2.3 through 7.1.2.12.

B. Comparison with Regulatory Guide recommendations for Water-Cooled Nuclear Power Plants, Division of Reactor Standards, Nuclear Regulatory Commission, is discussed in sections 7.1.2.6, 7.1.2.9, 7.1.2.10, and 7.1.2.13 through 7.1.2.32.

C. Quality assurance procedures are described in CENPD-210A, "Description of the C-E Nuclear Steam Supply System Quality Assurance Program (Reference 1).

D. General Design Criteria for Nuclear Power Plants, Appendix A to 10CFR50, July 7, 1971, as described in section 3.1.

E. The standards the upgraded Core Protection Calculator System (CPCS) were designed to are described in CENPD-396-P, "Common Qualified Platform Topical Report"[(4)]. However, Palo Verde has not increased its commitments to these new or revised standards.

7.1.2.1.2 Systems Required for Safe Shutdown

The design bases for the systems required for safe shutdown are described in section 7.4.

7.1.2.1.3 Safety-Related Display Instrumentation

The design bases for Safety-Related Display Instrumentation are described in section 7.5.

7.1.2.1.4 All Other Systems Required for Safety

The design bases for all other systems required for safety are described in section 7.6.

7.1.2.2 Conformance to IEEE 279

Conformance to IEEE 279-1971, is discussed in paragraphs 7.1.2.1, 7.1.2.1.1, 7.2.1.2, 7.2.2.3.2, 7.3.1.2, 7.3.2.3.1, 7.3.2.3.2, 7.4.2.1, 7.5.2.5 and 7.6.2.1.

7.1.2.3 Conformance to IEEE 308

Conformance to IEEE 308-1974, is discussed in section 8.3.

7.1.2.4 Conformance to IEEE 317

Electric penetrations and their conformance to IEEE 317-1972 are discussed in section 8.3.

7.1.2.5 Conformance to IEEE 323

The CESSAR Licensing scope compliance with IEEE 323-1974, "IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations", for instrumentation is discussed in Combustion Engineering Topical Report CENPD-255, "Qualification of Combustion Engineering Class 1E Instrumentation", (Reference 2). The basic qualification requirements of CESSAR Licensing scope equipment are discussed in section 3.11.

Qualification of Class IE electrical equipment not supplied by C-E, is discussed in sections 8.3 and 3.11.

7.1.2.6 Conformance to IEEE 336 as Augmented by Regulatory Guide 1.30

A planned quality assurance (QA) program, in compliance with IEEE 336-1971, has been implemented. This includes a comprehensive quality control and QA program.

7.1.2.7 Conformance to IEEE 338

The PPS and ESFAS Auxiliary Relay Cabinet circuits, as well as the RTSS, are designed so that they can be periodically tested in accordance with the criteria of IEEE 338-1971, "Periodic Testing of Nuclear Power Generating Station Protection Systems".

Testing criteria are specified in sections 7.2.2.3.3 and 7.3.2.3.3. Minimum testing frequency requirements are provided in the Technical Specifications.

Since operation of the ESF Systems is not expected, the systems are periodically tested to verify operability. Complete channels, in the NSSS ESFAS systems, can be individually tested without initiating protective action and without inhibiting the operation of the system.

The system can be checked from the sensor signal through the actuation devices. The functional modules in the sensors system can be tested during reactor operation. The sensors can be checked by comparison with similar channels.

Those actuated devices, which are not tested during the reactor operation will be tested during scheduled reactor shutdown to show that they are capable of performing the necessary functions.

In addition, in conformance to IEEE 338-1971, response time testing for all plant protection system (PPS) channels and equipment is performed during preoperational testing and each refueling interval. The Technical Specifications describe testing frequency.

7.1.2.8 Conformance to IEEE 344

The CESSAR Licensing scope compliance with IEEE 344-1971, "IEEE Guide for Seismic Qualification of Class 1 Electric Equipment for Nuclear Power Generating Stations" is discussed in Combustion Engineering Topical Report CENPD-182, "Seismic Qualification of Instrumentation Equipment" (Reference 3).

Conformance to IEEE 344-1975, is discussed in section 3.10.

7.1.2.9 Conformance to IEEE 379 as Augmented by Regulatory Guide 1.53

Instrumentation for the PPS and ESFAS Auxiliary Relay Cabinets, and the RTSS conform to the requirements of IEEE 379-1972, "IEEE Trial-Use Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protection Systems", as augmented by Regulatory Guide 1.53, "Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems". A discussion of the application of the single failure criterion is provided in sections 7.2.2.3.2 and 7.3.2.3.2 for these systems.

In addition, the essential safety-related supporting systems listed in paragraph 7.1.1.4 comply with the requirements of

IEEE 379-1972 as augmented by Regulatory Guide 1.53. The single failure criterion is discussed in subsection 7.3.2.

7.1.2.10 Conformance to IEEE 384 as Augmented by Regulatory Guide 1.75

The instrumentation for the safety-related electric systems conforms to the requirements of IEEE 384-1974, "IEEE Trial-Use Standard Criteria for Separation of Class 1E Equipment and Circuits", as augmented by Regulatory Guide 1.75, "Physical Independence of Electric Systems". A discussion of the physical independence is provided below which describes the compliance with section 4.6 of IEEE 279-1971 and General Design Criteria 3 and 21.

The PPS cabinet is divided into four bays which are separated by mechanical and thermal barriers. Each bay contains one of the four redundant channels of the RPS and ESFAS. This provides the separation and independence necessary to meet the requirements of section 4.6 of IEEE 279-1971.

Separation of redundant Class 1E circuits within the PPS cabinet is accomplished through 6 inch separation or barriers or conduit. However, in the formation of the logic matrices (AB, AC, BC, AD, BD, CD), initiation circuits, and actuation circuits, 6 inch separation is not maintained, nor can barriers or conduit be utilized. An analysis has been performed to show that the separation achieved is acceptable. Tests and analyses have also been completed to demonstrate that no single credible event in one PPS bay can prevent the circuitry in any other bay from performing its safety function.

The ESFAS Auxiliary Relay Cabinets provide separation and independence for the selective two-out-of-four actuation logics and actuation relays of the two redundant ESF Systems’ Trains. Each train's logic and relays are contained in a separate cabinet with all of the train A actuation circuits in one cabinet and all of the train B actuation circuits in the other cabinet. There are mechanical and thermal barriers within the cabinets to protect different portions of the selective two-out-of-four logic from spurious actuation. The two cabinets are physically separated from each other.

The RTSS consists of four RTSG. Each RTSG and its associated switches, contacts, relays, etc. is contained in a separate cabinet. Each cabinet is physically separated from the other cabinets. This method of construction ensures that a single credible failure in one RTSG cannot cause malfunction or failure in another cabinet.

The separation and independence of the power supplies for each of the above systems is discussed in Chapter 8.0. The interface requirements appear in section 7.1.3 while the implementation will appear in section 7.1.4. Protection system analog signals, sent to the Plant Monitoring System (PMS), are isolated from the protection system. Digital signals are also isolated for the associated signals coming from the protection system.

All of these isolation techniques ensure that no credible failures on the output side of the isolation device will effect the PPS side and that the independence of the PPS is not jeopardized.

In addition, compliance to General Design Criterion 17, IEEE 384-1974, and Regulatory Guide 1.75 is described in section 8.3 and section 1.8. Additionally, instrumentation for the safety-related electrical instrumentation and control systems supplied by C-E was designed using Regulatory Guide 1.75, Revision 0, 2/74.

7.1.2.11 Conformance to IEEE 387

Conformance to IEEE 387-1972 is discussed in section 8.1.

7.1.2.12 Conformance to IEEE 450

Conformance to IEEE 450 is discussed in subsection 8.3.2.

7.1.2.13 Comparison of Design with Regulatory Guide 1.6

A comparison of the design with Regulatory Guide 1.6 is provided in paragraph 8.1.4.3.1.

7.1.2.14 Comparison of Design with Regulatory Guide 1.11

Containment penetrations for the eight containment pressure detectors are consistent with the recommendations of Regulatory Guide 1.11. All other containment penetrations are in accordance with NRC General Design Criteria 55, 56, or 57. Isolation of containment penetrations is discussed in detail in subsection 6.2.4.

7.1.2.15 Conformance to Regulatory Guide 1.22

The PPS, ESFAS Auxiliary Relay Cabinets, and the RTSS, as described in section 7.1.1, conform to the guidance of

Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions". This conformance is described below.

A. Provisions are made to permit periodic testing of the complete PPS, ESFAS Auxiliary Relay Cabinets, and RTSS with the reactor operating at power or when shutdown. These tests cover the trip action from sensor input to the PPS cabinets through the protection system or ESFAS Auxiliary Relay Cabinets to and including the RTSS and the ESFAS actuated devices. Those ESFAS actuated devices which could affect operations are not tested while the reactor is operating but during reactor shutdown.

B. The provisions of this position are incorporated in the testing of the PPS, from sensor to actuation device, including the ESFAS and ESFAS Auxiliary Relay Cabinets and the RTSS.

   1. No provisions are made in the design of the PPS, ESFAS Auxiliary Relay Cabinets, and RTSS at the systems level to intentionally bypass an actuation signal that may be required during power operation. All bypasses are on a channel level to prevent an operator from inadvertently bypassing a trip function.

   2. The manual testing circuitry for an RPS channel is interlocked to prevent testing in more than one redundant channel simultaneously. Testing requiring a channel bypass is automatically indicated in the main control room.

3. Manual testing of an ESFAS channel requiring a channel bypass is automatically indicated in the main control room.

C. Actuated devices which cannot be tested during reactor operation will be tested by the ESFAS circuitry when the reactor is shutdown.

Additional information regarding conformance with Regulatory Guide 1.22 for non-C-E portions of the safety-related systems is provided in subsection 7.3.2.

7.1.2.16 Conformance to Regulatory Guide 1.29

The PPS and ESFAS and other instrumentation and controls necessary for safety conform to the guidance of Regulatory Guide 1.29, "Seismic Design Classification". This conformance is described below.

The systems designated as Seismic Category I are items listed in Regulatory Guide 1.29, Sections C.1.k, C.1.1, and C.1.q. The seismic classification and qualification are discussed in Combustion Engineering Topical Report CENPD-182 (Reference 3) and section 3.10. The Class 1E electric systems identified in C.1.q are discussed in section 8.3.

Those portions of structures, systems, or components whose continued function is not required, are designed so that the SSE will not cause a failure which will reduce the functioning of any plant safety feature to an unacceptable level, including incapacitating injury to the occupants of the control room. This is a qualification to Regulatory Guide 1.29 position C.1.r which would classify these items as Seismic Category I.

The classifications of non-CE systems and components which are described in sections 7.2, 7.3, 7.4, 7.5, and 7.6 are listed in section 3.2. The design methods are described in section 3.7, and test/analysis methods and results are given in section 3.10. Refer to section 1.8 for a discussion of PVNGS interpretation of Regulatory Guide 1.29.

7.1.2.17 Conformance to Regulatory Guide 1.30

Refer to section 1.8 for a discussion of PVNGS conformance to Regulatory Guide 1.30.

7.1.2.18 Conformance to Regulatory Guide 1.40

There are no Class 1E continuous-duty motors installed inside the containment.

7.1.2.19 Conformance to Regulatory Guide 1.47

The design of the RPS and the ESFAS as indicated in sections 7.2 and 7.3, is consistent with the recommendations of Regulatory Guide 1.47, "Bypassed and Inoperable Status Indication for Nuclear Power Plants Safety System". Conformance is described below.

Bypasses can be classified into two groups: operating bypasses and trip channel bypasses.

7.1.2.19.1 Operating Bypasses

The operating bypass is used during routine startup and shutdown. These bypasses must be manually inserted. They utilize permissive contact inputs generated from the

parameter(s) being bypassed to ensure the bypass is removed if plant conditions deviate to the point where the bypass is no longer safe. (Example: If the coolant system pressure rises above a predetermined setpoint, the RPS/ESFAS pressurizer pressure bypass is automatically removed.) Once a bypass is automatically removed, the manual switch must be turned to the normal (unbypassed) position and then returned to bypass in order to reinsert the bypass for all systems except the CPC system. This prevents cycling the bypass with the permissive contact status. Separate contacts from the manual switch and permissive relay are combined to provide a plant annunciator output. Indicator lamps are provided in the bypass circuit to monitor directly the application of the bypass. These are located on the PPS remote operator's modules and display bypass status for each channel. Operating bypasses include the RPS/ESFAS pressurizer pressure bypass, the high log power bypass and the DNBR/LPD trip bypass.

7.1.2.19.2 Trip Channel Bypasses

These bypasses are used to individually bypass channel trip inputs to the protection system logic for maintenance or testing. The trip logic is converted from a two-of-four to a two-of-three logic for the parameters being bypassed, while maintaining a coincidence two for actuation. Only one channel for any one parameter may be bypassed at any one time. This is accomplished by electrically interlocking the manual bypass switches. These bypasses must be manually initiated and removed. Individual bypass indicator lights are provided locally at the PPS and at the PPS remote operator's modules

located in the control room. The wiring for these indicators is run within their respective channels so that faults in any one module will not affect the other channel bypass indication or bypass status. A separate signal is provided to the plant annunciator when any trip channel bypass is present. In addition, the status of each bypass is provided to the Plant Monitoring System.

A. Annunciator outputs are provided to indicate, at the system level, the bypassing or deliberate inducing of inoperability of a protection system. The system level alarms are actuated when a component actuated by a protection system is bypassed or deliberately rendered inoperable.

B. Those auxiliary and support systems within the CESSAR Licensing scope provide automatic annunciator activation to indicate, on a system level, the bypassed or deliberately induced inoperability of an auxiliary or support system that effectively bypasses or renders inoperable a protection system and the systems actuated or controlled by a protection system.

C. Annunciation shall be provided in the control room, at the system level, for each bypassed or deliberately induced inoperable status in a protection system.

    1. These are supplied for those systems discussed in A. and B. above.

    2. All of these bypasses are expected to be used at least once a year.

3. All of these bypasses are expected to be usable when the annunciated system is expected to be operable.

D. The operator shall be able to activate each system level bypass indicator manually in the control room.

For a discussion of the non-CE systems listed in paragraph 7.1.1.3 regarding conformance with Regulatory Guide 1.47, see section 7.5.

7.1.2.20 Conformance to Regulatory Guide 1.53

The conformance to Regulatory Guide 1.53 is discussed in paragraph 7.1.2.9.

7.1.2.21 Conformance to Regulatory Guide 1.62

Manual initiation of the RPS is described in sections 7.2.1.1.1.11, and 7.2.2.3.2. Manual initiation of the ESFAS is described in sections 7.3.1.2 and 7.3.2.3.2. Conformance to Regulatory Guide 1.62, "Manual Initiation of Protective Actions", is as follows:

A. Each of the above systems has means for manual actuation.

B. Manual initiation of a protective action causes the same actions to be performed by the protection system as would be performed if the protection system had been initiated by automatic action.

C. Manual switches are located in the control room and at the RTSS for use by the operator. Some functions also have actuation at remote locations.

D. The amount of equipment common to the manual and automatic initiation paths is kept to a minimum, usually just the actuation devices. No single credible failure in the manual, automatic, or common portions of the protective system will prevent initiation of a protective action by manual or automatic means.

E. Manual initiation requires a minimum of equipment consistent with the needs of A., B., C., and D. above.

F. Once initiated, manual protective action will go to completion. (Refer to section 7.3.1.1.10.7.)

In addition, manual initiation of the portions of the ESFAS not supplied by C-E is discussed in section 7.3.

7.1.2.22 Conformance to Regulatory Guide 1.63

Conformance to Regulatory Guide 1.63 is discussed in section 1.8.

7.1.2.23 Conformance to Regulatory Guide 1.68

Conformance with Regulatory Guide 1.68, Preoperational and Initial Start-Up Test Program for Water-Cooled Power Reactors, is discussed in section 14.2.

7.1.2.24 Conformance to Regulatory Guide 1.73

The CESSAR Licensing scope electric valve operators intended to be installed inside the containment are qualified in compliance with Regulatory Guide 1.73, "Qualification Tests of Electric

Valve Operators Installed Inside the Containment of Nuclear Power Plants", (see section 3.11).

In addition, non-CE supplied electric valve operators installed within the containment are in compliance with Regulatory Guide 1.73 and are discussed in section 3.11.

7.1.2.25 Conformance to Regulatory Guide 1.75

The conformance to Regulatory Guide 1.75 is discussed in section 1.8. Procurement specifications for 1E systems and components required conformance to Regulatory Guide 1.75. A further description of the conformance is contained in paragraphs 8.3.1.2 and 8.3.1.4.

7.1.2.26 Conformance to Regulatory Guide 1.80

Regulatory Guide 1.80 has been withdrawn. It is replaced by Regulatory Guide 1.68.3.

7.1.2.27 Conformance to Regulatory Guide 1.89, Revision 1

The conformance to Regulatory Guide 1.89, Rev. 1 is given in section 1.8.

7.1.2.28 Conformance to Regulatory Guide 1.95

Not applicable; see section 1.8.

7.1.2.29 Conformance to Regulatory Guide 1.97

Conformance to Regulatory Guide 1.97 is presented in section 1.8. The post-accident monitoring instrumentation is described in paragraph 7.5.2.5.

7.1.2.30 Conformance to Regulatory Guide 1.100

Conformance to Regulatory Guide 1.100 is presented in section 3.10.

7.1.2.31 Conformance to Regulatory Guide 1.105

Conformance to Regulatory Guide 1.105 is presented in section 1.8.

7.1.2.32 Conformance to Regulatory Guide 1.118

Conformance to Regulatory Guide 1.118 is given in section 1.8 and implemented in the Technical Specifications. Specific test capabilities within the reactor protective system and the engineered safety features systems are described in paragraphs 7.1.2.7 and 7.3.1.1 and subsection 7.2.1.

7.1.2.33 Evaluation of IE Bulletin 79-27

Action Item 1.

IE Bulletin 79-27 addressed three review areas, as follows:

[Area] 1. Review the Class 1E and non-Class 1E buses supplying power to safety- and nonsafety-related instrumentation and control systems which could affect the ability to achieve a cold shutdown condition using existing procedures or procedures developed under [Area] 2 below. For each bus:

a. Identify and review the alarm and/or indication provided in the control room

to alert the operator to the loss of power to the bus.

b. Identify the instrument and control system loads connected to the bus and evaluate the effects of loss of power to these loads including the ability to achieve a cold shutdown condition.

c. Describe any proposed design modifications resulting from these reviews and evaluations, and your proposed schedule for implementing those modifications.

[Area] 2. Prepare emergency procedures or review existing ones that will be used by control room operators, including procedures required to achieve a cold shutdown condition, upon loss of power to each Class 1E and non-Class 1E bus supplying power to safety and nonsafety-related instrument and control systems. The emergency procedures should include:

a. The diagnostics/alarms/indicators/ symptom resulting from the review and evaluation conducted per [Area] 1 above.

b. The use of alternate indication and/or control circuits which may be powered from other non-Class 1E or Class 1E instrumentation and control buses.

c. Methods for restoring power to the bus.

Describe any proposed design modifications or administrative controls to be implemented resulting from these procedures, and your proposed schedule for implementing the changes.

[Area] 3. Re-review IE Circular No. 79-02, Failure of 120 Volt Vital AC Power Supplies, dated January 11, 1979, to include both Class 1E and non-Class 1E safety-related power supply inverters. Based on a review of operating experience and your re-review of IE Circular No. 79-02, describe any proposed design modifications or administrative controls to be implemented as a result of the re-review.

Evaluation

Our review has determined that the PVNGS design consists of two ungrounded non-Class 1E, 120 V-ac instrument distribution panels E-NNN-D11 and E-NNN-D12 and four ungrounded vital (Class 1E) 120 V-ac instrument distribution panels E-PNA-D25, E-PNB-D26, E-PNC-D27, and E-PND-D28.

Each ungrounded non-Class 1E volt ac instrument distribution panel is normally supplied from a 480 V-ac, non-Class 1E motor control center through a voltage regulator-transformer to a transfer switch. A backup source is provided from a 480 V-ac, Class 1E motor control center through a Class 1E voltage regulator-transformer as an isolation device to the transfer switch. The transfer switch automatically transfers, upon loss

of power on the normal source, to the backup source. Manual transfer is required to return to the normal source. The distribution panel is fed from the transfer switch through a panel feeder breaker. Distribution to the instrument cabinets is through branch circuit breakers.

Each undergrounded vital (Class 1E), 120Vac instrument distribution panels is normally supplied from a 125v-dc Class 1E control center through a Class 1E inverter and its manual or static transfer switches. A backup source is provided from a 480V-ac, Class 1E motor control center through a voltage regulating transformer connected to the manual or inverter static transfer switch. Transfer from the preferred normal inverter power to the voltage regulating transformer power will occur automatically on the inverter trouble or manually (when required) without loss of load. An additional source of power is provided from a swing inverter and swing line-up switch, if available, connected to the normal inverter manual transfer switch. Transfer to the swing inverter will require manual operations with no loss of load. The distribution panel is fed from the transfer switch through a panel feeder breaker.

Our specific response to [Area] 1.a is that an alarm for each non-Class 1E instrument distribution panel is provided to the operator in the control room. Annunciation will occur on the following:

- Normal source undervoltage
- Backup source undervoltage
- Ground detection

- Overload tripping of the panel feeder breaker
- Overload tripping of any branch circuit breaker

An alarm is provided for each Class 1E instrument distribution panel and an alarm for each Class 1E inverter and transfer switch. Annunciation will occur on the following:

- Inverter output breaker tripped
- Inverter DC input breaker tripped
- Inverter AC Bypass source breaker tripped, if available per implementation of DMWO 3232547
- Inverter output voltage low or high
- Inverter system output voltage high, if available per implementation of DMWO 3232547
- Inverter overcurrent (overload)
- Inverter DC input voltage low or high
- Loss of synchronization (of the inverter only)
- Transfer switch not on normal source
- Inverter fan failure
- Inverter fuse blown, if available per implementation of DMWO 3232547
- Distribution panel undervoltage
- Ground detection
- Overload tripping of the panel feeder breaker

For [Area] 1.b, the instrument and control system loads connected to each instrument distribution panel are provided as noted on table 8.3-4.

Those specific instrument parameters and controls detailed in 7.4.1.1.10.2 as being required to achieve cold shutdown are listed in table 7.1-2. Instrument loop displays and controls available to the control room operator and the instrument distribution panel supply are identified.

Motor-operated valves, pumps, pressurizer heaters, and solenoids required to achieve cold shutdown are powered from buses other than the instrument distribution panels.

Table 7.1-1

In response to [Area] 1.c, we have determined that loss of a single instrument distribution panel, Class 1E or non-Class 1E, will cause a loss of some of the indicators and recorders available to the control room operator. This failure mode is distinguishable and will not offer confusing information to the operator since the instrumentation and control systems lost will generate alarms and actuation of some equipment as the loop output contacts fail to their deenergized states. In addition, the loss of power to each analog instrument cabinet is alarmed in the control room. In the non-Class 1E instrument loops affecting safe shutdown circuits, i.e., pressurizer level control of the pressurizer backup heaters, selector switches are provided on the main control panel to enable the operator to provide control from the unaffected control loop. No control action generated by the loss of an instrument distribution panel will prevent the operator from controlling the required safe shutdown equipment or interfere with the safe shutdown functions. Upon detection of loss of an instrument distribution panel, adequate instrumentation and control functions from the list provided above will be available to the operator to enable the operator to achieve a cold shutdown condition. No design modifications are proposed.

Action Item 2.

Emergency procedures that will be used by control room operators, including procedures required to achieve a cold shutdown condition, upon loss of power to each Class 1E and non-Class 1E bus supplying power to safety- and nonsafety-related instruments and control systems will be prepared and

then reviewed at least 3 months prior to the operating license. The procedures will include the following information:

A. The diagnostics/alarms/indicators/symptom resulting from the review and evaluation conducted per Item 1 of IE Bulletin No. 79-27.

B. The use of alternate indication and/or control circuits which may be powered from other non-Class 1E or Class 1E instrumentation and control buses.

C. Methods for restoring power to the bus.

A description of any proposed design modifications or administrative controls to be implemented resulting from these procedures, and the proposed schedule for implementing the changes will also be provided.

Action Item 3.

IE Circular No. 79-02, Failure of 120 Volt Vital AC Power Supplies, has been re-reviewed in consideration of item 3 to include both Class 1E and non-Class 1E instrument distribution panel supplies. For the Class 1E inverters, the PVNGS design precludes the possibility of a transient causing a failure of a Class 1E inverter by utilizing a battery source in parallel with a dc charger. The battery source serves to eliminate any undervoltage transients that the charger may experience.

The non-Class 1E instrument distribution panels are not supplied through inverters. Both the normal and backup supplies are fed from 480 V-ac through a voltage regulator-transformer. The transfer switch will automatically transfer, upon loss of power on the normal source, to the

backup source. Manual transfer is required to return to the normal source. The switch is also equipped with a mechanical handle which bypasses electric circuitry and can switch to either source. No design modifications are proposed.

7.1.2.34 Evaluation of IE Bulletin 80-06

The ESF actuation signals incorporated in the PVNGS design include:

A. NSSS ESFAS

- Containment isolation actuation signal (CIAS)
- Containment spray actuation signal (CSAS)
- Main steam isolation signal (MSIS)
- Safety injection actuation signal (SIAS)
- Recirculation actuation signal (RAS)
- Auxiliary feedwater actuation signals (AFAS) 1 and 2

B. BOP ESFAS

- Fuel building essential ventilation actuation signal (FBEVAS)
- Containment purge isolation actuation signal (CPIAS)
- Control room ventilation isolation actuation signal (CRVIAS)

- Control room essential filtration actuation signal (CREFAS)

Manual reset of the ESF actuation signals in both the NSSS and BOP systems design can be performed only after the initiating signals, i.e., low pressurizer pressure, have cleared. Reset switches are located at the PPS, ESFAS auxiliary relay, and BOP ESFAS cabinets.

PVNGS equipment which may change position from the safety or emergency state on reset of an ESF actuation signal is identified in table 7.1-3. These actuated devices can be categorized as follows:

A. Certain actuated devices, i.e., jog type valves or the ESF load sequencer, require a maintained ESF signal through completion of their safety function. If an ESF actuation signal is reset prior to completion of the valve stroke or completion of ESF load sequencing, the valve will stop mid-travel or the sequencer will not complete sequencing on the required equipment (equipment already sequenced or does not stop). Since completion of these actions takes no more than 60 seconds, ESF actuation signal reset is not considered. Engineered safety features actuation, followed by clearing of the initiating signals with the requirement of manual reset at the appropriate cabinet, all occurring within a short period of time (<1 minute), is not credible under true accident conditions. No modification to these equipment control circuits is required.

Table 7.1-3

IDENTIFICATION OF ACTUATED DEVICES WHICH CHANGE POSITION ON RESET OF ESF ACTUATION SIGNAL (Sheet 1 of 4)

Actuated Device	Tag No.	Elementary Diagram	ESF Actuation Signal	Safety Mode	Action of ESF Actuation Signal Reset	Corrective Action
Auxiliary feedwater regulating valves to SG 1	J-AFB-HV-30 J-AFA-HV-32	13-E-AFB-003 13-E-AFB-004	AFAS-1	Open/ Close	Valves cycle on AFAS-1	None[(a)]
Auxiliary feedwater regulating valves to SG 2	J-AFB-HV-31 J-AFC-HV-33	13-E-AFB-003 13-E-AFB-006	AFAS-2	Open/ Close	Valves cycle on AFAS-2	None[(a)]
Auxiliary feedwater isolation valves to SG 1	J-AFB-UV-34 J-AFC-UV-36	13-E-AFB-005 13-E-AFB-006	AFAS-1	Open/ Close	Valves cycle on AFAS-1	None[(a)]

a. See Paragraph 7.1.2.34, listing D.

b. See Paragraph 7.1.2.34, listing C.

c. See Paragraph 7.1.2.34, listing A.

Table 7.1-3

IDENTIFICATION OF ACTUATED DEVICES WHICH CHANGE POSITION ON RESET OF ESF ACTUATION SIGNAL (Sheet 2 of 4)

Actuated Device	Tag No.	Elementary Diagram	ESF Actuation Signal	Safety Mode	Action of ESF Actuation Signal Reset	Corrective Action

B. An SIAS trips non-ESF equipment (CEDM normal ACU fans, containment normal ACU fans, pressurizer backup heaters, normal chillers) off the 1E buses. On reset of SIAS, this equipment will not be automatically loaded onto the 1E buses, but will be manually loaded onto the 1E buses at the discretion of the operator.

C. Certain actuated devices have different safety modes in response to different ESF actuation signals. In the event that ESF actuation signals requiring both safety modes occur, one safety mode by design will have priority. On reset of that particular ESF actuation signal, the actuated device will change position to the safety mode required by the remaining ESF actuation signal. This means of control does not defeat required ESF system functions, and no modification is required to these equipment control circuits.

D. The AFAS 1 and AFAS 2 signals to the auxiliary feedwater valves are designed to cycle based on steam generator level. This automatic resetting of the AFAS 1 and AFAS 2 does not affect the AFAS 1 and AFAS 2 signals to other actuated equipment. The auxiliary feedwater valve cycling represents the desired ESF system function and no modification is required to the equipment control circuits.

7.1.2.35 Evaluation of IE Information Notice 79-22

The high energy line break (HELB)/control system interaction analysis process employed in the review of the PVNGS Units 1,

2, and 3 design is illustrated by the logic diagram of figure 7.1-1. The events considered are those defined in chapters 6 and 15 of the PVNGS FSAR. The process consists of the following steps:

A. Identification of all nonsafety grade systems or control systems of significance to the FSAR chapters 6 and 15 analyses.

B. Identification of potential adverse control system malfunctions induced by HELB events.

C. Detailed system design reviews of control systems with a potentially significant impact on the course of FSAR chapters 6 and 15 events to determine which, if any, failure modes can be postulated to cause the adverse malfunctions.

D. Identification of the physical locations of control systems components whose malfunctions could be postulated to cause the adverse malfunction and determination if the components can be impacted by the HELB of concern.

E. Resolution of potential HELB/control system interaction issues through the use of backup systems and/or quantitative analyses to determine if the malfunctions effects are acceptable, and through detailed evaluations of the qualification status of control system components.

The HELBs considered in this analysis are: loss-of-coolant accident (LOCA) steam line break (SLB), feedwater line break (FWLB), and reactor coolant system (RCS) breaks which occur

outside of the containment. Completion of listings A through D disclosed four potential HELB/control system interactions which could exacerbate event consequences. These are:

1. Failure of the pressurizer pressure control system (PPCS) to deenergize pressurizer heaters when the low level cutout signal is given. This malfunction is of concern during a LOCA, or SLB due to the potential for the heater failure mode to impact the RCS pressure boundary.

2. Failure of the reactor regulating system (RRS) such that CEAs are withdrawn prior to reactor trip. The resultant core power increase is of concern during LOCA, SLB, and FWLB events.

3. Failure of the steam bypass control system (SBCS) such that the steaming rate is increased. This malfunction is of concern during SLBs because of the potential for a post-trip return to power.

4. Failure of the PLCS such that the RCS inventory is increased. This malfunction is of concern during FWLB events where a potential to fill the pressurizer could exist.

The impacts of the assumed malfunctions were determined in listing E. The results of these investigations demonstrate that the HELB/control system malfunction event consequences are bounded by the event consequences presented in the FSAR. Therefore, no design modifications or operator procedure revisions are needed to mitigate the consequences of HELB/control system interactions.

7.1.3 CESSAR INTERFACES

The following NSSS general interface requirements are repeated from CESSAR Section 7.1.3.

7.1.3.1 Power

Vital instrument power requirements for the safety-related systems are discussed in Section 8.3.1.

7.1.3.2 Protection from Natural Phenomena

Refer to Section 3.1.2. CESSAR Design Scope Class 1E equipment shall be located within the plant so as to ensure the various natural phenomena specified in GDC 2 which are applicable to the Applicant's site will not result in degradation of that equipment below the level required to allow it to perform required protective action assuming a single failure.

7.1.3.3 Protection from Pipe Failure

The location of safety-related instrumentation and control components shall take into account their potential damage due to piping failures, such as pipe whip, jet impingement, etc., from high or medium energy fluid systems.

The location of these components and the routing of 1E and associated cables and sensing lines should avoid such hazards or shall be provided with adequate protection such that required protective action can be performed assuming a single piping failure, its associated effects, and a single failure.

7.1.3.4 Missiles

The safety-related equipment shall be protected from potential missile sources. The 1E and associated cabling and sensing lines shall be handled in a similar fashion.

7.1.3.5 Separation

The routing of 1E and associated cabling and sensing lines from sensors shall be arranged to minimize the possibility of common mode failure. This requires that the cabling for the four safety channels be routed separately, however, the cables of different safety functions within one channel, may be routed together. Low energy signal cables shall be routed separately from all power cables. Safety-related sensors wired to separate channels shall be physically and electrically separated. The separation of their safety-related cables requires that the cables be routed in separate cable trays. Associated circuit cabling from redundant channels shall be separated, provided with isolation, analyzed, or tested to demonstrate that no single credible failure can adversely affect more than one redundant channel.

Non-Class 1E instrumentation circuits and cables (low level) which may be in proximity to associated circuits and cables, are to be treated as associated circuits if analyses or tests demonstrate that credible failures therein could adversely affect Class 1E circuits.

7.1.3.6 Independence

Cabling associated with redundant channels of safety-related circuits shall be installed such that a single credible event

cannot cause multiple channel malfunctions or interactions between channels.

7.1.3.7 Thermal Limitations

The safety-related equipment shall be located so as not to violate the temperature and humidity limits of Section 3.11.

7.1.3.8 Monitoring

Auxiliary and supporting systems for the safety-related instrumentation and controls shall be designed to cause a systems level bypass indication, when they are bypassed or deliberately made inoperable, for the safety-related system which would be affected by the bypassing or deliberate inoperability of the auxiliary or supporting system.

The RPS and ESFAS alarms and the remote PPS and DNBR/LPD Calculator Operator's Modules shall be located in the main control room.

7.1.3.9 Operational Controls

The RPS and ESFAS manual actuation devices shall be located in the control room. The instrumentation and control components of the safe shutdown systems on the Remote Shutdown Panel or at local locations shall be manually operable.

7.1.3.10 Inspection and Testing

The PPS, including sensors, shall be capable of being periodically tested in accordance with the Technical Specifications. Those portions which could adversely affect

reactor operations shall be capable of being tested when the reactor is shut down. All other safety-related instrumentation shall be capable of being tested during normal operation.

7.1.3.11 Chemistry/Sampling

The components of the safety-related equipment shall be located so as not to exceed the chemistry limits specified in Section 3.11.

7.1.3.12 Materials

Not applicable to the safety-related instrument and controls equipment.

7.1.3.13 System Component Arrangement

Safety-related components shall be located so as to conform to the separation, independence, and other criteria specified in this section. The safety-related components shall be located to provide access for maintenance, testing and operation as required.

Analog and digital signals provided to the safety-related components shall not share the same multiconductor cable, unless specifically called for or approved by Combustion Engineering.

7.1.3.14 Radiological Waste

Radiological waste discharge lines or components shall not be routed or located next to protection system electronic

components in a manner that will result in exceeding the radiation limits specified in Section 3.11.

7.1.3.15 Overpressure Protection

The components of the safety-related equipment shall be located so as not to exceed the pressure limits specified in Section 3.11.

7.1.3.16 Related Services

A fire protection system shall be provided to protect the safety-related equipment, including sensors, consistent with GDC 3. This shall include facilities for detection, alarming, and extinguishing of fires. Facilities and methods for minimizing the probability and effects of fires, including fire barriers, fire resistant and non-combustible materials, and other such items, shall be employed whenever possible. Adequate drainage shall be provided if water is used to extinguish fires.

Inadvertent operation or rupture of fire protection systems shall not result in the reduction of the functional capability of safety-related systems or components below that required to perform their safety function.

Physical identification shall be provided to enable plant personnel to recognize that PPS, ESFAS Auxiliary Relay Cabinets, RTSS, and their cabling are safety-related. The cabinets shall be identified by nameplates. A color coding scheme shall be used to identify the physically separated channel cabling from sensor to the PPS (refer to section

7.1.3.5); the same color code shall be used for interbay or intercabinet identification.

Cabling or wiring within a bay at the cabinet which is in the channel of its circuit classification shall not be color coded.

The cabinet nameplates and cabling shall be color coded as follows:

Protective	ESF Trains	Associated
Channel A: Red	A: Red	White Stripe with Red Stripe over Black Jacket or White Stripe over Red Jacket
Channel B: Green	B: Green	White Stripe with Green Stripe over Black Jacket or White Stripe over Green Jacket
Channel C: Yellow		White Stripe with Yellow Stripe over Black Jacket or White Stripe over Yellow Jacket
Channel D: Blue		White Stripe with Blue Stripe over Black Jacket or White Stripe over Blue Jacket

All non-panel mounted protection system instrumentation and control components are identified with a name tag which provides the channel number and the suffix A, B, C, or D to specifically identify the protection channel with which the component is identified.

7.1.3.17 Environmental

Environmental support systems shall be provided to ensure that the environmental conditions of the safety-related systems do not exceed the requirements for 1E equipment as defined in Section 3.11.

7.1.3.18 Mechanical Interaction

Seismic requirements for safety-related equipment are specified in Section 3.10.

7.1.3.19 Plant Monitoring System Inputs

The inputs to the RPS and ESFAS can be sent to the PMS for trending, data logging and other historical functions but are not used for other control functions. These inputs shall have proper isolation to prevent any failure in the PMS from adversely affecting the RPS or ESFAS.

7.1.4 CESSAR INTERFACE EVALUATIONS

Interface requirements listed in CESSAR Section 7.1.3 are met by the PVNGS design as follows:

7.1.4.1 Power

A. Vital instrument power interfaces are discussed in section 8.3.

B. Emergency diesel generator interfaces are discussed in section 8.3.

C. Power source failures are discussed in appendix 7A, Question 7A.4 response.

7.1.4.2 Protection from Natural Phenomena

Refer to subsection 3.1.2 for a description of applicable natural phenomena and references to the appropriate FSAR sections for methods of compliance.

7.1.4.3 Protection from Pipe Failure

Refer to section 3.6 for a description of the design to protect against pipe failures. Also, figures 7.2-1 through 7.2-3 and engineering drawing 13-J-ZYF-009 show locations of Class 1E instruments.

7.1.4.4 Missiles

Refer to section 3.5 for a description of designs provided for protection of 1E systems and components against missile damage.

7.1.4.5 Separation

A. Separation of cabling associated with redundant channels is provided as discussed in paragraph 8.3.1.4.

B. Separation of sensing lines associated with redundant channels is as discussed in subsection 7.1.3.

7.1.4.6 Independence

The installing methods used for redundant channels of safety-related circuits are described in paragraph 8.3.1.4.

7.1.4.7 Thermal Limitations

The C-E environmental criteria are presented in CESSAR Section 3.11 and the environmental qualification parameters for PVNGS are given in Appendix A of the Equipment Qualification Program Manual.

7.1.4.8 Monitoring

A. The bypass/inoperable status system is discussed in subsection 7.5.2.

B. The reactor protective system (RPS) and ESFAS alarms and the remote PPS and DNBR/LPD calculator operator's modules are located in the main control room.

7.1.4.9 Operational Controls

The RPS and ESFAS manual actuation devices are located in the main control room. A description of the remote shutdown capabilities which include manual actuation is in subsection 7.4.1.

7.1.4.10 Inspecting and Testing

PPS and ESFAS sensors are located to permit testing either during reactor operation or during shutdown. The test features are described in subsections 7.2.2 and 7.3.2.

7.1.4.11 Chemistry/Sampling

The components of the safety-related equipment are located to conform to the criteria listed in CESSAR Section 3.11 for C-E scope of supply and Appendix A of the Equipment Qualification Program Manual for the corresponding PVNGS environmental qualification parameters.

7.1.4.12 Materials

Not applicable.

7.1.4.13 System Component Arrangement

Locations have been selected to provide separation and access for maintenance, testing, and operation as discussed in section 7.2.

7.1.4.14 Radiological Waste

Criteria for radiation exposure limits for 1E system electronic components are given in Section 3.11. The methods by which these criteria are met are discussed in sections 3.11 and 12.3.

7.1.4.15 Overpressure Protection

The locations for C-E-furnished 1E equipment shown in figures 7.2-1 through 7.2-3 and engineering drawing 13-J-ZYF-009 meet the overpressure criteria given in CESSAR Section 3.11.

7.1.4.16 Related Services

A. Fire protection design is discussed in subsection 9.5.1.

B. Physical identification of safety-related systems, components, cabinets, and interconnecting cables is described in paragraph 8.3.1.3. The one-out-of-two ESF systems will be identified as follows:

- Channel A - Red
- Channel B - Green

7.1.4.17 Environmental

Environmental support systems are provided and discussed in CESSAR Section 3.11 for C-E scope of supply and sections 6.4 and 9.4 for the PVNGS specific design.

7.1.4.18 Mechanical Interaction

Refer to CESSAR Section 3.10 for C-E scope of supply and to section 3.10 for PVNGS specific design.

7.1.4.19 Plant Monitoring System Inputs

Isolation per Regulatory Guide 1.75 is provided for alarm signals originating from safety-related circuits that terminate in the plant monitoring system.

7.2 REACTOR PROTECTIVE SYSTEM

7.2.1 DESCRIPTION

7.2.1.1 System Description

The reactor protective system (RPS) consists of sensors, calculators, logic, and other equipment necessary to monitor selected nuclear steam supply system (NSSS) conditions and to effect reliable and rapid reactor shutdown (reactor trip), if any or a combination of the monitored conditions approach specified limiting safety system settings. The system's functions are to protect the core specified acceptable fuel design limits and reactor coolant system (RCS) pressure boundary for incidents of moderate frequency, and also to provide assistance in limiting conditions for certain infrequent events and limiting faults. Four measurement channels with electrical and physical separation are provided for each parameter used in the direct generation of trip signals, with the exception of control element assembly (CEA) position. A coincidence of two like trip signals is required to generate a reactor trip signal. The fourth channel is provided as a spare and allows bypassing of one channel while maintaining a two-out-of-three system.

The reactor trip signal deenergizes the control element drive mechanism (CEDM) coils, allowing all CEAs to drop into the core.

The reactor protective instrumentation setpoints shall be set consistent with the Trip Setpoint values shown in Table 7.2-1.

7.2.1.1.1 Trips

7.2.1.1.1.1 RPS Variable Overpower. The RPS variable overpower trip (RPS VOPT) is provided to trip the reactor when indicated neutron flux power either (1) increases at a great enough rate, or (2) reaches a preset value. The flux signal used is the average of the three linear subchannel flux signals originating in each nuclear instrument safety channel. The trip setpoints are provided in table 7.2-1.

Pre-trip alarms are initiated below the trip value to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.2 High Logarithmic Power Level. The high logarithmic power level trip is provided to trip the reactor when indicated neutron flux power reaches a preset value. The flux signal used is the logarithmic power signal originating in each nuclear instrument safety channel. The setpoint is provided in table 7.2-1. The trip may be manually bypassed by the operator. This bypass point is provided in table 7.2-2.

Pre-trip alarms are initiated below the trip value to provide audible and visible indication of approach to a trip condition. The trip bypass also bypasses the pre-trip alarms.

7.2.1.1.1.3 High Local Power Density. The high local power density trip is provided to trip the reactor when calculated core peak local power density reaches a preset value. The preset value is less than that value which would cause fuel centerline melting. The calculation of the peak local power density is performed by the core protection calculators (CPCs), which compensate the calculated peak local power density to

Table 7.2-1

REACTOR PROTECTIVE SYSTEM DESIGN INPUTS
(Sheet 1 of 3)

Type	Typical Value (full power)	Trip Setpoint	Typical Margin To Trip
High logarithmic power level	NA	≤0.010% of neutron rated thermal power	NA
RPS Variable overpower	100% power	≤110% of rated thermal power(m)	10% power
	0%/min	≤10.6%/min(m)	10.6% min
	NA	≤9.7% band(a)(m)	NA
Low DNBR	1.79(b)	≥1.34(k)	≤0.45
High local power density, kW/ft	≤13.5 (peak)(c)	≤21.0(k)	≥7.5
High pressurizer pressure, psia	2,250	≤2,383	133
Low pressurizer pressure, psia	2,250	≥1,837(d)	413
Low steam generator water level, %(f)	82	≥44.2	37.8
Low steam generator pressure, psia	1039	≥960e	79
High containment pressure, psig	0	≤3.0	3.0
High steam generator water level, %(g)	55	≤91.0	36
Low reactor coolant flow, floor	22.2 psid(h)	≥12.81 psid(j)	9.39 psid
rate	0.0 psi/sec	≤0.112 psid/sec(j)	N/A
band	NA	≤16.87 psid(j)	9.39 psid(n)
Supplementary Protection System Pressurizer Pressure - High, psia	2,250	≤2409	159

Table 7.2-1

REACTOR PROTECTIVE SYSTEM DESIGN INPUTS
(Sheet 2 of 3)

a. % band is percent above measured excore power level.

b. Calculated value of DNBR assures trip conservatively considering all sensor and processing time delays and inaccuracies. Calculated DNBR will be less than or equal to actual core DNBR.

c. Peak value is unit and cycle specific.

d. In MODES 3-4, the value may be decreased manually, to a minimum of 100 psia, as pressurizer pressure is reduced, provided:

(1) the margin between the pressurizer pressure and this value is maintained at less than or equal to 400 psi; and

(2) when the RCS cold leg temperature is greater than or equal to 485 degrees F, this value is maintained at least 140 psi greater than the saturation pressure corresponding to the RCS cold leg temperature.

The setpoint shall be increased automatically as pressurizer pressure is increased until the trip setpoint is reached. Trip may be manually bypassed below 400 psia; bypass shall be automatically removed whenever pressurizer pressure is greater than or equal to 500 psia.

e. In MODES 3-4, value may be decreased manually as steam generator pressure is reduced, provided the margin between the steam generator pressure and this value is maintained at less than or equal to 200 psi; the setpoint shall be increased automatically as steam generator pressure is increased until the trip setpoint is reached.

Table 7.2-1

REACTOR PROTECTIVE SYSTEM DESIGN INPUTS
(Sheet 3 of 3)

f. % of the distance between steam generator upper and lower level wide range instrument nozzles.

g. % of the distance between steam generator upper and lower level narrow range instrument nozzles.

h. Average full power steam generator primary differential pressure.

i. Not Used

j. RATE is the maximum rate of decrease of the trip setpoint. There are no restrictions on the rate at which the setpoint can increase.

FLOOR is the minimum value of the trip setpoint.

BAND is the amount by which the trip setpoint is below the input signal unless limited by Rate or Floor.

Setpoints are based on steam generator differential pressure.

k. As stored within the Core Protection Calculator (CPC). Calculation of the trip setpoint includes measurement, calculational and processor uncertainties. Trip may be bypassed when logarithmic power is < 1E-4% NRTP. Bypass shall be automatically removed when logarithmic power is ≥ 1E-4% NRTP.

l. not used

m. RATE is the maximum rate of increase of the trip setpoint. (The rate at which the setpoint can decrease is no slower than five percent per second.)

CEILING is the maximum value of the trip setpoint.

BAND is the amount by which the trip setpoint is above the steady state input signal unless limited by the rate or the ceiling.

n. Value reported here is the same as the value reported for the floor because the floor overrides the band.

Table 7.2-2

REACTOR PROTECTIVE SYSTEM BYPASSES

Title	Function	Initiated By	Removed By	Notes
DNBR and local power density bypass	Disable low DNBR and high local power density trips	Key-operated switch (1 per channel) (Note 1)	Automatic if power is $\geq 10^{-4}\%$	Allows low power testing
Pressurizer pressure bypass	Disables low pressurizer pressure trip, SIAS, and CIAS	Manual switch (1 per channel) if pressure is <400 psia	Automatic if pressure is ≥500 psia	Allows testing at low pressure and, heatup and cooldown with CEA's withdrawn
High log power level bypass	Disables high logarithmic power level trip	Manual switch (1 per channel) if power is $>10^{-4}\%$	Automatic if power is $\leq 10^{-4}\%$	Bypassed during reactor startup
Trip channel bypass	Disables any given trip channel	Manually by controlled access switch	Same switch	Interlocks allow only one channel for any one type trip to be bypassed at one time

NOTE 1 DNBR and LPD Bypass may be performed from the operations module and the maintenance and test panel by a "soft" switch (i.e., touch screen). A hard-wired key-operated switch is also located in each CPCS cabinet.

account for the thermal capacity of the fuel. A trip results if the compensated peak local power density reaches the preset value. The calculated trip assures that the safety limit for peak fuel centerline temperature is not exceeded. The trip setpoint is given in table 7.2-1. The effects of core burnup are considered in the determination of the local power density trip.

Pre-trip alarms are initiated below the trip value to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.4 Low Departure from Nucleate Boiling Ratio. The low departure from nucleate boiling ratio (DNBR) trip is provided to trip the reactor when the calculated DNBR approaches a preset value. The calculation of DNBR is performed by the CPCs based on core average power, reactor coolant pressure, reactor inlet temperature, reactor coolant flow, and the core power distribution. The calculation includes allowances for sensor and processing time delays and inaccuracies, such that a trip is generated within the CPCs before violation of the DNBR safety limit occurs in the limiting coolant channel in the core, during incidents of moderate frequency. The trip setpoint is given in table 7.2-1.

Pre-trip alarms are initiated above the trip value to provide audible and visible indication of approach to a trip condition.

The CPCs also have several trip functions that monitor parameters to limits other than low DNBR or High Local Power Density. These trip functions are called Auxiliiary Trips and, if a trip is generated, the DNBR and Local Power Density trip

contact outputs are set. Auxiliary Trips do not set the pre-trip contact outputs.

The low DNBR trip incorporates a low pressurizer pressure floor, with the value given in table 7.2-1A. At this pressure, a low DNBR auxiliary trip will automatically occur.

There are two additional trip functions that are based on the analyzed operating space of the limits of the DNBR correlation. The first trip function is a reactor coolant low flow trip, which is set at a low limit for pump rotational speed. If one or more reactor coolant pumps slow down sufficiently to exceed this low limit, penalties are applied to the DNBR and Local Power Density calculated values that are large enough to ensure DNBR and Local Power Density trips are generated. The low flow trip will set the DNBR and Local Power Density trip and pre-trip contact outputs. The second trip function is a quality margin trip that is based on the updated quality at the node of minimum DNBR. If the quality margin exceeds the limit, the DNBR trip and pre-trip contact outputs are set. The quality margin does not affect the Local Power Density trip and pre-trip conditions.

Table 7.2-1A summarizes these additional trip functions (including the CPC Auxliary Trips).

The CPC auxiliary trip response times are consistent with DNBR – low values listed in UFSAR table 7.2-4AA (Reactor Protective Instrumentation Response Times). The CPC program response time is based on the CPC execution periods and functions. All of the trips have a response time of

0.75 seconds with the exception of pump speed, which has a response time of 0.3 seconds.

7.2.1.1.1.5 High Pressurizer Pressure. The high pressurizer pressure trip is provided to trip the reactor when measured pressurizer pressure reaches a high preset value. The trip setpoint is provided in table 7.2-1.

Pre-trip alarms are initiated below the trip setpoint to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.6 Low Pressurizer Pressure. The low pressurizer pressure trip is provided to trip the reactor when the measured pressurizer pressure falls to a low preset value. The trip setpoint for normal operation is provided in table 7.2-1. At pressures below the normal operating range, this setpoint can be manually decreased to a fixed increment below the existing pressurizer pressure down to a minimum value. The incremental and minimum values are given in table 7.2-1. This ensures the capability of a trip when required during plant cooldown.

The trip may be manually bypassed by the operator. This bypass point is provided in table 7.2-2. The bypass is automatically removed as pressure is increased above a fixed value and the low pressure setpoint automatically increases, maintaining the fixed increment between the plant pressure and the setpoint until it reaches and limits at the value for normal operation. These values are shown in table 7.2-1.

REACTOR PROTECTIVE SYSTEM

Table 7.2-1A

CORE PROTECTION CALCULATOR SYSTEM
ADDITIONAL TRIP FUNCTIONS[a]
(Sheet 1 of 2)

Type	**Trip Setpoint**	**Typical Margin to Trip**
AUXILIARY TRIP FUNCTIONS[g]		
1. Core conditions outside analyzed operating space:		
Cold leg temperature, °F(Tc)	Tcmin ≥ 505.0, Tcmax < 590.0	50.0 35.0
Primary pressure, psia (P)	1860 ≥ P < 2388	390 (low), 138 (hi)
Hot pin axial shape index (AHP)	−0.5 ≥ AHP < +0.5	0.5
Integrated one pin radial peak (P1)	1.28 ≥ P1 < 7.0	0.2 (low), 5.5 (hi)
2. Variable Overpower Trip (VOPT)[b]		
Ceiling (% power)	< 110.0	10.0
Rate of change up (% RTP/execution)[c]	≤ 0.000835[(h)] (≤ 1% power/min)	0.000835[(h)]
Rate of change down (% RTP/execution)[c]	≤ 0.01389[(h)] (≤ 16.67% power/min)	0.01389[(h)]
Step or band (% power)	≤ 8.0	NA
Floor (% power)	= 30.0	NA
3. Asymmetric Steam Generator Transient Trip (ASGT)		
Cold leg temperature difference trip setpoint (°F)	≤ 15.0	12.5
Power dependent bias for cold leg temperature difference trip (°F)	= 0.0 At 100% power	0.0
4. Hot leg temperature saturation trip (°F)[d]	Thmax + Therr ≥ TSAT	23

CORE PROTECTION CALCULATOR SYSTEM
ADDITIONAL TRIP FUNCTIONS[a]
(Sheet 2 of 2)

Type	Trip Setpoint	Typical Margin to Trip
7. Internal processor fault detected[e]	NA	NA
OTHER TRIP FUNCTIONS		
1. Low Reactor Coolant Pump Rotational Speed (fraction of nominal rotational speed)[f]	≥ 0.95	0.05
2. Quality margin at node of minimum DNBR.	> 0.0	0.3

a. CPCS Auxiliary Trip conditions set only the DNBR and LPD trip contact outputs.

b. The VOPT conditions are defined as follows:

CEILING is the maximum value of the trip setpoint.

RATE (up or down) is the maximum rate of increase or decrease of the trip setpoint.

STEP OR BAND is the amount by which the trip setpoint is above the steady state input signal unless limited by the rate or the ceiling.

FLOOR is the minimum value of the trip setpoint.

c. Execution = 50 milliseconds (0.05 seconds) in CPC DNBR and Power Density UPDATE program.

d. The difference between the maximum hot leg temperature including uncertainties and the saturation temperature of water. The saturation temperature of water is based on the primary (pressurizer) pressure input.

e. These trip conditions are yes/no decisions. For CPC operating mode and internal processor faults, the system is either in the condition or not. Normal operation is with all 4 pumps operating. Operations with less than two pumps running is not allowed in Modes 1 and 2.

f. If one or more pumps are determined to be running at or below the trip setpoint, then penalties are applied to the DNBR and Local Power Density values to ensure a trip condition is reached and the trip contact outputs are set.

g. CPC pre-trip annunciators are provided for the following trips, strictly as operator aids; Variable Overpower Trip (VOPT), Axial Shape Index (ASI) Trip, Asymmetric Steam Generator Trip (ASGT), and Hot Leg Saturation Trip.

Pre-trip alarms are initiated above the trip setpoint to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.7 Low Steam Generator Water Level. The low steam generator water level trip is provided to trip the reactor when measured steam generator water level falls to a low preset value. Separate trips are provided from each steam generator. The trip setpoint is provided in table 7.2-1.

Pre-trip alarms are initiated above the trip setpoint to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.8 Low Steam Generator Pressure. The low steam generator pressure trip is provided to trip the reactor when the measured steam generator pressure falls to a low preset value. Separate trips are provided from each steam generator. The trip setpoint during normal operation is provided in table 7.2-1. At steam generator pressures below normal, the operator has the ability to manually decrease the setpoint to a fixed increment below existing system pressure. This is used during plant cooldown. During startup, this setpoint is automatically increased and remains at the fixed increment below generator pressure until it reaches and limits at the value for normal operation. These values are provided in Table 7.2-1.

Pre-trip alarms are initiated to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.9 High Containment Pressure. The high containment pressure trip is provided to trip the reactor when measured containment pressure reaches a high preset value. The trip setpoint is provided in table 7.2-1. The trip is provided as additional design conservatism (i.e., additional means of providing a reactor trip). The high containment pressure trip setpoint is selected in conjunction with the high-high containment pressure setpoint to prevent exceeding the containment design pressure during a design basis LOCA or main steam line break accident.

Pre-trip alarms are initiated to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.10 High Steam Generator Water Level. A high steam generator water level trip is provided to trip the reactor when measured steam generator water level rises to a high preset value. Separate trips are provided from each steam generator. The trip setpoint is provided in table 7.2-1.

Pre-trip alarms are initiated to provide audible and visible indication of approach to a trip condition.

7.2.1.1.1.11 Manual Trip. A manual reactor trip is provided to permit the operator to trip the reactor. There are four Manual Trip pushbuttons, each of the pushbuttons operates one of the reactor trip breakers. Depressing either of the pushbuttons in both trip legs will result in a reactor trip. There are also manual reactor trip switches at the reactor trip switchgear.

The remote manual initiation portion of the reactor protective system is designed as an input to the reactor trip switchgear system (RTSS). This design is consistent with the recommendations of Regulatory Guide 1.62. The amount of equipment common to both automatic and manual initiation is kept to a minimum. Once initiated, the manual trip will go to completion as required in Section 4.16 of IEEE Standard 279-971.

7.2.1.1.1.12 Low Reactor Coolant Flow. The low reactor coolant flow trip is provided to trip the reactor when the pressure differential across the primary side of either steam generator decreases below a rate limited variable setpoint, as shown in figure 7.2-0. A separate trip is provided for each steam generator. This function is used to provide a reactor trip for a reactor coolant pump sheared shaft event.

Pre-trip alarms are provided.

7.2.1.1.2 Initiating Circuits

7.2.1.1.2.1 Process Measurements. Various pressures, levels, and temperatures associated with the NSSS and the containment building are continuously monitored to provide signals to the RPS trip bistables. All protective parameters are measured with four independent process instrument channels. A detailed listing of the parameters measured is contained in table 7.2-3. The monitored ranges associated with these parameters are listed in table 7.2-4.

A typical protective channel, as shown in figure 7.2-0A, consists of a sensor/transmitter, converter/power supply,

current loop resistors, indicating meter or recorder, trip bistable/calculator inputs, and outputs for the plant monitoring system (PMS).

The piping, wiring, and components of each channel are physically separated from that of other like protective channels to provide independence. The output of each transmitter is an ungrounded current loop. Exceptions are (1) the nuclear instruments, and (2) the reactor coolant pump speed sensors which provide a pulsed voltage signal. Signal isolation is provided for computer inputs. Each redundant channel is powered from a separate vital ac bus.

7.2.1.1.2.2 CEA Position Measurements The position of each CEA is an input to the RPS. These positions are measured by means of redundant and independent reed switch position transmitters (RSPTs) on each CEA. The RSPTs transmit analog signals to eight redundant and independent control element assembly calculators (CEACs), two for each CPC channel. CEAC 1 in each CPC channel monitors RSPT1 on all CEAs. CEAC 2 in each CPC channel monitors RSPT2 on all CEAs.

Each RSPT consists of a series of magnetically actuated reed switches spaced at intervals along the CEA housing and wired with precision resistors in a voltage divider network (see figure 7.2-0B). A magnet attached to the CEA extension shaft actuates the adjacent reed switches, causing voltages proportional to position to be transmitted for each RSPT. The RSPT assemblies and wiring are physically and electrically separated from each other (see figure 7.2-0C).

Table 7.2-3

REACTOR PROTECTIVE SYSTEM SENSORS

Monitored Variable	Type	Number of Sensors	Location
Neutron flux power	Fission chamber	12	Biological shield
Cold leg temperature	Precision RTD	8	Cold leg piping
Hot leg temperature	Precision RTD	8	Hot leg piping
Pressurizer pressure (wide range)	Pressure transducer	4[a]	Pressurizer
Pressurizer pressure (narrow range)	Pressure transducer	4	Pressurizer
CEA positions	Reed switch assemblies	2/CEA	Control element drive mechanism
Reactor coolant pump speed	Proximity device	4/pump	Reactor coolant pump
Steam generator level (wide range)	Differential pressure transducer	4/steam generator[a]	Steam generators
Steam generator level (narrow range)	Differential pressure transducer	4/steam generator[a]	Steam generators
Steam generator pressure	Pressure transducer	4/steam generator[a]	Steam generators
Containment pressure	Pressure transducer	4[a]	Containment structure
Low steam generator primary differential pressure	Differential pressure transducer	4/steam generator	Steam generators

a. % of the distance between the wide range level instrument nozzles (above the lower nozzle).

b. % of the distance between the narrow range level instrument nozzles (above the lower nozzle).

The CEAs are arranged into subgroups that are controlled as control groups of CEAs. The subgroups are symmetric about the core center. The subgroups of a control group are required to move together and to follow a set insertion sequence.

Each CEAC monitors the position of all CEAs within each subgroup. Should a CEA deviate by more than a specific deadband limit, the CEACs will detect the event, sound an annunciator alarm, and transmit appropriate “penalty” factors to the CPCs.

The CPCS displays the position of each regulating, shutdown, and part-strength CEA to the operator in a bar chart format on a visual display. Optical isolation is utilized at each CPC channel to the CEA position display. The operator has the capability to select any channel for display. Selecting CPC channel A or B will display RSPT1. Selecting channels C or D will display RSPT2.

The CPCs utilize 22 selected “target” CEA position reed switch signals as a measure of CEA subgroup and group position. When the CPCs determine that the subgroups of a control group are not moving together, or that the control groups are not moving in the required sequence, they generate penalty factors. The CPCs utilize single CEA deviation penalty factors from the CEACs to modify calculational results in a conservative manner. These factors may result in a reduction in margins-to-trip for low DNBR and high LPD. This assures conservative operation of the RPS during CEA deviations which require a RPS trip. The detailed signal paths of CEA position information within the RPS are shown in figure 7.2-0D. Raw analog RSPT inputs undergo

analog to digital conversion in each of two redundant CEA position processors (CPPs) in each CPC channel. Each CPP transmits CEA position to the appropriate CEAC in all four CPC channels over isolated data links. The CPP also transmits target CEA position to the CPC processor in the same channel over the CEAC to CPC data link.

7.2.1.1.2.3 Excore Neutron Flux Measurements. The excore nuclear instrumentation includes neutron detectors located around the reactor core, and signal conditioning equipment located within the containment and the auxiliary building. Neutron flux is monitored from source levels through full power operation, and signal outputs are provided for reactor protection and information display. There are four channels of safety instrumentation (see figure 7.2-0E).

The four safety channels provide neutron flux information from startup neutron flux levels to 200% of rated power covering a single range of approximately 2 x 10^{-7} to 200% power (9 decades). Each safety channel consists of three fission chambers, a preamplifier and a signal conditioning drawer containing power supplies, a logarithmic amplifier (including combination counting and mean square variation techniques), linear amplifiers, test circuitry, and a rate-of-change of power circuit. These channels provide signals for the rate-of-change power display, RPS for logarithmic power level high and variable over power trips, and CPCs for use in calculations for low DNBR and high LPD trips.

The detector assembly provided for each safety channel consists of three identical fission chambers stacked vertically along

the length of the reactor core. The use of multiple subchannel detectors in this arrangement permits the determination of axial power shape during power operation.

The fission chambers are mounted in holder assemblies which in turn are located in four dry instrument wells (thimbles) at the primary shield. The wells are spaced around the reactor vessel to provide optimum neutron flux information.

Preamplifiers for the fission chambers are mounted outside the primary shield, with two inside containment, and two outside containment in the auxiliary building. Physical and electrical separation of the preamplifiers and cabling between redundant channels are provided.

7.2.1.1.2.4 Reactor Coolant Flow Measurements. The speed of each reactor coolant pump motor is measured to provide a basis for calculation of reactor coolant flow through each pump. The measurement of reactor coolant pump speed is accurate to within 0.43% of the actual pump speed. This requirement is only applicable to pump speeds greater than 700 rpm. Two metal discs, each with 44 uniformly spaced slots about its periphery, are scanned by proximity devices. The metal discs are attached to the pump motor shaft, one to the upper portion and one to the lower portion (see Figure 7.2-0F). Each scanning device produces a voltage pulse signal. The pulse train that is input to the CPCs to calculate flow rate is based upon every n^{th} pulse from the scanning device. The frequency of this pulse train is proportional to pump speed. Adequate separation between proximity devices is provided.

The mass flow rate is obtained using the pump speed inputs from the four reactor coolant pumps, the cold leg temperatures, and the hot leg temperatures. The volumetric flow rate through each reactor coolant pump is dependent upon the rotational speed of the pump and the pump head. This relationship is typically shown in pump characteristic curves. Flow changes resulting from changes in the loop flow resistances occur slowly (i.e., core crud buildup, increase in steam generator resistance, etc.). Calibration of the calculated mass flow rate will be performed periodically using instrumentation which is not part of the reactor coolant pump speed sensing system.

Flow reductions associated with pump speed reductions are more rapid than those produced from loop flow resistance changes. Mass flow rate is calculated for each pump from the pump speed, the density of the cold leg coolant, and a correction term based on hot leg temperature.

The mass flow rates calculated for each pump are summed to give a core mass flow rate. This flow rate is then used in the CPC DNBR and ΔT power algorithms.

7.2.1.1.2.5 Core Protection Calculators. The core protection calculator (CPC) system and CEA calculators provide their outputs and a number of their inputs as inputs to the plant monitoring system (PMS) by means of fiber-optic communication.

The CPC/CEAC data processing programs within the PMS perform cross-channel comparisons for each input signal and generate an alarm whenever the difference between any single channel's value and the average value of all four channels is greater

than a constant. On operator demand, a report is printed to show the results of the latest cross-channel comparison. Some CPC and CEAC parameters are also used to calculate and alarm CPC Aux trip pretrips on the CMC. The CPC and CEAC parameters are not supplied to or used by any program in the plant computer. Some CPC and CEAC parameters are supplied to the plant computer.

Four independent CPCs are provided, one in each protection channel. Calculations of DNBR and LPD are performed in each CPC, utilizing the input signals described below. The DNBR and LPD calculated are compared with trip setpoints for initiation of a low DNBR trip (paragraph 7.2.1.1.1.4) and high LPD trip (paragraph 7.2.1.1.1.3).

Two independent CEA calculators (CEACs) in each channel are provided as part of the CPC system to calculate individual CEA deviations from the position of the other CEAs in their subgroup.

Redundant CEA position processors (CPPs) mounted within each CPCs channel process all channel RSPT inputs. CPPs process target CEA position for use by the CPC in the channel of origin. CPPs also process CEA position for use in the CEACs in all four channels. CPPs in channels A and B provide RSPT 1 CEA positional data on all CEAs to CEAC 1 in all four CPC channels. CPPs in channels C and D provide RSPT 2 CEA positional data on all CEAs to CEAC 2 in all four CPC channels. Cross channel communication of CEA positional information from the CPPs to CEACs utilizes one-way isolated data links.

As shown in figure 7.2-0G, each CPC receives the following inputs: core inlet and outlet temperature, pressurizer pressure, reactor coolant pump speed, excore nuclear instrumentation flux power (each subchannel from the safety channel), selected CEA positions, and penalty factors for CEA deviations within a subgroup from the CEACs. Input signals are conditioned and processed. The following calculations are performed in the CPC or the CEACs:

A. CEA deviations;

B. Correction factor for excore flux power for shape annealing and CEA shadowing;

C. Reactor coolant flowrate from reactor coolant pump speeds and temperatures;

D. ΔT power from reactor coolant temperatures, pressure, and flow information;

E. Excore flux power: excore flux power signals are summed and corrected for CEA shadowing, shape annealing, and cold leg temperature shadowing. This corrected flux power is periodically calibrated to the actual core power measured independently of the reactor protective system. This calibration does not modify the inherent fast time response of the excore signals to power transients;

F. Axial power distribution from the corrected excore flux power signals;

G. Fuel rod and coolant channel planar radial peaking factors, selection of predetermined coefficients based on CEA positions;

H. DNBR;

I. Comparison of DNBR with a fixed trip setpoint;

J. Local power density;

K. Comparison of local power density with a fixed trip setpoint;

L. CEA deviation alarm;

M. Variable overpower trip (VOPT) and comparison of maximum power with VOPT setpoint;

N. Reactor coolant pump (RCP) speed and comparison of RCP speed with a minimum RCP speed trip setpoint; and

O. Compensated cold leg temperature difference and comparison of the compensated cold leg temperature difference to a cold leg temperature difference trip setpoint.

The Primary Outputs of each CPC are:

- Low DNBR trip and pretrip;
- DNBR margin (to control board indication);
- High local power density trip and pretrip;
- Local power density margin (to control board indication);
- Calibrated neutron flux power (to control board indication); and

- Control element assembly withdrawal prohibit (CWP).

Each calculator is mounted in the auxiliary protective cabinet with an operator's display and control module located on the main control board. From the four modules an operator can monitor all calculators, including specific inputs or calculated functions.

7.2.1.1.2.6 Trip Generation. Signals from the trip parameter process measurement loops are sent to voltage comparator circuits (bistables) where the input signals are compared to predetermined trip values (Figure 7.2-6). Whenever a channel trip parameter reaches the trip value, the channel bistable deenergizes the bistable output relay. The bistable output relay or, in the case of trips generated by the Core Protection Calculators, an external trip contact deenergizes trip relays. Outputs of the trip relays are in the trip logic (refer to Section 7.2.1.1.3).

The trip bistable setpoints are adjustable from the PPS cabinet. Access is limited, however, by means of a key-operated cover with an annunciator indicating cabinet door access. All bistable setpoints are capable of being read out on a meter located on the PPS cabinet.

Pretrip bistables and relays are also provided to generate audible and visible alarms.

7.2.1.1.2.7 CPC Software Design. The CPC software requirements specification descriptions of the CEAC and CPC algorithms in Reference 23 includes symbolic algebra. It

includes system requirements affecting the software, hardware, and man-machine interface design.

Typical software test results of Phase I and Phase II software testing are provided in Reference 17 and Reference 18. Typical CPC database material is provided in Reference 19.

The generation of detailed software design documentation and test documentation is included as part of the structured quality assurance design documentation. These types of design documents have been used in the design process on PVNGS 1, 2, and 3 and include the CPC system requirements specifications[23] and a data base document.

Subsequent to the completion of the PVNGS CPC software base design, any revisions to the PVNGS software base design and test documentation will be prepared in accordance with the protection algorithm software change procedure in Reference 20.

The algorithms associated with the CPC Improvement Program as described in CEN-304-P[6], CEN-305-P[1], CEN-308-P-A[15], CEN-310-P-A[16], and CEN-330-P-A[11], were implemented in Cycle 2 and apply to all subsequent cycles. Values for the Reload Data Block (RDB) constants will be evaluated for applicability and consistent with the cycle design, performance, and safety analyses. Any necessary changes to the RDB constants will be accomplished by a vendor in accordance with Reference 21 or by the Nuclear Fuel Management (NFM) Department in accordance with the NFM Design Control.[14]

Trip setpoints, uncertainty factors, and other addressable constants are determined consistent with the methodology and

software established in the CPC Improvement Program. Uncertainty factors are determined using the methods contained in CEN-356(V)-P-A.[13]

7.2.1.1.3 Logic

Tripping of a bistable (or trip contact opening in the case of a calculated trip) results in a channel trip which is characterized by the deenergization of three bistable trip relays (see Figure 7.2-8).

Contacts from the bistable relays of the same parameter in the four protective channels are arranged into six logic AND's, designated AB, AC, AD, BC, BD, and CD, which represent all possible coincidence of two combinations. To form an AND circuit, the bistable trip relay contacts of two like protective measurement channels are connected in parallel (e.g., one from A and one from B). This process is continued until all combinations have been formed.

Since there is more than one parameter that can initiate a reactor trip, the parallel pairs of bistable trip relay contacts for each monitored parameter are connected in series (Logic OR) to form six logic matrices. The six matrices are designated AB, AC, AD, BC, BD and CD.

Each logic matrix is connected in series with a set of four matrix output relays (matrix relays). Each logic matrix is powered from two separate 120V vital ac distribution buses through dual dc power supplies, as shown on Figure 7.2-8. The power supplies are protected from overload by means of input and/or output fuses or circuit breakers.

The contacts of the matrix relays are combined into four initiation circuits, one initiation circuit per channel.

Each reactor initiation circuit is formed by connecting six contacts (one matrix relay contact from each of the six logic matrices) in series. The six series contacts are in series with the initiation output relay. The initiation output relays serve to deenergize the Reactor Trip Switchgear System (RTSS) breakers as discussed in section 7.2.1.1.4.

7.2.1.1.4 Actuated Devices

The above logic causes the deenergizing of the four initiation relays whenever any one of the logic matrices is deenergized as described. Each initiation circuit output relay in turn will cause one trip circuit breaker in the RTSS to open. See Figure 7.2-8.

Power input to the RTSS comes from two full-capacity motor-generator sets, so that the loss of either set does not cause a release of the CEAs. Each line passes through two trip circuit breakers (each actuated by a separate initiation circuit) in series so that, although both sides of the branch lines must be deenergized to release the CEAs, there are two separate means of interrupting each side of the line. Upon removal of power to the CEDM power supplies, the CEAs fall into the reactor core by gravity.

Two sets of manual trip pushbuttons are provided to open the trip circuit breakers, if desired. The manual trip completely bypasses the trip logic. As can be seen in Figure 7.2-8, both

manual trip pushbuttons in a set must be depressed to initiate a reactor trip.

The trip switchgear is housed in separate cabinets from the RPS. In addition to the trip circuit breakers, the cabinet also contains current monitoring devices for testing purposes and pushbuttons on each RTSG which allow for reactor trip from a location other than the control room.

7.2.1.1.5 Bypasses

The bypasses listed in table 7.2-2 are provided to permit testing, startup, and maintenance. The bypass setpoints are provided in table 7.2-2.

The DNBR and local power density bypass, which bypasses the low DNBR and high local power density trips from the CPC, is provided to allow system tests at low power when pressurizer pressure may be low or reactor coolant pumps may be off. The bypass may be manually initiated if power is below the bypass setpoint and is automatically removed when the power level increases above the bypass setpoint.

The RPS/ESFAS pressurizer pressure bypass is provided for two conditions: (1) system tests at low pressure, and (2) heatup and cooldown with shutdown CEA's withdrawn. The bypass may be manually initiated if pressurizer pressure is below the bypass setpoint. The bypass is automatically removed as pressure is increased above the bypass setpoint.

The high logarithmic power level bypass is provided to allow the reactor to be brought to the power range during a reactor startup. The bypass may be manually initiated above the bypass

setpoint and is automatically removed when power decreases below the bypass setpoint.

The trip channel bypass is provided to remove a trip channel from service for maintenance or testing. The trip logic is thus converted to a two-out-of-three basis for the trip type bypassed; other type trips that do not have a bypass in any of their four channels remain in a two-out-of-four logic. The bypass is manually initiated and manually removed. The circuit utilized to accomplish the trip channel bypass is shown in Figure 7.2-10. This circuit, which is repeated for each type trip, contains an electrical interlock which allows only one channel for any one type trip to be bypassed at one time.

All bypasses are annunciated visibly to the operator.

7.2.1.1.6 Interlocks

The following interlocks are provided:

A. Trip Channel Bypasses

   An interlock prevents the operator from bypassing more than one trip channel at a time for any one type of trip. Different type trips may be simultaneously bypassed, either in one channel or in different channels.

B. Matrix Tests

   During system testing an electrical interlock will allow only the matrix relays in one of the six matrix test modules to be held at a time. The same circuit will allow only one bistable input signal to be perturbed at a time (see Figure 7.2-9).

C. Nuclear Instrumentation Test

Placement of the linear calibration switch on the NI drawer to other than "operate" will cause a channel variable overpower trip. Placement of the logarithmic calibration switch to other than "operate" will cause a channel high logarithmic power trip. In addition to these two trips, placing either of these calibration switches, or any other calibration switch on the NI drawer to other than "operate" will cause a Power Trip Test interlock to generate a low DNBR and high LPD trip in that channel.

D. Core Protection Calculation Test

The low DNBR and high local power density channel trips are interlocked such that they both must be bypassed to test a CPC channel.

7.2.1.1.7 Redundancy

Redundant features of the RPS include:

A. Four independent channels, from process sensors through and including channel trip relays. The CEA position input is from two independent channels.

B. Six logic matrices which provide the coincidence of two logic. Dual power supplies are provided for the matrix relays.

C. Four initiation circuits, including four control logic paths and four initiation relays.

D. Four manual trip pushbuttons with either of the pushbuttons in both trip legs being sufficient to cause a reactor trip.

E. AC power for the system from four separate vital instrument buses. DC power for the trip switchgear circuit breakers control logic is provided from four separate battery buses.

The result of the redundant features is a system that meets the single failure criterion, can be tested during reactor operation, and can be indefinitely shifted to two-out-of-three logic and retain a coincidence of two for trip.

The benefit of a system that includes four independent and redundant channels is that the system can be operated, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criterion. The only operating restriction while in this condition (effectively one-out-of-two logic) is that no provision is made to bypass another channel for periodic testing or maintenance. The system logic must be restored to at least a three operating channel condition prior to removing another channel for maintenance.

7.2.1.1.8 Diversity

The system is designed to eliminate credible multiple channel failures originating from a common cause. The failure modes of redundant channels and the conditions of operation that are common to them are analyzed to assure that a predictable common

failure mode does not exist (Reference 2). The design provides reasonable assurance that:

a. The monitored variables provide adequate information during design basis events (design basis events are listed in Sections 7.2.2.1.1 and 7.2.2.1.2).

b. The equipment can perform as required.

c. The interactions of protective actions, control actions and the environmental changes that cause, or are caused by, the design basis events do not prevent the mitigation of the consequences of the event.

d. The system will not be made inoperable by the inadvertent actions of the operating and maintenance personnel.

In addition, the design is not encumbered with additional components or channels without reasonable assurance that such additions are beneficial.

7.2.1.1.9 Testing

Provisions are made to permit periodic testing of the complete RPS with the reactor operating at power or when shutdown. These tests cover the trip actions from sensor input through the protective system and the trip switchgear. The system test does not interface with the protective function of the system. The testing system meets the criteria of IEEE 338-1971, "IEEE Trial-Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection System", and is consistent with the recommendations of NRC Regulatory Guide 1.22, "Periodic Testing of Protection System Actuator Functions."

The individual tests are described briefly below. Overlap between individual tests exists so that the entire RPS can be tested. Frequency of accomplishing these tests are listed in the Technical Specifications.

7.2.1.1.9.1 Sensor Check

During reactor operation, the measurement channels providing an input to the RPS are checked by comparing the outputs of similar channels and cross-checking with related measurements.

During extended shutdown periods or refueling, these measurement channels (where possible) are checked and calibrated against known standards.

7.2.1.1.9.2 Trip Bistable Tests

Testing of the trip bistables is accomplished by manually varying the input signal up to or down to the trip setpoint level on one bistable at a time and observing the trip action (Figure 7.2-6).

Varying the input signal is accomplished by means of a trip test circuit consisting of a digital voltmeter and a test circuit used to vary the magnitude of the trip signal supplied by the measurement channel to the trip input. The trip test circuit is interlocked electrically so that it can be used in only one channel at a time. A switch is provided to select the measurement channel, and a pushutton is provided to apply the test signal. The digital voltmeter indicates the value of the test signal. Trip action (deenergizing) of each of the bistable trip relays is indicated by individual lights on the

front of the cabinet, indicating that these relays operate as required for a bistable trip condition.

The variable setpoint bistable can be tested by manually varying a simulated process input signal. Upon decreasing this input the setpoint is verified to remain constant and the trip setpoint is within specified tolerances. By manually decreasing this input and then depressing the setpoint reset, the setpoint incremental change can be tested and verified. The tracking ability of the circuit can be tested by manually increasing the test input and observing that the setpoint tracks.

The rate limited variable setpoint bistable is tested in three different ways. Using a test ramp generator, the rate of change limit on the setpoint is verified to be within specified limits. The circuit is tested to verify that the setpoint will track the signal when it increases or decreases and maintains the proper separation (it should be noted that the setpoint is still rate limited so that a rapid change in the test signal may cause it to catch the setpoint as it increases and cause a trip). The third test verifies the trip setpoint limit accuracy by use of a manual test system. When one of the bistables of a protective channel is in the tripped condition, a channel trip exists and is annunciated on the control room annunciator panel. In this condition, a reactor trip would take place upon receipt of a trip signal in one of the other three like trip channels. The trip channel under test is therefore bypassed for this test, converting the RPS to a two-out-of-three logic for the particular trip parameter. In either case, full protection is maintained.

7.2.1.1.9.3 Core Protection Calculator Tests

The sensor inputs to each calculator are compared between units. Predetermined test inputs are then inserted into one calculator at a time. The calculator outputs are then checked for specific values. Multiple tests can be performed to check each phase of the calculator program.

The checking of the trip relays for the calculator-generated trips is conducted as described in Paragraph 7.2.1.1.9.2 by initiating a calculator trip and observing the individual bistable relay trip lights.

7.2.1.1.9.4 Logic Matrix Test

This test is carried out to verify proper operation of the six two-out-of-four logic matrices, any of which will initiate a bonafide system trip for any possible coincidence of two trip conditions from the signal inputs from each measurement channel.

Only the matrix relays in one of the six logic matrix test modules can be held in the energized position during tests. If, for example, the AB logic matrix hold switch is rotated to the "HOLD" or "TRIP" positions, actuation of the other matrix hold switches will have no effect upon their respective logic matrices.

Rotating the switch to the hold position will apply a test voltage to the test system hold coils of the selected double coil matrix relays. This voltage will provide the power necessary to hold the relays in their energized position when deactuation of the bistable trip relay contacts in the matrix

ladder being tested causes deenergization of the primary matrix relay coils. The bistable trip relay contacts are deactuated when the matrix hold switch is rotated to the "TRIP" position.

The logic matrix to be tested is selected using the system channel trip select switch. Then while holding the matrix hold switch in the "TRIP" position, rotation of the channel trip select switch will release only those bistable trip relays that have operating contacts in the logic matrix under test. The channel trip select switch applies a test voltage of opposite polarity to the bistable trip relay test coils, so that the magnetic flux generated by the coils opposes that of the primary coil of the relay. The resulting flux will be zero, and the relays will release. A simplified diagram of this testing system is shown in Figure 7.2-7 using the AB matrix.

Trip action can be observed by illumination of the trip relay indicators located on the front panel and by loss of voltage to the four matrix relays, which is indicated by extinguishing indicator lights connected across each matrix relay coil.

During this test, the matrix relay "hold" lights will remain on, indicating that a test voltage has been applied to the holding coils of the matrix relays of the logic matrix module under test.

The test is repeated for all six matrices and for each actuation signal. This test will verify that the bistable relay contacts operate correctly and that the logic matrix relays will deenergize if the matrix continuity is violated. The opening of the matrix relay contacts is tested in the trip path tests (see Section 7.2.1.1.9.5).

Each logic matrix test module provides the associated test circuitry for both the RPS and ESFAS logic matrices. The system channel trip select switch permits the selection of the desired actuation logic matrix to be tested as can be seen in Figure 7.2-8.

7.2.1.1.9.5 Trip Path/Circuit Breaker Tests

Each trip path is tested individually by rotating a matrix hold switch to the "TRIP" position (holding matrix relays), selecting any trip position on the channel trip select switch (opening the matrix), and selecting a matrix relay on the matrix relay trip select switch (deenergizing one of the matrix relays). This will cause one, and only one, of the trip paths to deenergize, causing one trip circuit breaker to open. CEDMs remain energized via the other trip circuit breakers.

The dropout lamps shown on Figures 7.2-7 and 7.2-8 are used to provide additional verification that the matrix relay has been deenergized, (e.g., the 6AB-1 matrix relay contact energizes the dropout lamp). Since the matrix test modules are also utilized for the ESFAS logic matrix testing, this dropout lamp is also shared via contacts 1AB-1 through 5AB-1 as shown on Figure 7.2-8. Proper operation of the actual trip path matrix relay contacts is verified by the trip path lamp located on the trip status panel.

Proper operation of all coils and contacts is verified by lights on a trip status panel; final proof of opening of the trip circuit breakers is the lack of indicated current through the trip breakers.

The matrix relay trip select switch is turned to the next position, reenergizing the tested matrix relay and allowing the trip breakers to be manually reset.

This sequence is repeated for the other three trip paths from the selected matrix. Following this the entire sequence is repeated for the remaining five matrices. Upon completion, all 24 matrix relay contacts and all 4 trip paths and breakers will have been tested.

7.2.1.1.9.6 Manual Trip Test

The manual trip feature is tested by depressing one of the four manual trip pushbuttons, observing a trip of a trip breaker, and resetting the breaker prior to depressing the next manual trip pushbutton.

7.2.1.1.9.7 Bypass

The system bypasses, as itemized in Table 7.2-2, are tested by appropriate test circuitry. Testing includes both initiation and removal features.

7.2.1.1.9.8 Response Time Tests

Time testing is addressed in the Technical Specifications. The methods, equipment, and test frequency are also provided in the Technical Specifications. The reactor protective instrumentation response time limits are identified in table 7.2-4AA.

7.2.1.1.10 Vital Instrument Power Supply

The vital instrument power supply requirements are discussed in section 7.2.3 and Chapter 8.0.

7.2.1.2 Design Bases

The RPS is designed to assure adequate protection of the fuel, fuel cladding, and RCS boundary during Incidents of Moderate Frequency. In addition, the system is designed to assist the ESF Systems in limiting the consequences of certain Infrequent Events and Limiting Faults. To ensure that these design bases are achieved, the reactor must be maintained within the limiting conditions of operation, as defined in Technical Specifications and the limiting safety system settings.

The system is designed on the following bases to assure adequate performance of its protective function:

A. The system is designed in compliance with the applicable criteria of the "General Design Criteria for Nuclear Power Plants", Appendix A of 10CFR50, July 15, 1971.

B. Instrumentation, function, and operation of the system conforms to the requirements of IEEE Standard 279-1971, "Criteria for Protective Systems for Nuclear Power Generating Stations".

C. System testing conforms to the requirements of IEEE Standard 338-1971, "Trial Use Criteria for Periodic Testing of Nuclear Power Generating Station Protection Systems".

D. The system is designed in consistence with the recommendations of Regulatory Guide 1.53, "Application of the Single-Failure Criterion to Nuclear Power Plant Protective Systems", and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions".

E. The system is designed to determine the following generating station conditions in order to provide adequate protection during Incidents of Moderate Frequency:

   1. Core power (neutron flux);

   2. Reactor coolant system pressure;

   3. DNBR in the limiting coolant channel in the core;

   4. Peak local power density in the limiting fuel pin in the core; and

   5. Steam generator water level.

F. The system is designed to determine the following generating station conditions in order to provide protective action assistance to the ESF during certain Infrequent Events and Limiting Faults:

   1. Core power;

   2. RCS pressure;

   3. Steam generator pressure; and

   4. Containment pressure.

G. The system is designed to monitor all generating station variables that are needed to assure adequate determination of the conditions given in listings E. and F. above, over the entire range of normal operation and transient

conditions. The full power nominal values and the maximum and minimum values that can be sensed for each monitored plant variable are given in Table 7.2-4. The type, number, and location of the sensors provided to monitor these variables are given in Table 7.2-3.

H. The system is designed to alert the operator when any monitored plant condition is approaching a condition that would initiate protective action.

I. The system is designed so that protective action will not be initiated due to normal operation of the generating station.

Nominal full power values of monitored conditions and their corresponding protective action (trip) setpoints are given in Table 7.2-1.

The selection of these trip setpoints is such that adequate protection is provided when all sensor and processing time delays and inaccuracies are taken into account. Response times and analysis setpoints used in the safety analyses are given in Chapter 15.0.

The trip delay times and analysis setpoints provided in Chapter 15.0 are representative of the manner in which the RPS and associated instrumentation will operate. These quantities are used in the transient analysis done in Chapter 15.0. Actual RPS uncertainties and delay times will be obtained from calculations and tests performed on the RPS and associated instrumentation. The verified system uncertainties are factored into all RPS settings and/or setpoints to assure that the system adequately

performs its intended function when the errors and uncertainties combine in an adverse manner.

J. All system components are qualified for environmental and seismic conditions in accordance with IEEE Standard 323-1974, and IEEE Standard 344-1971. Compliance is addressed in section 3.11 and in CENPD-255, "Qualification of Combustion Engineering Class 1E Instrumentation", (Reference 3); and in section 3.10 and CENPD-182, "Seismic Qualification of Instrumentation and Electrical Equipment", (Reference 4). In addition, the system is capable of performing its intended function under the most degraded conditions of the energy supply, as addressed in section 8.3.

K. The Regulatory Guides and IEEE standards the upgraded Core Protection Calculator System (CPCS) were designed to are listed in reference 22. However, Palo Verde has not increased its commitments to these new or revised regulatory guides and standards.

Instrument location layout drawings are presented in figures 7.2-1, 7.2-2, 7.2-3, and engineering drawing 13-J-ZYF-009.

7.2.1.3 Final System Drawings

The signal logics, block diagrams, layout drawings, and test circuit block diagrams are shown in Figures 7.2-0A through 7.2-0G and 7.2-5 through 7.2-14.

The following discussion compares the logics to be found in the preliminary CESSAR with those contained herein. The figure

numbers refer to the numbers used here and are not necessarily those of the preliminary CESSAR.

Figure 7.2-5 shows a simplified block diagram for the SPS.

The simplified functional diagram of Figure 7.2-8 has several changes incorporated. On the table of trip inputs the High Linear Power Level has been replaced with the Variable Overpower Trip. The undervoltage and shunt trip circuits have had contacts from the SPS circuit added. The Reactor Trip Switchgear consisting of nine breakers has been replaced with a four breaker Reactor Trip Switchgear System. These changes create a more reliable means of providing a reactor trip when it is required.

Figure 7.2-11 shows some changes in the interface logic from the PSAR. The first change is that the high-high containment pressure is now provided with a separate transmitter. Secondly, MSIS has added steam generator level signals and containment pressure. Third, the AFAS logic has been added. Finally, the turbine trip has been removed from the RPS.

In addition, for a list of applicable drawings and diagrams, see section 1.7.

Table 7.2-4AA

REACTOR PROTECTIVE INSTRUMENTATION RESPONSE TIMES
(Sheet 1 of 2)

FUNCTIONAL UNIT	RESPONSE TIME
I. TRIP GENERATION	
A. Process	
1. Pressurizer Pressure - High	≤ 0.50 seconds
2. Pressurizer Pressure – Low	≤ 1.15 seconds
3. Steam Generator Level – Low	≤ 1.15 seconds
4. Steam Generator Level – High	≤ 1.15 seconds
5. Steam Generator Pressure – Low	≤ 1.15 seconds
6. Containment Presssure – High	≤ 1.15 seconds
7. Reactor Coolant Flow – Low	≤ 1.00 seconds
8. Local Power Density - High	
a. Neutron Flux Power from Excore Neutron Detectors	≤ 0.75 second[a]
b. CEA Positions	≤ 1.35 second[b]
c. CEA Positions: CEAC Penalty Factor	≤ 0.75 second[b]
9. DNBR - Low	
a. Neutron Flux Power from Excore Neutron Detectors	≤ 0.75 second[a]
b. CEA Positions	≤ 1.35 second[b]
c. Cold leg Temperature	≤ 0.75 second[d]
d. Hot leg Temperature	≤ 0.75 second[d]
e. Primary Coolant Pump Shaft Speed	≤ 0.30 second[c] [f]
f. Reactor Coolant Pressure from Pressurizer	≤ 0.75 second[e]
g. CEA Positions: CEAC Penalty Factor	≤ 0.75 second[b]
B. Excore Neutron Flux	
1. Variable Overpower Trip	≤ 0.45 second[a]
2. Logarithmic Power Level – High	
a. Startup and Operating	≤ 0.50 second[a]
b. Shutdown	≤ 0.50 second[a]

B. Initiation Logic	Not Applicable
III. RPS ACTUATION DEVICES	
A. Reactor Trip Breakers	Not Applicable
B. Manual Trip	Not Applicable

a. Neutron detectors are exempt from response time testing. The response time of the neutron flux signal portion of the channel shall be measured from the detector output or from the input of first electronic component in channel.

b. Response time shall be measured from the output of the sensor.

c. The pulse transmitters measuring pump speed are exempt from response time testing. The response time shall be measured from the pulse shaper input.

d. Response time shall be measured from the output of the resistance temperature detector (sensor). RTD response time shall be measured in accordance with the Technical Specifications. The measured response time of the slowest RTD shall be less than or equal to 8 seconds.

e. Response time shall be measured from the output of the pressure transmitter. The transmitter response time shall be less than or equal to 0.7 second.

f. The response time for the Seized Rotor Event, 0.865 second, is a theoretical maximum value based on an instantaneous RCP seizure and is not tested.

7.2.2 ANALYSIS

7.2.2.1 Introduction

The RPS is designed to provide the following protective functions:

- Initiate automatic protective action to assure that acceptable RCS and fuel design limits are not exceeded during specified incidents of moderate frequency.
- Initiate automatic protective action during limiting faults to aid the ESF systems in limiting the consequences of certain infrequent events and limiting faults.

A description of the reactor trips provided in the RPS is given in paragraph 7.2.1.1.1. Paragraph 7.2.2.2 provides the bases for all the RPS trips and table 7.2-1 gives the applicable trip setpoints.

Most of the trips in the RPS are single parameter trips (i.e., a trip signal is generated by comparing a single measured variable with a fixed setpoint). The RPS trips that do not fall into this category are as follows:

A. Low pressurizer pressure trip

This trip employs a setpoint that is determined as a function of the measured pressurizer pressure or that is varied by the operator.

B. Low steam generator pressure trip

This trip employs a setpoint that is determined as a function of the measured steam generator pressure or that is varied by the operator.

C. High local power density trip

This trip is calculated as a function of several measured variables.

D. Low DNBR trip

This trip is calculated as a function of several measured variables.

E. Variable overpower trip

This trip employs a setpoint that will track the reactor power as indicated by neutron flux measurements as long as the rate of change is low enough. A fixed ceiling on the setpoint is also incorporated.

F. Low reactor coolant flow trip

This trip employs a setpoint that is determined as a function of the rate of change of the differential pressure across the primary side of the steam generator, a fixed setpoint rate, a predetermined offset from the measured variable, and a minimum limit.

The low DNBR and high LPD trips are provided in the CPCs. All RPS trips are provided with a pre-trip alarm in addition to the trip alarm. Pre-trip alarms are provided to alert the operator to an approach to a trip condition and play no part in the safety evaluation of the plant.

Each RPS setpoint is chosen to be consistent with the function of the respective trip. The adequacy of all RPS trip setpoints, with the exception of the low DNBR and high LPD trips, is verified through an analysis of the pertinent system transients reported in chapter 15. These analyses utilize an analysis setpoint (assumed trip initiation point) and system delay times associated with the respective trip functions. The analysis setpoint along with instrument uncertainties provides the basis for the calculation of the final equipment setpoints to be reported in the Technical Specifications and UFSAR. Limiting trip delay times are given in chapter 15. The manner by which these delay times and uncertainties will be verified is discussed in paragraph 7.2.1.2.

The adequacy of the low DNBR and high LPD trips was certified by a combination of static and dynamic analyses. These analyses provide assurance that the low DNBR and high LPD trips function as required, and provide the justification for the CPC time response assumed in the chapter 15 safety analyses. This is accomplished by certifying that algorithms used in these two trips predict results that are conservative with respect to the results obtained from standard design methods, models, and computer codes used in evaluating plant performance. This verification also takes into account all errors and uncertainties associated with these two trips, in addition to trip delay times, and will assure that the consequences of any incidents of moderate frequency do not include violation of specified acceptable fuel design limits. Examples of the computer codes that will be used in this verification are given in chapter 15.

7.2.2.1.1 Incidents of Moderate Frequency and Infrequent Events

Incidents of moderate frequency and infrequent events that are accommodated by the system are those conditions that may occur one or more times during the life of the plant. In particular, the occurrences considered include single component or control system failures resulting in transients which may require protective action.

The fuel design and RCPB limits used in the RPS design for incidents of moderate frequency are:

- The DNBR, in the limiting coolant channel in the core, shall not be less than the DNBR safety limit;
- The peak LPD in the limiting fuel pin in the core shall not cause the peak fuel centerline temperature safety limit to be exceeded; and
- The RCS pressure shall not exceed established pressure boundary limits.

The incidents of moderate frequency and infrequent events that provide the basis for the system design requirements are:

A. Insertion or withdrawal of full-strength or part-strength CEA groups, including:

   - Uncontrolled sequential withdrawal of CEA groups,
   - Out-of-sequence insertion or withdrawal of CEA groups,

- Malpositioning of the part-strength CEA group, or
- Excessive sequential insertion of full-strength CEA groups;

B. Insertion or withdrawal of full-strength or part-strength CEA subgroups, including:

- Uncontrolled insertion or withdrawal of a CEA subgroup,
- Dropping of one CEA subgroup, or
- Misalignment of CEA subgroups assigned to a designated CEA group;

C. Insertion or withdrawal of a single full-strength or part-strength CEA, including:

- Uncontrolled insertion or withdrawal of a single full-strength or part-strength CEA,
- A dropped 12-finger CEA,
- A single CEA sticking, with the remainder of the CEAs in that group moving, or
- A statically misaligned CEA;

D. Uncontrolled boron dilution;

E. Excess heat removal due to secondary system malfunctions;

F. Change of forced reactor coolant flow resulting from a simultaneous loss of electrical power to all reactor coolant pumps;

G. Inadvertent pressurization or depressurization of RCS resulting from anticipated single control system malfunctions;

H. Change of normal heat transfer capability between steam and reactor coolant systems resulting from improper feedwater flow or a loss of external load and/or turbine trip;

I. Complete loss of ac power to the station auxiliaries;

J. Asymmetric steam generator transient due to instantaneous closure of one MSIV; and

K. Uncontrolled axial xenon oscillations.

7.2.2.1.2 Limiting Faults

The limiting faults for which the system will take action are those unplanned events under any conditions that may occur once during the life of several stations, and certain combinations of unplanned events and degraded systems that are never expected to occur. The consequences of most of these limiting faults will be limited by the ESF systems; the RPS will provide action to assist in limiting these conditions for these limiting faults. The limiting faults for which the RPS will provide protective action assistance are:

- RCS pipe rupture, including double-ended rupture;
- Ejection of any single CEA;
- Steam system pipe rupture, including a double-ended rupture;

- Feedwater system pipe rupture, including a double-ended rupture;
- Reactor coolant pump shaft seizure;
- Depressurization due to inadvertent actuation of primary or secondary safety valves at 100% power;
- A reactor coolant pump sheared shaft; and
- Steam generator tube rupture.

7.2.2.2 Trip Bases

The RPS consists of fifteen trips in each RPS channel that will initiate the required automatic protective action utilizing a coincidence of two like trip signals.

A brief description of the inputs and purpose of each trip is presented in paragraphs 7.2.2.2.1 through 7.2.2.2.11.

7.2.2.2.1 Variable Overpower Trip

7.2.2.2.1.1 Input. The input is neutron flux power from the excore neutron flux monitoring system.

7.2.2.2.1.2 Purpose. This trip assures the integrity of the fuel cladding and RCS boundary in the event of a very rapid power increase, resulting from an uncontrolled withdrawal of CEAs from an initial Hot Zero Power condition. This trip also provides a reactor trip to assist the ESF systems in the event of an ejected CEA limiting fault.

7.2.2.2.2 High Logarithmic Power Level Trip

7.2.2.2.2.1 Input. The input is neutron flux power from the excore neutron flux monitoring system.

7.2.2.2.2.2 Purpose. This trip assures the integrity of the fuel cladding and RCS boundary in the event of unplanned criticality from a shutdown condition, resulting from either dilution of the soluble boron concentration or uncontrolled withdrawal of CEAs. In the event that CEAs are in the withdrawn position, automatic trip action will be initiated. If all CEAs are inserted, the boron dilution alarm system provides an alarm to alert the operator to take appropriate action in the event of an unplanned criticality. The boron dilution alarm system provides high neutron flux alarms to the main control room from the startup channels. This system is separate from, and independent of, the high logarithmic power level trip. The boron dilution alarm system is described in Section 7.7.1.1.11.

7.2.2.2.3 High Local Power Density Trip

7.2.2.2.3.1 Inputs. The inputs are

- Neutron flux power and axial power distribution based on the excore neutron flux monitoring system;
- Radial peaking factors based on CEA position measurement system (RSPTs);
- ΔT power based on coolant temperatures, pressure, and RCP speed measurements;

- Penalty factors from CEACs for CEA deviation within a subgroup; and
- Penalty factors generated within the CPC for subgroup deviation and groups out-of-sequence.

7.2.2.2.3.2 Purpose. This trip prevents the linear heat rate (kW/ft) in the limiting fuel pin in the core from exceeding fuel design limits for incidents of moderate frequency, and also to provide assistance in limiting conditions for certain infrequent events and limiting faults.

7.2.2.2.4 Low DNBR Trip

7.2.2.2.4.1 Inputs. The inputs are

- Neutron flux power and axial power distribution based on the excore neutron flux monitoring system;
- RCS pressure from pressurizer pressure measurement;
- Delta T power based on coolant temperatures, pressure, and RCP speed measurements;
- Radial peaking factors based on CEA position measurement (RSPTs);
- Reactor coolant mass flow based on reactor coolant pump speeds and temperatures;
- Core inlet temperature from reactor coolant cold leg temperature measurements;
- Penalty factors from CEACs for CEA deviation within a subgroup; and

- Penalty factors generated within the CPC for subgroup deviation and groups out-of-sequence.

7.2.2.2.4.2 Purpose. This trip prevents the DNB ratio in the limiting coolant channel in the core from exceeding the fuel design limit in the event of defined incidents of moderate frequency. In addition, this trip will provide a reactor trip to assist the ESF systems in limiting the consequences of the steam line break outside containment, steam generator tube rupture, and reactor coolant pump shaft seizure limiting faults.

7.2.2.2.5 High Pressurizer Pressure Trip

7.2.2.2.5.1 Input. The input is reactor coolant pressure from narrow range (1500 to 2500 psia) pressurizer pressure measurement.

7.2.2.2.5.2 Purpose. This trip helps assure the integrity of the RCS boundary for any defined incident of moderate frequency or infrequent incident that could lead to an overpressurization of the RCS.

7.2.2.2.6 Low Pressurizer Pressure Trip

7.2.2.2.6.1 Input. The input is reactor coolant pressure from wide range (0 to 3000 psia) pressurizer pressure measurement.

7.2.2.2.6.2 Purpose. This trip provides a reactor trip in the event of reduction in system pressure, in addition to the

DNBR trip, and to provide a reactor trip to assist the ESF systems in the event of a LOCA.

7.2.2.2.7 Low Steam Generator Water Level Trips

7.2.2.2.7.1 Input. The input is the level of water in each steam generator downcomer region from wide range differential pressure measurements.

7.2.2.2.7.2 Purpose. These trips provide protective action to assure that there is sufficient time for actuating the auxiliary feedwater pumps to remove decay heat from the reactor in the event of a reduction of steam generator water inventory.

7.2.2.2.8 Low Steam Generator Pressure Trips

7.2.2.2.8.1 Input. The input is the steam pressure in each steam generator.

7.2.2.2.8.2 Purpose. These trips provide a reactor trip to assist the ESF systems in the event of a steam line break.

7.2.2.2.9 High Containment Pressure Trip

7.2.2.2.9.1 Input. The input is pressure inside reactor containment.

7.2.2.2.9.2 Purpose. This trip assists the ESF systems by tripping the reactor coincident with the initiation of safety injection caused by excess pressure in containment.

7.2.2.2.10 High Steam Generator Water Level Trips

7.2.2.2.10.1 Input. The input is the level of water in each steam generator downcomer region from narrow range differential pressure measurements.

7.2.2.2.10.2 Purpose. These trips assist the ESF systems by tripping the reactor coincident with initiation of main steam isolation caused by a high steam generator water level.

7.2.2.2.11 Low Reactor Coolant Flow

7.2.2.2.11.1 Input. The input is pressure differential measured across the steam generator primary side.

7.2.2.2.11.2 Purpose. This trip provides a reactor trip in the event of a reactor coolant pump sheared shaft.

7.2.2.3 Design

7.2.2.3.1 General Design Criteria

Appendix A of 10CFR50, "General Design Criteria for Nuclear Power Plants", establishes minimum requirements for the principle design criteria for water-cooled nuclear power plants. This section describes how the requirements that are applicable to the RPS are satisfied.

Criterion 1 - Quality Standards and Records: Refer to subsection 3.1.1 for compliance.

Criterion 2 - Design Bases for Protection Against Natural Phenomenon: Refer to subsection 3.1.2 for compliance.

Criterion 3 - Fire Protection: Refer to subsection 9.5.1 for compliance.

Criterion 4 - Environmental and Missile Design Bases: Refer to subsection 3.1.4 for compliance.

Criterion 5 - Sharing of Structures, Systems, and Components: Refer to section 3.1.5 for compliance.

Criterion 10 - Reactor Design: Refer to subsection 3.1.6 for compliance. Typical margins between the normal operating value and the trip setpoint are given in table 7.2-1.

Criterion 12 - Suppression of Reactor Power Oscillations: Refer to subsection 3.1.8 for compliance.

The axial power distribution is continuously monitored by the RPS and factored into the low DNBR and high LPD trips. This assures that acceptable fuel design limits are not exceeded in the event of axial power oscillations. Allowances are made in the trip setpoints for azimuthal power tilts.

Criterion 13 - Instrumentation and Control: Refer to subsection 3.1.9 for compliance.

Criterion 15 - Reactor Coolant System Design: Refer to subsection 3.1.11 for compliance.

Criterion 16 - Containment Design: Refer to subsection 6.2.4 and subsection 3.1.12.

Criterion 20 - Protection System Functions: Refer to subsection 3.1.16 for compliance.

Criterion 21 - Protection System Reliability and Testability: Refer to subsection 3.1.17 for compliance.

Criterion 22 - Protection System Independence: Refer to subsection 3.1.18 for compliance.

Criterion 23 - Protection System Failure Modes: Refer to subsection 3.1.19 for compliance.

Criterion 24 - Separation of Protection and Control Systems: Refer to subsection 3.1.20 for compliance.

Criterion 25 - Protection System Requirements for Reactivity Control Malfunctions: Refer to subsection 3.1.21 for compliance.

Criterion 29 - Protection Against Anticipated Operational Occurrences: Refer to subsection 3.1.25 for compliance.

7.2.2.3.2 Equipment Design Criteria

IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes minimum requirements for safety-related functional performance and reliability of the RPS. This section describes how the requirements of Section 4 of IEEE 279-1971 are satisfied. As an exception, the PVNGS design provides a mono-directional data link from the core protection calculator (CPC) system to the plant monitoring system by means of fiber-optic communication. These data links are identical to the hardware utilized at each CEA calculator output (see paragraph 7.2.1.1.2.2). The non-conducting fiber-optic cable used ensures that no electrical failure at the plant monitoring system will affect the core protection

calculators or the CEA calculators. The following heading numbers correspond to the section numbers of IEEE 279-1971.

7.2.2.3.2.1 Section 4.1, General Functional Requirement. The RPS is designed to limit reactor fuel, fuel cladding, and coolant conditions to levels within plant and fuel design limits. Instrument performance characteristics, response times, and accuracy are selected for compatibility with and adequacy for the particular function. Trip setpoints are established by analysis of the system parameters. Factors such as instrument inaccuracies, bistable trip times, CEA travel times, and circuit breaker trip times are considered in the design of the system.

7.2.2.3.2.2 Section 4.2, Single Failure Criterion. The RPS is designed so that any single failure within the system shall not prevent proper protective action at the system level. No single failure will defeat more than one of the four protective channels associated with any one trip function. The wiring in the system is grouped so that no single fault or failure, including either an open or shorted circuit, will negate protective system operation. Signal conductors and power leads coming into or going out of each cabinet are protected and routed separately for each channel of each system to minimize possible interaction. Single failures considered in the design of the RPS are described in the failure modes and effects analysis (FMEA) shown on table 7.2-4A. Also see reference 24 for the FMEA of the upgraded Core Protection Calculator System (CPCS).

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 1 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
1) Excore Flux Monitor (68)	a) Low Output.	Loss of H.V. Power Supply Breakdown in insulation Resistance	Loss of data, erroneous data. Failure to detect HI flux levels.	Not annunciating. Automatic sensor. validity test. 3-channel comparison. Periodic manual test	3-channel redundancy. (4th channel in bypass)	Makes reactor Trip Logic for variable overpower HI LOG PWR, LO DNBR and HI PWR DENS 1-out-of-2 coincidence	Loss of H.V. Power Supply will fail all three subchannel detectors. To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) High Output	Detector shorts, continuous ionization	Erroneous data. Possible channel Trip for Trip for HI LINEAR PWR, LO DNBR, HI LOG PWR, or HI PWR DENSITY	Annunciating Pre-Trip and Trip HI LIN PWR alarm. Nuclear Instrument Inoperative Alarm	3-channel redundancy. (4th channel bypass)	Makes reactor Trip Logic for HI LIN PWR, LO DNBR, and HI PWR DENS 1 out-of-2 coincidence Power Reduction Signals (PRS) Logic 1-out-of-2 coincidence	To restore the sys-tem logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
2) Core Out-Let Temp. $T_{hot(80)}$	a) Low Output.	Power supply failure. RTD bridge network failure	Reduces ΔT power indication. Channel will not trip on a valid hi temp. condition.	Annunciating. Automatic sensor validity test. 3-channel comparison Plant Computer monitor and alarm Periodic test.	3-channel redundancy. (4th channel bypass)	Reactor Trip Logic for LO DNBR and HI PWR DENS is con-verted to 2-out-of-2 coincidence.	Calculated values of DNBR calibrated nuclear power and local power density (LPD) will change. To restore the system logic to 2-out-of-3 coin-cidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 2 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) High Output	RTD opens or Network failure.	Increases ΔT power indication. Possible channel trips (DNBR, LPD).	Annunciating	3-channel redun-dancy. (4th channel bypass)	Reactor Trip Logic for LO DNBR and HI PWR DENS is converted to 1-out-of-2 coincidence	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
3) Core Inlet Temperature $T_{hot(82)}$	a) One spurious low.	Power Supply failure. RTD bridge network failure.	Increases ΔT power indication. Possible channel trips (DNBR, LPD).	Annunciating. Automatic sensor. validity test . 3-channel comparison plant computer monitor and alarm. Periodic test	3-channel redun-dancy. (4th channel bypass)	Reactor Trip Logic for LO DNBR and HI PWR DENS is converted to 1-out-of-2 coincidence	To restor the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) One spurious high	RTD opens network failure.	Decrease in ΔT power indication. Channel not trip if T_{cold} goes low.	Annunciating.	3-channel redun-dancy. (4th channel bypass)	Reactor trip logic for LO DNBR and HI PWR DENS is converted to 2-out-of-2 coincidence	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
4) Reactor Coolant Pump speed sensor (84)	a) One spurious loss of trans-mission	Power supply or pulse amplifier failure, mech. damage to sensor.	Loss of data. Low DNBR channel trip possible.	Annunciating. Plant Computer monitor and alarm, trip status indication.	3-channel redun-dancy trip bypass.	Reactor trip logic for LO DNBR is converted to 1-out-of-2 coincidence.	Sensor transmits pulses. Pulse rate related to flow. To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 3 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) High signal rate.	Electronic noise.	HI RCP speed input to CPC indicating hi RCS flow, or normal flow when flow actually low. Calculated DNBR will be high channel will not trip on valid low RCS flow.	3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	RCP trip logic for lo DNBR becomes 2-out-of-2 coincident.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	c) Low signal rate.	High resistance in lines, loss of signal strength, intermittent failure.	Low RCP speed input to CPC indicating lo RCS flow. Possible lo DNBR trip in channel.	Pre-trip/trip alarms, 3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	RPS trip logic for lo DNBR would become 1-out-of-2 coincident.	To restor the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
5) Non-Target CEA Position (149)	a) Low or High	Shorted resistor, power supply malfunction.	Erroneous data input to CEA calculator.	Annunciation. Automatic sensor validity test, CEA deviation.	A penalty factor.	A penalty factor is initiated in the core protection calculators (operating temperature margins reduced).	One CEA calculator in each channel will show CEA deviation to all CPC calculators. Possible reactor trip will occur.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 4 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) Other than actual position.	Shorted resistors, shorted reed switches, power supply malfuction.	Erroneous data input to two CEA calculator.	Annunciation, automatic sensor validity test, CEA deviation.	A penalty factor.	A penalty factor is initiated in the core protection calculators (operating temperature margins reduced).	One CEA calculator will show CEA deviation to all CPC calculation. Possible reactor trip will occur.
	c) Off scale	Broken wire, open resistor, electrical short, power supply malfunction.	Loss of data.	Annunciation, automatic sensor validity test, CEA deviation.	A penalty factor.	A penalty factor is initiated in the core protection calculators (operating temperature margins reduced).	One CEA calculator will show CEA deviations to all CPC calculation. Possible reactor trip will occur.
	d) Single CPP failure	Module failure. CEA position data link failure	Loss of one of two redundant CEA position inputs to 1 CEAC in 1 or more channels	Annunciation and alarm	Reduadant CPP in each channel provides CEA position input to CEAC	None	There are two redundant CPPs and associated CEA position data links each CPC channel
	e) Failure of both CPPs in one channel	Power supply failure	Loss of both redundant CEA position inputs to 1 CEAC in all four channels. Loss of CEA position display if that channel is selected for display	CEAC Fail alarm and annunciation	Two channel redundancy (two CEACs per channel) CPC uses other CEAC.	None	CPC uses data from the other CEAC and annunciates failure CPP failure will also cause loss of target CEA position input in the failed channel
6) Target CEA Position (87)	a) Low	Shorted resistor, power supply malfunction	Erroneous data input affects DNBR and LPD calculation	Annunciation, automatic sensor validity test, 3-channel comparison	3-channel redundancy. (4th channel in bypass)	Makes reactor trip logic for LO DNBR and HI power density 1-out-of-2 coincidence	Possible trip in one safety channel. Trip effected will show CEA deviation.
	b) High	Shorted resistor, power supply malfunction	Erroneous data input to CPC Calculator and (two) CEA Calculators	Annunciation, automatic sensor validity test, CEA deviation.	3-channel redundancy. (4th channel in bypass)	Makes reactor trip logic for LO DNBR and HI power density 1-out-of-2 coincidence.	Possible trip in one safety channel. Trip effected will show CEA deviation.
	c) Other than actual position.	Shorted resistor, shorted reed switches,power supply malfunction.	Erroneous data input to Core Protection Calculators and (two) CEA Calculators.	Annunciation, automatic sensor validity test. CEA deviation.	3-channel redundancy. (4th channel in bypass)	Makes reactor trip logic for LO DNBR and HI POWER DENS 1-out-of-2 coincidence.	Possible trip in one safety channel. Trip effected will show CEA deviation.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 5 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	d) Off scale	Broken wire, open resistor, electrical short, power supply mal-function	Loss of data	Annunciation; automatic sensor validity test. CEA deviation.	3-channel redun-dancy. (4th channel in bypass)	Makes reactor trip logic for LO DNBR and HI PWER DENS 1-out-of-2 coinci-dence.	Possible trip in one safety channel. Trip effected will show CEA deviation.
	e) Single CPP failure	Module failure. CEAC to CPC data link failure	Loss on one of two redundant CEA position inputs to CPC in the same channels	Annunciation and alarm	Redundant Target CEA position input from other CEAC to CPC data link provides CEA position input to CPC	None	There are two redundant CPPs and CEAC to CPC data links in each CPC channel. Target CEA position is redundantly transmitted.
	f) Failure of both CPPs in one channel	Power supply failure	Loss of both redundant Target CEA position inputs to one CPC channel	CPC Fail. Low DNBR and High power density channel trips, alarm and annunciation	Three channel redundancy (4th channel in bypass)	Makes reactor trip logic for Low DNBR and High Power Density 1-out-of-2 coincidence	Diagnostic message identify cause of trip
7) Wide Range PZR pressure (press) signal (61)	a) One fails on. (High pressure signal level)	Sensor failure, component failure.	High PZR press signal to: LP PZR Press P/S. LO PZR pressure B/S does not trip for a bona fide condition	Periodic test; 3 channel comparison	3-channel redun-dancy. (4th channel in bypass)	Reactor Trip logic for LP PZR Press is coverted to 2-out-of-2 concidence and CSAS, SIAS logic LO PZR Press 2-out-of-2 coincidence	Back-up for SIAS is the containment pressure measurement channel. To restore the system logic to 2-out-of-3 coinci-dence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) One fails off. (Low pressure signal level).	Sensor failure; dc power supply fall; open circuit	Low PZR Press signal to LO PZR. Press B/S. Bistable changes logic state and initiates channel trip	Annunciating; pre-trip and trip alarm in channel	3-channel redun-dancy Trip Channel Bypass	Reactor trip logic for LO PZR Press is converted to 1-out-of-2 coincidence and CSAS, SIAS logic 1-out-of-2 coincidence	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 6 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
8) PZR Narrow Range Pressure (PRESS) Signal (91)	a) On (High pressure signal level)	Sensor failure, component failure	High PZR press signal to HI PZR Press B/S and calculator HI PZR PRESS B/S will change logic state and initiate channel trip	Annunciating, Pre-trip and trip alarms in HI PZR channel.	3-channel redundancy (4th channel in bypass)	Reactor TRIP logic for LO DNBR is converted to 2-out-of-2 coincidence for HI PZR PRESS. CWP becomes 1-out-of-2 coincidence for HI PZR PRESS	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Off (Low Pressure signal level)	Sensor failure, dc power supply fail open circuit	LO PZR PRESS B/S will decrease DNBR Margin and initiate LO DNBR channel trip. HI PZR PRESS B/S will not trip for bona fide condition	Annunciating; pre-trip and trip alarms in LO DNBR channel	3-channel redundancy (4th channel in bypass)	Reactor TRIP logic for LO DNBR is coverted to 1-out-of-2 coincidence. CWP logic becomes 2-out-of-2 coincidence for this parameter.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
9) SG No.2 Level Signal (51) SG NO.1 Level signal (55) (Wide Range)	a) Off (Low signal level)	Sensor failure, dc power supply fail; open circuit	Low steam generator water level signal to channel bistables. Low level bistables (B/S) change logic state and trip channel for affected steam generator	Annunciation; Pre-trip and trip alarms on low steam generator water level	3-channel redundancy. (4th channel in bypass)	Reactor TRIP and AFAS logic for affected steam generator low water level is converted to 1-out-of-2 coincidence	One channel inoperative for affected steam generator To restore the system logic to 2-out of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 7 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) On (High Signal level)	Sensor failure, component failure	High steam generator water level signal to channel bistables. Lo level bistables for affected steam generator will not trip on LO level	Annunciation on high S/G level. Periodic test, 3-channel comparision	3-channel redundancy. (4th channel in bypass)	Reactor TRIP and AFAS logic for low steam generator water level is converted to 2-out-of-2 coincidence for affected steam generator. System will still operate on non-failed SG level	One channel inoperative for affected steam generator. To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
10) Narrow Range level Sensor, Steam Generator No. 1 (20); Narrow Range Level Sensor, Steam Generator No. 2 (19)	a) Off (Low Signal Level)	Sensor failure, dc power supply fail open circuit	Lo Level Signal to one High SG level bistable for the affected steam generator. Bistable will not trip on actual HI level in steam generator	Periodic test, 3-channel comparison	3-channel redundancy (4th channel in bypass)	Reactor Trip Logic for HI steam generator level and the MSIS actuation Logic for HI steam Generator Level will be changed to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) On (High Level Signal)	Sensor failure component failure	False HI Level Signal sent to one steam generator HI Level Bistable for affected steam generator. Bistable will change logic state and trip the channel	Channel pre-trip and trip alarms	3-channel redundancy (4th channel in bypass)	Reactor Trip Logic and MSIS actuation logic for HI steam generator logic on the affected steam generator will be changed to 1-out-of-2	Same as above

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 8 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
11) S/G Pressure Signal No. 2 (27) S/G Pressure signal No. 1 (42)	a) One spurious off, (Low signal level)	Sensor failure, dc power fail; open circuit	Low steam generator pressure signal to SG Low Pressure (LO PRESS) bistable (B/S) in RPS and ESFS channels, SG Low Pressure, SG1.SG2, and SG2.SG1 B/S's. B/S's change their logic state and initiates channel trip in SG LO PRESS for reactor TRIP, and MSIS actuation. Also, differential 8 SG pressure signal input to one AFAS train actuation logic.	Annunciating; pre-trip and trip alarm on low steam generator pressure	3-channel redundancy (4th channel in bypass)	Reactor TRIP logic for steam generator steam pressure is converted to 1-out-of-2 coincidence	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) One spurious on, (High signal level)	Sensor fails component failure	High steam generator pressure signal to SG LO PRESS and SG1.SG2 Press or SG2.SG1 Press Bistables. One SG LO Press Channel for affected SG will not trip for valid LO Press condition. The SG1.SG2 Press (or SG2.SG1) Bistables will change state	Annunciating; periodic rest. 3-channel comparison	3-channel redundancy (4th channel in bypass)	AFAS Reactor Trip and MSIS actuation Logic for LO SG Press changes to 2-out-of-2. AFAS actuation logic for opposite SG changes to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 9 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
12) SG1 Diff.Pres. Signal, (13) SG2 Diff. Pres. Signal (12)	a) One fails on (High signal level)	Sensor failure, other component failure	HI or normal differential pres. Signal received by one SG LO FLOW bistable for affected steam generator. One channel will not trip on valid LO flow condition in affected steam generator	Periodic test, 3-channel comparison	3-channel redundancy (4th channel in bypass)	Reactor Trip Logic for LO flow in affected SG changes to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) One fails off (LO signal level)	Sensor fails dc power failure, open circuit	LO Differential pres. signal received by one SG LO Flow bistable for affected steam generator. Bistable will change state, initiating a channel trip	Annunciating	3-channel redundancy (4th channel in bypass)	Reactor Trip Logic for LO flow in affected SG changes to 1-out-of-2	Same as above
13) Con-tainment Pressure Signal (6)	a) ON (goes high)	Component failure	High CONT PRESS signal to: HI CONT PRESS bistable in RPS channel and in ESFS channel. B/S change logic state, and initiates channel trip for high containment pressure for RPS TRIP, SIAS, CIAS, and MSIS actuation	Annunciating; pre-trip, and alarm on high containment pressure ESF channel indication	3-channel redundancy (4th channel in bypass)	Reactor Trip Logic redundancy pressure is converted to 1-out-of-2 coincidence and CIAS, SIAS and MSIS logic for HI containment pressure 1-out-of-2 coincidence	Same as above

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 10 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) Off goes low)	Component failure, dc power supply failure open circuit.	Low CONT PRESS signal to: HI CONT PRESS B/S in RPS channel, and ESFS channel. B/S in channel do not change their logic state and trip for bona fide high contanment condition	Periodic test 3-channel comparison	3-channel redundancy (4th channel in bypass)	Reactor Trip logic for HI containment pressure is con-verted to 2-out-of-2 coincidence, and CIAS, SIAS, and SMIS logic for HI containment pressure 2-out-of-2 coincidence	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
14) Con-tainment Pressure Signal (10)	a) ON (HI Signal Level)	Sensor failure other component failure	HI Cont. Pres. Signal received by one HI-HI cont. pres. bi-stable changes state, initiating channel trip for CSAS actuation	Annunciating	3-channel redundancy (4th channel in bypass)	Actuation logic for CSAS becomes 1-out-of-2	Same as above
	b) Off (LO signal level)	Sensor dc power supply failure, open circuit	One HI-HI Cont. Pres. bistable constantly receives a LO or normal containment pres. signal. Bistable will not change logic state for a valid HI-HI cont. pres. condition	Periodic test 3-channel comparison	3-channel redundancy (4th channel in bypass)	Actuation logic for CSAS changes to 2-out-of-2	Same as above
15) RWT Level Signal (1)	a) Off (goes low)	Failed Sensor dc power supply fails	Low RWT level signal to REFUEL TANK LO LEVEL Bistable in ESFS channel. Bistable changes logic state and initiates channel trip for RAS actuation in ESFS	Annunciating; pre-trip and trip PPS alarms	3-channel redundancy (4th channel in bypass)	Makes RAS logic for low refueling water tank level 1-out-of-2 coincidence	Same as above
	b) On (goes high)	Sensor fails; component failure	High RWT level signal to REFUEL TANK LO LEVEL Bistable in ESFS channel. Bistable will not change logic state in RAS channel when bona fide low RWT level condition exists	Periodic test 3-channel comparison	3-channel redundancy (4th channel in bypass)	Makes RAS logic for low refueling water tank level 2-out-of-2 coincidence	Same as above

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 11 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
16) Refuel-ing Water Tank LO Level Bistable (2), Channel A typical)	a) Setpoint power fails off	Component failure, open circuit.	Refueling Water Tank (RWT) level setpoint drops to zero Bistable will not change state on valid LO level signal	Periodic test	3-channel redundancy (4th channel in bypass)	RAS Actuation Logic changes to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Trip Setpoint fails low	Component failure	Same as 16 a)	Same as 16 a)	Same as 16 a)	Same as 16 a)	Same as 16 a)
	c) Trip setpoint set fails high	Component failure	Bistable will trip at a greater than desired RWT level	Periodic test	3-channel redundancy (4th channel in bypass)	No impact on RAS actuation logic unless bistable trips at normal RWT level, then actuation logic will become 1-out-of-2	Same as above
	d) Trip voltage comparator fails off	Open circuit, component failure	Bistable relays will be deenergized resulting in half trips in the AB, AC and AD RAS Actuation Logic matrices	Annunciating	3-channel redundancy (4th channel in bypass)	RAS actuation logic becomes 1-out-of-2	Same as above
	e) Trip voltage comparator fails on	Component failure	Bistable relays will not be deenergized for a valid LO RWT Level Signal	Periodic test	3-channel redundancy (4th channel in bypass)	RAS actuation logic becomes 2-out-of-2	Same as above
	f) Pre-trip setpoint set fails low or off	Component failure, open circuit	Pre-trip setpoint decreases, pre-trip relay will not de-energize when RWT level reaches desired pre-trip level	Periodic test	3-channel redundancy (4th channel in bypass)	RAS Pre-trip indication logic will change to 1-out-of-2. No impact on RAS actuation logic	Same as above

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 12 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	g) Pre-Trip setpoint set fails HI	Component failure	Pre-trip relay will be de-energized at a higher than desired RWT level	Pre-trip alarm and test	None	Spurious RAS Pre-trip alarms. No impact on RAS actuation logic	Same as 16 c)
	h) Pre-trip voltage comparator fails off	Open circuit component failure	Same as 16 g)	Same as 16 g)	Same as 16 g)	Same as 16 g)	Same as 16 g)
	i) Pre-trip voltage comparator fails on	Component failure	Pre-trip relay will not be deenergized when RWT level reached pre-trip setpoint level	Periodic test	3-channel redundancy (4th channel in bypass)	RAS Pre-trip indication logic changes to 1-out-of-2	Same as above
	j) Pre-trip Opto-isolator fails off	Open circuit, component	Pre-trip relay will be deenergized	Annunciating	None	Spurious Pre-trip alarms. RAS actuation logic not affected	Same as above
	k) Pre-trip relay driver fails off	Open circuit transistor failure	Same as 16 j)	Same as 16 j)	Same as 16 j)	Same as 16 j)	Same as 16 j)
	l) Pre-trip relay driver fails on	Emittor to collector short circuit	Same as 16 i)	Same as 16 i)	Same as 16 i)	Same as 16 i)	Same as 16 i)
	m) Pre-trip relay coil fails open	Mechanical failure	Same as 16 j)	Same as 16 j)	Same as 16 j)	Same as 16 j)	Same as 16 j)

(Sheet 13 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	n) Pre-trip relay NC contact in annunciator circuit fails open	Corrosion mechanical damage	RAS pre-trip for channel A will not be annunciated	Periodic test	Visual indication not affected, 3-channel redundancy (4th channel in bypass)	RAS actuation logic unaffected, Pre-trip annunciation logic becomes 1-out-of-2	Same as 16 j)
	o) Pre-trip relay NC contact in annunciator circuit fails closed	Contact arcing	Spurious pre-trip alarm for RAS	Annunciating	None	RAS Actuation logic unaffected	Same as above
	p) Pre-trip relay NC contact in indicator circuit fails open	Mechanical damage corrosion	No visual indication of channel A pre-trip	Periodic test	Audible annun-ciation not affected, 3-channel redundancy (4th channel in bypass)	RAS Actuation logic unaffected pre-trip indication log becomes 1-out-of-2	Same as above
	q) Pre-trip relay NC contact in indicator circuit fails closed	Contact arcing	Spurious RAS pre-trip indication	Visual pre-trip indication	None	RAS Actuation logic unaffected	Same as above
	r) Trip Opto-isolator fails off	Open circuit, component failure	Same as 16 d)	Same as 16 d)	Same as 16 d)	Same as 16 d)	Same as 16 d)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 14 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	s) Trip Relay Driver (TR1, TR2 TR3 or R4) fails off	Open circuit, transistor failure	One bistable relay coil de-energized resulting in a spurious half trip in one logic matrix (i.e. AB, AC, or AD) or a spurious trip indication.	Trouble annunciator for TR-1, 2 and 3 and trip indication for R4	3-channel redundancy for TR-1, 2, and 3 (4th channel in bypass)	RAS Actuation logic becomes 1-out-of-2 selective or any 2-out-of-3	Same as 16 j)
	t) Trip Relay Driver fails on	Emittor to collector short on transistor	Affected trip relay will not deenergize for valid RWT LO level signal, one RAS actuation logic matrix, (i.e., AB, AC or AD) will not deenergize	Periodic test	3-channel redundancy (4th channel in bypass)	RAS Actuation logic becomes 2-out-of-2	Same as above
	u) Trip Relay Coil (TR-1 TR-2, TR-3, or R-4) fails open	Mechanical failure	Same as 16 s)	Same as 16 s)	Same as 16 s)	Same as 16 s)	Same as 16 s)
	v) Trip Relay Form C contacts in logic matrix fail to the NC Pole	Contacts welded by arcing, fuse failure	Affected RAS actuation logic matrix becomes half tripped, and Channel A trip indicator in affected matrix illuminated	Visual indication	3-channel redundancy (4th channel in bypass)	RAS Actuation logic remains 2-out-of-3 with one logic matrix half tripped	Same as above
	w) Trip Relay form C contacts in logic matrix fail to the NO Pole	Contacts welded	The affected RAS Actuation logic matrix (AB, AC or AD) will not deenergize for valid RWT LO Level signal, and channel A trip indicator in affected matrix will not illuminate	Periodic test	3-channel redundancy (4th channel in bypass)	RAS actuation logic becomes 2-out-of-2	Same as above

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 15 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	x) Trip Relay Form C contacts in trouble annun. circuit fail to the NO Pole	Contacts welded	Relay coil or relay driver failure will not be annunciated by trouble annunciator	Periodic test	Channel trip indictors in logic matrixes will indicate possible relay coil or relay driver failures	RAS Actuation logic not affected	Same as 16 j)
	y) Trip Relay Form C Contacts in trouble annun. circuit fail to the NC Pole	Fuse failure contacts	Spurious relay coil/relay driver failure indications	Annunciating	None	RAS Actuation logic not affected	Same as above
17) SG1 LO Level Bistable (59) SG2 LO level Bistable (52)(Channel A typical)			Failure modes and the effects on RPS Trip Logic for LO steam generator level trips are equivalent to the failure modes and effects on RAS Actuation Logic provided in line item 16, Failure modes a) through y).				
18) HI-HI Cont. Pres. Bistable (7) (Channel A typical)	a) Trip setpoint power supply fails off	Open circuit, component failure	HI-HI cont pres. setpoint goes to zero, and all Channel A bistable relays are de-energized by trip voltage comparator	Annunciating	3-channel redundancy (4th channel in bypass)	CSAS Actuation logic is converted to 1-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	Failure Modes b) through y), and the effects on CSAS Actuation Logic are equivalent to the Failure Modes and effects on RAS Actuation Logic provided in Line item 16, Failure Modes b) through y).						

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 16 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
19) SG1 HI Level Bistable (135), SG2 HI Level Bistable (134) (Channel A Typical)	a) Trip setpoint power supply fails off	Open circuit, component failure	HI SG Level setpoint goes to zero. All channel A bistable relays for RPS Trip Logic and ESF Actuation Logic for HI SG level are deenergized	Annunciating	3-channel redundancy (4th channel in bypass)	RPS Trip Logic and ESF Actuation Logic for HI SG Level is converted to 1-out-of-2.	To restore the system logic to 2-out-of-3 coincidence the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Trip setpoint set fails low	Component failure	Same as 19 a)	Same as 19 a)	Same as 19 a)	Same as 19 a)	Same as 19 a)
	c) Trip setpoint set fails high	Component failure	Bistable will not change states for valid SG HI Level	Periodic test	3-channel redundancy (4th channel in bypass)	RPS Trip and ESF Actuation Logic for HI SG Level changes to 2-out-of-2	Same as 19 a)
	d) Trip Voltage Comparator fails off	Open circuit component failure	All Channel A bistable relays for RPS Trip and ESF Actuation Logic for HI SG Level will be deenergized. AB, AC and AD Logic matrixes will be half tripped	Annunciating	3-channel redundancy (4th channel in bypass)	RPS Trip and ESF Actuation Logic for HI SG Level changes to 1-out-of-2	Same as 19 a)
	e) Trip Voltage Comparator fails on	Component failure	Same as 19 c)	Same as 19 c)	Same as 19 c)	Same as 19 c)	Same as 19 a)
	f) Pre-trip setpoint set fails off or low	Open circuit, component failure	Pre-trip relay for HI SG Level deenergized. Spurious HI SG Level Pre-trip indication	Annunciating	None	No impact on RPS Trip or ESF Actuation Logic. Spurious pre-trip indication	Same as 19 a)

	j) Pre-Trip Opto-isolator fails off	Component failure	Same as 21 f)	Same as 21 f)	Same as 21 f)	Same as 21 f)	Same as 21 f)
	k) Relay Driver (Pre-trip or CWP) fails off	Open circuit transistor failure	Affected relay coil de-energized resulting in either a spurious HI PZR Pres. pre-trip alarm or half trip of the CWP Logic Matrix	Annunciating for pre-trip relay, periodic test for CWP	3-channel redundancy (4th channel in bypass)	Spurious pre-trip alarm, or CWP on HI PZR Pres. converts to 1-out-of-2	Same as 21 f)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 23 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	l) Relay Driver (Pre-trip of CWP) fails on	Emitter-to-collector short	Affected relay coil will not deenergize for valid HI PZR Pres. Pre-trip signal	Periodic test	3-channel redundancy (4th channel in bypass)	CWP Logic goes to 2-out-of-2, or pre-trip alarm goes to 1-out-of-2	Same as 21 f)
	m)Relay Coil (Pre-trip of CWP) Fails open	Mechanical failure	Same as 21 k)	Same as 21 k)	Same as 21 k)	Same as 21 k)	Same as 21 k)
	• • •						
	z) CWP Relay Form C Contacts (one of two) fails open	Mechanical failure, corrosion	Part of CWP Logic Matrix is half tripped	Annunciating	3-channel redundancy (4th channel in bypass)	CWP Actuation logic remains 2-out-of-3 with a half trip in one logic matrix	Same as 21 f)
	AA) CWP Relay Form C Contacts (one of two) fails closed	Contact weld	One A Channel contact in CWP logic matrix remains closed on valid HI PZR Pres. pre-trip signal	Periodic test	3-channel reduncancy (4th channel in bypass)	CWP Actuation logic becomes 2-out-of-2	Same as 21 f)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 24 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
22) Hi Log PWR Level Bistable(75)			Failure modes for this bistable, and the effects on the RPS Trip Logic for HI Log PWR are equivalent to the failure modes and the effects on RPS Trip Logic for HI SG Level as provided in Line Item 19, failure modes a) through y).				
23) HI Local Power Density Bistable (96) (Channel A typical)	a) Trip input contact from CPC fails closed	Contacts welded	Bistable trip relays not de-energized for valid HI local PWR density signal	Periodic test	3-channel redundancy, (4th channel in bypass)	RPS Trip Logic for HI local power density changes to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Trip input contacts from CPC fails open	Open circuit, mechanical failure corrosion	Bistable trip relays for Channel A will be de-energized	Annunciating	3-channel redundancy, (4th channel in bypass)	RPS Trip Logic for HI local power density becomes 1-out-of-2	Same as 23 a)
	c) Pre-trip Input contacts from CPC fails closed	Contacts welded	Pre-trip relay will not deenergize for valid HI local power density pre-trip signal	Periodic test	3-channel redundancy, (4th channel in bypass)	Pre-trip alarm logic for HI local power density becomes 1-out-of-2	Same as 23 a)
	d) Pre-trip input contacts form CPC fails open	Open circuit, Mechanical failure	HI local power density pre-trip relay is deenergized, spurious pre-trip alarm	Annunciating	None	Spurious pre-trip alarm, no impact on RPS trip logic	
	Failure modes e through r for this “bistable”, and their effects on RPS Trip Logic for HI Local Power Density are equivalent to Failure Modes k) through q), and s) through y) of line Item 19.						

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 25 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
24) LO DNBR Bistable Relay Cards (92) (Channel A typical)		The Failure Modes for these bistable relay cards, and their effect on RPS Trip Logic are equivalent to the failure modes and effect on RPS Trip Logic Power Density as presented in Line Item 23.					
25) SG1 Low Level Bistable (104), SG2 Low Level Bistable (103) (Channel A typical)	a) Trip setpoint power supply fails off	Open circuit, component failure	LO SG LVL Pre-trip and trip setpoints go to zero LO SG LVL bistable relays will not deenergize for valid LO SG LVL	Periodic test	3-channel (4th channel in bypass)	AFAS-1 actuation logic goes to 2-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Trip setpoint set fails low	Component failure	If LO SG LVL Trip setpoint goes to zero, pullup resistor changes effective setpoint to +10V, deenergizing bistable relays Otherwise B/S will trip at a lower level than desired.	Annunciating, Periodic Test.	3-channel redundancy (4th channel in bypass)	If setpoint goes to zero, AFAS-1 actuation for Channel A changes to "SG2.SG1 pres. and not (SG1.SG2 pres. and SG2 LO LVL)" Actuation logic remains 2-out-of-3, otherwise, none.	Same as 25 a)
	c) Trip setpoint set fails HI	Component failure	Bistable relays will be deenergized at a higher than desired SG LVL	Annunciating	3-channel redundancy (4th channel in bypass)	Same as above	Same as 25 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 26 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	d) Trip Voltage comparator fails off	Component failure, open circuit	SG LO LVL bistable relays will be deenergized. Spurious LO SG Level input to AFAS actuation logic	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 25 b)	Same as 25 a)
	e) Trip Voltage comparator fails on	Component failure	Same as 25 a)	Same as 25 a)	Same as 25 a)	Same as 25 a)	Same as 25 a)
	f) Pre-trip setpoint set fails off	Open circuit, component fail	LO SG LVL Pre-trip setpoint goes to zero. Pullup resistor changes effective pre-trip set point, relays are deenergized. Spurious pre-trip alarm.	Annunciating	None	No impact on AFAS actuation logic	Same as 25 a)
	g) Pre-trip setpoint set fails HI	Component failure	SG Low Level Pre-trip bistable relays deenergized at higher than desired SG Level. Spurious pre-trip alarms	Annunciating	None	Same as above	Same as 25 a)
	h) Pre-trip voltage comparator fails off	Open circuit, component failure	Same as 25 f)	Same as 25 f)	Same as 25 f)	Same as 25 f)	Same as 25 f)

	s) Trip Relay 1 Driver fails off	Open circuit, transistor failure	Trip relay 1 is deenergized, closing contacts in AFAS Logic circuit for Channel A	Annunciating	3-channel redundancy (4th channel in bypass)	AFAS Logic for Channel A remains the same with one set of contacts “actuated”, Actuation logic remains 2-out-of-3	Same as 25 a)
	t) Trip Relay 1 Driver fails on	Collector-to-emitter short	Trip relay 1 will not be de-energized on valid LO SG LVL signal	Periodic test	3-channel redundancy (4th channel in bypass)	Channel A AFAS logic becomes “LO SG LVL” logic for other channels unaffected. Actuation Logic remains 2-out-of-3	Same as 25 a)
	u) Trip Relay 2 Driver fails off	Open circuit, transistor failure	Trip relay 2 is deenergized, opening contacts in AFAS logic circuit. AFAS Channel A actuation logic trip	Annunciating	3-channel redundancy (4th channel in bypass)	AFAS Act. Logic becomes 1-out-of-2	Same as 25 a)
	v) Trip Relay 2 Driver fails on	Emitter-to-collector short	Trip relay 2 will not be deenergized on valid LO SG LVL signal AFAS Act. Channel A will not trip	Periodic test	3-channel redundancy (4th channel in bypass)	AFAS actuation logic becomes 2-out-of-2	Same as 25 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 30 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	w) Trip Relay Form C Contacts in trouble annunc. circuit fails open	Mechanical damage, open circuit	Relay coil/relay driver failure will not be annunciated by trouble annunciator	Periodic test	None	No impact on AFAS actuation logic	Same as 25 a)
	x) Trip Relay Form C Contacts in trouble annunc. circuit fail closed	Contact arcing and weld	Spurious relay/relay driver trouble indication	Annunciating	None	Same as above	Same as above
26) SG1>SG2 Pres. bistable (48) SG2>SG1 Pres. bistable (102) (Channel A typical)	a) Setpoint power supply fails off	Component failure, open circuit	Diff. voltage goes to zero, bistable relays 4 and 6 will deenergize. Trip alarm and SG diff. pres. input to Channel A AFAS logic	Annunciating	3-channel redundancy (4th channel in bypass)	AFAS logic for Channel A (AFAS 1 typical) becomes “LO SG 1 LVL and not AFAS 2)” AFAS actuation logic remains 2-out-of-3	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 31 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	b) Set-point PWR supply fails HI	Short circuit, component	Trip and pre-trip setpoint voltages go to +15V, pulldown resistors change effective setpoints to 0V and bistable relays 4 and 6 are deenergized	Annunicating	3-channel redundancy (4th channel in bypass)	Same as 26 a)	Same as 26 a)
	c) Trip setpoint set fails low	Short circuit, component fail	Equiv. to 25 b)	Equiv. to 25 b)	Equiv. to 25 b)	Equiv. to 25 b)	Equiv. to 25 b)
	d) Trip setpoint set fails HI	Component failure	Trip setpoint voltage goes to +10V, pulldown resistor changes effective setpoint to 0V and bistable relays 4 and 6 are deenergized	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 26 a)	Same as 26 a)
	e)Process "A" input buffer fails off	Open circuit, component failure	Ref. pres. signal goes to zero trip and pre-trip comparators deenergize bistable relays 4, 6, and 7.	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 26 a)	Same as 26 a)
	f) Process "A" input buffer fails HI	Short circuit, component failure	Ref. pres. signal goes HI, bistable will not change state for valid HI diff. SG pres.	Periodic test	3-channel redundancy (4th channel in bypass)	Channel A AFAS logic becomes "LO SG LVL" AFAS actuation logic remains 2-out-of-3	Same as 26 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 32 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	g) Process "B" input buffer fails off	Open circuit, component failure	Measured SG diff. pres. goes, negative. Bistable will not change state for valid HI diff. SG pres.	Periodic test	3-channel redundancy (4th channel in bypass)	Same as 26 f)	Same as 26 a)
	h) Process "B" input buffer fails HI	Short circuit, component failure	Measured SG pres. diff. goes Hi and bistable relays 4, 6 and 7 are deenergized	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 26 a)	Same as 26 a)
	Failure modes i) through t) (for pre-trip portion of bistable) are equivalent to failure modes f) through q) of Line Item 25						
	u) Trip voltage comparator fails off	Component failure, open circuit	Same as 26 a)	Same as 26 a)	Same as 26 a)	Same as 26 a)	Same as 26 a)

	AK) Bi-stable Trip Relay Contacts in Trouble Annunc. Circuit fail open	Mechanical damage open circuit	Trip Relay/Relay Driver failure (off) not annunciated by trouble annunciator.	Periodic test	Logic matrix indicator lights	No impact on AFAS actuation logic	Same as 26 a)
	AL) Bi-stable Trip Relay Contact in Trouble Annunc. Circuit fail closed	Contact arcing and weld	Spurious TRIP Relay/Relay Driver Trouble Annunciator	Annunciating	None	Same as above	Same as 26 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 37 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
27) SG1 LO Pres. Bi-stable (45) SG LO Pres. Bistable (30) (Channel A typical)	a) Bi-stable setpoint power supply fails off	Component failure open circuit	Step adjust, min. adjust and max. adjust for trip and pre-trip setpoints go to zero Trip and pre-trip setpoints equiv. to last process input. Bistable trip will occur on any momentary process input decrease.	Annunciating	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic becomes 1-out-of-2	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Bi-stable setpoint Power Supply fails HI	Component failure, short circuit	Step adjust, min. adjust and max. adjust for trip and pre-trip setpoints go high. Set-points go high, and compara-tors initiate bistable trip.	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	c) 15V Power Supply fails off	Component failure open circuit	Loss of bistable setpoint power supply. See 27 a)	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	d) 15V Power Supply fails HI	Component failure	HI volt input to clock circuit digital representation circuit limiter circuit, and setpoint power supply. Probable over-stress and loss of setpoint power supply. See 27 a)	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 38 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	e) Setpoint step adjust fails open	Mechanical damage component failure	Setpoint step goes to zero, and setpoint equals last process input. Decrease in process input will cause bistable trip.	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	f) Setpoint step adjust fails high	Short circuit	Setpoint step goes to +10V and setpoint goes LO. Pullup circuit in comparator initiates bistable trip	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	g) Setpoint max. adjust fails open	Component failure open circuit	Max. setpoint goes ot 0Vs and stays there. Pullup circuit in comparator initiates bistable trip	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	h) Setpoint max. adjust shorted	Component failure	Max. setpoint goes HI, Set-point will continue to track process input above desired max. Possible bistable trip in SG press. operating range.	Periodic test, annunciating for trip	3-channel redundancy (4th channel in bypass)	No effect unless channel trip occurs, then trip logic becomes 1-out-of-2	Same as 27 a)
	i) Setpoint min. adjust fails open	Component failure open circuit	Setpoint min. goes to zero, setpoint can drop below desired minimum during power decreases. Possible failure to initiate channel trip on loss of SG pres. at LO PWR LVLs	Periodic test	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic for LO SG Pres. becomes 2-out-of-2 at LO PWR LVLs	Same as 27 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 39 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	j) Setpoint min. adjust shorted.	Comp. failure.	Setpoint minimum goes hi. Unable to reset setpoint during power decreases. Possi-ble channel trip during power decrease.	Periodic test, annunciating during power decreases.	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic for LO SG press. becomes 1-out-of-2 during power decreases.	Same as 27 a)
	k) Pre-trip setpoint adjust fails open	Comp. failure, open circuit.	Pre-trip bias voltage goes to zero. Pre-trip and trip set-points become identical. Loss of pre-trip indication for channel.	Periodic test.	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic unaffected. Pre-trip logic becomes 1-out-of-2.	Same as 27 a)
	l) Pre-trip setpoint adjust shorted.	Comp. failure.	Pre-trip bias voltage goes hi, driving pre-trip setpoint hi. Spurious pre-trip alarm.	Annunciating.	None.	No impact on RPS trip and MSIS logic.	Same as 27 a)
	m) Reset button (1 of 3) fails open.	Mech. damage, corrosion.	Unable to reset trip and pre-trip setpoints from 1 location during power decrease. Proba-ble ch. trip during power decrease.	Periodic test, annunc. ch. trip during power decrease.	3-channel redun-dancy, reset buttons at other locations. (4th channel in bypass)	RPS trip and MSIS logic for LO SG press. becomes 1-out-of-2 during power decrease.	Same as 27 a)
	n) Reset button (1 of 3) shorted.	Contact weld.	Contacts remain closed after reset, and reset logic becomes disabled for all locations. Ch. trip on power decrease.	Periodic test, ch. trip alarm during power decrease.	Same as above.	Same as above.	Same as 27 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 40 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	o) Clock circuit fails HI	Comp. failure.	Faster generation of digital representation of process input. No other impact.	Periodic test.	None required.	No impact on RPS trip or MSIS logic.	Same as 27 a)
	p) Clock circuit fails Low	Comp. failure.	Slower generation of digital representation of process input. Setpoint lags input during power increase. No adverse effect.	Periodic test.	None required.	No impact on RPS trip or MSIS logic.	Same as 27 a)
	P1) 15VDC variable setpoint power supply fails low or off	Component failure in power supply	15 VCD power to clock and other circuits on variable setpoint card lost. Setpoint output from card goes to 0 VDC. Trip set-point goes to zero. Bistable will not trip on valid low pressure condition.	Periodic test	3-channel redundancy (4th channel in bypass)	RPS trip logic for LO-SG-Press. becomes 2-out-of-2 coincident	Same as 27 a)
	P2) 15VDC variable setpoint power supply output goes high	Component tolerance buildup, component failure.	Voltage to clock and other circuits on variable setpoint exceeds 15V. Clock frequency may increase and setpoint output voltage may increase. If setpoint increases, bistable will trip at a higher pressure.	Periodic test, annunciating if bistable trips.	3-channel redundancy (4th channel in bypass)	If bistable trips, RPS trip logic for LO-SG-Press will becomes 1-out-of-2 coincident	Same as 27 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 41 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
27) SG1 Lo Press. Bi-stable (45), SG2 Lo Pres. Bistable (30) (Ch. A Typ.) (Cont.)	q) Digital represent. circuit fails off.	Comp. failure.	Bias voltage to setpoint generators goes to zero. Set-points track process input up and down. Unable to trip ch.	Periodic test.	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic goes to 2-out-of-2.	Same as 27 a)
	r) Digital represent. Circuit fails hi.	Comp. failure.	Bias voltage to setpoint generators goes hi, driving setpoints up. Possible ch. trip if setpoints exceed process input.	Periodic test, annunciating for ch. trip.	3-channel redundancy (4th channel in bypass))	RPS trip and MSIS logic for LO SG press. becomes 1-out-of-2.	Same as 27 a)
	s) Setpoint limiter fails off.	Open circuit, comp. failure.	Trip and/or pre-trip setpoint goes to zero. Pullup circuit in comparator initiates ch. trip.	Annunciating.	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	t) Setpoint limiter fails low	Comp. failure.	Trip and/or pre-trip setpoints are limited at too low a value Bistable will not trip at proper SG press.	Periodic test.	3-channel redundancy (4th channel in bypass)	RPS trip and MSIS logic changes to 2-out-of-2.	Same as 27 a)
	u) Setpoint limiter fails HI.	Comp. failure, short circuit.	Trip and/or pre-trip setpoint limit values go hi. Trip set-point can follow process input into normal operating range. Possible spurious ch. trip under normal SG pressure fluctuations.	Periodic test, annunc. for ch. trip.	3-channel redundancy (4th channel in bypass)	Same as 27 a)	Same as 27 a)
	Failure modes v) through an) and their effects on RPS trip and MSIS logic for LO SG Press. are equivalent to Line Item 19s Failure modes d), e), and h) through y) and their effects on RPS trip and MSIS logic for HI SG Level.						

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 42 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
28) LO PZR Pres. Bi-stable (62) (Ch. A Typ.)	The Failure Modes for this bistable and their effects on RPS trip logic for LO PZR Press. are equivalent to the failure modes and their effects on RPS trip logic for Lo SG Press. as presented in Line Item 27.						
29) Variable Overpower Bistable (72) (Ch. A. Typ.)	a) Bi-stable setpoint power supply fails off	Comp. failure, open circuit.	Step adjust, max. adjust, and min. adjust voltages for trip and pre-trip setpoints go to zero. Trip and pre-trip set-points go to zero and bi-stable trips.	Annunciating.	3-channel redundancy (4th channel in bypass)	RPS trip logic for overpwr. Goes to 1-out-of-2.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Bi-stable setpoint power supply fails HI	Comp. failure, short circuit.	Step adjust, max. adjust, and min. adjust voltages for trip and pre-trip setpoints go high. Trip and pre-trip setpoint values increase, as do the limit values. Ch. bistable not respond properly to increasing power level or to HI power level.	Periodic trip.	3-channel redundancy (4th channel in bypass)	RPS trip logic for variable power goes to 2-out-of-2.	Same as 29 a)
	c) 15 V power supply fails off.	Open circuit, comp. failure.	Loss of bistable setpoint power supply. See 29 a).	Same as 29 a)	Same as 29 a)	Same as 29 a)	Same as 29 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 43 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
29) (Cont.)	d) 15 V power supply fails HI	Comp. failure.	HI voltage input to clock circuit, digital representation circuit, limiter circuit and bistable setpoint power supply. Possible overstress of clock circuit or setpoint power supply. Probable Ch. trip.	Annunciating	3-channel redundancy (4th channel in bypass)	RPS trip logic for overpower goes to 1-out-of-2.	Same as 29 a)
	e) Setpoint step adjust fails open	Mech. damage, comp. failure.	Offset between process input and trip setpoint goes to zero and bistable trips.	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 29 a)	Same as 29 a)
	f) Setpoint step adjust fails HI	Short circuit, comp. failure.	Offset between process input and trip setpoint goes hi. Time to reach setpoint during power increase transient slightly longer than it should be. No effect during steady state operation as setpoint is limited by max. adjust.	Periodic test.	3-channel redundancy (4th channel in bypass) in bypass)	Same as 29 b)	Same as 29 a)
	g) Setpoint max. adjust fails open	Mechanical damage component failure	Max. setpoint value for power goes to zero. Bistable trips	Annunciating	3-channel redundancy (4th channel in bypass)	Same as 29 a)	Same as 29 a)

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 52 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
33) LO PZR Pressure Operating Bypass (33, 36, 60, 34) Channel A typical	a) Bi-stable PWR supply fails off	Component failure open circuit	Trip setpoint goes to zero. Operator unable to bypass LO PZR Pres. Bistable at LO pres. or operating bypass automatically removed, Possible channel trip on LO PZR Pres.	Annunc., Periodic test, operator when initiate operating bypass	3-channel redundancy (4th channel in bypass)	RPS Trip Logic for LO PZR Pres. goes to 1-out-of-2 at LO PWR/ Pres. operator	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel
	b) Bi-stable setpoint PWR supply fails HI	Component failure	Trip setpoint voltage goes HI, The pre-set point at which the LO PZR Pres. operating bypass is automatically removed increases LO PZR Pres. bistable will remain bypassed.	Periodic test. bypass indicator lit at power	3-channel redundancy (4th channel in bypass)	RPS Trip Logic for LO PZR Pres. becomes 2-out-of-2	Same as 33 a)
	c) 15V PWR supply fails off	Component failure open circuit	Loss of bistable setpoint PWR supply. See 33 a)	See 33 a)	See 33 a)	See 33 a)	See 33 a)
	d) 15V PWR supply fails HI	Component failure short circuit	Overstress of bistable setpoint PWR supply. Setpoint power supply output may go hi (see 33 b) for effects) or setpoint power supply may burn out and its output go to 0 VDC (see 33 a) for effects)	See 33 a) and 33 b)	See 33 a) and 33 b)	See 33 a) and 33 b)	See 33 a) and 33 b)

(Sheet 57 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
33) (Cont.)	w) Contact in Latch Circuit shorts	Mechanical failure	Bypass transistor will remain latched "on" after bypass switched is turned to "normal" Low PZR Press. trip will be bypassed.	Unable to unlatch transistor manually status light lit	Redundant channel	Bypass	Same as 33 a)
	x) Contact in Latch Circuit opens	Mechanical failure	Unable to latch bypass transistor "on"; Low PZR Press. trip will not bypass	Status light not lit	Redundant channel	None	Same as 33 a)
	y) Contact in Annun-ciated Circuit short	Mechanical failure	Annunciator and status light actuated	Alarm	None required	Nuisance Alarms and indications	Same as 33 a)
	z) Contact in Annun-ciated Circuit open		No annunciation	No status indication		Redundant channel	None
	aa) Low PZR Pressure Trip Bypass Switch Contact Bypass Circuit short	Mechanical failure	Low pressurizer pressure trip automatically bypassed in the affected channel when PZR Pres. aux. B/S permits bypass condition	Periodic PPS test-ing. Bypass condi-tion before manual action	3-channel redundancy (4th channel in bypass)	During a condition of low pressurizer pressure the bi-stable will be bypassed	If a bypass is required the other 2-channels may be bypassed as they are unaffected by the fault

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 58 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
33) (Cont.)	ab) Low PZR Pressure Trip Bypass Switch Contact Bypass Circuit Open	Mechanical failure	Bypass transistor will not switch “ON”. Low PZR Pres. trip will not be bypassed when desired	Unable to bypass. Status light not lit	One bistable alone cannot cause trip. Other two channels can be bypassed (4th channel already in bypass)	None	The low pressurizer pressure bypass circuits in the other 2 channels are unaffected and will respond properly.
	ac) Contact Normal Circuit shorts	Mechanical failure	Bypass transistor remains “OFF” and bypass condition will not latch on	Status light not lit	Same as 33 ab)	None	Operator would have to hold bypass switch in bypass position to maintain bypass in this channel
	ad) Contact Normal Circuit open	Mechanical failure	Bypass transistor will not switch “OFF” manually	Unable to manually remove bypass status light status	Same as 33 ab)	None	Function of circuit is not impaired, nuisance

Table 7.2-4A

(Sheet 59 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) Safety Channel Nuclear Instument (83) (Ch. A Typical)	a) Trouble annunc. bistable fails off.	Failure causes equiv. to trip ch. bistable fail modes.	Trouble annunc. relays de-energized. Spurious N.I. trouble indication and spurious LPS and DNBR ch. trips.	Annunciating.	3-channel redundancy for LPD and DNBR. None for trouble annunc. (4th channel in bypass)	RPS trip logic for LPD and DNBR goes to 1-out-of-2.	To restore the system logic ot 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) Trouble annunc. bistable fails on.	Failure causes equiv. to trip ch. bistable fail. modes.	Trouble annunc. relays not de-energize during NI test or when there is trouble in the NI Drawer. Loss of trouble annunc. LPD and DNBR bistables not tripped. LPD and DNBR bistables may not trip during NI test due to erroneous data.	Periodic test, lack of annunc. during NI test.	3-channel redundancy (4th channel in bypass)	RPS trip logic for LPD and DNBR may go to 2-out-of-2.	Same as 34 a)
	c) Trouble bistable relay contacts in annunc. circuit fail closed	Contact arc and weld.	NI test or trouble in NI not annunciated.	Periodic test, lack of annunc. during NI test.	None.	RPS trip logic not affected.	Same as 34 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 60 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) (Cont.)	d) Trouble bistable relay contacts in annunc. fail open.	Open circuit, mech. failure.	Spurious NI trouble alarms.	Annunciating.	None.	RPS trip logic not affected.	Same as 34 a)
	e) Trouble bistable relay contacts in power trip test interlock fail closed.	Contact arc and weld.	LPD and DNBR bistables in affected ch. will not be tripped during NI ch. test or when there is trouble in the NI drawer. LPD and DNBR bistables may not trip due to erroneous data.	Periodic test, lack of LPD/DNBR trip indic. during NI test.	3-channel redundancy (4th channel in bypass)	RPS trip logic may go to 2-out-of-2.	Same as 34 a)
	f) Trouble bistable relay contacts in power trip test interlock fail open.	Open circuit, mech. failure.	Spurious ch. trips for LPD and DNBR if bypass relays are not engaged.	Annunciating.	3-channel redundancy (4th channel in bypass)	RPS trip logic for LPD and DNBR goes to 1-out-of-2.	Same as 34 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 61 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) (Cont.)	g) 10^{-4} % log power bistable fails off.	Failure causes equiv. to trip ch. bistable fail modes.	Bistable will not energize when power exceeds 10^{-4}%. One HI log power trip ch. cannot be bypassed. Probable ch. trip for high log power.	Periodic test, annunc. ch. trip HI log power bypass permissive light not come on at power.	3-channel redundancy. (4th channel in bypass)	One ch. of HI log power tripped at power. Other 2 channels can still be bypassed for operation.	Same as 34 a)
	h) 10^{-4} % log power bistable fails on.	Fail. causes equiv. to trip ch. bistable failure modes.	Bistable will be energized at all power levels. Operator can bypass HI log power bistable at less than 10^{-4} % power.	3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	RPS trip logic for high log power becomes 2-out-of-2 if ch. is bypassed.	Same as 34 a)
	i) 10^{-4} % log power bistable fails off.	Fail. causes equiv. to trip ch. bistable failure modes.	Bistable relay will not be energized below 10^{-4} % power. CWP will not be bypassed and CPC cannot be bypassed. Spurious LPD and DNBR ch. trips at Lo power plus spurious CWP's at Lo power.	Periodic test, 3-channel comparison.	3-channel redundancy. (4th channel in bypass)	One ch. for LPD, DNBR and CWP tripped at Lo power. Other 2 channels can still be bypassed.	Same as 34 a)
	j) 10^{-4} % log power bistable fails on.	Fail. causes equiv. to trip ch. bistable failure modes.	Bistable relay will remain energized above 10^{-4} % power. One CPC will remain bypassed and one ch. for CWP will remain bypassed.	CPC bypass permissive indication, test	3-channel redundancy. (4th channel in bypass)	RPS trip logic and CWP logic for LPD or DNBR beomes 2-out-of-2.	Same as 34 a)
	k) 10^{-4} % log power bistable contacts in CWP fail open.	Mech. failure, open circuit.	CWP will not be bypassed for LPD and DNBR below 10^{-4} % power. Possible spurious CWP ch. trip at Lo power if CPS is not bypassed.	Periodic test, annunc. for CWP ch. trip.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic or CWP as other chs. Are bypassed.	Same as 34 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 62 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) (Cont.)	l) 10^{-4} % log power bistable contacts in CWP fail closed.	Contact arc and weld.	CWP for LPD and DNBR will remain bypassed all power levels.	Periodic test.	3-channel redundancy. (4th channel in bypass)	CWP on LPD or DNBR pre-trip goes to 2-out-of-2.	Same as 34 a)
	m) 10^{-4} % log power bistable contacts in CPC fail open.	Mech. failure, open circuit.	CPC bypass permissive for one channel not enabled below 10^{-4} % power. Unable to bypass one CPC. Possible LPD and DNBR ch. trips at low power.	Periodic test, annunc. for ch. trip.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic as other CPC's can still be bypassed.	Same as 34 a)
	n) 10^{-4} % log power bistable contacts in CPC fail closed.	Contact arc and weld.	CPC bypass will not be automatically removed at 10^{-4} % power. CPC will be bypassed.	CPC bypass indic. test	3-channel redundancy. (4th channel in bypass)	RPS trip logic for LPD and DNBR becomes 2-out-of-2.	Same as 34 a)
	o) Rate of change of power bistable fails on.	Fail. causes equiv. to trip ch. bistable fail. modes.	Loss of annunc. at HI rate of change of power for on channel.	Periodic test.	3-channel redundancy. (4th channel in bypass)	HI rate of change of power annunc. logic goes to 1-out-of-2.	Same as 34 a)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 63 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) (Cont.)	d) Rate of change of power bistable fails off.	Fail. causes equiv. to trip ch. bistable fail. modes.	Spurious HI rate of change of power alarms.	Annunciating.	None.	No impact on RPS trip logic.	Same as 34 a)
	q) Log power level summers fail HI.	Comp. failure.	Erroneous log power level indic. at main control board or remote shutdown area.	3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	
	r) Log power level summers fail off.	Comp. failure, open circuit.	Loss of log power level indic. at main control board or remote shutdown area.	Operator.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	
	s) Calibrated linear power level summer fails HI.	Comp. failure.	HI linear power indic. at main control board.	3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	
	t) Calibrated linear power level summer fails off.	Comp. failure, open circuit.	Loss of one channel of linear power indic. on main control board.	Operator.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 64 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
34) (Cont.)	u) Rate of change of power summer fails HI.	Comp. failure.	Erroneous power change rate indic. at main control board.	3-channel comparison, periodic test.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	
	v) Rate of change of power summer fails off.	Comp. failure, open circuit.	Loss of rate of change of power indic. for one channel.	Operator.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic.	
35) High Log Power Operating Bypass (70, 71, 79) (Ch. A Typ.)	a) Bypass relay AK27 coil open.	Sustained overvoltage.	High log power trip bypass cannot be obtained in Ch. A.	Whenever a bypass of high log power is attempted in the affected channel. Periodic PPS testing.	3-channel redundancy. (4th channel already in bypass)	Bistable will be tripped when the power level exceeds 1 to 2% full power.	The other 2 channels are unaffected and can be bypassed. Bypassing the other 2 channels precludes a trip caused by high LOG power as a coincidence of at least two channels is required to produce a trip.
	b) Bypass relay AK27 coil short		Shorted coil will cause auxiliary logic power supply voltage to be reduced to approximately zero when the power level exceeds 10^{-4}% full power.	Periodic test annunciation of power supply failure	3-channel redundancy. (4th channel in bypass)	High log power bistable cannot be bypassed above 10^{-4}% power, channel will trip	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 65 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
35) (Cont.)	c) Bypass relay AK27 N.O. contact in bistable bypass circuit short.	Welded contact	High LOG power trip can be bypassed in the affected channel regardless of power level. Bypass not auto. removed.	Periodci PPS testing.	3-channel redundancy. (4th channel in bypass))	Bistableis continually bypassed. Logic becomes 2-out-of-2 for Hi Log Power	System becomes 2-out-of-2 for that parameter at low power.
	d) Bypass relay AK27 N.O. contact in bistable bypass circuit open.	Deterioration of contact.	High LOG power trip cannot be bypassed in the affected channel.	Whenever a bypass of high LOG power is attempted in the affected channel. Periodic PPS testing.	3-channel redundancy. (4th channel in bypass)	Bistable will be tripped when the power level exceeds 1 to 2% full power.	
	e) Relay AK27 N.O. contacts in permissive indic. circuit fail open.	Corrosion, mech. damage, open circuit.	Loss of bypass permissive indic. for ch. Operator not bypass HI log power bistable above 10^{-4}% power. Probable channel trip.	3-channel comparison, annunc. for ch. trip, periodic test.	Bypasses not affected for other 2 channels (4th channel in bypass)	Trip logic for HI log power not affected as other 2 chs. will be bypassed.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 66 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
35) (Cont.)	f) Relay AK27 N.O. contacts in permissive indic. circuit fail closed.	Contact weld.	Spurious operating bypass permissive indication. Bypass cannot be initiated.	Visual indication, 4-channel comparison.	Bypass capability not affected.	RPS trip logic not affected. Bypass cannot be initiated at less than 10^{-4}% power	Same as 35 e)
	g) Relay AK27 N.C. contacts in bypass annunc. circuit fail closed.	Contact weld, open circuit	Operating bypass permissive will not be annunciated when it is initiated.	Visual bypass permissive indic. with no annunc., periodic test.	Visual indication of ch. bypass permissive, bypass capability not affected.	RPS trip logic not affected as bypass can still be initated.	
	h) Bypass relay driver fails off.	Open circuit, transistor failure.	Operating bypass for channel cannot be initiated. Probable HI log power channel trip above 10^{-4}% power.	Operator when initiating bypass.	Bypasses in other 2 channels not affected. (4th channel already bypassed)	Trip logic for HI log power will not be affected as other 2 channels can be bypassed.	Same as 35 e)
	i) Bypass relay driver fails on.	Emitter-to-collector short.	One channel operating bypass for HI log power will be automatically generated whenever power exceeds 10^{-4}% power.	Bypass annunc. before Operator initiates bypass.	Other 2 channels still must be manually bypassed. (4th channel already bypassed)	RPS trip logic for HI log power not affected. This trip normally bypassed above 10^{-4}% power. Bypasses automatically removed below 10^{-4}% power.	Same as 35 e)

	l) Relay AK20 contacts in bypass circuit fail closed.	Contact weld.	Hi log power operating bypass for Ch. A will be engaged at all times. HI log power bistable will be bypassed at all power levels.	Visual bypass indic. at low power.	3-channel redundancy for HI log power trip. (4th channel in bypass)	RPS trip logic for HI log power goes to 2-out-or-2.	Same as 35 e)
	m) Relay AK20 N.C. contacts in "Bypass OFF" circuit fail closed.	Open circuit, contact weld.	Spurious and erroneous "Bypass OFF" indic. when bypass is in effect.	Concurrent "Bypass" and "Bypass OFF" indications.	Bypass not affected.	No impact on RPS trip logic.	Same as 35 e)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 68 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
35) (Cont.)	n) Relay AK20 N.C. contacts in "Bypass OFF" cir-cuit fail open.	Corrosion, mech damage.	Loss of "Bypass OFF" indic. for one channel. Bypass not affected.	"Bypass OFF" and "Bypass" lamps off at same time.	Bypass not affected.	No impact on RPS trip logic.	
	o) Relay AK20 N.O. contacts in annunc. circuit fail open.	Open circuit, contact weld, corrosion.	Operating bypass permissive annunciator will not be turned off when the HI log power bypass is initiated.	Operator when initiating bypass.	None required.	No impact on RPS trip logic or bypass capability	
	p) Relay AK20 N.O. contacts in annunc. circuit fail closed.	Contact weld.	Same as 35 g)	Same as 35 g)	Same as 35 g)	Same as 35 g)	
	q) Manual bypass init. Switch (2 locations) open.	Comp. failure, contact corrosion.	Unable to manually initiate or remove HI log power operating bypass. (Bypass automatically removed below 10^{-4}% power.)	Operator when attempting to initiate or remove bypass.	Redundant bypass switches.	No impact on RPS trip logic. Bypass can be initiated from alternate locations.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 69 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
35) (Cont.)	r) Manual bypass switch (2 locations) fails to "bypass) position.	Contact weld.	Same as 35 i)	Same as 35 i)	Same as 35 i)	Same as 35 i)	Same as 35 i)
	s) Manual bypass switch (2 locations) fails to "OFF" position.	Contact weld.	Unable to manually initiate operating bypass using either switch. HI log power bistable in ch. will not be bypassed above 10^{-4}% power. Probable ch. trip at power.	Operator when attempting to initiate bypass, annunc. for channel trip.	3-channel redundancy for HI log power and operating bypass. (4^{th} channel in bypass)	No impact on RPS trip logic. Other 2 channels can still be bypassed so reactor trip will not be initiated.	
	t) Aux. logic power supply fails off.	Open circuit, comp. failure.	Unable to bypass HI log power bistable. Probable ch. trip for HI log power above 10^{-4}% power.	Power supply trouble alarm, loss of all bypass indic. lamps in channel.	Separate power supplies used for bypasses in other channels.	No impact on RPS trip logic as other 2 channels can still by bypassed. (4^{th} channel already in bypass)	
36) Power Trip Test Interlock (90, 95) (Ch. A Typ.)	a) 12 V aux. logic power supply fails off.	Open circuit, comp. failure.	Relay AK28 will be deener-gize and its contacts will open, deenergizing (tripping) the Ch A bistables for DNBR and LPD, if they are not bypassed.	Power supply trouble annunc. channel trip annunciation.	3-channel redundancy for LPD and DNBR. (4th channel in bypass)	RPS trip logic for LPD and DNBR goes to 1-out-of-2.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.

36) (Cont.)	j) Trip channel bypass relay AXCK3-6 N.O. contacts in DNBR circuit fail closed.	Contact weld.	Same as 36 f)	Same as 36 f)	Same as 36 f)	Same as 36 f)	
37) CWP Logic (69, 99, 121) (Ch. A Typ.)	a) CWP contact from CPC fails open.	Open circuit, mech. damage, contact cor-rosion.	Relay AK11 is deenergized and contacts in the CWP logic matrix are opened. Spurious CWP ch. trip.	Visual indication.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic, CWP logic goes to 1-out-of-2.	To restore the system logic to 2-out-of-3 coincidence, the operator must restore the bypassed channel to operation and then bypass the failed channel.
	b) CWP contact from CPC fails closed.	Contact weld.	Relay AK11 will not be de-energized on LPD and DNBR pre-trip signals.	Periodic test, LPD or DNBR pre-trip indic. with no ch. A CWP indication.	3-channel redundancy. (4th channel in bypass)	No impact on RPS trip logic. CWP logic goes to 2-out-of-2.	
	c) CWP indic. lamp burn out	Overstress, end natural life.	No visual indication of Ch. A CWP trip.	Periodic test.	None required.	No impact on CWP logic or RPS trip logic.	

Table 7.2-4A

38) (Cont.)	i) Relay AK57 N.O. contacts fail open.	Contact corrosion, open circuit.	Equivalent to 38 a)	Equiv. to 38 a)	Equiv. to 38 a)	Equiv. to 38a)	
	j) Relay AK57 N.O. contacts fail closed.	Contact weld.	Equivalent to 38 b)	Equiv. to 38 b)	Equiv. to 38 b)	Equiv. to 38 b)	
	k) Aux logic power supply (Ch. A) fails off.	Comp. failure, open circuit.	Equivalent to 38 a)	Power supply trouble annunication.	None.	No impact on RPS logic	
39) Trip Input By-pass Switch AXS-1 (BXS-1, CXS-1 DXS-1)	a) Switch fails in normally off posi-tion	Mechanical binding of switch	Switch cannot be turned to the “trip input bypass” position for testing of the channel A (B, C, or D) bistable for trip parameter 1	Operator when pre-paring to test bistable, visual indication	None for bypass. 3 channel redun-dancy for PPS trip logic (4th channel in bypass)	No direct effect on PPS trip logic. However, will not be able to test the bistable in channel A.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 77 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
39) (Cont.)	b) Switch fails in the on “bypass” position	Mechanical binding or other mechanical failure of switch	Switch cannot be returned to the off position. The trip inputs to the AB, AC and AD logic matrices will be bypassed for Trip Parameter 1. Also, trip input bypass capability for trip parameter 1, channels B, C and D will be lost.	Operator when attempting to remove trip input bypass after test, visual indication	None for trip input bypass switch. 3 channel redundancy for PPS (4th channel is bypassed at the bistable)	PPS trip logic for trip parameter 1 becomes 2-out-of-2 coincident.	To restore PPS trip logic to 2-out-of-3 coincident, the channel that is bypassed at the bistable must be restored to service and channel A bypassed at the bistable until the trip input bypass switch is repaired.
40)	This item left blank intentionally.						
41)	This item left blank intentionally.						

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 78 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
42) Bypass Relay Coil AXK-1	a) Open	Sustained overvoltage.	Bistable “1” in Ch. A cannot be bypassed.	Periodic PPS testing or when attempting to bypass the bistable.	Noise for bypass, 3 channel redundancy for PPS Trip Logic (4th channel bypassed at bistable)	If the bistable is tripped, the system becomes any 1-out-of-2 logic for the affected function.	
	b) Short.	Deterioration of insulation.	No symptoms until an attempt is made to bypass bistable “1” in Ch. A. Inserting the bypass will force the supply voltage down and cause all bypasses in channel A to be removed.	Periodic PPS testing or when attempting to bypass the bistable.	Same as 42 a)	If the bypass is attempted it will result in the loss of all bypass capability for that channel.	If that particular bypass is not attempted there will be no effect upon the other bypass circuits in that channel.
43) Bypass relay (AXK1 Typcial) N.O. Contacts Set 1, Set 2 or Set 3	a) Contacts fail open.	Contact corrosion, open circuit.	Bistable trip relay contacts in one logic matrix will not be bypassed. Affected logic matrix will be half-tripped during bistable test.	Periodic test.	3-channel redundancy. (4th channel bypassed at bistable)	RPS trip logic for affected parameter is essentially 2-out-of-2 or 1-out-of-2 selective.	
	b) Contacts shorted.	Contact weld.	Bistable trip relay contacts in one logic matrix will be permanently bypassed. Affected logic matrix will not trip for valid signal coincidence.	Periodic test.	3-channel redundancy. (4th channel bypassed at bistable)	RPS trip logic for affected parameter becomes 2-out-of-2.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 79 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
44) Bypass Relay (AXK1 Typical) N.O. Contacts in Indicator Circuit	a) Contacts fail open.	Contact corrosion.	No visual indication of channel bypass.	Operator when by-passing channel.	Audible bypass annunciation.	RPS trip logic not affected.	
	b) Contacts shorted.	Contact weld. Open circuit.	Spurious visual indication of channel bypass.	Visual indication.	None.	No impact on RPS trip logic.	
45) Bypass Relay (AXK1 Typical) N.O. Contact in Annunc. Circuit	a) Contacts fail open.	Contact corrosion, open circuit.	No annunciation when channel is bypassed.	Operator when by-passing channel.	Visible bypass indication.	No impact on RPS trip logic.	
	b) Contacts shorted.	Contact weld.	Spurious channel bypass alarms.	Annunciating.	None.	No impact on RPS trip logic.	
46) Bypass Relay Cotnact Set 6A, 6B	These contact sets (1 N.O. and 1 N.C.) are spares for all parameters except HI LPD and LO DNBR. For these two parameters, these contact sets are used in the Power Trip Test Interlock and the CPC Test enable. See Line Items 36 and 38.						
47) Auxil-iary Bypass Relay AXKB6, AXKB9, AXKB10, AXKB11, AXKB12 or AXKB13.	a) Coil fails open.	Mech. damage, overstress.	The ESFS actuation relays associated with the affected parameter (LO PZR press. for AXKB6, etc.) will not be by-passed when the trip bistable is tested. Three ESFS actu-ation logic mtrices (i.e., AB, AC and AD for Ch. A bi-stable) for a specific ESFS function (i.e., SIAS for LO PZR press, AXKB6) will be half-tripped.	Periodic test.	3-channel redundancy. (4th channel bypassed at bistable)	Actuation logic for a given ESF function goes to 1-out-of-2.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 80 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
48) Auxil-iary Bypass Relay Contact Sets 1, 2 or 3	a) Contact set fails open.	Corrosion, mech. damage, open circuit.	Bistable trip relay contacts in one ESF actuation logic matrix will not be bypassed when the bistable is tested. Affected logic matrix is half-tripped during bistable test.	Periodic test, visual indication	3-channel redundancy. (4th channel bypassed at bistable)	Actuation logic for one ESF function becomes 1-out-of-2 selective or any 2-out-of-2.	
	b) Cont-tacts shorted.	Contact weld.	Bistable trip relay contacts in one ESF actuation logic matrix will be permanently bypassed. ESF logic matrix will not trip for valid signal coincidence.	Periodic test.	3-channel redundancy. (4th channel bypassed at bistable)	Actuation logic for one ESF function becomes 2-out-of-2.

49) Trip Channel Bypass Power Supplies (PS-49, PS-52, Ch. A Typ.)	One Fails off	Comp. failure, open circuit.	Loss of one of two redundant power supplies for the trip channel bypass relays.	Visual indication	Redundant power supply.	No impact RPS Trip or ESFS Actuation logic.	
50) Trip Channel By-pass Power Supply Indi-cator Lamp	Fails off	Broken Fila-ment, end of natural life, open circuit.	Spurious trip channel bypass power supply failure indica-tion.	Visual indication.	None required.	No impact on trip logic.	
51) RPS 2-of-4 Trip Logic Matrix (AB Typical)	a) One of two matrix power sup-plies (PS9 or PS-4 Typ.) fails off	Comp. failure, open circuit.	Loss of one of two logic matrix power supplies. Two of the four matrix relays will be de-energized.	Power supply trouble alarm, visual indication.	Second power supply provides power to both sides of “Logic Ladder”, and to the two remaining logic matrix relays.	RPS trip logic remains 2-out-of-3. Two “Series” trip paths are tripped. (4th channel bypassed at bistables)	RPS trip path logic is 2-out-of-3 selective.
	b) One of two matrix power sup-plies fail HI.	Component failure.	Possible overstress of 2-of-4 logic matrix relays. Relays may fail open and logic matrix will become half tripped.	Visual indication if matrix relays fail open.	Same as above.	Same as above.

(Sheet 87 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
52) EFSAS Actuation Logic Matrix (AB Typical)	Failure Modes a through i and their effects on the ESFAS Actuation Logic for all ESF functions are equivalent to failure modes a) through i) of Line item 51, and their effects on RPS trip logic.						
	j) Bistable relay trip indicator lamp fails off.	Broken fila-ment, burnt out.	Loss of visual indication for a bistable relay trip for one ESF function (i.e., CSAS) in the AB matrix.	Periodic test.	Bistable relay trouble annunci-ator.	No impact on ESFAS actuation logic for any ESF function.	
	k) Bistable relay trip indicator lamp tran-sistor driver fails off.	Transistor failure, open circuit.	Same as 52 j)	Same as 52 j)	Same as 52 j)	Same as 52 j)	
	l) Bistable relay trip indicator lamp transistor driver fails on.	Emitter-to-collector short.	Spurious visual indication of the trip of one bistable relay for one ESF function in the AB matrix.	Visual indication.	None required.	No impact on ESFAS actuation logic for any ESF function.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 88 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
	m) One logic matrix relay driver for one ESF function fails off.	Open circuit, transistor failure.	One logic matrix relay for the affected ESF function is de-energized, tripping 1 of 4 actuation paths.	Visual indication.	ESF actuation path logic is 2-of-3 selective. The other 2 actuation paths are not affected. (4th channel bypassed)	ESF actuation still requires a 2-of-3 signal coincidence.	
	n) One logic matrix relay driver for one ESF function fails on.	Emitter-to-collector short.	One logic matrix relay for the affected ESF function will not be deenergized for a valid signal coincidence, and the associated trip path will not trip.	Periodic test.	The remaining 2 logic matrix relays for the ESF function (in matrix AB) are not affected and can still generate a ESF trip on a valid signal coincidence.	ESFAS actuation logic remains 2-of-3, but the trip path logic for the AB matrix for the affected ESF becomes 2-out-of-2 selective. (4th channel in bypass)	
	o) One logic matrix relay for one ESF function fails open.	Overstress, mech. damage, coil open, coil shorted	Same as 52 m)	Same as 52 m)	Same as 52 m)	Same as 52 m)

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 90 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
53) RPS Trip Path (Path A Typ.)	a) Trip path power supply (PS-34 Typ.) fails off.	Comp. failure.	RPS trip A Relay and all ESF actuation path A Relays are deenergized. One trip path for RPS trip and ESF actuation is tripped.	Multiple visual and audible alarms.	The remaining 3 trip paths for RPS trip and ESF actu-ation are not affected.	Trip path logic for all functions changes from 2-of-4 selective to 1-of-3 selective.	
	b) Trip path power suuply (PS-34 Typ.) fails HI.	Failure internal to power supply.	Possible overstress of trip relays in one of the Ch. A trip paths (RPS trip or ESF actuation).	None.	P/S output Zener will maintain 12 VDC to trip paths.	None.	
	c) Trip path power supply indicator lamp fails off.	Burnt out, broken fila-ment.	Spurious visual indication of power supply failure.	Visual indication.	None required.	No impact on trip path.	
	d) Trip path power supply output Zener fails open.	Comp. failure.	Loss of overpower protection for Ch. A trip paths. If power supply fails high, trip path fuses will blow. Effect equivalent to 53 a).	None, unless P/S fails high, then trip path trip indications.	Same as 53 a)	Same as 53 a)	
	e). Trip path power supply output Zener shorted.	Overstress, comp. failure.	The trip path power supply will be shorted. See 53 a)	See 53 a)	See 53 a)	See 53 a)	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 91 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
53) RPS Trip Path (Ch. A Typ.) (Cont.)	f) RPS trip path fuse fails open.	Overstress, mech. damage.	Loss of power to RPS trip relay K1, one set of trip breakers open.	Annunciting.	The 3 remaining trip breakers are not affected.	Trip path logic becomes 1-of-3 selective, but a 2-out-of-3 signal coincidence is still required for RPS trip.	
	g) Ground detection circuit shorted.	Mech, failure, comp. failure.	Spurious indication of grounded trip path.	Annunciating.	None required.	No impact on RPS trip logic or RPS trip path.	
	h) Ground detection, circuit fails open.	Comp. failure, open circuit.	Loss of ground detection capa- bility for one trip path. If ground occurs, power supply will be loaded down. Fuse will probably blow. See 53 f)	None.	See 53 f)	See 53 f)	
	i) Trip relay (K-1 Typ.) fails open.	Mech. damage, overstress, open circuit, coil shorted.	K-1 relay contacts in trip breaker actuation circuits will change state and one set of trip circuit breakers (TCBs) will open.	Breaker status indication.	Other three TCBs are not affected.	Trip path logic becomes 1-of-3 selective, but 2-out-of-3 signal coincidence still required for trip.	
	j). Trip relay con- tacts in undervolt- age trip circuit fail open.	Mech. damage, open circuit.	Undervoltage trip circuit will deenergize, causing the trip circuit breaker to open.	Same as 53 i)	Same as 53 i)	Same as 53 i)	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 92 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
53) RPS Trip Path (Ch. A Typ.) (Cont.)	k) Trip relay contacts in undervoltage trip circuit fail closed.	Contact weld.	Undervoltage trip circuit for one TCB will not deenergize for valid trip signal. One TCB will not open.	Periodic test.	Other 3 TCBs are not affected and are sufficient to produce trip.	Trip path logic becomes 2-of-3 selectives, but 2-out-of-3 signal coincidence still required for trip.	
	l) Trip Relay contacts in shunt trip circuit fail closed.	Open circuit, contact weld, contamination.	Shunt trip circuit will be energized and one TCB will open.	Same as 53 i)	Same as 53 i)	Same as 53 i)	
	m) Trip relay contacts in shunt trip circuit fail open.	Contact corrosion.	Shunt trip circuit for one TCB will not be energized for valid trip signal.	Same as 53 k)	Same as 53 k)	Same as 53 k)	
	n) Remote indicator SSR fails open.	LED failure, SS transistor failure.	Spurious remote indicator of trip path A trip.	Visual indication.	None required.	No impact on RPS trip path or RPS trip logic.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 93 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
53) RPS Trip Path (Path A Typ.) (Cont.)	o) Remote indicator SSR fails on.	Emitter-to-collector short.	Loss of remote visual indication of trip path A trip.	Periodic test.	Local indication and plant annunc.	Same as above.	
	p) Local indicator SSR fails off.	LED failure, SS transistor failure.	Spurious local indication of trip path A trip.	Visual indication.	None required.	Same as above.	
	q) Local indicator SSR fails on.	Emitter-to-collector short.	Loss of local indication of trip path A trip.	Periodic test.	Remote indication and plant annunc.	Same as above.	
	r) Plant Annunc. SSR fails off.	LED failure, SS transistor failure.	Spurious annunciation of trip path A trip.	Annunciation	None required.	Same as above.	
	s) Plant annunc. SSR fails on.	Emitter-to-collector short.	Loss of annunciation for trip path A trip.	Periodic test.	Remote and local indication.	Same as above.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 94 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
53) RPS Trip Path (Path A Typ.) (Cont.)	t) One dropping resistor for one SSR fails open.	Mech. damage, overstress, open lead.	The affected SSR will be de-energized. See 53 n), p), or r) for affects.	See 53 n),p), or r)	See 53 n),p), or r)	See 53 n),p),or r)	
	u) One dropping resistor for one SSR shorted.	Comp. failure.	The affected SSR will see a higher control signal voltage SSR will probably fail open due to overstress.	See 53 n),p) or r)	See 53 n),p) or r)	See 53 n),p) or r)	
54) Trip Circuit Breaker Actuation (TCB-1 Typ.)	a) Bus 1, 125 VDC, fails off.	Mech. damage, ground.	TCB-1 undervoltage trip circuit will be deenergized, and TCB-1 will open.	Breaker status indication.	Other 3 TCBs are not affected.	One TCB open RPS trip still requires 2-out-of-3 signal coincidence.	
	b) Bus 1, fuse fails open.	Mech. damage, overstress.	Same as 54 a)	Same as 54 a)	Same as 54 a)	Same as 54 a)	
	c) Manual trip push-button contacts in undervolt-age trip circuit fail closed.	Mech binding, contact weld.	Undervoltage trip circuit for one TCB will not be deenergized by its manual trip button. Shunt trip circuit can still open TCB.	Periodic test.	Auto trip function not affected, shunt grip circuit not affected. Other 3 TCBs not affected.	No impact on trip function.	

Table 7.2-4A

(Sheet 95 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
54) Trip Circuit Breaker Actuation (TCB-1 Typ.) (Cont.)	d) Manual Trip button contacts in under-voltage circuit fail open.	Open circuit	Undervoltage trip circuit will be deenergized and the TCB will open.	Breaker status indication.	Other 3 TCBs are not affected.	Same as 54 a)	
	e) Manual trip button contacts in shunt trip circuit fail open.	Open circuit, mech. damage. contact corrosion.	Shunt trip circuit for the TCB will not be energized by manual trip button. Shunt trip circuit will not trip TCB.	Periodic test.	Underfreq. trip circuit will still open TCB. Other 3 TCBs not affected. Auto trip function not affected.	Same as 54 b)	
	f) Manual trip button conttacts in shunt trip circuit fail closed.	Short circuit.	Shunt trip circuit will be energized and one TCB will open.	Breaker status indication.	Same as 54 a)	Same as 54 a)	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 96 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
54) Trip Circuit Breaker Actuation (TCB-1 Typ.) (Cont.)	g) Supplementary protection system (SPS) contacts in undervoltage trip circuit fail open.	Open circuit, mech. damage, SPS failure.	Undervoltage trip circuit for the TCB will be deenergized and the TCB will open.	Same as 54 a)	Same as 54 a)	Same as 54 a)	
	h) SPS contacts in undervoltage trip circuit fail closed.	Contact weld, SPS failure.	SPS will not deenergize the undervoltage trip circuit for one TCB on a valid trip signal.	Periodic test.	SPS still energizes shunt trip circuit to trip TCB auto and manual trip functions not affected. Other 3 TCB s not affected.	Same as 54 c)	
	i) SPS contacts in shunt trip circuit fail closed.	Short circuit, contact weld.	Shunt trip circuit for the TCB will energize and the TCB will open.	Same as 54 a)	Same as 54 a)	Same as 54 a)	
	j) SPS contacts in shunt trip circuit fail open.	Open circuit, mech. damage.	SPS will not energize shunt trip circuit for one TCB on valid trip signal.	Periodic test.	SPS will deenergize undervoltage trip circuit to trip TCB auto and manual trip funct. not affected.	Same as 54 c)	

Table 7.2-4A

(Sheet 97 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
54) Trip Circuit Breaker Actuation (TCB-1) (Cont.)	k) Under-voltage trip circuit fails open.	Open circuit, comp. failure.	Same as 54 d)	Same as 54 d)	Same as 54 d)	Same as 54 d)	
	l) Shunt trip circuit fails open.	Open circuit, comp. failure.	Unable to energize shunt trip circuit on valid trip signal, shunt trip circuit will not open TCB.	Periodic test.	Undervoltage trip circuit will open TCB. Other 3 TCBs unaffected.	Same as 54 c)	
	m) Closing circuit pushbutton fails closed.	Contact corrosion, mech. damage, open circuit.	Unable to energize TCB closing circuit to close TCB after test or trip.	Operator, TCB status indicator.	Other 3 TCBs are not affected.	Same as 54 a)	
	n) Closing circuit pushbutton fails closed.	Short circuit, mech. damage, contact weld.	Closing circuit will remain energized, and oppose the shunt trip circuit. TCB opening will rely on spring for trip signal.	Periodic test.	TCB will still open on trip signal. Other 3 TCBs are not affected, circuit breaker spring loaded to open.	Trip actuation logic remains 2-of-4 selective. Trip still requires a 2-out-of-3 signal coincidence.	No impact on RPS Trip Logic or trip actuation.
	o) Closing circuit fails off.	Open circuit, comp. failure.	Same as 54 m)	Same as 54 m)	Same as 54 m)	Same as 54 m)	

Table 7.2-4A

54) Trip Circuit Breaker Actuation (TCB-1 Typ.) (Cont.)	u) TCB NC contacts in status circuit fail open.	Contact corrosion, mech. damage.	“TCB Open” lamp will not come on when breaker opens.	Periodic test.	“TCB Closed” lamp goes off when breaker opens, TCB not affected.	Same as 54 r)	
	v) “TCB Open” lamp fails off.	Burnt out, mech. damage.	Same as 54 u)	Same as 54 u)	Same as 54 u)	Same as 54 u)	
	x) “TCB Closed” lamp fails off.	Burnt out, mech. damage.	Same as 54 r)	Same as 54 r)	Same as 54 r)	Same as 54 r)	
55) 480 V ac Bus (Bus 1 Typ.)	Fails off.	Short mech. damage.	Loss of one of two redundant 480 V ac supplies to the CEDMs	Bus current indic.	Redundant bus.	None.	
56) MG Set Input Breaker (MG-1 Typ.)	a) Fails Open.	Open circuit, mech. damage	Loss of 480 V ac input to 1 MG set. Loss of 1 of 2 redund. Supplies to CEDMs.	Input breaker status indication.	Redundant MG set and bus.	None.	
	b) Fails Closed.	Contact weld, Mech. binding.	No impact on normal operation. Loss of overcurrent protect, for MG set. Possible damage to MG set if overcurrent occurs.	None.	MB output breaker, redundant MG set and bus.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 100 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
57) Motor-Generator Set (MG-1 Typ.)	Fails off	Motor fails, generator fails, fly-wheel failure.	Loss of 1 of 2 480 V ac inputs to the CEDMs.	MG Set status indic.	Redundant MG set.	None.	
58) MG Set Output Breaker	a) fails Open.	Open circuit, mech damage.	Same as 57 a)	Same as 57 a)	Same as 57 a)	Same as 57 a)	
	b) Fails Closed.	Contact weld, mech. binding.	No impact on normal operation, loss of overload protect for MG output. Possible damage to generator on overcurrent.	None.	Redundant MG set.	None.	
59) MG Set Load Con-tactors	a) Fails Open.	Open circuit, mech. damage, contact cor-rosion	Same as 57 a)	Same as 57 a)	Same as 57 a)	Same as 57 a)	
	b) Fails Closed.	Contact weld, short circuit.	No impact on normal operation. Possible damage to generator due to motoring when MG set is unloaded.	None.	MG set breakers, redundant MG set.	None.	
60) CEDM Ring Bus Current Status Indicator (1 of 2)	Fails off	Open circuit, comp.failure.	Spurious indication of loss of current in one side of ring bus.	Indicating.	None required.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 101 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
61) Syn-chronizing Circuit (SIAS, Ch. A Typ.)	Fails HI or LOW	Comp. failure.	Unable to synchronize one MG set to the CEDM bus possible MG set.	Operator, when trying to synch. MG set.	Redundant MG set.	None.	
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.)	Failure Modes a) through e) and their effects on the ESFAS Initiation Circuit are equivalent to Line Item 53, Failure Modes a) through e) and their effect on RPS trip initiation circuit.						
	f) ESFAS initiation circuit (SIAS, Ch. A Typ) fuse fails open.	Overstress, mech. damage, degradation.	Loss of power to Ch. A initia-tion relays, one leg of the actuation circuit open for Train A and Train B.	Annunciating, visual indication.	The other 3 ESFAS init. channels are not affected.	ESFAS Init. path logic becomes 1-of-3 selective, but a 2-out-of-3 signal coincidence still required for ESFAS actuation.	
	g) Remote manual pushbutton fails open.	Mech. damage, contact cor-rosion, open circuit.	Same as 62 e)	Same as 62 e)	Same as 62 e)	Same as 62 e)	
	h) Remote manaul pushbutton fails closed.	Contact weld, short circuit, mech damage.	Unable to deenergize the Ch. A init. relays for one ESFAS function using the remote manual pushbutton.	Periodic test.	Auto init. Capa-bility not affec-ted. Other 3 init. circuits can init. desired ESFAS function manually.	Auto ESFAS init. un-affected. Manual ESFAS init. for one function becomes 2-of-3 selective.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 102 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.) (Cont.)	i) SSR lockout relay fails off.	LED failure, SS transistor failure.	No impact on normal operation. Unable to reset ESFAS init. relays for one ESFAS function after chan. Has been tripped.	Operator, when re-setting channel.	Same as 62 e)	Init. path logic for one ESFAS funct. be-comes 1-of-3 selec-tive, actuation requires 2-out-of-3 signal coincidence.	
	j) SSR Lockout relay fails on.	Emitter-to-collector short.	No impact on normal operation. After trip, initiation circuit for one ch. of one ESFAS function can reset itself if trip clears on all foru initi-ating bistables.	Periodic test.	Other 3 init. circuit ch. not affected and will remain locked out.	None.	
	k) Lockout reset pushbutton fails open	Contact cor-rosion, mech. damage, open circuit.	Same as 62 h)	Same as 62 h)	Same as 62 h)	Same as 62 h)	
	l) Lockout reset pushbutton fails closed.	Contact weld, short circuit, mech. damage.	No impact on normal operation. The affected init. circuit will automatically reset when the reset key switch is engaged.	Operator, when resetting ch.	Other 3 init. cir-cuit chans. for affected funct. are not affected.	None.	
	m) Lockout key switch fails open	Mech. binding. open circuit, contact cor-rosion.	Same as 62 h)	Same as 62 h)	Same as 62 h).	Same as 62 h)

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 103 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.) (Cont.)	n) Lockout key switch fails closed.	Contact weld, mech. binding or damage, short circuit.	No impact on normal operation. Operator will be able to reset the affected init. circuit after trip without using the reset key.	None.	Other 3 init. circuits are not affected.	None.	Operator will not know that the init. circuit can be reset without the reset key.
	o) Lockout keyswitch relay (K1201) fails open.	Open circuit, mech. damage, overstress.	Same as 62 h)	Same as 62 h)	Same as 62 h)	Same as 62 h)	
	p) Lockout keyswitch relay contacts in reset circuit fail open.	Contact corrosion, open circuit, mech. damage.	Same as 62 h)	Same as 62 h)	Same as 62 h)	Same as 62 h)	
	q) Lockout keyswictch relay contacts in reset circuit fail closed.	Contact weld, short circuit.	Same as 62 m)	Same as 62 m)	Same as 62 m)	Same as 62 m)	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 104 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.) (Cont.)	r) Train A or B initiation relay coil (SIAS, CIAS, or MSIS only) fails open.	Mech. damage, overstress, open circuit.	One set of relay contacts in the actuation circuit for one train of one ESF function will open.	Annunciating	Remaining 3 init. relays for the affected ESF func. train are still energized	ESFAS actuation still requires 2-out-of-3 signal coincidence. Initiation relay logic changed to 1-of-3 selective.	
	s) Train A or B initiation relay N.O. contact in actuation circuit fails open (SIAS, CIAS, or MSIS only).	Open circuit, contact cor-rosion, mech. damage.	Same as 62 q)	Same as 62 q)	Same as 62 q)	Same as 62 q)	
	t) Train A or b init. relay N.O. contacts in actuation circuit fail closed (SIAS, CIAS, or MSIS only).	Contact weld, short circuit.	One set of relay contacts in the actuation circuit for one train of one ESF function will not open on a valid 2-out-of-4 signal coincidence.	Periodic test.	Remaining 3 init. relays for the affected ESF func. train are capable of actuating the train.	Actuatuion for one ESF function train becomes 2-of-3 selective. ESFAS actuation still requries a 2-out-of-3 signal coincidence.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 105 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.) (Cont.)	u) Train A or B solid init. relay fails off. (CSAS, RAS, AFAS-1 or AFAS-2).	LED failure, SS trans. failure, open circuit, drop ping resistor failure.	Equivalent to 62 q)	Equiv. to 62 q)	Equiv. to 62 q)	Equiv. to 62 q)	
	v) Train A or B solid state initiation relay fails on. (CSAS, RAS, AFAS-1, or AFAS-2).	Emitter-to-collector short.	Equivalent to 62 s)	Equiv. to 62 s)	Equiv. to 62 s)	Equiv. to 62 s)	
	w) Remote Indication SSR fails off.	LED failure, SS transistor failure, dropping resistor fail.	Spurious indication of initiation Ch. trip on remote PPS module.	Visual indication.	None required.	None.	
	x) Remote indication SSR fails on.	Emitter-to-collector short.	Loss of remote visual indication for initiation circuit trip.	Periodic test.	Local visual indicator.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 106 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
62) ESFAS Initiation Circuit (SIAS, Ch. A Typ.) (Cont.)	y) Local indication SSR fails off.	LED failure, SS transistor failure, resistor failure.	Spurious local indication of initiating circuit trip.	Visual indication.	None required.	None.	
	z) Local indication SSR fails on.	Emitter-to-collector short.	Loss of local visual indication of initiation circuit trip.	Periodic test.	Remote visual trip indicator.	None.	
	aa) Initiation reset flasher SSR fails off.	LED failure, SS transistor failure, dropping resistor failure.	Initiation reset flasher in test circuit will flash, indicating a spurious channel initiation.	Visible indication.	None required.	None.	
	ab) Initiation reset flasher SSR fails on.	Emitter-to-collector short.	Initation reset flasher in test circuit will not provide indication that a channel initiation has occurred during test. Operator may test another channel - leading to actuation.	Local and remote initiation indication without initiation reset indic. during test.	Local and remote initiation indication.	Possible ESF function actuation during test. Possible reactor trip if MSIVs are closed.	Operator error needed to produce ESF actuation during test. No adverse safety impact on plant. Failure not affect normal PPS operation.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 107 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, MSIS, or CIAS).	a) One 36 V dc power supply fails off.	Component failure.	Loss of one of two redundant power supplies for one set of component actuation relays.	Annunciating.	Redundant power supply.	None.	
	b) One 120 V ac vital bus circuit breaker fails open.	Mech. damage, high current.	Equivalent to 63 a)	Equiv. to 63 a)	Equiv. to 63 a)	Equiv. to 63 a)	
	c) One 120 V ac vital bus circuit breaker fails closed.	Contact weld, mech. damage.	No impact on normal operation. Power supply is supplied with a 30 A input fuse. Fuse will open if input current exceeds 30A and the power supply will lose input power.	Periodic test, power supply failure is annunciated.	Redundant power supply.	None.	
	d) 36 V dc power supply indicator lamp fails off.	End of life, burnt out, mech. damage.	Spurious visual indication of power supply failure.	Visual indication.	None required.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 108 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, MSIS, or CIAS). (Cont.)	e) 36 V dc power supply trouble annunciator relay fails open.	Overstress, mech. damage, open coil winding.	Spurious power supply failure alarm.	Annunciating.	None required.	None.	
	d) 36 V dc power supply trouble annunc. relay shorted.	Insulation failure.	Output of one 36 V dc P/S will be shorted. Automatic elec-tronic current limiting circuit limits output current to a preset value.	Annunciating for power supply failure.	Redundant power supply.	None.	
	g) One auction-eering diode fails open.	Overstress, open circuit, mech. damage.	Equivalent to 63 a)	Equiv. to 63 a)	Equiv. to 63 a)	Equiv. to 63 a)	
	h) Auc-tioneering diode shorted.	Overstress, internal failure.	Loss of isolation between two 36 V dc power supplies.	Periodic test.		None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 109 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, MSIS, or CIAS). (Cont.)	i) One manual actuation pushbutton fails open.	Mech. damage, open circuit, contcat deteriora-tion.	One leg of the actuation cir-cuit for one ESFAS function will open up. Power for actu-ation relays will be supplied via opposite leg of circuit.	Annunciating.	Opposite leg of actuation circuit will supply power to actuation relays.	Manual ESFAS actu-ation becomes 1-of-1, auto initiation becomes 1-of-4 selective.	Auto ESFAS actuation still requires a 2-out-of-3 signal coincidence.
	j) One manual actuation pushbutton fails closed.	Contact weld, mech. damage.	The manual actuation button will not open one leg of actuation circuit.	Periodic test.	Automatic ESFAS actuation not affected.	Unable to manually actuate one ESFAS function.	
	k) Annunc-iation diodes fail open.	Overstress, open lead, mech. damage.	Equivalent to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	
	l) Annunc. diodes short.	Overstress, internal failure.	Voltage drop across diodes goes to zero, annunc. “sees” open circuit, spurious annunc. of one actuation circuit leg opening up.	Annunciating.	None required.	None.	
	m) Actuator circuit indicator lamp fails off.	Filament burnt out, mech. damage.	Spurious visual indication that one leg of the actuator circuit has opened up.	Visual indication.	None required.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 110 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, MSIS, or CIAS). (Cont.)	n) Lockout reset button fails open.	Contact de-terioration, mech. damage, open circuit.	Unable to reset one leg of the actuation circuit after test or an actuation. Other leg can still be reset, which will reenergize lockout relay in affected leg.	Visual indication.	Reset pushbutton in other leg of actuation circuit.	None.	
	o) Lockout reset pushbutton fails closed.	Contact weld, mech. damage.	No imapct during normal opera-tion, after auto. actuation. If actuation is caused by using manual actuation button, actuation relays will auto-matically reset.	Periodic test.	Automatic actua-tion and manual ESFAS initiation capabilities not affected.	One ESFAS function cannot be manually actuated from the actuation relay level.	Auto ESFAS actuation and manual ESFAS actuation from the initiation circuit not affected.
	p) Lockout relay N.O. contacts fail open.	Open circuit, contact deteriora-tion.	Equivalent to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)
	q) Lockout relay N.O. contacts fail closed.	Contact weld.	Same as 63 o)	Same as 63 o)	Same as 63 o)	Same as 63 o)	Same as 63 o)
	r) Lockout relay coil fails open.	Mech. damage, open winding.	Equivalent to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)	Equiv. to 63 i)

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 111 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, MSIS, or CIAS). (Cont.)	s) Lockout relay coil shorted.	Insulation failure, mech. short.	One group of actuation relays (either pumps or valves) will be shorted out, and will de-energized. Circuit breaker for affected group will probably open on high current.	Annunciating.	Only pumps or only valves will be actuated, so the full safety system will not be spur-iously actuated.	Either the pumps or the valves (but not both) in one train of one ESFAS function will be actuated.	
	t) Lockout relay surge protectiond iode fails open.	Overstress, mech damage.	Loss of surge protection for lockout relay. Possible damage to relay due to inductive kick when relay deenergizes. Relay may fail open.	Periodic test.	None required.	None.	
	u) Lockout relay surge protection diode shorted.	Overstress, internal failure.	Same as 63 s)	Same as 63 s)	Same as 63 s)	Same as 63 s)	Same as 63 s)
	v) One actuation relay coil fails open.	Mech. damage, open winding, open lead.	One valve or one pump will be actuated in one train of one ESFAS function.	Status indicator for affected valve or pump.	Only one component actuated, the full train for the affected ESFAS fucntion will not be spuriously actuated by failure of one actuation relay.	Full ESFAS actuation still requires a 2-out-of-3 signal coincidence. Only a single comp. affec-ted by this failure. (4th input signal bypassed at bi-stable).

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 113 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
63) ESFAS Actuation Circuit (SIAS, CSAS, RAS, or CIAS). (Cont.)	aa) Actuation relay test relay N.C. contacts fail closed.	Contact weld, mech. damage.	Same as 63 z)	Same as 63 z)	Same as 63 z)	Same as 63 z)	
	ab) Actuation relay test relay N.C. contacts fail open.	Contact deterioration, mech. damage.	Same as 63 v)	Same as 63 v)	Same as 63 v)	Same as 63 v)	
	ac) Power return line circuit breaker fails open.	Contact deterioration, mech. damage.	Power return line for one group of actuation relays (pumps or valves) in one train of one ESF function opens up. Relays are de-energized.	Annunciating.	None.	All valves, or all pumps (but not both) in one train of one ESF function are actuated.	
	ad) Power return line circuit breaker fails closed.	Contact weld, mech. damage.	Loss of overcurrent protection for one leg of one actuation circuit.	Breaker test during shutdowns.	None.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 114 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
64) ESFAS Actuation Circuit (AFAS-1, AFAS-2, or MSIS)	Failure Modes a) htrough h) and their effects are the same as for Line Item 63, Failure Modes a) through h).						
	i) Annunciator diodes fail open.	Overstress, mech. damage.	One actuation leg for AF pumps (or MSIVs) will open up. Corresponding aux. FW valve actuation leg not affected.	Annunciating	Opposite actuation leg for aux. FW pumps (or MSIVs) will provide power to act. relays.	AFW pump actuation becomes 1-of-2 selective. Valve act. not affected.	AFAS actuation still requires a 2-out-of-3 signal coincidence. (4th input signal bypassed at bistable)
	j) Annunc. diodes shorted.	Internal failure, overstress, mech short.	Voltage drop across annunc. diodes goesto zero. Annunc. “sees” an open circuit. Spurious AFAS (or MSIS actuation alarm.	Annunciating	None required.	None.	
	k) Actuation circuit indicator lamp fails off	Burnt out, mech. damage.	Spurious visual indication that one actuation leg has opened up.	Visual inciation.	None required.	None.	
	l) Lockout reset pushbutton fails open.	Contact deterioration, mech. damage.	No imapct on normal operation. Unable to reset the AFW pump (or MSIV) portion of one actuation leg after test or actuation. Reset button in opposite leg will provide power to reset relay and reset the affected leg.	Periodic test.	Reset pushbutton in opposite actuation leg.	None.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 115 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
64) ESFAS Actuation Circuit (AFAS-1, AFAS-2, or MSIS) (Cont.)	m) Lockout reset pushbutton fails closed.	Contact weld, mech. damage.	No impact during normal operation or after automatic actuation. If actuation is via manual actuation button, actuation relays for AFW pump (or MSIV) will automatically reset when manual actuation button released.	Periodic test.	Automatic actuation and manual initiation not affected.	AFW pumps (MSIVs) cannot be manually actuated from the actuation circuit for either AFAS-1 or AFAS-2 (MSIS A, MSIS B).	Auto AFAS (MSIS) actuation and manual AFAS (MSIS) actuation from the initiation circuit not affected.
	n) Manual actuation button fails closed.	Contact weld, mech. damage.	Unable to manually actuate one AFAS Train (or MsiS Train).	Periodic test.	Same as above	Unable to manually actuate AFW pumps and one set of valves from the actuation circuit.	Same as above.
	o) Manual actuation button fails open.	Contact deterioration, mech damage.	One leg of one AFAS (MSIS) actuation circuit open. AFAS valve relay will de-energize and actuate valves. Pump relays will be powered by opposite leg.	Annunciating.		One set of AFAS valves will be actuated.	Full AFAS actuation still requires a 2-out-of-3 signal coincidence. (4th input signal by passed at bistable).
	p) Lockout relay fails open.	Open winding, overstress, mech. damage.	Equivalent to 64 i)	Equiv. to 64 i)	Equiv. to 64 i)	Equiv. to 64 i)	Equiv. to 64 i)

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 119 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
64) ESFAS Actuation Circuit (AFAS-1, AFAS-2, or MSIS). (Cont.)	dd) AFAS valve act. relay shorted.	Insulation breakdown mech. short.	Equivalent to 64 q)	Equiv. to 64 q)	Equiv. to 64 q)	Equiv. to 64 q)	Equiv. to 64 q)
	ee) AFAS valve act. relay N.O. contacts in pump act. cir cuit fail open.	Open lead, mech. damage, contact deterioration.	Same as 64 i)	Same as 64 i)	Same as 64 i)	Same as 64 i)	Same as 64 i)
	ff) AFAS valve act. relay N.O. contacts in pump act. cir-cuit fail closed.	Contact weld, mech. damage.	SSR1A unable to actuate pump and valve group for one actuation leg.	Periodic test.	Manual actuation, SSR3A not affected.	Full actuation of AFAS (MSIS) requires 2-of-4 selective input from init. circuit.	AFAS actuation still requires 2-out-of-3 signal coincidence. (4th input signal bypassed at bis table).
	gg) Power return circuit breaker open.	Mech. damage, open circuit.	One entire actuation leg for one AFAS (MSIS) train is de-energized. One AFAS valve set and one pump set (MSIV) actuated.	Annunciating.	None.	For AFAS, one valve set and one pump set in one AFAS train are actuated. For MSIS, one MSIV closes, probable reactor trip.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 120 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
64) ESFAS Actuation Circuit (AFAS-1, AFAS-2, or MSIS). (Cont.)	hh) Power return line circuit breaker fails closed.	Contact weld, mech. damage.	Loss of overcurrent protection for one leg of the actuation circuit.	Periodic breaker tests.	None.	None.	
65) Test Power Supply	a) High output voltage.	Internal failure.	Depends upon ability of compo-nents to sustain overvoltage.	Possible power supply indicator light inoperative.	None required.	Unable to test PPS.	No effect upon operation of PPS. Overvoltage condition may cause failure of affected bistable test coils when matrix hold push button is depressed during test.
		Mechanical damage.	Possibilities: 1. Matrix pushbutton system channel trip select, and RPS channel trip select switch fail closed or open. 2. Bistable test coils fail open or short. 3. Bistable test coil surge suppression diodes fail open or short.	Inability to conduct bistaable relay test.	None required.		
	b) Low or no output voltage.	Internal failure, mech. damage, input under-voltage, input CRT breaker open.	No test capability.	Test power supply and matrix relay hold indicator lights in-operative.	None required.	Unable to test PPS.	No effect upon operation of PPS.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 121 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
66) Matrix Hold Switch e.g., “AB” Matrix)	a) Open – Matrix relay circuit contacts.	Mech. failure, contact deterioration.	Unable to energize matrix relay test coils which inhibits matrix response when selected pair of contacts in “AB” logic matrix is actuated. Matrix will pass test signal as bonafide actuation signal (e.g., CSAS).	Matrix relay hold and drop-out indicator lights inoperative. Annunciation.	None required	Matrix Relay Hold Switch has a detent in the “hold” posi-tion, which allows detection of open contacts before switch is rotated to the “trip” position.	Test procedure requires matrix and channel switch at off position. The failure of these contact pairs can be deteced before channel is tested.
	b) Closed – Matrix relay circuit contacts	Mech. damage, welded contacts.	Matrix relay test coils remain energized, preventing reactor trip initiated by same matrix.	Matrix relay hold and drop-out indicator lights remain on.	Removal of test power.	Affected logic matrix cannot initiate trip when required during test.	Reactor trip logic becomes 2-out-of-2 during test period only. (4th input signal bypassed at bistable.)
	c) Open – Bistable relay circuit contacts.	Mech. failure, contact deterioration.	Unable to energize any system channel trip select switch or RPS channel trip select switch, bistable test relay coils.	Unable to release bistable relay. No trip indicator lights.	None required	None. Unable to conduct matrix logic test for “AB” matrix.	No affect on operation of PPS. Operator cannot test bistables, pair associated with matrix logic (e.g., “AB”).
	d) Closed – Bistable relay circuit contacts	Mech. damage, welded contacts	Bistable relay test coils connected to system channel trip select switch remains energzied during test.	Bistable relay trip indicator light is on	Removal of test power supply or positioning CRT switches to off.	Actuation signal is initiated when test switch is turned on.	First position of system channel trip select switch is RPS trip, and when Operator starts test sequence the reactor may trip.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 122 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
67) System Channel Trip Select Switch	Intermit-tent contact (Open)	Mech. damage, contact deterioration.	Unable to energize bistable relay test coils associated with system channel trip select switch.	No bistable test light indication.	None required	Unable to test logic matrices for affected system channel trip.	
68) RPS Channel Trip Select Switch	Intermit-tent contact (Open)	Mech. damage, contact deterioration.	Unable to energize bistable relay test coils associated with test switch position.	No bistable test light at test switch position location.	None required	Unable to test logic matricees for affected bistable pair.	No affect on opera-tion of PPS.
69) Bi-stable relay test coil (e.g., A1-1)	a) Open	Overvoltage, mech. damage.	Unable to energize affected bistable test coil to initiate relay trip for the particular parameter under test.	Bistable test light stays off.	None required	Unable to test that portion of logic matrices completely for the parameter under test.	No effect on opera-tion of PPS.
	b) Short	Mech. damage.	Test power supply will be reduced to approx. zero.	Power supply indi-cator light inoper-ative.	None required	Unable to test logic matrices completely.	
		Deterioration of Insulation	Bistable relay test coil cannot be energized.	Bistable test light stays off.	None required		
70) Matrix Relay Trip Select Switch	Intermit-tent contact (Open) (e.g., po-sition 1).	Mech. damage, contact deterioration.	Matrix relay test coils for the affected position (e.g., “1” remain de-energized during test period.	Matrix relay hold indicator light inoperative Annunciation.	None required	Reactor trip could occur during bista-ble relay trip test.	

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 123 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
71) Matrix Relay Test coil (e.g., 1AB-1)	a) Open	Overvoltage, mech. damage.	Unable to energize affected test coil to inhibit matrix relay trip.	Matrix relay hold indicator lights do not illuminate.	None required	Unable to conduct test of trip path (e.g., #1) for affected matrix logic (e.g., “AB”).	No affect on operat-tion of PPS.
	b) Short	Deterioration of Insulation	Test power supply will be reduced to approx. zero.	Power supply and matrix hold indi-cator lights do not illuminate.	None required	Unable to conduct test of trip path (e.g., #1) for affected matrix logic (e.g., “AB”).	No affect on opera-tion of PPS.
72) Matrix Relay Hold Indicators	Open	Overvoltage, mech. damage.	Test coil state cannot be visually determined.	Visual, periodic test.	None.	None.	No affect on opera-tion of PPS.
73) Matrix Relay Drop-Out Indicators	Open	Overvoltage mech. damage.	Matrix relay state cannot be determined.	Visual, periodic test.	None.	None.	No affect on opera-tion of PPS.
74) Matrix Test dc/dc Converter	a) Fails off.	Comp. failure, open circuit, fuse fails open.	Unable to provide dc power to one matrix test circuit. Unable to test one matrx (i.e., “AB”).	Operator, when attempting matrix test.	None.	No impact on PPS operation.	
	b) Fails hi.	Comp. failure.	Possible damage to components on matrix test circuits, bistable test coils may fail open. Test switches may fail open. Unable to properly test one matrix.	Operator, when attempting matrix test.	None.	No impact on PPS operation.

(Sheet 126 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
77) Ch. A Test Relay	c) One N.O. contact in power circuit fails closed.	Contact weld, mech. binding	None.	None.	None.	None.	
78) PPS Calibration and Test Panel Trip Test Pushbutton (PB -) (e.g., Channel "A")	a) Open	Mech. damage, contact deterioration.	Unable to energize bistable relay trip test circuit and supply test signal to bistable selected for test.	No bistable trip indication.	None.	None.	No effect on operation of PPS. May not be able to test bistables in affected channel (e.g., Channel "A").
	b) Closed	Mech. damage welded contacts.	Bistable relay trip test circuit energized when test signal power supply is turned on.	Bistable in test indicator.	Rotating matrix hold switch to the "Hold" position and/or reducing signal level below trip level.	Half logic matrix trip could occur during testing.	Operator will be aware of problem as soon as test power supply is turned on and before test sequence starts.
79) Trip Test Circuit Relay (K-1, e.g., Channel A")	a) Open coil.	Overvoltage, mech. damage.	Unable to energize trip test circuit. The contacts which connect the bistable selected for test to the test signal will not be energized.	No trip signal indication.	None.	Selected bistable relays cannot be tested in affected channel (e.g., "A")	No effect on operation of PPS.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 127 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
79) Trip Test Circuit Relay (K-1, e.g., Channel "A") (Cont.)	b) Shorted coil.	Deterioration of insulation, mech. damage.	Test power supply could be reduced to approx. zero.	Test power supply indicator light will extinguish. No signal reading on DVM.	None.	Selected bistable relays cannot be tested in affected channel (e.g., "A")	No effect on operation of PPS.
	c) Contact open.	Deterioration of contact, mech. damage.	Unable to energize trip circuit. Bistable selected for test cannot be connected to the test signal.	No trip signal indication.	None.	Selected bistable relays cannot be tested in affected channel (e.g., "A")	No effect on operation of PPS.
	d) Contact short.	Weld contact.	Trip test circuit remains energized.	Possible signal reading on DVM. Bistable trip indication.	Bistable select and meter input switch in off position.	Should test signal be inputted half logic matrix trip can occur during test only.	
80) NI Drawer Log Level Trip Test Switch (S2) (e.g., Channel "A")	a) Open contacts: "A"	Mech. damage, contact deterioration.	Unable to transmit test signal to next channel (e.g., "B") when next channel is selected for test.	No response of next channel during test. No bistable trip indication.	None. channels B, C, D	Unable to test ch. A Nuclear Drawer.	No effect on operation of PPS.
	"B"		Unable to test channel "A" when conducting channel test. Relay AK 60 will not energize when test is run.	No response from channel under test. No bistable trip indication.	None.	Unable to test ch. A Nuclear Drawer.	No effect on operation of PPS.
	"D"		Unable to transmit selected test signal to log level trip circuitry.	No bistable trip indication.a	None.	Unable to test ch. A Nuclear Drawer.	No effect on operation of PPS.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 128 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
80) NI Drawer Log Level Trip Test Switch (S2) (e.g., Channel "A") (Cont.)	b) Closed contacts: "A"	Mech. damage, welded contacts.	Unable to disconnect nest channel, when ch. "A" is in test. Interchannel interlock during test is overridden.	Multichannel bi-stable tirp indicaiton.	None	Possible reactor trip during test.	Operator must deliberately depress ch. "A" test switch coincidence with other channel to initiate inadvertent trip.
	"B"		Unable to discard channel "A" from test during test program.	Multichannel bi-stable trip indication.	None.	Possible reactor trip during test.	
81) HI Drawer Test Relay (AK60) (e.g., "A")	a) Open coil.	Overvoltage, mech. damage.	Unable to energize relay contacts which transmit test signal to log level trip circuitry when channel is under test.	No bistabel trip indication.	None.	Unable to test channel A Nuclear Drawer.	No effect on operation of PPS.
	b) Short coil.	Deterioration of insulation.	Test power supply may reduce to approximately zero.	No bistable trip light. Power supply test light not lit.	None.	Unable to test ch. A Nuclear Drawer.	No effect on operation of PPS.
	c) Open contacts.	Deterioration of contact, mech. damage.	Unable to transmit selected test signal to log level trip circuitry.	No bistable trip indication.	None.	Unable to test ch. A Nuclear Drawer.	No effect on operation of PPS.
	d) Short contacts.	Deterioration of contact, welded contact.	Interlock feature of relay AK60 is inhibited, cannot cause multi-test condition with failure in "A" channel.	Bench test.	Design of inhibit circuit would not allow trip condition if failure occurs in "A" channel.	Possible to have a reactor trip during test.	Operator must deliberately actuate two channel test switches to obtain trip effect.

Table 7.2-4A

PLANT PROTECTIVE SYSTEM FAILURE MODES AND EFFECTS ANALYSIS
(Sheet 129 of 129)

Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
82) Log Trip Level Adjust (R8)	Open or Intermit-tent.	Failed resis-tive element.	Operator will be unable to trim test signal level.	DVTM	None.	Unable to test ch. A, Nuclear Drawer.	
83) Initia-tion Reset Flasher Circuti	a) Fails on	Flasher failure, data coupler failure, dis-crete comp. failure.	Reset lamp will flash, giving spurious indication of a channel trip for ESFAS or a TCB trip.	Visual indication.	None.	None.	
	b) Fails off.	Comp. failure.	Reset lamp will not flash when a channel trip is induced by test.	During test, flasher not flash but trip indi-cators come on.	Trip indic. for each channel of each PPS function.	None.	

7.2.2.3.2.3 Section 4.3, Quality Control of Components and Modules. The systems which function to provide protective action are designed in accordance with Topical Report-CENPD-210A, "Description of the C-E Nuclear Steam Supply System Quality Assurance Program".[5]

7.2.2.3.2.4 Section 4.4, Equipment Qualification. The RPS meets the equipment requirements described in section 3.10 and CENPD-182, "Seismic Qualification of Instrumentation and Electrical Equipment",[4] and section 3.11 and CENPD-255, "Qualification of Combustion Engineering Class 1E Instrumentation".[3]

7.2.2.3.2.5 Section 4.5, Channel Integrity. Type testing of components, separation of sensors and channels, and qualification of the cabling are utilized to ensure that the channels will maintain their functional capability required under applicable extremes of environment, power supplied, malfunction, and fault conditions. Loss of or damage to any one channel will not prevent the protective action of the RPS. Sensors are connected so that blockage or failure of any one connection does not prevent protective system action. The process transducers located in the containment building are specified and rated for the intended service. Components which must operate during or after a limiting fault are qualified for the most limiting environment for the period of time for which they must maintain their functional capability. Results of type tests are used to verify this. Separation requirements for the components of the RPS are discussed in subsection 7.2.3.

7.2.2.3.2.6 Section 4.6, Channel Independence. Each redundant channel is independent of the other redundant channels. The sensors are separated, cabling is routed separately and, in cabinets, each redundant channel is located in a separate compartment which provides thermal and mechanical barriers. This minimizes the possibility of a single event causing more than one channel's failure. The outputs from these redundant channels are isolated from each other so that a single failure does not cause impairment of the system function. The RSPT signals are sent to separate CEA calculators. To provide the required input to the CEAC, the signals utilized as inputs are sent through isolation amplifiers (see figure 7.2-0D).

Outputs from the redundant channels to non-safety related areas are isolated so that failure in the non-safety related area does not cause loss of the safety system function. Outputs from the components of the RPS to the control boards are isolated if they go to non-1E portions of the board. The signals originating in the RPS which feed the plant monitoring system (PMS) are isolated to maintain their channel independence.

7.2.2.3.2.7 Manual Initiation

A manual trip is effected by depressing either of the pushbuttons in both trip legs on the main control board for the RPS or the pushbuttons on the RTSS. No single failure will prevent a manual trip.

7.2.2.3.2.8 Control and Protection System Inspection

A. Classification of Equipment

No portion of the RPS is used for both protective and control functions with the following exception: The RPS' DNBR, LPD, and high pressurizer pressure provide a CEA Withdrawal Prohibit (CWP) which is treated as an associated circuit, and is isolated in the CEDMCS auxiliary cabinets before going to the CEDMCS. As an associated circuit it meets the requirements of IEEE 279-1971.

B. Isolation Devices

Signals from the RPS are isolated such that a failure will not affect the protective action of the RPS. The CWP is isolated in the CEDMCS Auxiliary Cabinets to prevent a failure in the CEDMCS from propagating back into the RPS.

C. Single Random Failure

This criterion is not applicable. The CWP which is sent to the CEDMCS is only a permissive signal and does not cause a control action which could require a protective action.

D. Multiple Failures Resulting From a Credible Single Event

This cannot exist since the CWP cannot initiate a control action, only permit it.

7.2.2.3.2.9 Derivation of System Input. Insofar as is practicable, system inputs are derived from signals that are direct measures of the desired variables. Variables that are measured directly include neutron flux, temperatures, and pressures. Level information is derived from appropriate differential pressure measurements. Flow information is derived from reactor coolant pump speed measurement and coolant temperature.

7.2.2.3.2.10 Capability for Sensor Checks. RPS sensors are checked by cross-channel comparison. Each channel has a known relationship with the other channels of the same parameter.

7.2.2.3.2.11 Capability for Test and Calibration. The RPS design complies with IEEE 338-1971, "Trial Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems" and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuator Functions", as discussed in section 7.2.2.3.3.

7.2.2.3.2.12 Channel Bypass or Removal From Operation. Any one of the four protection channels in the RPS may be tested, calibrated, or repaired without impairing the systems' protective action capability. In the RPS, individual trip channels may be bypassed to create a two-out-of-three logic on the remaining channels which maintains the coincidence of two required for trip. The single failure criterion is met during this condition. Testing of each of the two CEA position indication channels can be accomplished in a very brief time.

The probability of failure of the other position indication system is acceptably low during such testing periods.

7.2.2.3.2.13 Operating Bypasses. Operating bypasses are provided as shown on Table 7.2-2. The operating bypasses are automatically removed when the permissive conditions are not met. The circuitry and devices which function to remove these inhibits are designed in accordance with IEEE 279-1971.

7.2.2.3.2.14 Indication of Bypasses. Indication of test or bypass conditions, or removal of any channel from service is given by annunciators. Operating bypasses that are automatically removed at fixed setpoints are alarmed and indicated.

7.2.2.3.2.15 Access to Means for Bypassing. Trip channel bypasses have access controlled by means of key locked doors. When the first parameter is bypassed there is an audible and visible alarm to indicate which channel is being bypassed. The specific parameter or parameters which are being bypassed are indicated by lights at the PPS cabinet and its remote operator's module.

The operating bypasses have audible and visible alarms. The operating bypasses have automatic features which provide a permissive range at which they can be actuated. Should the permissive range be exceeded, the bypass will be automatically removed.

7.2.2.3.2.16 Multiple Setpoints. Manual reduction of the setpoints for low pressurizer pressure and low steam generator

pressure trips are used for the controlled reduction of pressurizer pressure and steam generator pressure as discussed in sections 7.2.1.1.1.6 and 7.2.1.1.1.8. The setpoint reductions are initiated by main control board pushbuttons for each channel, one pushbutton for the pressurizer pressure and one pushbutton for both steam generator pressures within the one channel. This method of setpoint reduction provides positive assurance that the setpoint is never decreased below the existing pressure by more than a predetermined amount.

The variable overpower trip setpoint tracks the actual reactor power from a minimum value to a high value or vice versa, if the power changes slowly enough. The variable overpower trip setpoint is designed with a maximum rate of decrease or increase. Should the actual power increase at too rapid a rate, it will catch up with the more slowly increasing setpoint and cause a trip.

The low reactor coolant flow trip setpoint automatically tracks below the input variables by a fixed margin for all decreasing inputs with a rate less than the rate limit. The setpoint decreases at a fixed rate for all decreasing input variable changes greater than the rate limit, except that there is a fixed minimum limit on the setpoint. Should the input variable decrease at too rapid a rate, it will catch up with the more slowly decreasing or limited setpoint and cause a trip. The setpoint automatically increases as the input variable increases independent of rate.

7.2.2.3.2.17 Completion of Protective Action Once it is Initiated. The system is designed to ensure that protective

action (reactor trip) will go to completion once initiated. Operator action is required to clear the trip and return to operation. Protective action is initiated when the reactor trip circuit breakers open. Protective action is completed when the CEAs arrive at their full-in position.

7.2.2.3.2.18 Access to Setpoint Adjustments, Calibration and Test Points. Keys or built-in features are provided to control setpoints, calibration, and test point adjustments. Access is indicated to the operator. The Applicant shall control access via key locks, administrative procedures, and other means to limit access.

7.2.2.3.2.19 Identification of Protective Action. Indication lights are provided for all protective actions, including identification of channel trips. The breaker status and current indication are available to the operator.

7.2.2.3.2.20 Information Readout. Means are provided to allow the operator to monitor all trip system inputs, outputs and calculations. The specific displays that are provided for continuous display are described in section 7.5.

7.2.2.3.2.21 System Repair. Identification of a defective input channel will be accomplished by observation of system status lights or by testing as described in section 7.2.1.1.9. Replacement or repair of components is accomplished with the affected input channel bypassed. The affected trip function then operates in a two-out-of-three trip logic while maintaining the coincidence of two required for trip.

7.2.2.3.2.22 Identification. All equipment, including panels, modules, and cables, associated with the trip system will be marked in order to facilitate identification. Interconnecting cabling will be color coded as discussed in section 7.1.3.16. Interface requirements of section 7.2.3 ensure that equipment supplied by the Applicant meets this requirement.

7.2.2.3.3 Testing Criteria

Conformance to IEEE 338-1971 and Regulatory Guide 1.22 are discussed in paragraphs 7.1.2.7 and 7.1.2.15. Test intervals and their bases are included in the Technical Specifications and their Bases. A complete channel can be tested without causing a reactor trip and without affecting system operability. Overlap in the RPS channel tests is provided to assure that the entire channel is functional. The testing scheme is discussed in detail in paragraph 7.2.1.1.9. For the organization for testing and documentation, refer to chapter 13.

Since operation of the RPS will be infrequent, the system is periodically and routinely tested to verify its operability. A complete channel can be individually tested without initiating a reactor trip, without violating the single failure criterion, and without inhibiting the operation of the system. The system can be checked from the sensor signal through the circuit breakers of the RTSS. The RPS can be tested during reactor operation. The sensors can be checked by comparison with similar channels or channels that involve related information. Minimum frequencies for checks, calibration, and testing of the

RPS instrumentation are given in the Technical Specifications. Overlap in the checking and testing is provided to assure that the entire channel is functional. The use of individual trip and ground detection lights, in conjunction with those provided at the supply bus, assures that possible grounds or shorts to another source of voltage will be detected.

7.2.2.4 Failure Modes and Effects Analysis (FMEA)

A FMEA for the RPS and ESFAS is provided in table 7.2-4A. The FMEA is for protection systems' sensors, and coincidence and actuating logics. The logic interface for the protection systems is shown in figure 7.2-11.

7.2.2.4.1 Potential Impacts of Control Systems Failures

Table 7.2-5 identifies the control systems that were considered in the evaluation of potential impacts on plant safety due to common power source or common sensor failures. As discussed below, the consequential malfunctioning of these systems due to a common power/sensor failure has less impact on plant safety than the bounding chapter 15 analyses.

Table 7.2-5

CONTROL SYSTEMS CONSIDERED TO HAVE POTENTIAL IMPACTS UPON PLANT SAFETY DUE TO COMMON POWER SOURCE OR COMMON SENSOR FAILURES

Control System	Acronym
Reactor regulating system	RRS
Control element drive mechanism control system	CEDMCS
Reactor power cutback system	RPCS
Boron control system	BCS
Steam bypass control system	SBCS
Turbine-generator control system	TGCS
Moisture separator reheat control system	MSRCS
Feedwater control system	FWCS
Main feedwater turbine pump control system	MFTPCS
Condenser level control system	CLCS
Pressurizer level control system	PLCS
Pressurizer pressure control system	PPCS

7.2.2.4.1.1 Power Source Failures. The power source failures which would affect more than one control system, and a brief description of the impact on each control system, are provided below. Except for the loss of offsite electrical power, which is specifically addressed by the chapter 15 analyses, no other power failures have been identified which would introduce additional control system malfunctions to those described. This is due to the degree of separation inherent in the

electrical power distribution network and the availability of backup power sources within the network.

7.2.2.4.1.1.1 Impact Due to Loss of 120 V-ac Distribution Panel E-NNN-D11.

SBCS - The control system cannot generate quick open and modulate open signals to open the turbine bypass valves. In addition, control room indication of the automatic permissive signal will be lost.

RPCS - The control system will be unable to generate CEA drop demand and turbine runback signals.

PLCS
PPCS - The letdown control valve closes and the normally running and standby charging pumps will not operate. They can be started manually from BO3. With either HS-100 and/or HS-100-3 in "Y" position, the 1E and non-1E backup heaters and the proportional heaters will trip off.

CEDMCS - Loss of one of two redundant power sources to the interlock relays. Therefore, CEDMCS will not be impacted.

7.2.2.4.1.1.2 Impact Due to Loss of 120 V-ac Distribution Panel E-NNN-D12.

SBCS - Inability to generate an automatic motion inhibit (AMI) signal. In addition, the SBCS

valves will fail closed and cannot be operated in manual due to a loss of logic power.

RRS - Inability to generate CEA motion demand signals. Loss of CEA motion demand indication in the control room

PPCS - The PPCS controller fails to zero causing the pressurizer spray valve to fail close. With either HS-100 and/or HS-100-3 in "X" position, all 1E and non-1E backup heaters and proportional heaters will trip off. With both HS-100 and HS-100-3 in "Y" position, the proportional heaters will turn fully on with no controls, while the 1E and non-1E backup heaters will be fully on with control. PPCS pressure indication on recorder PR100 in the control room goes to 0 psia.

CLCS - Inability to generate condensate storage tank control valve opening signal. The valve will remain in its normally closed state.

CEDMCS - Loss of one of two redundant power sources to the interlock relays. Therefore, CEDMCS will not be impacted.

7.2.2.4.1.1.3 Impact Due to Loss of 125 V-dc Load Center E-NKN-M45.

SBCS - Inability to actuate turbine bypass valve quick open or permissive solenoids. Loss of quick open indication in the control room.

PPCS - All the non-Class 1E backup heaters will
PLCS remain at their previous (on or off) setting. The 1E backup heaters will trip off. Silicon controlled rectifiers of proportional heaters cannot be tripped.

CLCS - Inability to open condensate storage tank control valve due to solenoid deenergization.

MSRCS - Inability to isolate the extraction lines from the high- and low-pressure turbines to the feedwater heaters.

MFTPCS - Inability to automatically trip main feedwater pumps or use pump logic. Manual trip is still available.

Table 7.2-6 identifies the control systems that share a common sensor or instrument tap. No other common sensors/taps have been identified.

Table 7.2-6
CONTROL SYSTEMS SHARING A COMMON SENSOR OR COMMON INSTRUMENT TAP

Sensor	Control Systems[a]
RCS cold leg temperature	CEDMCS, RRS, PLCS
Pressurizer level	PLCS, PPCS
Pressurizer pressure	PPCS, SBCS
Main steam flow	FWCS, SBCS
Sensors Sharing Tap	
Pressurizer level and	PPCS, PLCS
pressurizer pressure	PPCS, SBCS

a. Control system acronyms are defined in table 7.2-5.

7.2.2.4.1.2 Evaluation of Common Failures. As discussed below, the consequences of common power source, common sensor, and common instrument tap failures are bounded by chapter 15.

7.2.2.4.1.2.1 Evaluation of Common Power Source Failures.

A. Panel E-NNN-D11 Failure

The failure of distribution panel E-NNN-D11 will: 1. cause the PLCS and the PPCS to reduce letdown flow to 0 gpm, 2. stop flow from two of the three charging pumps, 3. may result in loss of control of primary system mass, and 4. may cause the 1E and non-1E pressurizer backup and proportional heaters to trip off on loss of pressurizer level control.

All charging pumps remain available if manually started, and the concurrent closing of the letdown control valves ensures primary system mass is controllable within the time frame before operator action. The loss of backup heaters is within the analysis, and they become available in any event upon switching control to the unaffected loop.

The SBCS and RPCS will be unable to automatically respond to any challenges on a failure of distribution panel E-NNN-D11.

This scenario is bounded by the CVCS Malfunction-Pressurizer Level Control System malfunction with loss of offsite power presented in subsection 15.5.2.

B. Panel E-NNN-D12 Failure

The loss of this panel will result in the loss of automatic pressurizer pressure control. However, if HS-100 and HS-100-3 are in the "Y" position, the 1E and non-1E backup heaters will be available. With either hand switch in the "X" position, backup heaters will trip off. Also, when HS-100 and HS-100-3 are in the "Y" position, proportional heaters will turn full on with no control, and with either hand switch in the "X" position, the proportional heaters will trip off. The condenser hotwell level may decrease due to the inability to automatically control it. In addition, the RRS will behave as if it is in manual mode of operation. In addition, the SBCS valves will fail closed and cannot be operated due to a loss of logic power.

The loss of heaters with closure of spray valves is not a concern. Auxiliary spray remains available to control increases in RCS pressure and all heaters will be available if control is switched to the unaffected control loop. With HS-100 or HS-100-3 in the "Y" position, proportional heaters will turn full on with no automatic control, but are still able to be deenergized from the control room. A total loss of feedwater flow (LOFW) due to the condenser hotwell level decrease may occur. However, the LOFW event presented in subsection 15.2.7 assumed that the PPCS, SBCS, and RRS are in the manual mode of operation, unable to automatically respond to challenges.

Therefore, the LOFW event bounds the panel failure event.

C. Load Center E-NKN-M45 Failure

Failure of this load center effectively results in the CLCS and MFTPCS being placed in the manual mode of operation. The SBCS valves will fail closed and cannot be operated in manual due to a loss of logic power. In addition, pressurizer pressure control will be hindered, due to lack of control of all the non-Class 1E heaters. If RCS pressure drifts below the backup heater actuation setpoint the class 1E-powered backup heaters cannot be energized due to the presence of a trip signal. The loss of backup heaters is within the bounds of chapter 15 analyses and is listed in the analyzed failures of table 15.0-0. This panel failure is not of concern with respect to peak RCS pressure, fuel performance, or radiological releases.

7.2.2.4.1.2.2 Evaluation of Common Sensor Failures.

A. RCS Cold Leg Temperature Sensor (CEDMCS, RRS, PLCS)

The PLCS receives an average reactor coolant temperature (T_{avg}) signal from the RRS based on either loop or both loop cold leg and hot leg temperatures (T_{cold} and T_{hot}) measurements. The measured T_{avg} determines the programmed pressurizer level. If a T_{cold} channel fails such that T_{avg} (indicated) does not agree with T_{avg} (actual) then the PLCS will adjust charging

and letdown to change the pressurizer level to the new programmed level within the normal operating band.

The RRS and CEDMCS have several features which protect against inadvertent CEA motion following failure of T_{cold} channel. These include input channel deviation alarm, automatic motion inhibit, and automatic withdrawal prohibit. In addition, the consequences of inadvertent CEA insertion (withdrawal) resulting from indicated T_{cold} failing higher (lower) than actual T_{cold} in combination with pressurizer level variations within the control band are bound by the CEA withdrawal event described in subsection 15.4.2.

B. Pressurizer Level Sensor (PPCS, PLCS)

In response to a high indicated pressurizer level (L_{pzr}) the PLCS will decrease charging flow and increase letdown flow resulting in a slow decrease in RCS inventory and pressurizer level. If the indicated L_{pzr} is high enough, a high level alarm will be generated, the normally running charging pump will be secured, and an insufficient charging alarm will be generated. In addition, if the pressurizer level error L_{pzr} (indicated) - L_{pzr} (programmed) is large enough, the PLCS will signal the PPCS to energize pressurizer heaters. The high indicated L_{pzr} will disable one of two channels of heater cutout. Normally, however, one channel is sufficient to activate the heater interlock and generate a low L_{pzr} alarm. Also, under the

conditions of maximum letdown flow and minimum charging flow, it would require in excess of 30 minutes for pressurizer level to drop from the full power programmed level to the level corresponding to the top of the heaters. This time interval would allow the operator to arrest the level transient prior to heater uncovery.

The thermal-hydraulic effects of the slow decrease in RCS inventory are bounded by the double-ended break of a letdown line as described in subsection 15.6.2.

If the indicated L_{pzr} fails low, the PLCS would increase charging and decrease letdown. This would result in a slow increase in RCS inventory. If the indicated L_{pzr} fails low enough, a low level alarm would be activated, as would the heater interlock in the PPCS, thus preventing pressurizer heater operation. The effects of this transient are bounded by the PLCS malfunction event described in subsection 15.5.2.

C. Pressurizer Pressure Sensor (PPCS, SBCS)

Failure of a pressurizer pressure (P_{pzr}) sensor cannot result in inadvertent operation of the SBCS. The SBCS has two independent circuits (main circuit and permissive circuit) both of which must be activated in order to generate either a turbine bypass valve (TBV) modulation signal or quick open signal. Failure of a P_{pzr} sensor, therefore, can only affect the PPCS. Failures in single control systems have already been considered in the chapter 15 safety evaluation.

D. Main Steam Flow Sensor (FWCS, SBCS)

Similarly, failure of a main steam flow (Fms) sensor cannot result in inadvertent operation of the SBCS. Failure of an Fms sensor, therefore, can only affect the FWCS. Failures in single control systems have been considered in the chapter 15 safety evaluation.

7.2.2.4.1.2.3 Evaluation of Common Instrument Tap Failure: Tap for Pressurizer Pressure and Level Sensors (PPCS, PLCS, SBCS). As previously indicated, the SBCS utilizes two independent circuits; therefore, the SBCS will not open bypass valve due to the instrument tap failure. The response to the tap failure is limited to various combinations of PPCS and PLCS malfunctions which can cause slow pressurizer pressure and level increases or decreases. The evaluation is similar to that provided above for the pressurizer level sensor failure. The potential consequences of this instrument tap failure are bounded by the PLCS malfunction event and the double-ended break of a letdown line event described in subsection 15.5.2 and subsection 15.6.2, respectively.

7.2.3 REACTOR PROTECTIVE SYSTEM INTERFACE REQUIREMENTS

The interface requirements discussed below are specific to the RPS. General interface requirements are discussed in subsection 7.1.3.

7.2.3.1 Power

Vital instrument power interface requirements are discussed in subsection 8.3.1. Power failure evaluations for the control systems are also discussed in paragraph 7.2.2.4.1.

7.2.3.2 Protection From Natural Phenomena

Refer to subsection 3.1.2. Class 1E equipment shall be located so as to be provided with the maximum protection from natural phenomena which are specific to the PVNGS site.

7.2.3.3 Protection From Pipe Failure

Refer to paragraph 7.1.3.3.

7.2.3.4 Missiles

Refer to paragraph 7.1.3.4.

7.2.3.5 Separation

Refer to paragraph 7.1.3.5.

Preamplifiers for the fission chambers shall be mounted outside the biological shield, with two inside the containment building and two outside the containment building in the auxiliary building. The preamplifiers and cabling shall be provided with physical and electrical separation.

7.2.3.6 Independence

Refer to paragraph 7.1.3.6.

7.2.3.7 Thermal Limitations

Refer to paragraph 7.1.3.7.

7.2.3.8 Monitoring

Refer to paragraph 7.1.3.8.

7.2.3.9 Operational/Controls

Administrative procedures or other suitable means shall be used to control changes to CPC constants, adjustments to variable setpoints, and the bypassing of channels which could affect operation.

7.2.3.10 Inspection and Testing

Refer to paragraph 7.1.3.10.

7.2.3.11 Chemistry/Sampling

Refer to paragraph 7.1.3.11.

7.2.3.12 Materials

Not applicable.

7.2.3.13 System Component Arrangement

Refer to paragraph 7.1.3.13. The separation, independence, etc., criteria specified in paragraph 7.2.2.3.2 shall be adhered to.

7.2.3.14 Radiological Waste

Refer to paragraph 7.1.3.14.

7.2.3.15 Overpressure Protection

Refer to paragraph 7.1.3.15.

7.2.3.16 Related Services

Refer to paragraph 7.1.3.16.

7.2.3.17 Environmental

Refer to section 3.11 and CENPD-255.[3]

7.2.3.18 Mechanical Interaction

Refer to section 3.10 and CENPD-182.[4]

7.2.4 REACTOR PROTECTIVE SYSTEM INTERFACE EVALUATION

The interface requirements listed in CESSAR Section 7.2.3 are met by the PVNGS design as discussed in paragraphs 7.2.4.1 through 7.2.4.18.

7.2.4.1 Power

Vital instrument power interface evaluations are discussed in subsection 8.3.5.

7.2.4.2 Protection From Natural Phenomena

Refer to subsection 3.1.2. Class 1E equipment has been located so as to be provided with the maximum protection from natural phenomena which are specific to the PVNGS site.

7.2.4.3 Protection From Pipe Failure

Refer to paragraph 7.1.4.3.

7.2.4.4 Missiles

Refer to paragraph 7.1.4.4.

7.2.4.5 Separation

Refer to paragraph 7.1.4.5.

Preamplifiers for the fission chambers have been mounted outside the biological shield, with two inside the containment building and two outside the containment building in the auxiliary building. The preamplifiers and cabling are provided with physical and electrical separation.

7.2.4.6 Independence

Refer to paragraph 7.1.4.6.

7.2.4.7 Thermal Limitations

Refer to paragraph 7.1.4.7.

7.2.4.8 Monitoring

Refer to paragraph 7.1.4.8.

7.2.4.9 Operational/Controls

Administrative procedures or other suitable means are used to control changes to CPC constants, adjustments to variable setpoints, and the bypassing of channels which could affect operation.

7.2.4.10 Inspection and Testing

Refer to paragraph 7.1.4.10.

7.2.4.11 Chemistry/Sampling

Refer to paragraph 7.1.4.11.

7.2.4.12 Materials

Not applicable.

7.2.4.13 System Component Arrangement

Refer to paragraph 7.1.4.13. The separation, independence, and other criteria specified in paragraph 7.2.2.3.2 have been adhered to in the PVNGS design.

7.2.4.14 Radiological Waste

Refer to paragraph 7.1.4.14.

7.2.4.15 Overpressure Protection

Refer to paragraph 7.1.4.15.

7.2.4.16 Related Services

Refer to paragraph 7.1.4.16.

7.2.4.17 Environmental

Refer to section 3.11.

7.2.4.18 Mechanical Interaction

Refer to section 3.10.

7.2.5 SUPPLEMENTARY PROTECTION SYSTEM

The supplementary protection system (SPS) augments reactor protection by utilizing a separate and diverse trip logic from the reactor protective system (RPS) for initiation of reactor trip to satisy the requirments of 10CFR50.62 for Anticipated Transient Without Scram (ATWS). The addition of the SPS provides a simple, reliable, yet diverse mechanism which is designed to increase the reliability of initiating reactor trip. The SPS will initiate a reactor trip when pressurizer pressure exceeds a predetermined value shown on Table 7.2-1. The SPS logic is shown in Figure 7.2-5.

The SPS design uses a selective two-out-of-four logic to interrupt the power supplied to the CEDM's and thereby causes the CEA's to drop into the core by gravity. The Technical Specifications provide the required actions if a channel is removed for testing or maintenance. The SPS is independent and separate from all control systems.

The SPS is designed to conform to the same criteria as the PPS. Each SPS channel is called the Supplementary Protection Logic Assembly (SPLA).

Four identical SPLA's are provided for each SPS system. Each SPLA is electrically and physically separated from each other.

7.2.5.1 Functional Description of the SPLA

Each SPLA contains an input circuit, comparator circuit, output circuit, test circuit, annunciator circuit, trip circuit breaker (TCB) control and indication circuit, and instrumentation power supplies. See figure 7.2-5.

7.2.5.1.1 Input Circuit

The input circuit receives a 4 to 20 milliampere (ma) "Process Current" signal from its pressurizer pressure transmitter. This signal is converted within the circuit to a (+) 1 to (+) 5 VDC signal via a precision dropping resistor. This "Converted Process" signal is then transmitted via conditioning circuits to the comparator circuit (as the "Process Voltage" signal) for further processing and to the digital voltmeter for displays. A second dropping resistor in the input circuit provides a (+) 1 to (+) 5 VDC "Process Indication" signal to a remote display indicator.

The input circuit also receives a 0 to (+) 5 VDC "Test" signal from the test circuit. The "Test" signal, when applied, adds a 0 to (+) 5 VDC signal to the "Converted Process" signal.

The input circuit contains conditioning circuits for overvoltage protection and noise suppression. The purpose of the overvoltage protection circuit is to protect the equipment downstream of the input circuit from damage due to a high voltage fault on the transmitter field cabling. The purpose of the noise suppression circuit is to filter out unwanted noise picked up during "Process Current" signal transmission.

7.2.5.1.2 Comparator Circuit

The comparator circuit continuously compares the 1 to 5 VDC "Process Voltage" signal to a fixed trip setpoint signal. When the "Process Voltage" signal passes through the trip setpoint level, the comparator circuit recognizes this and generates a trip output signal.

The trip signal derived from the comparator circuitry must be present for a specified period of time before it is allowed to pass through to the output circuit. When the trip signal has been present for the required period of time (adjustable from 10-150 msec), the time delay circuit recognizes this and provides the trip signal to the initiation relay drive circuit.

Upon receipt of a trip signal, the initiation relay drive circuit de-energizes the output circuit's initiation relay. When a trip signal is not present, the drive circuit maintains the initiation relay energized. A front panel tripped indicator is provided and receives its logic from the initiation relay drive circuit.

7.2.5.1.3 Output Circuit

The output circuit provides the necessary contact switching to affect the opening of a remotely located trip circuit breaker (TCB) and M-G set load output contactors.

The output circuit receives a trip signal from the comparator circuit's initiation relay drive circuit. This signal controls the application and removal of initiation relay input power. During normal operation, the initiation relay is energized and its contacts maintain the TCB and M-G set load output contactors closed. For a trip condition, the initiation relay is deenergized and its contacts change state to affect opening of the TCB and M-G set load output contactors.

The initiation relay provides two contacts which interface with the TCB undervoltage and shunt trip coils. This contact interface controls TCB opening. A third contact provided by

the initiation relay interfaces via an isolation relay with each of the M-G set load output contactors. These contact interfaces provide for opening the M-G set load output contactors upon a selective two-out-of-four SPLA channel trips. An open signal by this contact also indirectly results in a signal to the remote annunciator. The annunciator serves to inform the operator of a SPLA "trip" condition.

7.2.5.1.4 Trip Circuit Breaker (TCB) Control and Indication Circuit

This circuit provides a signal to control the closing of a remotely located trip circuit breaker. In addition, this circuit receives "OPEN" and "CLOSED" position indication signals from this same trip circuit breaker. These position indication signals are used to light indicators mounted on the front panel.

The TCB closing signal is a contact closure provided by a momentary switch. This switch is located on the front panel. Closing the switch contacts completes the TCB closing coil control circuit. Completing the TCB closing coil control circuit affects closure of the breaker.

This circuit receives two contact input position indication signals from TCB auxiliary switches. These indication signals are used to energize "OPEN" and "CLOSED" indicators on the front panel. An indicator is energized when a contact closure input is received from its respective auxiliary switch. Power to the indicators and auxiliary switch is supplied by the SPLA.

7.2.5.1.5 Test Circuit

The purpose of the test circuit is to provide the capability for testing the SPLA. Testing of the SPLA is performed to verify its proper operation.

Testing of the SPLA is accomplished by applying a 0 to 5 vdc "Test" signal to the input circuit. The "Test" signal is applied in such a way that it is added to the 1 to 5 vdc "Converted Process" signal. The "Test" signal is manually adjusted until the "Process Voltage" signal reaches the trip setpoint value. Upon reaching the trip setpoint value, the trip circuit breaker associated with the SPLA opens.

The test circuit is comprised of a voltage reference, a voltage adjust circuit, a test enable switch, a digital voltmeter (DVM), and a DVM input select switch. The voltage adjust circuit, in conjunction with the voltage reference, generates the "Test" signal. The test enable switch applies the "Test" signal to the Input Circuit. The DVM indicates the value of the "Converted Process," "Test" signal, calibration voltages, setpoint value, or external input.

7.2.5.1.6 Annunciator Circuit

The annunciator circuit provides the circuitry necessary for interfacing SPLA status signals with remote annunciators.

Three status signals are generated within the SPLA. Only two of the status signals are supplied to the annunciator circuit.

The annunciator circuit receives one status signal from the SPLA door alarm switch and one status signal from the test enable switch.

The third status signal is generated indirectly by the output circuit and is termed the "Trip" status signal. This status signal directly interfaces with its remote annunciator and therefore is not supplied by the annunciator circuit.

7.2.5.1.7 Instrumentation Power Supplies

The power supplies contain the equipment required for powering all SPLA equipment including the pressurizer pressure transmitter.

7.2.5.1.8 SPLA Test Points

The front panel has the following test jacks available for external measurement: 1) voltage reference, 2) time delay input, 3) time delay output, and 4) test jacks for each of the supply voltages provided. Also available for measurement via test jacks in the SPLA are the following: 1) the setpoint voltage value, and 2) the process input voltage value.

7.2.5.2 Supplementary Protection System (SPS) Diversity to the Reactor Protective System (RPS)

The supplementary protection logic assembly (SPLA) of the SPS is designed to be a diverse design with respect to the RPS. The following design differences between the systems outline these qualities:

Each of the SPLA circuits is described below:

A. Manufacturing Diversity - Different vendors were used which produced a (1) different design, (2) different

system production techniques, and (3) different testing procedures.

B. System Part Diversity - The vendor used different Components than the RPS, and MIL spec parts whenever possible.

C. Cabinet Diversity - The SPLA uses one cabinet per channel (4 channel system).

D. Electrical Diversity - Each SPLA channel is electrically isolated and separated from the others. There is no crosschannel communication between SPLA channels.

E. Initiation Logic Diversity - The RPS and SPLA utilize different designs for initiation logic.

F. Sensor Diversity – The sensors (pressure transmitters) used in the RPS and SPLA are produced by the same manufacturer. Both systems monitor the pressurizer pressure via a common tap per channel in the pressurizer. The instruments have separate shutoff valves and a common root valve per channel.

10CFR50.62 requires that each pressurized water reactor must have equipment from sensor output to final actuation device that is diverse from the reactor trip system. Based on this requirement, lack of diversity between the sensors is satisfactory, since the equipment from the sensor output to the actuation devices in the SPLA is diverse from that of the RPS.

G. Power Supply Diversity - The SPLA uses a custom power supply while the RPS uses a commonly available "off-the-shelf" power supply.

H. Human Factors Diversity - 1) smaller SPLA cabinet, 2) each SPLA channel is in its own cabinet, 3) front panel controls are in different locations and are much fewer in the SPLA, 4) adjustment controls for the test and setpoint voltages are different, and 5) the SPLA front panel has fewer test points than the RPS system.

7.3 ENGINEERED SAFETY FEATURE SYSTEMS

7.3.1 DESCRIPTION

BOP ESFAS. The following actuation signals are generated by the BOP Engineered Safety Feature Actuation System (ESFAS) when the monitored variables reach levels that require protective action:

- Fuel building essential ventilation actuation signal (FBEVAS)
- Containment purge isolation actuation signal (CPIAS)
- Control room essential filtration actuation signal (CREFAS)
- Control room ventilation isolation actuation signal (CRVIAS)

These actuation signals automatically actuate the following ESF systems:

- Fuel building essential ventilation system
- Containment purge isolation system
- Control room essential ventilation system

The control room essential ventilation system is also actuated by a manually initiated ESF signal, the control room ventilation isolation actuation signal (CRVIAS).

The manually actuated ESF systems are the containment combustible gas control system and the CRVIAS.

The BOP ESFAS system hardware and software also provides load sequencing and logic for the diesel generator start signal (DGSS), loss of power (LOP), and load shed (LS) functions. These functions are described in section 8.3.

The additional automatically actuated ESF systems use one-out-of-two input signal logic. The actuation circuits for all one-out-of-two actuation systems are described in paragraph 7.3.1.1. The actuated devices for these systems are described in paragraph 7.3.1.1.10.

NSSS ESFAS. The safety-related instrumentation and controls of the Engineered Safety Features Systems (ESF Systems) are those of the NSSS and BOP Engineered Safety Features Actuation System (ESFAS) which consists of the electrical and mechanical devices and circuitry, from sensors to actuation device input terminals, involved in generating those signals that actuate the required ESF Systems.

The NSSS ESFAS includes sensors to monitor selected generating station variables. The following actuation signals use a two-out-of-four logic system and are generated by the NSSS ESFAS when the monitored variable reaches the levels that are indicative of conditions which require protective action:

A. Containment Isolation Actuation Signal (CIAS)

B. Containment Spray Actuation Signal (CSAS)

C. Main Steam Isolation Signal (MSIS)

D. Safety Injection Actuation Signal (SIAS)

E. Recirculation Actuation Signal (RAS)

F. Auxiliary Feedwater Actuation Signal (AFAS)

The ESF System actuation device circuitry receives actuation signals from the ESFAS or the operator. The ESFAS signals actuate the ESF Systems equipment. The control circuitry for the components provides sequencing necessary to provide proper ESF Systems operation.

The actuation circuitry for all ESF Systems is essentially identical, except for the sensed parameter and its setpoint. Therefore, the actuation circuits for all ESF Systems are described in one section. The specific instrumentation and controls associated with each system are described separately in section 7.3.1.1.10.

7.3.1.1 NSSS Engineered Safety Features Actuation System (ESFAS)

The ESFAS system consists of the sensors, bistables, initiation logic, and actuation logic that monitor selected plant parameters and provide an actuation signal to each individual actuated component in the ESF system if the plant parameters reach preselected setpoints. There is one actuation system for each of the ESF systems. Each actuation system is identical except that specific inputs and logic (and blocks, where provided) vary from system to system and the actuated devices are different.

Within the PPS, the matrix logic is like that shown in figures 7.3-9a, 7.3-9b and 7.3-9c. This provides the AB, AC, AD, BC, BD, and CD combinations which create the coincidence of

two logic. Each of these matrices operates an initiation circuit which opens the initiation relays. The outputs of the initiation relays go to the ESFAS auxiliary relay cabinets where they create the selective two-out-of-four logics, i.e., 1A/2A, 1A/4A, 3A/2A, or 3A/4A for the given train shown in figures 7.3-8a and 7.3-8b.

Only those ESF systems that, when actuated, do not cause a plant condition requiring protective action, or disturb reactor operations, are controlled by the one-out-of-two BOP ESFAS. The one-out-of-two BOP ESFAS logic is contained in the separate enclosures isolated from the two-out-of-four ESFAS and reactor protective system (RPS) logic. The overall logic is shown in figures 7.3-1, 7.3-2, 7.3-7a through 7.3-7d.

7.3.1.1.1 Engineered Safety Features Actuation System Measurement Channels

BOP ESFAS. Process measurement channels are used to perform the following functions:

- Continuously monitor each selected generating station variable
- Provide indication of operational availability of each sensor to the operator.
- Transmit signals to bistables within the BOP ESFAS initiating logic.

Protective parameters are measured with two independent process measurement channels.

A measurement channel consists of instrument sensing lines, sensor, transmitter, power supplies, isolation device, indicator, and interconnecting wiring. For the radiation measurement channels description see section 11.5.

Each measurement channel is separated from other like measurement channels to provide physical and electrical isolation of the signals to the ESFAS initiating logic. The isolation devices will prevent a high voltage fault to either the A or B sensor outputs from disabling both of the one-out-of-two actuation logic devices. Signal isolation is provided for computer inputs and annunciation. Each BOP ESFAS channel is supplied by two sources from a separate 120V vital ac distribution bus and its associated 125 VDC vital ESFAS.

Display information, which provides the operator with the operational availability of each measurement channel, is described and tabulated in section 7.5.

Testing of the BOP and NSSS ESFAS measurement channels is described in paragraph 7.3.1.1.8.

NSSS ESFAS. Process measurement channels, similar to those described in section 7.2.1.1.2.1 are utilized to perform continuous monitoring of each selected generating station variable, provide indication of operational availability of each sensor to the operator, and transmit analog signals to bistables within the ESFAS initiating logic. All protective parameters are measured with four independent process instrument channels.

A typical measurement channel is shown in Figure 7.2-0A. It consists of a sensor/transmitter, current loop resistors, converter/power supply, indicators, outputs for the Plant Monitoring System, and interconnecting wiring.

Each measurement channel is separated from other like measurement channels to provide physical and electrical separation of the signals to the ESFAS coincidence logic. Associated circuits are handled in accordance with the interface requirements of Section 7.3.3. Cabling is separated within the cabinets and signals to non-IE indicators are isolated. Each channel is supplied from a separate 120 volt vital AC distribution bus.

7.3.1.1.2 Logic

7.3.1.1.2.1 Engineered Safety Features Actuation System Bistable and Initiating Logic.

BOP ESFAS. The Balance of Plant Engineered Safety Features Actuation System (BOP ESFAS) provides initiation signals to components requiring automatic or manual actuation. These signals are generated whenever monitored variables reach levels that require protective action.

The BOP ESFAS uses two measurement channels for the one-out-of-two logic and four measurement channels for the two-out-of-four logic as inputs to the initiation signal.

The ESFAS initiating logic consists of bistables, bistable output relays, trip output signals, indicating lights, and

interconnecting wiring. For the radiation measurement signal initiation logic description, see section 11.5.

Signals from the protective measurement channels are sent to comparator circuits (bistables) where the input signals are compared to predetermined setpoints. Whenever a channel parameter reaches the predetermined setpoint, the channel bistable deenergizes an output relay. When the coincidence logic is satisfied an actuation signal is provided to the appropriate components. Each bistable relay (i.e., each channel) is supplied from a separate 120V vital ac distribution bus. The bistable setpoints are adjustable from the front of the cabinet. Access is limited, however, by means of a key-operated switch. Bistable setpoints are capable of being read out on a display located on the cabinet.

NSSS ESFAS Bistable and Coincidence Logic. The ESFAS Coincidence Logic compares the analog signal from the sensors with predetermined initiation setpoints in the bistable circuit (see Figure 7.2-6). If the signal exceeds the setpoint the channel bistable output relay deenergizes three trip relays.

The setpoint values are controlled administratively. The setpoints are adjusted at the PPS cabinet. Access to the adjustments is limited by means of a key-operated cover with an annunciator indicating cabinet access. The bistable setpoints are capable of being read out on a meter located on the PPS cabinet. Some setpoints are externally variable to avoid inadvertent initiation during normal operations such as startup, shutdown, and cooldown, and evolutions such as low

power testing. The steam generator and pressurizer pressure setpoints can be decreased by pushbuttons and will automatically increase as pressure increases.

The output of the trip relays is formed into the six logic matrices (refer to Figure 7.3-10). The four channels, A, B, C, and D, form into AB, AC, AD, BC, BD, and CD to create all possible coincidence of two combinations. Each logic matrix actuates four matrix relays. Six matrix relays (one from each of the six logic matrices) have their output contacts joined in series to form an initiation circuit. Four initiation circuits are used to form four channels 1, 2, 3, and 4. The output of the initiation circuits are initiation relays, A and B which send signals to the actuation logics in their respective ESF train cabinet.

Besides the automatic actuation of the initiation circuit by the matrix relays, the circuit can be tripped by remote manual switches. All ESFAS can be manually initiated by the operator in accordance with procedures provided by the Applicant. Following initiation, each ESFAS, except AFAS, must be manually reset to restore the initiation logic to the non-actuated state.

7.3.1.1.2.2 Actuating Logic.

NSSS ESFAS. The ESFAS actuation logic is physically located in two ESFAS auxiliary relay cabinets. One cabinet contains the logic for ESF train A equipment the other cabinet contains the logic for ESF train B.

The four initiation circuits in the PPS actuate a selective two-out-of-four logic in the ESFAS auxiliary relay cabinets. In an actuation matrix (see figures 7.3-8a and 7.3-8b), each signal also deenergizes the lockout relays when the selective two-out-of-four logic actuates the train's group actuation relays. The lockout relays ensure that the signal is not automatically reset once it has been initiated.

Receipt of two selective ESFAS initiation channel signals will deenergize the ESF subgroup relays, which generate the actuation channel signals. This is done independently in both ESFAS auxiliary relay cabinets, generating both train A and train B signals. The group relays are used to actuate the individual ESF components which should be actuated to mitigate the consequences of the occurrence which caused the ESFAS.

<u>BOP ESFAS</u>. The BOP ESFAS actuating logic, however performs the following functions:

- Receive ESFAS signals from the ESFAS initiating logic
- Form one-out-of-two coincidence of like ESFAS signals
- Provide a means for remote manual initiation
- Provide status information to the operator

The BOP ESFAS actuating logic is physically located in two cabinets. One cabinet contains the logic for ESF load group 1 equipment, while the other cabinet contains the logic for ESF load group 2 equipment. These two cabinets are in addition to those ESFAS auxiliary relay cabinets described above.

Actuation signals are generated following receipt of the proper combination of initiation signals, resulting in de-energizing the appropriate ESF group relay. This actuates all components required by the particular ESF system. The final actuation devices are the sub-group relays and the actuated equipment consists of valves, air handling units (AHU), air filtration units (AFU), large electrical loads as listed in section 8.3, and diesel generators.

Each actuation channel is supplied from a separate 120 V-ac distribution bus and a separate Class 1E 125 V-dc distribution bus.

Figure 7.3-3 is a simplified functional diagram of a typical one-out-of-two ESFAS logic.

Testing of logic and trip is described in paragraph 7.3.1.1.8.

7.3.1.1.2.2.1 Group Actuation.

BOP ESFAS. Components in each ESF system are actuated by actuation relays. The actuation relay contacts are in the power control circuit for the actuated components of each ESF system.

The logic described in paragraph 7.3.1.1.2 causes deenergization of the actuation relay whenever the BOP ESFAS logic is satisfied. The circuit is shown in figure 7.3-3 for a typical ESFAS. Deenergization of the actuation relay actuates the ESF system components.

NSSS ESFAS. The group relays actuate all of the ESF System components required by the ESFAS. These generally consist of either solenoid operated valves, motor operated valves, or motors of pumps. Figures 7.3-11a, b and c show how each of these components can be operated by the ESFAS signals.

In Figure 7.3-11a, a solenoid operated valve can be operated by a relay contact. If the valve control switch contact is closed and the ESFAS contact is closed the solenoid valve will open. In the circuit shown in Figure 7.3-11a, the ESFAS signal opens the contact which closes the valve.

The valve motor circuit of Figure 7.3-11b shows the valve closed. When an ESFAS actuating signal is reset, the ESFAS contact in the closing circuit is closed and the contact in the opening circuit is open, thereby restoring normal operation. Upon receipt of an ESFAS signal the valve which is normally closed would open in the following sequence. The Mc_b contact and the Ts and Ls Contacts in the Mo circuit are closed because the valve is fully closed. The ESFAS contact would close causing the Mo coil to pick up which shuts the Mo contactors driving open the valve.

The pump motor control circuit shown in Figure 7.3-11c shows that the ESFAS actuation signal will take out the time overcurrent contacts (numbered 51) but leaves in the instantaneous overcurrent contacts (numbered 50). With the circuit breaker lockout relay (numbered 86) contact closed and the ESFAS contact closed the pump motor breakers will close if

the control switch is in the automatic position. Thus an ESFAS actuation signal will cause the pump motor to start.

If components have to be sequenced the sequencing will be done in the components' control circuit. Sequencing is described in section 7.3.1.1.7.

7.3.1.1.3 Bypasses

7.3.1.1.3.1 Channel Bypasses.

BOP ESFAS. Trip channel bypasses are provided in the one-out-of-two ESFAS as shown in table 7.3-1. The trip channel bypass is similar to the RPS trip channel bypass (Section 7.2.1.1.5) and is employed to remove a trip channel from service for maintenance.

The trip logic is thus converted to a single active channel for the trip type bypassed. Other type trips that do not have bypasses in either of their two channels remain in a one-out-of-two logic. The bypass time interval for maintenance is so short that the probability of failure of the remaining channel is acceptably low during maintenance bypass periods. The bypass is manually initiated and manually removed. An electrical interlock allows only one channel for any one type trip to be bypassed at one time. Bypasses are annunciated visually and audibly to the operator.

In some cases, bypass of more than one parameter within a channel may be required in the event of an equipment failure. Specific requirements are provided in the Technical Specifications.

NSSS ESFAS. For two-out-of-four logic bypass capability, refer to section 7.2.1.1.5.

Bypasses are provided, in the PPS, as shown in table 7.3-1c. The trip channel bypass is identical to the RPS trip channel bypass (section 7.2.1.1.5) and is employed for maintenance and testing of channel.

7.3.1.1.3.2 Operating Bypasses

BOP ESFAS. For the one-out-of-two logic, there are no operating bypasses.

NSSS ESFAS. The low pressurizer pressure bypass as shown in figure 7.3-7a, is provided to allow plant depressurization without initiating protective actions when not desired. The bypass may be initiated manually in each protective channel. However, the bypass cannot be initiated if pressurizer pressure is greater than that shown in table 7.3-1c. Once the bypass is initiated, it is automatically removed when the pressurizer pressure increases above the value shown in the table.

Table 7.3-1
ONE-OUT-OF-TWO ESFAS BYPASSES

Title	Function	Initiated By	Removed By
Trip Channel Bypass[a]	Disables any given trip channel	Manually by controlled access switch	Same switch

a. Interlocks allow only one channel for any type trip to be bypassed at one time.

7.3.1.1.3.3 DAFAS Bypasses. The key-lock bypasses shown in table 7.3-1A are provided in the auxiliary relay cabinets for maintenance and test purposes. The bypasses function to block actuation of the DAFAS-1 or DAFAS-2 initiation relays in trip legs 1-3 and 2-4. There are no interlocks associated with the bypass functions other than a separate key-lock switch for each bypass. There are two key-lock bypasses for DAFAS-1 and DAFAS-2, one each for trip legs 1-3 and 2-4 in the auxiliary relay cabinet bay 5 and bay 8. The bypasses are indicated locally on the ARC status indicator assemblies, located within the ARC. The bypasses are also installed and removed by the MMI (man machine interface) automated test programs when each DAFAS PLC is placed in test by control of a key-locked test switch and the appropriate password protected automated test program command is given.

Table 7.3-1A
DAFAS BYPASSES

TITLE	FUNCTION	INITIATED BY	REMOVED BY
DADAS-1 OR DAFAS-2	DISABLE TRIP LEG 1 – 3 OR 2 – 4	DAFAS-1 OR DAFAS-2 BYPASS SWITCH IN BAY 5 OR BAY 8 OF ARC OR MMI AUTO TEST	BYPASS SWITCH OR TEST SWITCH

7.3.1.1.4 Interlocks

BOP ESFAS. The one-out-of-two ESFAS interlocks prevent the operator from bypassing more than one trip channel for one type trip at a time. Different type trips may be bypassed simultaneously, either in the same channel or in different channels.

NSSS ESFAS. The ESFAS interlocks, located in the PPS, prevent the operator from bypassing more than one trip channel of a trip parameter at a time. Different trip parameters may be bypassed simultaneously, either in the same channel or in different channels. This function is shown in figure 7.2-9.

During system testing an electrical interlock prevents more than one set of four matrix relays from being held at one time. The same circuit will allow only one process measurement loop signal to be perturbed at a time for testing. The matrix relay hold and loop perturbation switches are interlocked so that only one or the other may be used at any one time.

7.3.1.1.5 Redundancy

BOP ESFAS. Redundant features of the one-out-of-two ESFAS include:

A. Two independent channels, from process sensor/transmitter through and including bistable output relays, are provided.

B. Two trip paths are present for each actuation signal.

C. Each actuation signal actuates two output trains so that redundant system components may be actuated from separate trains.

D. Power for the system is provided from two separate buses. Power for control and operation of redundant actuated components comes from separate buses. Load group 1 components and systems are energized only by the load group 1 bus and load group 2 components and systems are energized only by the load group 2 bus.

E. Power to each BOP ESFAS division is provided from a vital AC source (PN) and a vital DC source (PK) to redundant power supplies that are auctioneered.

The result of the redundant features is a system that meets the single failure criterion and can be tested during plant operation.

NSSS ESFAS. There are many redundant features within the ESFAS. There are four independent channels for each parameter from process sensor through and including the initiation circuits located in four PPS bays. There are six logic

matrices, to actuate the initiation circuits, each of which has two power supplies for the four logic relays of each matrix.

In the ESFAS Auxiliary Relay Cabinets the selective two-out-of-four logic matrix has two power supplies per leg. Each Auxiliary Relay Cabinet controls one ESF System train and there are two totally redundant Auxiliary Relay Cabinets used to operate two totally redundant ESF trains.

Overall, the entire ESFAS receives vital AC power from four separate buses and the power for control and operation of separate trains comes from separate buses.

The result is a system which meets the single failure criterion, can be tested during operation and shifted to two-out-of-three logic, when a channel is removed for testing or maintenance without affecting system availability.

7.3.1.1.6 Diversity

BOP ESFAS. The one-out-of-two ESFAS is designed to eliminate credible dual channel failures originating from a common cause. The failure modes of redundant channels and the conditions of operation that are common to them are analyzed to ensure reasonable assurance that:

A. The monitored variables provide adequate information during the accidents.

B. The equipment can perform as required.

C. The interactions of protective actions, control actions, and the environmental changes that cause, or are caused

by, the design basis events do not prevent the mitigation of the consequences of the event.

D. The system cannot be made inoperable by the inadvertent actions of operating and maintenance personnel.

In addition, the design is not encumbered with additional components or channels without reasonable assurance that such additions are beneficial.

NSSS ESFAS. The system is designed to eliminate credible multiple channel failures originating from a common cause. The failure modes of redundant channels and the conditions of operation that are common to them are analyzed to assure that a predictable common failure mode does not exist.

The design provides reasonable assurance that the protective system cannot be made inoperable by the inadvertent actions of operating or maintenance personnel. The design is not encumbered with additional channels or components without reasonable assurance that such additions are beneficial.

7.3.1.1.7 Sequencing

There is no sequencing for any ESF equipment other than that necessary for ESF bus loading. The automatic load sequencer is discussed in paragraph 8.3.1.1.3.

7.3.1.1.8 Testing

Provisions are made to permit periodic testing of the BOP and NSSS ESFAS. These tests cover the trip actions from sensor input through the protection system and the actuation devices.

The system test does not interfere with the protective function of the system. The testing system meets the criteria of IEEE Standard 338-1971 and Regulatory Guide 1.22. Testing criteria is presented in Section 7.3.2.3.3. For the testing of the radiation measurement channels, see section 11.5 and the ODCM.

For the two-out-of-four ESFAS overlap between individual tests exist so that the entire ESFAS can be tested.

Testing of the BOP ESFAS load sequencer functions is discussed in section 8.3.1.1.3.10.1.

Since actuation of the ESF systems controlled by the BOP ESFAS does not disturb normal plant operating conditions, the one-out-of-two ESFAS is tested by complete actuation. Frequency of accomplishing the tests is listed in the Technical Specifications.

7.3.1.1.8.1 Sensor Checks. During reactor operation, the measurement channels providing an input to the BOP and NSSS ESFAS are checked by comparing the outputs of similar channels, and by cross-checking with related measurements.

During extended shutdown periods or refueling, these measurement channels are checked and calibrated against known standards.

7.3.1.1.8.2 Trip Bistable Test.

BOP ESFAS. Testing of the system is accomplished by manually varying the input signal to the trip setpoint level on one bistable at a time and observing the trip action.

When the bistable of a protective channel is in a tripped condition, the following conditions should exist:

- The bistable output relay is deenergized.
- The group relay in each actuation channel is deenergized.
- The ESF components are in the ESFAS actuation position.
- Actuation is annunciated on the control room annunciator panel.

Proper operation may be verified by the following:

- Checking the position of each ESF component
- Checking the actuation annunciation
- Checking the ESF component status indication

The test is repeated for the other bistable.

NSSS ESFAS. Testing of a trip bistable, located in the PPS, is accomplished by manually varying a simulated process input signal locally on the PPS Bistable Control Panel. This signal is increased, or decreased, until the trip setpoint is reached and the trip action is observed (See Figure 7.2-6).

Varying the simulated input signal is accomplished by means of a trip test circuit which consists of a digital voltmeter and a test circuit which can change the magnitude of the signal supplied by the measurement channel. The trip test circuit is electrically interlocked so that it can be used in only one channel at a time (See Figure 7.2-9). A switch selects the

measurement channel and a pushbutton applies the test signal. The digital voltmeter indicates the test signal value. The test circuit permits various rates of change of signal input to be used. Trip action of each of the bistable trip relays is indicated by individual lights on the front of the cabinet (See Figure 7.2-7), indicating that the contacts of these relays, which are located in the coincidence of two logic matrices, operated as required for a trip condition.

The variable setpoint test is accomplished by manually varying a simulated process input signal. Upon decreasing this input, the setpoint is verified to remain constant and the trip setpoint is within specified tolerances. By manually decreasing this input, and then depressing the setpoint reset button, the setpoint incremental change can be tested and verified. The tracking ability of the circuit can be tested by manually increasing the test input and observing that the setpoint tracks.

When one of the bistables of a protective channel is in the tripped condition, a channel trip exists and is annunciated on the control room annunciator panel. In this condition, an actuation would take place upon receipt of a trip signal in one of the other three like channels. The trip channel under test is, therefore, bypassed for this test converting the ESFAS to a two-out-of-three logic which is still a coincidence of two for the particular trip parameter.

7.3.1.1.8.3 Logic Matrix Tests. This PPS logic test is carried out to verify proper operation of the six coincidence

logic matrices, located in the PPS, any one of which will initiate a system actuation for any possible coincidence of two trip condition from the signal inputs of each measurement channel. The test circuits are shown in Figures 7.2-8 and 7.2-7.

The system is interlocked so that only one logic matrix set (i.e., all AB or all AC, etc.) can be held at a time as discussed in CESSAR Section 7.3.1.1.4. Rotating the switch to the "Hold" position will apply a test voltage to the test system hold coils of the double coil matrix relays in their energized position. The deactuation of the trip relay contacts in the matrix ladder being tested caused deenergization of the primary matrix relay coils (see Figure 7.2-7).

The logic matrix to be tested is selected using the System Channel Trip Select Switch. By holding the matrix hold switch in the "trip" position and rotating the System Channel Trip Select Switch through each of its positions, the trip relays in the logic matrix will be deenergized. The System Channel Trip Select Switch applies a test voltage of the opposite polarity to the bistable trip relay test coils so that the magnetic flux generated by these coils cancels that of the primary coil causing the relays to release.

Trip action can be observed by illumination of the trip relay indication located on the front panel and by loss of voltage to the four matrix relays, which is indicated by loss of illumination of the indicator lights connected across each matrix relay coil. During the test the matrix relay hold

lights will remain on, indicating that a test voltage has been applied to the holding coils of the matrix relays of the logic matrix under test.

This test is repeated for each actuation signal, by use of the System Channel Trip Select Switch, and for all six logic matrices. This test will verify that the logic matrix relays will deenergize if the logic matrix continuity is interrupted.

7.3.1.1.8.4 Initiation Channel Tests. Each initiation circuit, in the PPS, is tested individually by rotating a matrix hold switch to the "trip" position (holding four matrix relays), selecting any trip position on the System Trip Select Switch and selecting a matrix relay on the Matrix Relay Trip Select Switch (see Figure 7.2-11). This causes the appropriate initiation circuit to deenergize. Proper operation of both initiation relay coils and contacts is verified by monitoring the current through the appropriate leg of the actuation logics selected two-out-of-four circuit.

The matrix Relay Trip Select Switch is turned to the next position, re-energizing the test matrix relay and permitting the reset of the initiation circuit relays. The whole sequence is repeated for the remaining three initiation circuits from the selected matrix. The entire sequence is repeated for the remaining five matrices. Upon completion of testing, all six matrices, all 24 matrix relay contacts, and all eight initiation relays have been tested.

In addition, the remote manual switches for the initiation circuits can be tested. The indication of proper manual initiation will be the same as for automatic initiation. Only one switch is used at a time.

7.3.1.1.8.5 ESFAS Actuation Logic Test. This test verifies the proper operation of the ESFAS actuating logic circuits (refer to Figure 7.3-8a). The selective two-out-of-four logic circuit, located in the ESFAS Auxiliary Relay Cabinets, of each ESFAS train is tested in a manner identical to the RPS trip breaker system. (See Section 7.2.1.1.9.5). One current leg of the selective two-out-of-four logic matrix is interrupted by opening one of the current legs contacts and loss of current in that current leg is verified. Each contact in both current legs is checked in this manner.

The lockout contacts are checked via the group relay test system as described below and the PPS initiation relay contacts are checked as described in the preceding section.

7.3.1.1.8.6 ESFAS Actuating Device Test. Proper operation of the ESFAS group relays, in the ESFAS Auxiliary Relay Cabinets, is verified by deenergizing the group relays one at a time via a test relay contact (See Figure 7.3-8a) and noting proper operation of all actuated components in that group. The relay will automatically reenergize and return its components to the pretest condition when the test keylock pushbutton is removed from the test position.

The design of the test system is such that only one group relay may be deenergized at a time. The test switch must be positioned to the group to be tested; selection of more than one group is impossible. The test circuit is electrically locked out upon actuation of a particular test group and another test group cannot be actuated for one minute after selecting another switch position. This time delay is a "stop and think" feature to assist the operator in conducting tests.

Since this test causes the ESF components to actuate by interrupting the normal safety signal current leg to individual group relays, the propagation of a valid trip during test is not impeded and the system will proceed to full actuation by interrupting the current leg to all group relays.

7.3.1.1.8.7 Bypass Tests. System bypasses in the PPS, as itemized in Table 7.2-2, are tested on a channel basis using internally generated test signals. This testing includes both manual initiation and automatic removal features.

7.3.1.1.8.8 Response Time Tests. The design of the ESFAS is such that connections may be made for any of a variety of methods. The hardware design includes test connections on instrument lines for pressure and differential pressure transmitters, and test points wired out to convenient test jacks or terminal strips.

Response time testing required at refueling intervals are given in the Technical Specifications. These tests include the sensors for each ESFAS channel and are based on the criteria

defined in paragraph 7.3.2.3.3. The ESF response time limits are identified in table 7.3-1B.

7.3.1.1.9 Vital Instrument Power Supply

The vital instrument power supply for the ESFAS is described in chapter 8.

7.3.1.1.10 Actuated Systems

The ESF Systems are maintained in a standby mode during normal operations. Actuating signals, generated by the ESFAS are provided to assure that the ESF Systems provide the required protective actions. The following descriptions of the instrumentation and controls of the ESF Systems is applicable to each ESF System. Table 7.3-2 presents the Design Basis Events (DBE) which require specific ESF System action. Table 7.3-3 presents the monitored variables required for ESF System actuation. The variables and their ranges are shown on Table 7.3-3a.

7.3.1.1.10.1 Containment Isolation System. Section 6.2.4 contains a description of the Containment Isolation System. The actuation system is composed of redundant trains A and B. The instrumentation and controls of the two trains are physically and electrically separate and independent as discussed above such that the loss of one train will not impair the safety function.

The Containment Isolation System instrumentation and controls are designed for operation during all phases of plant operation as required by the Technical Specifications.

The Containment Isolation System is automatically actuated by a CIAS from the ESFAS.

A. See table 6.2.4-2 for a list of devices actuated on a containment isolation actuation signal (CIAS).

B. Figure 7.3-7B, ESFAS signal logic (CIAS).

C. Figure 6.2.4-1, containment penetration valve arrangements.

D. Figure 7.2-2, instrumentation location layout drawing for CIAS input services.

Removal of the containment isolation system from service is controlled by plant procedures.

TABLE NOTATIONS

a. Diesel generator starting and sequence loading delays included. Response time limit includes movement of valves and attainment of pump or blower discharge pressure.

b. Diesel generator starting delays not included. Offsite power available. Response time limit includes movement of valves and attainment of pump or blower discharge pressure.

c. MFIV valves tested at simulated operating conditions; valves tested at static flow conditions to ≤ 8.6[(a)]/8.6[(b)] seconds.

d. Radiation detectors are exempt from response time testing. The response time of the radiation signal portion of the channel shall be measured from the detector output or from the input of first electronic component in channel to closure of dampers M-HJA-M01, M-HA-M52, M-HJB-M01 and M-HJB-M55.

e. Dampers M-HJA-M01, M-HJA-M52, M-HJB-M01, and M-HJB-M55.

f. For Mode 3 operation, the Palo Verde Safety Analyses do not credit Main Steam Isolation due to a Steam Generator Level - High initiating signal. A 15 second response time was selected to comply with Palo Verde Technical Specification Surveillance Requirement 3.3.5.4 and Table 3.3.5-1.

TABLE 7.3-1C

NSSS ESFAS BYPASSES

Title	Function	Initiated By	Removed By	Notes
Trip Channel Bypass	Disables any given trip channel	Manually by controlled access switch	Same switch	Interlocks allow one channel for any type trip to be bypassed at one time.
Pressurizer Pressure Bypass	Disables low pressurizer pressure portion of SIAS/CIAS*	Manual switch (1 per channel) If pressure is $<$ 400 psia	Automatic if pressurizer pressure is $\geq$ 500 psia	

* SIAS/CIAS actuation due to high containment pressure not affected.

Removal of the containment spray system from service is controlled by plant procedures.

7.3.1.1.10.3 IODINE REMOVAL SYSTEM(Abandoned in Place)

7.3.1.1.10.4 Main Steam Isolation System. Refer to Section 10.3, "Main Steam Supply System," for a description of the Main Steam Isolation System. Refer to Section 10.4.7, "Condensate and Feedwater System," for a description of the Main Feedwater Isolation System. Refer to Section 10.4.8, "Steam Generator Blowdown System," for a description of the Blowdown Isolation System. Interface requirements for the Main Steam Isolation System are provided in Section 5.1.4.

The actuation system is composed of redundant trains A and B. The instrumentation and controls of the train A valve actuators are physically and electrically separate and independent of the instrumentation and control of the train B valve actuators.

The separation and independence are such that a failure of one train will not impair the protective action.

The Main Steam Isolation Valves (MSIV), Main Feedwater Isolation Valves (MFIV) and the isolation valves for the blowdown lines are actuated by an MSIS.

These valves effectively isolate the steam generators from the rest of the main steam and feed systems.

A variable steam generator pressure setpoint is implemented to allow controlled pressure reductions, such as shutdown depressurization, without initiating an MSIS. The pressure setpoint will track the pressure up until it reaches its normal setpoint value. Also, refer to figures and tables listed below:

A. Table 6.2.4-2 for a list of devices actuated on a main steam isolation signal (MSIS)

B. Figure 7.3-7c, ESFAS signal logic (MSIS)

C. P&I diagram 01, 02, 03-M-SGP-002 and –001 (main steam system)

D. Figures 7.2-2 and 7.2-3, instrumentation location layout drawing for MSIS input devices

7.3.1.1.10.5 <u>Safety Injection System</u>. Refer to Section 6.3, "Emergency Core Cooling System," for a description of the Safety Injection System (SIS). The SIS is actuated by an SIAS. Interface requirements for the Safety Injection System are provided in Section 6.3.1.3.

The actuation system is composed of redundant trains A and B. The instrumentation and controls of train A are physically and electrically separate and independent of instrumentation and controls in train B. Since each train is a 100% capacity system the SIS can sustain the loss of an entire train and still provide its required protective action. The SIS instrumentation and controls are designed to operate under all plant conditions. The low pressurizer pressure setpoint can be decreased as described in section 7.2.1.1.1.6 to avoid inadvertent operation during startup and shutdown. As pressurizer pressure increases, the setpoint will follow up to its normal value. Also refer to figures and tables listed below:

A. Table 6.2.4-2 for a list of devices actuated on a safety injection actuation signal (SIAS)

B. Table 7.3-6 for additional SIAS actuated devices

C. Figure 7.3-7a, ESFAS signal logic (SIAS)

D. P&I diagram 01, 02, 03-M-SIP-001, -002 and -003 (safety injection system)

E. Figures 7.2-1 and 7.2-2, instrumentation location layout drawing for SIAS input devices

In addition, the procedure for removing the safety injection system from service is controlled by plant procedures.

7.3.1.1.10.6 Recirculation Actuation. An RAS is generated when the level in the RWT falls below a predetermined level. When an RAS is received the LPSI pumps are stopped and the HPSI

and CSS pumps shift suction to the containment recirculation sump. Refer to Section 7.3.1.1.10.2 for references applicable to the recirculation actuation signal.

In addition, removing a RAS from the LPSI pumps to allow them to be used for the shutdown cooling system is controlled by plant procedures.

7.3.1.1.10.7 Auxiliary Feedwater System. Interface requirements are provided in section 5.1.4.

The AFWS is actuated by an AFAS. The instrumentation and controls of train A are physically and electrically separate and independent of the instrumentation and controls of train B. Thus, if a single failure prevents actuation of one train the other train will still receive an actuation signal.

The AFAS signal latches the pumps in either the manual or automatic mode and will cycle the valves on the steam generator level signals.

The Seismic Category I portion of the auxiliary feedwater system is provided to automatically initiate residual heat removal capability during emergency conditions such as a steam line rupture, loss of normal feedwater, or loss of offsite and normal onsite power. The non-Seismic Category I portion of the auxiliary feedwater system is provided for normal nonemergency operation during startup, cooldown, and hot standby. The non-Seismic Category I portion of the auxiliary feedwater system is not an engineered safety feature system and, therefore, is not addressed in this section. Subsequent references in this

section to the auxiliary feedwater system apply to the Seismic Category I portions only. The Seismic Category I portion of the auxiliary feedwater system is described in subsection 10.4.9.

7.3.1.1.10.8 Fuel Building Essential Ventilation Systems. Radioactive contamination may occur in the spent fuel area in the unlikely event that a spent fuel element is severely damaged during handling. If a fuel handling accident occurs, sensors in the fuel building detect the fission products released from the fuel and initiate appropriate action, as discussed in section 9.4, to reduce the release of fission products into the environment.

P&ID	Description	Function
01, 02, 03-M-PWP-001	Essential chilled water system	Refer to paragraph 9.2.9
01, 02, 03-M-SCP-004	Steam generator blowdown isolation valves (4)	Close

The fuel building essential ventilation system, as described in section 9.4, is composed of components in redundant load groups, load group 1 and load group 2. The instrumentation and controls of the components and equipment in load group 1 are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in load group 2. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events shown in table 7.3-2 that require fuel building ventilation isolation.

The fuel building essential ventilation system is automatically actuated by a FBEVAS from the ESFAS. The FBEVAS is initiated by one-out-of-two high airborne activity signals from radiation monitors, one of which is a gaseous monitor in the fuel building normal exhaust duct, and the other of which is an area radiation monitor on a wall overlooking the fuel pool. The system is designed so that loss of electric power to one-out-of-two electronic remote indication and control units or to the actuating logic actuates the fuel building essential ventilation system.

Manual initiation of the fuel building essential ventilation system is provided in the control room.

The safety-related display instrumentation for the fuel building essential ventilation system, which provides the operator with sufficient information to monitor and perform the required safety functions, is described in section 7.5. Further information on the actuation system is provided by the following:

A. Table 7.3-8(A), fuel building essential ventilation actuation signal actuated devices list during FBEVAS

B. Table 7.3-8(B), fuel building/auxiliary building essential ventilation actuated devices list during SIAS

C. Figure 7.3-1, ESFAS signal logic (FBEVAS)

D. P&I diagram 01, 02, 03-M-HFP-001 (fuel building HVAC)

E. Section 12.3, instrument location layout drawing for FBEVAS input devices

The FBEVAS is combined with the SIAS in the device control circuits so that any one of the signals (logical OR) activate the devices listed in table 7.3-8B. During SIAS operation, the fuel building/auxiliary building essential ventilation system is aligned to exhaust from the auxiliary building. The SIAS signal takes precedence over FBEVAS should both signals be present at the same time.

7.3.1.1.10.9 Containment Purge Isolation System. Radioactive contamination may occur in the containment building in the event that a spent fuel element is severely damaged during handling. The containment purge isolation system detects abnormal amounts of radioactive material in the containment building and initiates appropriate action to prohibit the release of radioactive material into the environment. Refer to section 9.4 for a description of the containment purge isolation system.

The containment purge isolation system is composed of components in redundant load groups, load group 1 and load group 2. Instrumentation and controls of the components and equipment in load group 1 are physically and electrically separate and independent of instrumentation and controls of the components and equipment in load group 2. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events shown in table 7.3-2 that are mitigated by the containment purge isolation system.

The containment purge isolation system is automatically actuated by the CPIAS from the ESFAS. CPIAS is initiated by one-out-of-two high airborne activity signals from two redundant radiation monitors located in close proximity to the power access purge exhaust duct and the refueling purge exhaust duct. The monitors are identified as the "PAPA-A" and "PAPA-B" monitors.

The system is designed so that loss of electric power to one-out-of-two electronic remote indication and control units or to the actuating logic actuates the containment purge isolation system.

The CPIAS is combined with the CIAS in the control circuits of the isolation valving common to both the containment purge isolation system and the containment isolation system so that either signal (logical OR) can actuate these valves. Figure 7.3-4 presents a typical control logic for these valves.

The safety-related display instrumentation for the containment purge isolation system that provides the operator with sufficient information to monitor and perform the required safety functions is described in section 7.5.

Further information on the actuation system is provided by the following:

A. Table 6.2.4-2 for a list of devices actuated on a CPIAS

B. Figure 7.3-1, ESFAS signal logic (CPIAS)

C. P&I diagram 01, 02, 03-M-HTP-001 (containment purge system)

D. Section 12.3, instrument location layout drawing for CPIAS input devices

7.3.1.1.10.10 Control Room Essential Ventilation Systems.

The control room essential ventilation systems are the control room ventilation isolation system and the control room essential filtration system.

Upon detection of a high airborne activity signal in the normal air intake, the control room essential filtration system is actuated. Both control room essential ventilation systems, as discussed in section 6.4, are composed of components in redundant load groups, load group 1 and load group 2. Instrumentation and controls of the components and equipment in load group 1 are physically and electrically separate and independent of instrumentation and controls of the components and equipment in load group 2. Independence is adequate to retain the redundancy required to maintain control room habitability following those design basis events shown in table 7.3-2.

The control room essential filtration system is automatically actuated by a CREFAS. The CREFAS is initiated by one-out-of-two air intake high airborne activity signals, a FBEVAS, or a CPIAS as shown in figure 7.3-2. The CPIAS is discussed in paragraph 7.3.1.1.10.9. The FBEVAS is discussed in paragraph 7.3.1.1.10.8. The system is designed so that loss of electrical power to one-out-of-two electronic remote indication and control units or to the actuating logic actuates the control room essential filtration system.

The CREFAS is combined with the SIAS in the device control circuits so that any one of the signals (logical OR) actuates

the devices listed in table 7.3-9. The development of the SIAS is discussed in CESSAR Section 7.3.2.2.1. Figure 7.3-5 presents a typical control logic to show the combination of these signals.

In addition to the automatic initiating signals, two independent smoke detectors are provided in the outside air intake plenum.

Upon detection of smoke, an audible and visible alarm will alert the operator to manually initiate the control room ventilation isolation system.

Manual initiation of the control room ventilation isolation system and the control room essential filtration system is provided in the control room.

The safety-related display instrumentation for the control room essential ventilation systems, which provides the operator with sufficient information to monitor and perform the required safety functions, is described in section 7.5.

Further information on the actuation system is provided by the following:

A. Table 7.3-9, Control Room Essential Filtration Actuation Signal Actuated Devices List

B. Table 7.3-10, Control Room Ventilation Isolation Actuation Signal Actuated Devices List

C. Figure 7.3-2, ESFAS signal logic (CREFAS and CRVIAS)

7.3.1.1.10.11 Containment Combustible Gas Control System. The containment hydrogen gas concentration may increase to a combustible concentration following a LOCA. In the unlikely event that a LOCA does occur, the containment hydrogen gas concentration is maintained less than the lower combustible limit by operation of the containment combustible gas control system.

The containment combustible gas control system, as described in subsection 6.2.5, is composed of components in redundant load groups, load group 1 and load group 2. Instrumentation and controls of components and equipment in load group 1 are physically and electrically separate and independent of instrumentation and controls of components and equipment in load group 2. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events in table 7.3-2 that are mitigated by the containment combustible gas control system.

The containment combustible gas control system components are controlled manually from control switches located at local panels. The local panel(s) will be accessible after a design basis accident (DBA).

The safety-related display instrumentation for the combustible gas control system that provides the operator with sufficient information to monitor and perform the required safety functions is described in section 7.5.

The principal parameter monitored, for determining when the containment combustible gas control system is to be placed in service, is hydrogen. The containment hydrogen analyzer is not normally in service; however, following a DBA, the hydrogen analyzer is placed in service with controls mounted in the main control room.

A control switch with an override feature is provided for each of the containment combustible gas control system isolation valves. This control switch override feature is functional only after receipt of the CIAS, and permits control of each valve independent of the CIAS. The open and closed positions of these valves, in addition to the override status, are indicated in the control room. A typical logic diagram showing implementation of the override signal is shown in figure 7.3-6.

The containment combustible gas control system test pressure is greater than the peak containment design pressure. This precludes system overpressurization by the inadvertent opening of the isolation valves.

Further information on the system is provided by the following:

A. Table 7.3-11, Containment Combustible Gas Control System Actuated Devices List

B. P&I diagram 01, 02, 03-M-HPP-001 (containment combustible gas control system)

7.3.1.2 Design Basis Information

BOP ESFAS. The actuation setpoints are given in table 7.3-12. The design bases for the additional one-out-of-two ESFAS are as follows.

The one-out-of-two ESFAS is designed to provide initiating signals for components that require automatic actuation following a DBA.

The systems are designed on the following bases to ensure adequate performance of their protective functions:

A. The system is designed in compliance with the applicable criteria of Appendix A of 10CFR50, 1971.

B. System testing conforms to the requirements of IEEE Standard 338-1971 and Regulatory Guide 1.22.

C. IEEE 279-1971 establishes specific protection system design bases. The following paragraphs describe how the design bases listed in Section 3 of IEEE 279-1971 are implemented.

   1. The additional generating station condition that requires protective action is:

      a. Fuel handling accident

      b. Fire/smoke-plant vicinity

   2. The system is designed to monitor the following additional parameters in order to provide protective actions:

      a. Containment radiation/airborne activity

   b. Fuel building radiation/airborne activity

   c. Control room air intake activity

   d. Control room air intake smoke

3. The number and location of the sensors required to monitor the variables listed in sublisting C.2 above are contained in table 7.3-13A.

4. The normal operation limits for each variable are provided in table 7.3-12.

5. The margin between the operation limits and actuation setpoints are provided in table 7.3-12.

6. The actuation setpoints are provided in table 7.3-12.

Table 7.3-11A

ENGINEERED SAFETY FEATURES ACTUATION SYSTEM SETPOINTS AND MARGINS TO ACTUATION

Actuation Signal	Typical Full Power	Normal Operation Range	Trip Setpoint	Margin to Actuation
SIAS & CIAS				
Low pressurizer pressure	2,250 psia	2,100-2,350 psia	≥ 1,837 psia[a]	263 psi
High containment pressure	0 psig	0 psig	≤ 3 psig	3 psi
CSAS				
High-High containment pressure	0 psig	0 psig	≤ 8.5 psig	8.5 psi
RAS				
Low refueling water tank level	--	81.2-98%[h]	9.4% of span	71.8%
MSIS				
Low steam generator pressure	1039 psia	1010-1170 psia	960 psia[d]	79 psi
High containment pressure	0 psig	0 psig	≤ 3 psig	3 psi
High steam generator level	55%	30-74%	≤ 91% NR[e]	17%
AFAS				
Low steam generator level and	82%	72-90%	≥ 25.8% WR[f]	46.2
Steam generator differential pressure[b]	0 psid	0 psid	≤ 185 psid	185 psi
DAFAS				
Low steam generator level[c]	82%	72-90%	20.3%	51.7
LOP				
4.16 kV Emergency Bus Loss of Voltage	4160 V		[g]	
4.16 kV Emergency Bus Degraded voltage	4160 V		3744 V	

a. In MODES 3-4, the value may be decreased manually, to a minimum of 100 psia, as pressurizer pressure is reduced, provided:

(a) the margin between the pressurizer pressure and this value is maintained at less than or equal to 400 psi; and

(b) when the RCS cold leg temperature is greater than or equal to 485 degrees F, this value is maintained at least 140 psi greater than the saturation pressure corresponding to the RCS cold leg temperature.

The setpoint shall be increased automatically as pressurizer pressure is increased until the trip setpoint is reached. Trip may be manually bypassed below 400 psia; bypass shall be automatically removed whenever pressurizer pressure is greater than or equal to 500 psia.

b. This is a calculated, not sensed, variable.

c. Low steam generator levels, diverse scram signals present without normal ESFAS initiation of AFAS or MSIS (ATWS requirements).

d. In MODES 3-4, value may be decreased manually as steam generator pressure is reduced, provided the margin between the steam generator pressure and this value is maintained at less than or equal to 200 psi; the setpoint shall be increased automatically as steam generator pressure is increased until the trip setpoint is reached.

e. % of the distance between steam generator upper and lower level narrow range instrument nozzles.

f. % of the distance between steam generator upper and lower level wide range instrument nozzles.

g. See figure 8.3-3.

h. Technical Specification minimum required RWT level to high level alarm (Mode 1-4 limits).

Table 7.3-12
BOP ESF SYSTEM ACTUATION SETPOINTS AND
MARGINS TO ACTUATION (Sheet 1 of 2)

Actuation Signal	(Full Power) Nominal	Normal Operation Limit	Actuation Setpoint Refer to Table 11.5-1	Margin to Actuation
FBEVAS				
Fuel building exhaust duct high activity	Less than sensitivity $\left(< 10^{-6}\ \frac{\mu Ci}{cm^3}\right)$	Less than sensitivity $\left(< 10^{-6}\ \frac{\mu Ci}{cm^3}\right)$	$2x10^{-6}\ \frac{\mu Ci}{cm^3}$	$1x10^{-6}\ \frac{\mu Ci}{cm^3}$
Fuel pool high radiation level	0.5mr/h	0.5 mr/h	$<$ 15 mr/h	14.5 mr/h
CPIAS				
Power access purge exhaust area radiation level	$<$2.5 mr/h	$<$2.5 mr/h	2.5 mr/h	Negligible
CREFAS				
Control room air intake high activity level	Less than sensitivity $\left(< 10^{-6}\ \frac{\mu Ci}{cm^3}\right)$	Less than sensitivity $\left(< 10^{-6}\ \frac{\mu Ci}{cm^3}\right)$	$2x10^{-5}\ \frac{\mu Ci}{cm^3}$	$1.9x10^{-5}\ \frac{\mu Ci}{cm^3}$

Table 7.3-12
BOP ESF SYSTEM ACTUATION SETPOINTS AND MARGINS TO ACTUATION (Sheet 2 of 2)

Actuation Signal	(Full Power) Nominal	Normal Operation Limit	Actuation Setpoint	Margin to Actuation
CRVIAS				
Control room air intake high smoke level (manual initiation of CRVIAS upon detection of smoke)	Less than sensitivity	Less than sensitivity	1.25% obscuration	1.25% obscuration

7. System components are qualified for the environmental conditions discussed in section 3.11. In addition, the system is capable of performing its intended functions under the most degraded conditions of the electric support system as discussed in section 8.3.

8. The one-out-of-two ESFAS is designed with consideration given to unusual events that could degrade system performance so that:

   a. A loss of power to the measurement channels and/or to the logic system causes system actuation.

   b. Any single failure within the system shall not prevent proper protective action at the system level. The single failure criterion is discussed in paragraph 7.3.2.3.2.

   c. The environmental conditions under which the ESFAS shall be capable of performing its intended function are described in section 3.11.

   d. The seismic conditions under which the ESFAS shall be capable of performing its intended function are described in section 3.10.

Table 7.3-13A
BOP ESF SYSTEMS ACTUATION SENSORS

Monitored Variable	Type	Number of Sensors	Location
Power access purge exhaust area radiation level	Geiger-Mueller	2	Outside containment between power access purge exhaust duct and refueling purge exhaust duct
Fuel building exhaust duct radiation level	β-Scintillation	1	Fuel building exhaust duct
Fuel pool area radiation level	Geiger-Mueller	1	Overlooking spent fuel pool
Control room air intake activity level	β-Scintillation	2	Control room outside air intake duct

9. The minimum performance requirements of the one-out-of-two ESFAS are as follows:

   a. The ESFAS system response times are provided below. The total ESFAS response times represent the sum of the sensor response time plus the one-out-of-two ESFAS response time.

		Sensor Response Time	One-Out-of-Two ESFAS Response Time
(1)	Containment power access purge exhaust area radiation	Ref.table 11.5-1 note aa +	2.0s
(2)	Fuel pool area radiation	Ref.table 11.5-1 +	2.0s
(3)	Fuel building exhaust air-borne activity	Ref.table 11.5-1 +	2.0s
(4)	Control room air intake airborne activity	Ref. table 11.5-1 +	2.0s
(5)	Control room air intake smoke	50s	N.A. (Manual Initiation)

b. The accuracies of the ESFAS measurement channels are:

(1)	Containment power access purge exhaust area radiation	$\pm 20\%$
(2)	Fuel pool area radiation	$\pm 20\%$

<u>NSSS ESFAS</u>. The design bases of the ESF Systems are discussed in Chapter 6.0. The ESFAS is designed to provide initiating signals for ESF components which require automatic actuation following the design bases events shown on Table 7.3-2.

The systems are designed in compliance with the applicable criteria of the NRC, "General Design Criteria for Nuclear Power Plants," Appendix A, 10CFR50. System testing conforms to the requirements of IEEE 338-1971, "Trial Use Criteria for Periodic Testing of Nuclear Power Generating Station Protection Systems," and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions."

Specific design criteria for the ESFAS are detailed in IEEE 279-1971 "Criteria for Protection Systems for Nuclear Power Generating Stations," Section 3. The following is a discussion of the specific items in IEEE 279-1971 and their implementation.

The generating station conditions requiring actuation of the ESFAS are listed on Table 7.3-2, which also shows which system will actuate for each event. The monitored variables required for ESF System protective action are listed on Table 7.3-3, which also shows which signals are generated by the variable. The number and location of the sensors required to monitor the variables are listed in Table 7.3-13B. The normal operating ranges, actuation setpoints, the nominal full power value, and the margin between the last two are listed on Table 7.3-11A.

The ESFAS is designed with consideration given to unusual events which could degrade system performance. System components are qualified for the environmental conditions discussed in Section 3.11 and the seismic conditions discussed in Section 3.10. These two topics are discussed in Combustion Engineering Topical Reports CENPD-182, "Seismic Qualification of Instrumentation and Electrical Equipment," and CENPD 255, "Qualification of Combustion Engineering Class IE Instrumentation," (References 2 and 3). A single failure within the system will not prevent proper protective action at the system level. The single failure criterion is discussed in section 7.3.2.3.2.

7.3.1.3 Final System Drawings

The signal logic and typical control circuits are shown in figures following this section.

The RAS has added manual actuation which gives the operator greater operational flexibility.

The MSIS logic (Refer to Figure 7.3-7c) has added the high steam generator water level and high containment pressure. This protects downstream equipment from two-phase flow and reduces the amount the Reactor Coolant System could be cooled due to excessive feedwater flow.

For a list of applicable design drawings and diagrams, see section 1.7.

7.3.1.4 Engineered Safety Features Actuation System Supporting Systems

The systems required to support the ESFAS are discussed in Section 7.4. The electrical power distribution is discussed in Section 8.3.

7.3.2 ANALYSIS

7.3.2.1 Introduction

BOP ESFAS. The analysis for the additional one-out-of-two ESFAS and instrumentation is similar to that presented for the NSSS ESFAS as is the ESF manual actuation of the combustible gas control system.

NSSS ESFAS. The ESFAS is designed to provide protection against the Design Basis Events listed on Table 7.3-2. The ESF Systems that are actuated are discussed in Chapter 6.0, along with their design bases and evaluations.

The signals which will cause each ESFAS are listed on Table 7.3-3; the bases are discussed in Section 7.3.1.2; the actuation setpoints are given on Table 7.3-11a. Most ESFAS signals are single parameter, fixed setpoint actuations. The ESFAS that do not fall into this category are:

A. Low pressurizer pressure - can be decreased to 400 psi below the existing pressurizer pressure by the operator;

B. Low steam generator pressure - can be decreased to 200 psi below the existing steam generator pressure by the operator.

These resets are controlled by administrative procedures.

Additionally, several ESFAS can be actuated by more than one parameter. That is, different parameters can cause the same ESFAS. The ESFAS which fall into this category are:

A. SIAS by either low pressurizer pressure or high containment pressure;

B. CIAS by receiving the SIAS for that channel so that it actuates on low pressurizer pressure or high containment pressure;

C. MSIS by high steam generator water level in either steam generator, low steam generator pressure in either steam generator, or high containment pressure.

One ESFAS is, essentially, a multi-parameter actuation. An AFAS is generated on low steam generator water level unless that steam generator has been identified as being ruptured. A steam generator is identified as being ruptured when its pressure is some differential value below the pressure of the other steam generator, coincident with its own low level signal and with the other steam generator being identified as not ruptured.

Each ESFAS setpoint is selected to be consistent with the function of the respective ESF System requirements. The setpoints are selected to provide ESF actuation in sufficient time to provide the necessary actions to mitigate the consequences of the Design Basis Events which caused the ESFAS.

The adequacy of all ESFAS trip setpoints is verified through an analysis of the pertinent system transients reported in Chapter 15.0. These analyses utilize an Analysis Setpoint (assumed trip initiation point) and system delay times associated with the respective trip functions. The Analysis Setpoint along with instrument uncertainties provides the basis for the calculation of the final equipment setpoints to be reported in the Technical Specifications. Limiting trip delay times are given in Table 7.3-1B. The manner by which these delay times and uncertainties will be verified is discussed in Section 7.2.1.2.

7.3.2.1.1 Design Basis Events (DBE)

The DBE conditions for which the system will take action are those unplanned events under conditions that may occur once during the life of several nuclear generating stations, and certain combinations of unplanned events and degraded systems that are never expected to occur during the life of all nuclear power plants. The consequences of these events should be limited by the ESF Systems. The ESF Systems have a major responsibility to mitigate the consequences of the events listed below. This includes minimizing fuel damage and subsequent release of fission products or other related effects. The limiting fault conditions for which the ESFAS actuate are:

A. RCS pipe rupture including a double ended rupture;

B. Single CEA ejection;

C. Steam system pipe rupture, including a double ended rupture;

D. Depressurization due to inadvertent actuation of primary or secondary safety valves at 100% power; and

E. Feedwater system pipe rupture including a double-ended rupture.

The ESFAS will also act to mitigate the consequences of Incidents of Moderate Frequency (IMF) and Infrequent Events as follows:

A. Excess heat removal due to secondary system malfunctions;

B. Inadvertent pressurization or depressurization of the RCS;

C. Change in normal heat transfer capability between steam and reactor coolant systems including:

   1. Improper main feedwater; and

   2. Loss of external load; and

D. Steam generator tube rupture.

7.3.2.2 Actuation Bases

NSSS ESFAS. The ESFAS consists of six signals based on five parameters. Each ESFAS has manual actuation switches locally on the main control board or at the ESFAS Auxiliary Relay Cabinets.

7.3.2.2.1 Safety Injection Actuation Signal (SIAS)

Input

Pressurizer pressure, containment pressure, or manual pushbuttons. The pressure signals are shared with the RPS.

Function

The SIAS actuates the components necessary to inject borated water into the reactor coolant system and actuates components for emergency cooling. SIAS is also initiated by a loss of power to two channels.

7.3.2.2.2 Containment Spray Actuation Signal (CSAS)

Input

Containment pressure signals or manual pushbuttons.

Function

The CSAS actuates the Containment Spray System. CSAS is also initiated by a loss of power to two channels.

7.3.2.2.3 Recirculation Actuation Signal (RAS)

Input

Refueling Water Tank (RWT) Level, or manual pushbuttons.

Function

The RAS is provided to actuate the recirculation mode of operation of the Emergency Core Cooling System. RAS is also initiated by a loss of power to two channels.

7.3.2.2.4 Containment Isolation Actuation Signal (CIAS)

Input

Pressurizer pressure, containment pressure, or manual pushbuttons. The pressurizer and containment pressure signals are provided via the SIAS.

Function

The CIAS actuates the isolation of lines penetrating the containment. CIAS is also initiated by a loss of power to two channels.

7.3.2.2.5 Main Steam Isolation Signal (MSIS)

Input

Pressure from each steam generator, containment pressure, level from each steam generator, or manual pushbuttons.

Function

The MSIS is provided to actuate the isolation of each steam generator. MSIS is also initiated by a loss of power to two channels.

7.3.2.2.6 Auxiliary Feedwater Actuation Signal (AFAS)

Input

Level and pressure from each steam generator with "not ruptured" calculated signal or manual switches.

Function

The AFAS actuates auxiliary feedwater on low water level to the intact steam generator(s). AFAS is also initiated by a loss of power to two channels. The AFAS is based on the following conditions: where low steam generator water level trip exists, its pressure is greater than the other steam generator's pressure by a predetermined value or the other steam generator is identified as not ruptured.

Actuation circuit AFAS I pertains to steam generator 1 and AFAS II actuation circuit pertains to steam generator 2.

7.3.2.3 Design

7.3.2.3.1 General Design Criteria

BOP ESFAS

A. Criterion 16: Containment Design

Refer to subsection 3.1.12.

B. Criterion 20: Protection System Functions

Engineered safety features action will be automatically initiated upon sensing the presence of accident conditions except for the combustible gas control system and the control room ventilation isolation system. Engineered safety features actuation system action will be manually initiated for this section since it is not required immediately after a DBA. Sufficient information is provided to allow the operator to make a timely decision as to system operating requirements.

C. Criterion 22: Protection System Independence

Independence is ensured through the redundance and diversity described in paragraphs 7.3.1.1.6 and 7.3.1.1.7. Two independent sensor channels are provided for the one-out-of-two ESFAS inputs. Two independent output paths are provided for the one-out-of-two ESFAS outputs.

NSSS ESFAS

Appendix A, 10CFR50, "General Design Criteria for Nuclear Power Plants," established minimum requirements for the principle design criteria for water cooled nuclear power plants. This section describes the requirements that are applicable to the ESFAS. Most references will be to Section 3.1 where the criteria are first addressed. Section 7.2.2.3.1 will be referenced if other comments from the RPS are applicable.

Criterion 1 - Quality Standards and Records:

Refer to Section 3.1.1 for compliance.

Criterion 2 - Design Bases for Protection Against Natural Phenomena:

Refer to Section 3.1.2 for compliance.

Criterion 3 - Fire Protection:

Refer to Section 3.1.3 for compliance

Criterion 4 - Environmental and Missile Design Bases:

Refer to Section 3.1.4 for compliance.

Criterion 13 - Instrumentation and Control:

Refer to Section 3.1.9 for compliance. Variables monitored are those which affect ESF Systems.

Criterion 16 - Containment Design:

Refer to Section 3.1.12 for compliance.

Criterion 20 - Protective System Functions:

Refer to Section 3.1.16 for compliance.

Criterion 21 - Protection System Reliability and Testability:

Refer to Section 3.1.17 for compliance.

Criterion 22 - Protection System Independence:

Refer to Section 3.1.18 for compliance.

Criterion 23 - Protection System Failure Modes:

Refer to Section 3.1.19 for compliance.

From the PPS cabinet the signals are sent to two ESFAS Auxiliary Relay Cabinets. In each cabinet is the selective actuation logic for each train. There is no interconnection between the two Auxiliary Relay Cabinets or the trains they actuate so that train A is completely independent of train B.

Criterion 24 - Separation of Protection and Control Systems:

Refer to Section 3.1.20 for compliance.

Criteria 34, 35, 37, 38, 40, 41, 43, 44 and 46:

Refer to Sections 3.1.30, 31, 33, 34, 36, 37, 39, 40 and 42 for compliance.

The ESFAS provides the actuation which meets the requirements of IEEE 279-1971 and IEEE 338-1971. The single failure criterion is met for all ESFAS. The ESFAS is fully testable. Those components which cannot be tested during power operations are tested when the plant is shutdown.

7.3.2.3.2 Equipment Design Criteria

BOP ESFAS. IEEE Standard 279-1971 establishes minimum requirements for safety-related functional performance and reliability of the ESFAS. The following additional paragraphs provide the IEEE 279, Section 4, criteria numbers and titles followed by an explanation as to how they are satisfied.

4.2 Single Failure Criterion

The one-out-of-two ESFAS is designed so that any single failure within the protection system shall not prevent proper protective action at the system level when required. No single failure will defeat more than one of the two protective channels associated with any one trip function.

Although no single failure will defeat more than one of the two protective channels, a single failure may cause spurious actuation. However, this spurious actuation is allowable since it does not create plant conditions requiring protective action nor does it interfere with normal reactor operations.

A complete analysis of single failures for one-out-of-two is presented in tables 7.3-14 through 7.3-17. The worst case single failure is the failure of a group actuation relay to

deenergize. This condition causes loss of one of the two redundant sets of associated ESF equipment.

4.10 Capability for Test and Calibration

Testing is described in paragraph 7.3.1.1.8 and is in compliance with IEEE 338 as discussed in paragraph 7.3.2.3.3.

4.11 Channel Bypass or Removal from Operation

Testing of the one-out-of-two ESFAS is done by channel actuation. Either one of the two channels may be calibrated or repaired without detrimental effects on the system. Individual trip channels may be bypassed to effect a single channel logic on the ESFAS signal. Maintenance and calibration of the bypassed channel can be accomplished in a short time interval. Probability of failure of the remaining channel is acceptably low during such maintenance periods.

4.12 Operating Bypasses

There are no operating bypasses.

4.15 Multiple Setpoints

There are no multiple setpoints.

4.21 System Repair

Identification of a defective channel will be accomplished by observation of system status lights or by testing as described in paragraph 7.3.1.1.8. Replacement or repair of components in the actuation logic is accomplished with the affected channel bypassed. The affected trip function then operates in a single active channel trip logic.

NSSS ESFAS

Many of the design criteria for protection systems are discussed in section 7.1.2. IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes minimum requirements for safety-related functional performance and reliability of the ESFAS. This section describes how the requirements of Section 4 of IEEE 279-1971 are satisfied. The following heading numbers correspond to the section numbers of IEEE 279-1971.

4.1 General Functional Requirements

The ESFAS is designed to actuate the appropriate ESF Systems, when required, to mitigate the consequences of the specified Design Basis Events. Instrument performance characteristics, response times, and accuracies are selected for compatibility with, and adequacy for, the particular function. Actuation setpoints are established by analysis of the RCS parameters, steam generator parameters and containment pressure. Factors such as instrument inaccuracies, bistable trip delay times, valve travel times and pump starting times, are considered in establishing the margin between the actuation setpoints and the safety limits. In addition, the possible loss of AC power and the time required to start standby power and to sequence loads must also be considered. The final determination of all of these times is the Applicant's responsibility. The time response of the sensors or protection systems are evaluated for abnormal conditions. Since all uncertainty factors are considered as cumulative for the derivation of these times, the

actual response time may be more rapid. However, even at the maximum times, the system provides conservative protection.

4.2 Single Failure Criterion

The ESFAS is designed so that any single failure within the system will not prevent proper protective action at the system level. No single failure will defeat more than one of the four protective channels associated with any one trip function.

The effects of single faults in the RPS are discussed in section 7.2.2.3.2. A similar analysis is applicable to that portion of the ESFAS located in the PPS cabinet. The initiating signal from the PPS goes to two separate ESFAS Auxiliary Relay Cabinets. Each cabinet contains the actuation circuitry and group relays for each train, therefore, a failure in one cabinet cannot affect the circuitry and actuated equipment of the other cabinet.

Single faults of initiation relay or actuation relay buses have no effect, as a selective two-out-of-four logic is required for actuation.

Single faults of the actuation (or control) circuitry will cause, at worst, only a failure of a component, group of components, or actuation of a system within one of the two redundant actuation trains; actuation of the remaining redundant train components is sufficient for the protective action.

4.3 Quality Control of Components and Modules

The system is designed in accordance with the Topical Report CENPD-210A, "Description of the C-E Nuclear Steam Supply System Quality Assurance Program" (Reference 4).

4.4 Equipment Qualification

The ESFAS equipment is qualified in accordance with the methodology discussed in Sections 3.10 and 3.11.

4.5 Channel Integrity

Type testing of components, separation of sensors and channels, and qualification of cabling are utilized to ensure that the channels will maintain their functional capability required under applicable extremes of environment, power supplied, malfunction, and DBE conditions. Loss or damage of any one path will not prevent the protective action of the ESFAS. Sensors are piped using materials of comparable quality to the systems to which they are attached so that, in the unlikely event of blockage or failure of any one connection, protective action is not prevented. The process sensors located in the containment building are specified and rated for the intended service. Components which must operate during or after DBEs are rated for the expected post-event environment. Results of type tests are used to verify these ratings.

The separation requirements for the components not within the CESSAR Licensing scope are discussed in section 7.3.3 "Engineered Safety Features Actuation System Interface Requirements".

4.6 Channel Independence

The location of the sensors, for the ESFAS, and the points at which the sensing lines are connected to the process loop have been selected to provide physical separation of the channels within the system, thereby precluding a situation in which a single event could remove or negate a protective action. The routing of cables from protection system transmitters is arranged so that the cables are separated from each other, and from power cabling, to minimize the likelihood of common event failures. This includes separation of the containment penetration areas. The initiation paths are located in four bays of the PPS cabinet and the actuation devices are fed from the two ESFAS Auxiliary Relay Cabinets. Mechanical and thermal barriers within these cabinets minimize the possibility of a common mode failure. Common mode failure is addressed in Topical Report CENPD-148, "Review of Reactor Shutdown System (PPS Design) for Common Mode Failure Susceptibility" (Reference 5).

The output from these redundant channels are isolated from each other so that loss of a channel does not cause loss of the system. The signals from the ESFAS which supply the PMS are isolated at the PMS input. The ESFAS annunciators are isolated as necessary to ensure the ESFAS maintains its channel independence.

The criteria for separation and physical independence of channels are based on the need for decoupling the effects of DBE consequences and power supply transients, and for reducing

the likelihood of channel interaction during testing or in the event of a channel malfunction.

4.7 Control and Protection System Interaction

4.7.1 Classification of Equipment

No portion of the ESFAS is used for both protective and control functions.

4.7.2 Isolation Devices

Signals sent from the ESFAS to the PMS are isolated at the PMS and annunciators are isolated at the annunciators such that a failure in these areas will not affect the protective action of the ESFAS.

4.7.3 Single Random Failure

This criterion is not applicable since there are no channels used for both control and protection. Therefore a single random failure can only occur in either a control or a protection channel.

4.7.4 Multiple Failures Resulting from a Credible Single Event

This cannot exist because control and protection channels have nothing in common.

4.8 Derivation of Signal Inputs

Insofar as possible, inputs are derived from signals that are direct measurements of the desired variable. Directly measured variables include pressurizer, containment, and steam generator pressures. The steam generator and refueling water tank levels

are derived from differential pressure signals. The differential between the steam generator pressures, for the AFAS, is a calculated value.

4.9 Capability for Sensor Checks

ESFAS sensors are checked by cross-channel comparison. Each channel has a known relationship with the other channels of the same parameter.

4.10 Capability for Test and Calibration

The ESFAS design complies with IEEE 338-1971, "Trial-Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection System Actuation Functions," as discussed in section 7.3.2.3.3.

4.11 Channel Bypass or Removal from Operation

Any one of the four protection channels in the ESFAS may be tested, calibrated, or repaired without detrimental effect on the system. Individual actuation channels (i.e., pressurizer pressure, containment pressure, steam generator level) may be bypassed to create a two-out-of-three logic while maintaining the coincidence of two on the remaining channels. The single failure criterion is met during this condition.

4.12 Operating Bypasses

Operating bypass is provided as shown on Table 7.3-1c. The operating bypass is automatically removed when the permissive condition is not met. The circuitry and devices which function to remove this inhibit are designed in accordance with IEEE 279-1971.

4.13 Indication of Bypasses

Indication of test or bypass conditions, or removal of any channel from service is given by annunciators. The operating bypass that is automatically removed at a fixed setpoint, is alarmed and indicated.

4.14 Access to Means for Bypassing

Trip channel bypasses have access controlled by means of key locked doors. When the first parameter is bypassed there is an audible and visible alarm to indicate which channel is being bypassed. The specific parameter or parameters which are being bypassed are indicated by lights at the PPS cabinet and its remote operator's module.

The operating bypasses also have audible and visible alarms. The operating bypasses have automatic features which provide a permissive level at which they can be actuated and a second level at which they are automatically removed.

4.15 Multiple Setpoints

Manual reduction of the setpoints for low pressurizer and low steam generator pressures are used for the controlled reduction of pressures as discussed in sections 7.3.1.1.10.4 and 7.3.1.1.10.5. The setpoint reductions are initiated by main control board pushbuttons for each channel, one pushbutton for the pressurizer pressure and one pushbutton for both steam generator pressures within the one channel. Operation of the pushbutton will reduce the pressure actuation setpoint a selected increment below the existing system pressure. As the pressurizer or steam generator pressure increases the actuation

setpoint will increase automatically with the pressure, maintaining a fixed increment, until the setpoint reaches its normal actuation setpoint value.

4.16 Completion of Protective Action Once It is Initiated

The ESFAS is designed to ensure that protective action will go to completion once initiated. Actuation of an ESFAS can be cleared by the operator manually resetting the ESFAS at the PPS cabinet and the ESFAS Auxiliary Relay Cabinets. A protective action is initiated when the selective two-out-of-four logic reaches the proper coincidence of two state. A protective action is completed when all of the appropriate ESF actuated components have assumed the proper state for their ESF function. The AFAS valves are not locked into its actuation but the pumps are locked in. AFAS is designed to cycle based on the steam generator level signal. When the low level signal clears, the AFAS is lost, until the level drops to the actuation setpoint again.

4.17 Manual Initiation

A manual initiation is effected by operating manual switches in the main control room or at the ESFAS Auxiliary Relay Cabinets. These are arranged in a selective two-out-of-four logic. No single failure will prevent a manual actuation at the system level.

4.18 Access to Setpoint Adjustments, Calibration and Test Points

A key is required for access to setpoint adjustments, calibration and test points. Access is also annunciated. Setpoints are continuously monitored by the PMS.

4.19 Identification of Protective Action

Indication lights are provided for all protective actions, including identification of the channel trips.

4.20 Information Readout

Means are provided to allow the operator to monitor all actuation system inputs, outputs, and calculations. The specific displays that are provided for continuous display are described in Section 7.5.

4.21 System Repair

Identification of a defective channel will be accomplished by observation of system status lights, or by testing as described in section 7.3.1.1.8. Replacement or repair of components is accomplished with the affected channel bypassed. The affected function is then in a two-out-of-three logic, but still maintaining a coincidence of two for actuation.

4.22 Identification

All equipment associated with the actuation system, including panels, modules, and cables, is marked in order to facilitate identification. Interconnecting cabling will be color coded as discussed in section 7.1.3.16. The equipment to be supplied by the Applicant shall have this requirement specified in the interface section.

ONE-OUT-OF-TWO ESFAS
CONTROL ROOM ESSENTIAL FILTRATION ACTUATION SIGNAL
FAILURE MODES AND EFFECTS ANALYSIS (Sheet 3 of 3)

Failure Mode	Effect on System	Detection	Remarks
Output relay mechanically jammed	Loss of system level actuation of one load group	Periodic testing	Other load group available and manual device control fully operable
Output relay fails deenergized	System actuation of one load group	Visual observation of system status	Actuation of one load group

The compliance of the ESFAS to the requirements of IEEE 384-1974, "IEEE Trial-Use Standard Criteria for Separation of Class IE Equipment and Circuits," and Regulatory Guide 1.75, "Physical Independence of Electric Systems," is discussed in section 7.1.2.10.

7.3.2.3.3 NSSS and BOP ESF Testing Criteria

IEEE Standard 338-1971 and Regulatory Guide 1.22 provide guidance for development of procedures, equipment, and documentation of periodic testing. The basis for the scope and means of testing are described in this section. Test intervals and their bases are included in the Technical Specifications. The organization for testing and for documentation is described in chapter 13. Since operation of the ESF system is not expected, the systems are periodically tested to verify operability. Complete channels can be individually tested without violating the single failure criterion and without inhibiting the operation of the systems. The system can be checked from the sensor signal through the actuation devices during reactor operation, except as noted below, since most ESF system actuations do not damage equipment or disturb reactor operation. Thus, testing completely simulates valid actuation. Minimum frequencies for checks, calibration, and periodic testing of the ESFAS instrumentation and control are given in the Technical Specifications.

Additional basis documents for NSSS ESFAS and BOP ESFAS testing criteria include CEN-403, Rev. 1 and the companion NRC SER, NRC Letter from B.A. Boger to CEOG, dated 2/27/1996. The SER

includes criteria developed from a study NUREG-1366, "Improvements to Technical Specifications Surveillance Requirements". The study found that while some testing at-power is essential, 1.) safety can be improved, 2.) equipment degradation decreased, and 3.) unnecessary personnel burden can be prevented by reducing the amount of testing at-power. These three conclusions were formed using the following four criteria that were used to justify changes in surveillance test intervals. These same criteria may be used to justify changes in the surveillance test procedures that control at-power or refueling outage testing of ESFAS relays, "actionuation devices" and "actuated equipment". Criterion that may be used with procedure changes supporting the above conclusions are as follows:

- Criterion 1 – The surveillance could lead to plant transient.
- Criterion 2 – The surveillance results in unnecessary wear to equipment
- Criterion 3 – The surveillance results in radiation exposure to plant personnel not justified by the safety significance of the surveillance.
- Criterion 4 – The surveillance places an unnecessary burden on plant personnel because the time required is not justified by the safety significance of the surveillance.

Most ESF relays are tested during power operation along with all actuated equipment. However, some ESF relays tested

at-power have equipment that cannot be actuated, but can be racked out, bypassed or otherwise prevented from actuating while the actuation device/relay is being tested at-power. This will not preclude the relay from being tested but will not actuate the locked-out equipment associated with the relay. These exceptions are controlled within the surveillance procedures and are acceptable given that one or more of the criteria listed above would potentially be challenged by at-power testing of the actuated equipment. In those instances, the actuated equipment will still be tested in accordance with the test bases in judiciously selected groups during refueling outage tests.

Certain ESF subgroup relays are exempt from testing during at-power operation but shall be tested in accordance with the Technical Specification SR 3.3.6.2 note. These exemptions are controlled within the surveillance procedures and are acceptable because one or more of the four criterion listed above would be challenged by at-power testing. In those instances, the relays will still be tested in accordance with the test bases in judiciously selected groups during refueling outage tests.

The use of individual trip and ground detection lights, in conjunction with those provided at the supply bus, ensure that possible grounds or shorts to another source of voltage will be detected.

The response time from an input signal to protect system trip bistables through the opening of the actuation relays is

verified by measurement during plant startup testing. Sensor responses are measured during factory acceptance tests. Paragraph 7.3.1.1.8.8 provides additional information on response time testing.

7.3.2.4 Failure Modes and Effects Analysis

Refer to CESSAR Table 7.2-5. The failure modes and effects analysis for the additional ESF systems is given in tables 7.3-14 through 7.3-18.

7.3.3 CESSAR ENGINEERED SAFETY FEATURES ACTUATION SYSTEM INTERFACE REQUIREMENTS

The following interface requirements are repeated from CESSAR Section 7.3.3:

The interface requirements discussed below are specific to the ESFAS.

General requirements are discussed in Section 7.1.3. Those items specific to the RPS are discussed in Section 7.2.3.

7.3.3.1 Power

Refer to Section 8.3.

7.3.3.2 Protection from Natural Phenomena

Refer to Sections 3.1.2 and 7.1.3.2.

7.3.3.3 Protection from Pipe Failure

Refer to Section 7.1.3.3.

Table 7.3-18
FAILURE MODES AND EFFECTS ANALYSIS
CONTAINMENT COMBUSTIBLE GAS CONTROL SYSTEM

Failure	Effect on System	Detection	Remarks
Loss of one channel ac control power (motorized valve control)	Loss of redundancy	Immediate--indicator lights	Remaining channel fully functional
Control switch or wiring failure (motorized valve control)			
Open	Loss of redundancy	Periodic testing or spurious operation	Remaining channel fully functional
Short	Spurious operation may occur		Remaining channel fully functional

7.3.3.4 Missiles

Refer to Section 7.1.3.4.

7.3.3.5 Separation

Refer to Section 7.1.3.5.

7.3.3.6 Independence

Refer to Section 7.1.3.6.

7.3.3.7 Thermal Limitations

Refer to Section 7.1.3.7.

7.3.3.8 Monitoring

Refer to Section 7.1.3.8.

7.3.3.9 Operational/Controls

Refer to Section 7.1.3.9.

7.3.3.10 Inspection and Testing

Refer to Section 7.1.3.10.

7.3.3.11 Chemistry/Sampling

Refer to Section 7.1.3.11.

7.3.3.12 Materials

Not applicable to the safety-related instrument and control equipment.

7.3.3.13 System Component Arrangement

Refer to Section 7.1.3.13.

7.3.3.14 Radiological Waste

Refer to Section 7.1.3.14.

7.3.3.15 Overpressure Protection

Refer to Section 7.1.3.15.

7.3.3.16 Related Services

Refer to Section 7.1.3.16.

7.3.3.17 Environmental

Refer to Section 7.1.3.17.

7.3.3.18 Mechanical Interaction

Refer to Section 7.1.3.18.

7.3.3.19 Plant Monitoring System Inputs

Refer to Section 7.1.3.19.

7.3.4 CESSAR INTERFACE EVALUATION

The CESSAR interface requirements listed in subsection 7.3.3 are met by PVNGS design as follows:

7.3.4.1 Power

Refer to subsection 8.3.1.

7.3.4.2 Protection from Natural Phenomena

Refer to paragraph 7.1.4.2.

7.3.4.3 Protection from Pipe Failure

Refer to paragraph 7.1.4.3.

7.3.4.4 Missiles

Refer to paragraph 7.1.4.4.

7.3.4.5 Separation

Refer to paragraph 7.1.4.5.

7.3.4.6 Independence

Refer to paragraph 7.1.4.6.

7.3.4.7 Thermal Limitations

Refer to paragraph 7.1.4.7.

7.3.4.8 Monitoring

Refer to paragraph 7.1.4.8.

7.3.4.9 Operational/Controls

Refer to paragraph 7.1.4.9.

7.3.4.10 Inspection and Testing

Refer to paragraph 7.1.4.10.

7.3.4.11 Chemistry/Sampling

Refer to paragraph 7.1.4.11.

7.3.4.12 Materials

Not applicable

7.3.4.13 System Component Arrangement

Refer to paragraph 7.1.4.13.

7.3.4.14 Radiological Waste

Refer to paragraph 7.1.4.14.

7.3.4.15 Overpressure Protection

Refer to paragraph 7.1.4.15.

7.3.4.16 Related Services

Refer to paragraph 7.1.4.16.

7.3.4.17 Environmental

Refer to paragraph 7.1.4.17.

7.3.4.18 Mechanical Interaction

Refer to paragraph 7.1.4.18.

7.3.4.19 Plant Monitoring System Inputs

Refer to paragraph 7.1.4.19.

7.3.5 DIVERSE AUXILIARY FEEDWATER ACTUATION SYSTEM (DAFAS)

The DAFAS monitors plant conditions and actuates auxiliary feedwater during conditions indicative of an ATWS event and S/G low level conditions. The DAFAS interfaces with the process protective cabinets(PPC), the auxiliary relay cabinet (ARC), and the diverse scram system (DSS). The interface with the DSS is accomplished through a connection with the supplementary protection system (SPS) trip signal in the Class 1E portions of the electronic isolation system (EIS).

There are two channels of DAFAS, train A and train B. The two DAFAS channels are independent and isolated from each other as well as from the interfacing systems noted above by the use of fiber optic data links.

A DAFAS block diagram is shown in figure 7.3-7e.

7.3.5.1 Design Bases and Design Considerations

The PVNGS DAFAS is designed to be a highly reliable system that initiates auxiliary feedwater flow upon conditions indicative of an ATWS combined with selective low S/G level signals. DAFAS will stop AFW flow to the affected S/G after reaching a predetermined level setpoint (about 30 minutes after actuation) at which time manual operator intervention will control the system. The DAFAS is designed to meet the intent of 10CFR50.62 and is diverse and independent from the existing reactor protective system. The DAFAS design further complies with NRC guidance provided with 10CFR50.62 and the quality assurance requirement of Generic Letter 85-06. Compliance with the

guidelines are integrated into the design for PVNGS DAFAS as discussed below.

7.3.5.1.1 Safety Related (IEEE-279)

The DAFAS is not required to be safety related. However, the implementation of DAFAS is such that the existing protection system continues to meet all applicable safety related criteria.

The DAFAS consists of several equipment groups. The DAFAS sub-assembly in the process protective cabinets (J-SBA-C02A, J-SBB-C02A, J-SBC-C02A and J-SBD-C02A), the DAFAS cabinets (J-SAA-C05 and J-SAB-C06), the DAFAS sub-assembly in the auxiliary relay cabinets (J-SAA-C01 and J-SAB-C01), and the DAFAS sub-assembly in the electronic isolation system (EIS) cabinets (J-SAA-C04, J-SAB-C04, J-SAC-C04 and J-SAD-C04). The DAFAS equipment in the PPC, ARC and EIS cabinets are considered safety related equipment since they interface directly with class 1E systems. The DAFAS equipment in the existing 1E cabinets are designed, constructed, and installed in accordance with the requirements for PVNGS safety related equipment.

The DAFAS cabinets are considered safety related. They are designed, constructed, and installed in accordance to the requirements for PVNGS safety related equipment which exceeds requirements of 10CFR50.62. However, the DAFAS does not have a manual trip and utilizes the manual trip capability of the existing AFAS. PVNGS has elected to classify the DAFAS as a safety related system to provide enhanced functionality and availability.

The DAFAS power supplies that power the fiber optic transmitters (FOTs) and receivers (FORs) are grounded. The justification for the grounding of the power supplies is discussed below.

IEEE-279 requires that each redundant channel of a safety system be independent from its redundant counterpart. Independence is measured by the ability of a redundant system to perform its function when confronted by a credible "single failure." The single failure, if it compromises the function of the safety system, must be able to be detected by periodic testing. From these criteria, it can be seen that grounding the power supply that powers the fiber optic transmitters and receivers does not compromise the independence of the DAFAS. Postulated single failures, that are credible for the DAFAS in terms of fault voltage and energy, will, at worst, cause a channel failure that is either self annunciating or detectable during periodic testing. There is no failure or fault in the DAFAS that prevent the system from performing its intended function.

7.3.5.1.2 Redundancy

Redundancy alone does not preclude common mode failure occurrences. Therefore, there are no requirements for redundancy of the DAFAS. However, the system should be reliable and minimize the possibility of spurious actuation. PVNGS has elected to install a two train DAFAS for PVNGS units 1, 2, and 3 to increase system reliability and decrease the probability of spurious actuation. The installation of a two

train system also permits testing at full power, allowing the remaining DAFAS channel to provide a measure of protection.

7.3.5.1.3 Physical Separation From Existing Reactor Protective System

DAFAS physical separation from existing reactor protective system is not required unless redundant divisions and channels in the existing reactor protective system are not physically separated. The DAFAS implementation must be such that separation criteria applied to the existing protection system are not violated.

DAFAS physical separation from the existing PPS is provided. The DAFAS is isolated via qualified fiber optic devices and is physically and electrically separate from the existing PPS. The DAFAS does not degrade the existing separation criteria of the PPS or the ARC cabinets. Physical separation is maintained and electrical protection is provided for the channel (division) A, B, C and D vital instrument busses providing power to the DAFAS ARC control panel assemblies. The DAFAS ARC control panels are part of the train (division) A or B ARC in which they are located. The required isolation is provided by the circuit breakers in the ARC. These isolation devices have been evaluated as acceptable per IEEE-384, 1981, by calculation 13-JC-SA-202.

7.3.5.1.4 Seismic Qualification (IEEE-344)

The DAFAS equipment mounted inside the PPC, EIS and ARC cabinets are tested and qualified to meet or exceed the seismic

qualification criteria of the existing cabinets so that the qualification of the existing safety related cabinets remain valid. Although the DAFAS system is not required to be Class 1E qualified, the DAFAS equipment will be constructed and mounted consistent with the existing requirements of PVNGS Class 1E safety related equipment. DAFAS equipment will be tested and qualified in accordance with IEEE-344, 1975 to enhance the system performance and reliability.

7.3.5.1.5 Environmental Qualification (IEEE-323)

The DAFAS equipment is not located in a harsh environment. Therefore, environmental qualification requirements of 10 CFR 50.49 are not applicable. However, the equipment inside the DAFAS cabinets and the DAFAS equipment housed inside the PPC, ARC and EIS cabinets will be qualified for the environmental conditions inside the cabinets resulting from AOO's. The environmental qualification is in accordance with IEEE-323, 1974.

7.3.5.1.6 Quality Assurance For Test, Maintenance And Surveillance

Compliance with Generic Letter 85-06 is addressed in section 7.3.5.1.12. Testing, maintenance and surveillance are addressed in section 7.3.5.1.8 below.

7.3.5.1.7 Safety Related Power Supply

The power required to operate the DAFAS is provided by the following sources:

- Two Class 1E 120 VAC vital instrument buses Channel A to the DAFAS A cabinet and Channel B to the DAFAS B cabinet.
- The four existing cabinet Class 1E power sources (A, B, C and D) in the EIS, PPC and ARC.

The power required for the DAFAS cabinets and the DAFAS sub-assembly mounted inside the ARC cabinets is supplied from the 120 VAC vital instrument buses. The 120 VAC vital buses are required to supply power to its respective DAFAS equipment channel. The power required for the DAFAS sub-assembly mounted inside the EIS cabinets is supplied by the existing 24 VDC power supplies in the EIS cabinets. The use of existing DC power supplies was considered to minimize the space required for interfacing with the existing plant equipment. In such cases, a load calculation was performed to verify that the additional load required by the DAFAS would not cause an overload condition to exist.

Power supply faults such as over-voltage and under-voltage conditions, degraded frequencies, and over-current will not compromise the RPS, AFAS or safety related equipment in the ARC cabinets. Loss-of-power to a DAFAS train will cause the "DAFAS Trouble" alarm in the control room. The vital 120 VAC system faults are alarmed in the control room along with battery charger and inverter faults. The control room alarms

provide for early detection of degraded voltage and frequency conditions to allow for operator corrective action while the affected circuits/components are still capable of performing their intended functions.

7.3.5.1.8 Testability At Power

The DAFAS provides for both on-line and off-line testing. The on-line testing of the system is performed one train at a time, and is manually initiated at the DAFAS, and the Auxiliary Relay Cabinets.

The DAFAS cabinet testing involves testing the logic system. Testing at the ARC cabinets involves verifying proper operation of the DAFAS circuitry and the initiation relays. The DAFAS total functional testing and calibration will be performed prior to operation to demonstrate that the hardware and software conform to the design specifications. The DAFAS equipment will be periodically tested and calibrated to ensure that the testing requirements established by PVNGS are satisfied. The measuring and test equipment which will be used to determine the DAFAS functionality will be controlled in accordance with existing procedures. A system level test will be conducted each refueling outage, which will consist of functional testing from the sensor output to and including the DAFAS initiation relays. This test will include a check of the input calibration, simulating the inputs, verifying DAFAS initiations, bypasses and alarms.

Maintenance and test bypasses for the DAFAS will not involve installing jumpers, lifting leads, pulling fuses or other

circuit modifications. The test bypasses will be provided as an integral part of the DAFAS design.

7.3.5.1.9 Diversity From Existing Reactor Protective System (RPS)

The equipment used in the design of the DAFAS is entirely diverse from the existing PPS (plant protection system) except for the S/G level sensors and the final actuation devices, both of which are not required to be diverse in accordance with the ATWS Rule and guidance. The DAFAS uses programmable logic controllers with solid state I/O modules as compared to the PPS which uses analog bistable trip units to perform the same function. The DAFAS uses fiber optic communication links to receive and transmit signals to and from its distributed DAFAS subsystems.

The DAFAS final interface devices with the AFAS are the DAFAS initiation relays located on the DAFAS ARC control panel assemblies in the auxiliary relay cabinet. These relays energize to actuate auxiliary feedwater flow while the existing AFAS is a de-energize to actuate system. These relays are of a different manufacturer from the existing PPS/RPS initiation relays, and their use, therefore, is diverse from the existing RPS. The DAFAS and AFAS use the same final actuation devices. The final actuation devices are the existing cycling and subgroup relays used to control the pumps and valves in the auxiliary feedwater system.

7.3.5.1.10 Electrical Independence From Existing Reactor Protective System

The power required to operate the DAFAS is provided by Class 1E power sources which are independent channelized sources. The DAFAS logic is isolated from the auxiliary relay cabinet logic, process protective cabinets, and electronic isolation system cabinets through the use of fiber optic isolation which meets the intent of the guidance for isolation between safety related circuits. The NRC has accepted this configuration to be in compliance with the intent of the ATWS Rule (reference 1).

7.3.5.1.11 Inadvertent Actuation

The DAFAS is designed with features to minimize inadvertent actuations and challenges to the safety system. The DAFAS actuation setpoint is set at a level below the existing AFAS setpoint in the PPS and the DAFAS response time will be longer than the PPS AFAS response time in order to prevent the possibility of the DAFAS initiating auxiliary feedwater (AFW) flow before the properly operating PPS. The DAFAS initiates AFW flow upon energizing the DAFAS initiation relays while the AFAS initiates AFW flow upon de-energizing the PPS initiation relays. Both signals deenergize the AFW subgroup and cycling relays. The energize-to-actuate design of the DAFAS initiation relays minimizes relay power failures or I/O system power failures from causing an inadvertent actuation since these relays are normally de-energized.

The DAFAS is blocked by AFAS-1 or AFAS-2 signals, if the DAFAS has not actuated since this would indicate normal protection system operation and therefore no need for this ATWS mitigation system actuation. If DAFAS actuates before an AFAS, the DAFAS protection signal will go to completion as required by IEEE-279, unless blocked by an MSIS. The MSIS signals will block a DAFAS actuation prior to, during or after a DAFAS actuation in order to prevent interference with the MSIS capability for S/G high energy line break protection. When the PPS initiates AFAS or MSIS, indicating that PPS is operating normally and that conditions for an ATWS do not exist, blocking logic is activated which disables the DAFAS initiation relay. The DAFAS is further blocked until a selective 2/4 diverse scram system (DSS) logic matrix is satisfied, such that the DAFAS can operate only if a DSS actuation is in progress.

If an inadvertent actuation of the DAFAS were to occur, thus initiating AFW flow, an increase in feedwater flow to the steam generator secondary side could result. Although undesirable, this event has been considered in the analysis of the plant in section 15.1.2, Increase in Feedwater Flow.

7.3.5.1.12 Conformance to Generic Letter 85-06

Generic Letter 85-06 was issued by the NRC to provide explicit quality assurance (QA) guidance required for non-safety related ATWS equipment. The PVNGS DAFAS is in compliance with the QA guidance of this generic letter by invoking on PVNGS the requirements of a 10CFR50, Appendix B, QA program on the DAFAS and its equipment.

7.3.5.1.13 Conformance to ANSI 45.2.11

The DAFAS was designed in accordance with the PVNGS configuration management program. In addition, ABB-Combustion Engineering (ABB-CE) support was performed in accordance with the ABB-CE Quality Assurance Manual (QAM-100) which complies with ANSI/ASME NQA-1-1983 which is based on the contents of ANSI/ASME N45.211-1977

7.3.5.1.14 Conformance to 10CFR50, Appendix A

The DAFAS is designed in compliance with the applicable criteria of the NRC, "General Design Criteria for Nuclear Power Plants," 10CFR50 Appendix A.

7.3.5.1.15 Conformance to 10CFR50, Appendix B

The DAFAS was designed in accordance with the PVNGS configuration management program. In addition, ABB-CE provided support using their quality assurance program (QAM-100) and is in compliance with the NRC, "Quality Assurance criteria for Nuclear Power Plants and Fuel Reprocessing Plants," 10CFR50, Appendix B.

7.3.5.1.16 Conformance to Regulatory Guide 1.75

The DAFAS design is in compliance with the "Physical Independence of Electrical System", Regulatory Guide 1.75.

7.3.5.1.17 Conformance to Regulatory Guide 1.22

The DAFAS is in compliance with Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Function", in conjunction with the current AFAS actuation devices.

7.3.5.1.18 Conformance to Regulatory Guide 1.53

The DAFAS is in compliance with Regulatory Guide 1.53, "Application of the Single-Failure Criterion to Nuclear Power Plant Protection System."

7.3.5.1.19 Conformance to IEEE-338, 1971

The DAFAS system testing conforms to the IEEE-338 Standard, "Trial-Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems."

7.3.5.1.20 Conformance to IEEE-384

The DAFAS fiber optic and internal module connection wiring conforms to IEEE-384, 1981, "Criteria for Independence of Class 1E Equipment and Circuits." The interfaces with the DAFAS in the PPC, EIS and ARC are also in compliance with this standard.

7.3.5.1.21 Conformance to IEEE-379

The DAFAS is in compliance with the applicable criteria of IEEE-379, 1977, "Application of the Single Failure Criterion to Nuclear Power Generating Station Class 1E System."

7.3.5.2 Functional Description of the DAFAS

The DAFAS actuation mitigates the consequence of an ATWS event. This consequence is high RCS pressure due to reduced heat removal through the S/Gs. The DAFAS actuation is provided following an ATWS, which is characterized as an Anticipated Operational Occurrence (AOO) requiring auxiliary feedwater, coincident with a failure of the PPS to initiate a reactor trip. Failure of the PPS is indicated by a reactor trip initiated on high-high pressurizer pressure by the supplementary protection system (SPS), also known as (AKA) the supplementary protection logic assemblies (SPLA), AKA the diverse scram system (DSS). The DAFAS initiation signals cause actuation of the auxiliary feedwater systems (train A and B) only if there is a demand for auxiliary feed as indicated by low S/G level, and there is an SPS initiated reactor trip, and there is no MSIS and an AFAS-1 or -2 has not been generated by the PPS. Indication of an MSIS or an AFAS in the PPS concurrent with the absence of an enable from the DSS indicates that conditions indicative of an ATWS have not occurred and the DAFAS actuation is not necessary. Therefore, under these conditions the DAFAS actuation will be blocked through DAFAS logic in the auxiliary Relay Cabinets.

7.3.5.2.1 DAFAS Input

The DAFAS uses four existing wide range safety channels (A, B, C and D) level sensor inputs from each of the two steam generators at the process protective cabinets (PPC) JSBA-C02A, JSBB-C02A, JSBC-C02A and JSBD-C02A. Each of the DAFAS channels

(A and B) receive these eight steam generator level inputs. These level signals are input to a fiber optic transmitter (FOT) which converts the analog voltage signal to an optical signal. The optical signals are then split by fiber optic splitters (FOS) for transmission to both of the DAFAS cabinets over FO cables. These fiber optics communications links provide the required isolation between the PPC signals (Divisions A, B, C, D) and the DAFAS (Divisions A and B).

Similarly, each DAFAS train also receives indication of the four DSS trip inputs from the four channels A, B, C, and D of the SPS via FO cables. Channels A, B, C and D of the EIS (cabinets J-SAA-CO4, J-SAB-CO4, J-SAC-CO4 and J-SAD-CO4) each contains a FOT and a FOS to transmit the associated DSS permissive signals to each DAFAS train. These signals are input to the digital input modules (DIM's) and the selective two-out-of-four logic is performed by the PLC. Channels A and B of the EIS also contain two FOR modules per channel to receive the status of the respective DAFAS train. One FOR carries the TRIP information while the other contains TEST/TROUBLE status. These signals are transmitted to the plant annunciator via the EIS. These fiber optics communications links provide the required isolation between the EIS signals (Divisions A, B, C, D) and the DAFAS (Divisions A and B).

In the ARC (J-SAA-C01 and J-SAB-C01) the DAFAS logic solvers read status of the relays in the ARC through FO links from the I/O systems located within the ARC. These inputs include AFAS and MSIS cycling relay status, initiation relay status, and bypass relay status. The logic solver output logic controls the

DAFAS initiation and bypass relays. Isolation between divisions is provided in the ARC by similar (to the EIS and PPC) fiber optic communications links. And for the power systems, the DAFAS is isolated by use of circuit breakers on the vital bus feeder cables.

7.3.5.2.2 DAFAS Logic

Each of the two DAFAS cabinets (J-SAA-C05 and J-SAB-C06) contains the logic for one DAFAS train. Each train consists of F.O. receiver (FOR) modules, F.O. modems (FOM), fiber optic transmitter (FOT) modules, power supplies, the status and test panel or man machine interface (MMI), I/O modules, and two programmable logic controllers (PLC). Each of the DAFAS cabinets contains eight FOR modules that convert the optical input signals from the PPC FOT modules to analog voltage signals. The eight (8) analog signals are sent to input modules for the two PLC systems, which perform the logic to determine if conditions for a DAFAS initiation exist. The FOR modules contain a fault indicator LED and contact output that is activated upon loss of the optical signal (e.g., severed F.O. cable). This fault indication is provided to assist in troubleshooting problems that may be encountered with the input signals. The isolated analog input signals (0-5 VDC) are directed to analog input modules where analog to digital (A/D) conversion is performed. Digitized analog values are automatically reported to the PLC upon interrogation during each PLC scan cycle. Analog input modules include self test and auto calibration features to minimize the need for periodic

calibration of inputs. The converted analog values are compared to the low S/G level setpoint in the PLC processor. The PLC generates a DAFAS-1 or DAFAS-2 initiation signal when the setpoint is exceeded, provided the requisite permissives and block conditions previously discussed are satisfied.

Four DSS trip permissive signals, channels A, B, C, and D are received by digital input modules (DIM's) from the EIS. The DAFAS then performs the same selective two-out-of-four logic that is performed by the DSS supplementary protection logic assembly (SPLA). The DAFAS trip output signal is disabled if the DSS logic indicates DSS has not actuated.

The DAFAS PLC outputs are set up as a two-out-of-two logic system where a DAFAS signal from both PLCs is required to initiate auxiliary feedwater flow. Each PLC provides a trip signal to one of the two AFAS trip legs of each ARC. Putting one of the channels into test will not result in initiating feedwater flow as a DAFAS signal from both PLCs is required to cause feedwater flow and the bypass relay contact is enabled prior to cycling each leg's initiation relay by the automated test features in the MMI. A DAFAS signal from one of the PLCs results in only one ARC trip leg, 1-3 or 2-4, to be tripped. However, both trip legs are required to be tripped in order to drop out the subgroup relays resulting in feedwater flow.

The DAFAS initiation signals cause actuation of the feedwater pumps and valves only if there is a demand for auxiliary feedwater and an AFAS or MSIS has not been generated. The occurrence of AFAS without the DSS enable indicates that

conditions indicative of an ATWS have not occurred and DAFAS actuation is not necessary. Under these conditions, DAFAS actuation is blocked by AFAS through logic in the ARC's.

DAFAS will also be blocked by a MSIS to prevent undesired interactions during non-ATWS events when conditions for a MSIS exist. The MSIS signals initiate isolation of each steam generator to rapidly terminate blowdown and feedwater flow if a high energy line rupture occurs. The MSIS block of DAFAS is done to minimize interference with this type event by preventing DAFAS initiated auxiliary feedwater flow.

The overall logic is shown in figure 7.3-7f.

7.3.5.2.3 DAFAS Output

The auxiliary relay cabinet (ARC) DAFAS equipment includes four I/O systems, two interfacing with DAFAS A (PLC-A1 and PLC-A2) and two with DAFAS B (PLC-B1 and PLC-B2). The I/O systems consist of FOMs, high speed logic solver (HSLS) assemblies with a discrete input and output capacity, initiation relays, bypass relays and power supplies. The I/O systems are located in Bay 5 and Bay 8 of each ARC. The I/O systems receive inputs from the DAFAS cabinet through a serial F.O. data link. The HSLS then generates discrete outputs which control the DAFAS-1 and DAFAS-2 initiation and bypass relays. The bypass relays may be activated through the HSLS using a key-lock switch or by the MMI during a manually initiated automated test. The I/O system also acquires inputs and makes them available to be read by the PLC through the serial data link. The inputs include AFAS-1, AFAS-2, MSIS, as well as initiation and bypass relay status.

DAFAS initiation demand is directed to the ARC via RS-232 F. O. data links. The data links are supported by ASCII/Basic modules in the PLC chassis. The trip demand is received by the HSLS which energizes the initiation relay thereby interrupting power to the existing 1-3 or 2-4 trip paths. These HSLS also accept AFAS and MSIS actuation status signals from the ARC logic to block a DAFAS actuation as required.

7.3.5.3 DAFAS Diversity From Existing Reactor Protective System

Refer to Section 7.3.5.1.9

7.3.5.4 Failure Modes and Effects

As previously discussed, the DAFAS is designed to be a highly reliable system and the equipment used in the system will be qualified to the requirements of PVNGS Class 1E safety related equipment. The qualification includes seismic, environmental, electro-magnetic interference (EMI) and fault testing. The DAFAS design includes circuits that allow the plant operators to periodically test the overall operational status of the system. Controls and indicators located on the DAFAS test and control panel permit actuation of one train at a time to demonstrate the functionality of the components in that train. Any failures of the DAFAS will be detected during periodic testing of the system.

The provisions inherent in the DAFAS design which compensate for component failures include the following:

- The redundancy provided by the four S/G level signal paths which permit the system to still function in the event of a channel failure.
- The redundant PLCs within each DAFAS channel. Two-out-of-two ARC initiation logic which minimizes inadvertent operation of the system and is compatible with the existing ARC logic scheme in the event of a spurious actuation signal.
- Power is required for the energize-to-actuate DAFAS initiation relays. Therefore, the relay and the system are normally in a similar mode to the failure mode, which is consistent with the ATWS guidance.
- There is an interlock between the DAFAS and the AFAS which prevents activation of the DAFAS if the AFAS has been activated.
- There is a selective two-out-of-four permissive signal from the DSS which enables the DAFAS for a condition of abnormally high RCS pressure.
- There is a DAFAS inhibit on a MSIS which prevents actuation of the DAFAS in the event of a S/G high energy line break.

The DAFAS is designed so that any single failure within the system will not prevent protection action at the system level. No single failure will defeat more than one of the two DAFAS

trains. The failure modes analyzed for the design of the DAFAS include DAFAS initiation relay failure to actuate, and DAFAS inadvertent actuation. These failure modes are discussed below.

7.3.5.4.1 DAFAS Initiation Relay Failure to Actuate

A failure to actuate either a train A or train B DAFAS initiation relay (mounted in the ARC cabinets J-SAA-C01 or J-SAB-C01) could be caused by the following component failures:

- Failure of the fiber optic modems or cables used for transmitting input and output signals to the DAFAS cabinets.
- Failure of one of the programmable logic controllers (PLC) or supporting equipment located in either one of the two DAFAS cabinets.
- Failure of one of the HSLS modules located in the ARC cabinets.

A single failure described above could result in disabling one of the two DAFAS trains. Each of the two DAFAS trains is capable of performing the intended function of the system. The DAFAS initiation relay which is added to the ARC cabinets has its output contact located in series with a string of relay contacts. These contacts are normally held closed and open to initiate auxiliary feedwater flow. The added DAFAS relay contacts are closed when the relay is not energized. The failures with the highest probability for one of the DAFAS trains would leave the DAFAS relay in the de-energized state

(contacts closed) and thereby have no effect on the normal operation of AFAS, nor would this cause an inadvertent actuation of auxiliary feedwater flow. Therefore, the postulated failure is in a safe direction.

7.3.5.4.2 DAFAS Inadvertent Actuation

As discussed in section 7.3.5.1.11, the DAFAS is designed with features to minimize inadvertent actuations. However, per the Standard Review Plan (NUREG 0800 Sections 7.1, 7.3 and 7.7) and IEEE-279 and IEEE-379, it is required to assume the DAFAS will fail to a mode which will result in a DAFAS actuation signal at the system level.

If an inadvertent actuation of the DAFAS were to occur, thus initiating auxiliary feedwater flow, an increase in feedwater flow to the steam generator secondary side could result. Although this event has been considered in the analysis of the plant (section 15.1.2, Increase in Feedwater Flow), it is undesirable, and the addition of another auxiliary feedwater initiation system will increase the probability of the occurrence of the event. However, the number of system interlocks has provided sufficient protection from inadvertent actuation. The NRC has concluded in a Safety Evaluation (reference 1) that this design is acceptable.

7.4 SYSTEMS REQUIRED FOR SAFE SHUTDOWN

A listing of systems fulfilling the functional requirements for safe shutdown in the event of a fire (per 10CFR50, Appendix R) is provided in appendix 9B.

The instrumentation and control functions which are required to be aligned for maintaining safe shutdown of the reactor are discussed in this section. These functions will permit the necessary operations that will:

A. Prevent the reactor from achieving criticality in violation of the Technical Specifications.

B. Provide an adequate heat sink such that design and safety limits are not exceeded.

7.4.1 DESCRIPTION

The following systems are required for safe shutdown of the reactor:

- Auxiliary feedwater system (AFS) (paragraph 7.4.1.1.6)
- Atmospheric steam dump system (ASDS) (paragraph 7.4.1.1.7)
- Shutdown cooling system (SCS) (paragraph 7.4.1.1.8)
- Chemical and volume control system (CVCS), boron addition portion (paragraph 7.4.1.1.9)
- Condensate storage system (CSS) (subsection 9.2.6)

The following auxiliary support systems are also required to function.

- Essential spray pond system (ESPS) (subsection 9.2.1 and paragraph 7.4.1.1.4)
- Essential cooling water system (ECWS) (subsection 9.2.2 and paragraph 7.4.1.1.5)
- Onsite power system (OPS) (paragraph 8.3.1.1.2), including diesel generator systems (DGSs) (subsections 9.5.4 through 9.5.8 and paragraph 7.4.1.1.1)
- Heating, ventilating, and air conditioning (HVAC) systems (sections 6.4 and 9.4)

7.4.1.1 System Description

7.4.1.1.1 Emergency Generators

Two independent, 100% capacity diesel generators provide a dependable onsite power source capable of starting and supplying the essential loads necessary to shut down the plant safely and to maintain it in a safe shutdown condition under loss of offsite power (LOP) conditions (voltage degradation to the 4.16 kV ESF bus). Load sequencers are provided to sequentially load the diesel generators and are a part of the engineered safety features (ESF) system actuation.

The diesel generators are started automatically by a loss of offsite power (LOP), by an auxiliary feedwater actuation signal (AFAS), by a safety injection actuation signal (SIAS), or by a

containment spray actuation signal (CSAS). All are DG emergency mode starts with the exception of CSAS, which starts the DG in test mode. A LOP also initiates automatic load sequencing of the diesel generators.

The actuation system instrumentation and controls for the diesel generators are described below. Refer to paragraph 8.3.1.1.3 for a description of the ESF power system, including automatic load shedding and load sequencing. Paragraph 8.3.1.1.4 describes the standby power supply (diesel generator) and the diesel generator starting system is described in subsection 9.5.6. Additional information on diesel generator supporting auxiliaries may be found in subsections 9.5.4, 9.5.5, 9.5.7, and 9.5.8.

A. Sensors

The undervoltage monitors consist of four sensor circuits for each 4.16 kV ESF bus. The components and operation of the undervoltage monitors are described in section 8.3.1.1.3.13, subsection B.

The sensors for AFAS, CSAS and SIAS signals are described in section 7.3.

B. Initiating Circuits and Logic

The undervoltage starting signal (LOP) for the diesel generators is produced by coincidence of two-out-of-four trip of the undervoltage sensors described in section 8.3.1.1.3.13, subsection B.

There is no time delay in initiating start of the diesel generator for loss of offsite power except for an inverse time response lag and delayed time lag provided in the undervoltage monitors. Manual starting control also is provided at the diesel generator and in the control room to facilitate testing.

C. Interlocks and Bypasses

The various interlocks and actuation bypasses built into the diesel generator system are presented in paragraphs 8.3.1.1.4.4 and 8.3.1.1.4.5, respectively.

D. Redundancy

Redundant sensing with two-out-of-four coincidence logic and control is provided for diesel generator automatic actuation. Independent actuation is provided so that each diesel generator is started by its own actuation system.

E. Actuated Devices and Automatic Load Sequencing System

The actuated devices for automatic diesel generator starting are the diesel air starting solenoid valves.

In the event that diesel generators are required to power ESF or safe shutdown loads, sequential loading must be employed to avoid diesel generator

overloading. Loads to be supplied and the loading sequences are described in subsection 8.3.1.

Diesel generator load sequencing is actuated when the diesel generator output breakers close. The signal to close the diesel generator output breaker is blocked by circuit breaker interlocks that are provided to prevent automatic closing of a diesel generator breaker to an energized or faulted bus. A faulted bus is detected by inverse time overcurrent relays in the main feeder circuits of each 4.16 kV ESF bus. A sequencer is provided for each load group. The sequencer loads safe shutdown and ESF equipment onto the ESF bus so that essential loads are started within the time limits specified in Table 8.3-3.

Undervoltage trip outputs are delayed in accordance with the inverse time characteristics of the loss of voltage relays and the discrete time delay setting of the degraded voltage relays. These relays are used to confirm that a power failure has occurred. The time delays prevent spurious diesel generator actuation.

Undervoltage on the ESF bus trips all bus load automatically. After the diesel generator attains rated speed and voltage, its own circuit breaker is ready to close automatically without delay, but automatic or manual closure is blocked whenever an

ESF bus fault exists. A diesel generator breaker closed signal starts the loading sequence.

Redundant actuation and control are provided for diesel generator automatic load sequencing in that each load group is provided with its own independent automatic load sequencing system. The time at which energization of the various loads is permitted by the automatic ESF load sequencers is given in table 8.3-3. The automatic ESF load sequencing system is supported by independent 120V vital ac and Class 1E 125 V-dc sources described in paragraphs 8.3.1.1.6 and 8.3.2.1.2. The automatic load sequencing system logic is shown in figure 8.3-1.

7.4.1.1.1.1 Design Bases Information. The design bases for the diesel generator automatic load sequencing are the emergency power source requirements listed in subsection 8.3.1.

Design bases for diesel generator automatic actuation are listed in paragraph 8.1.4.2.

The diagrams used to support the design bases are given by the following:

- Logic diagram, figure 8.3-1
- P&I diagram, 01, 02, 03-M-DGP-001
- Electrical one-line diagram, 13-E-MAA-001 and 01, 02, 03-E-MAA-002

7.4.1.1.2 Emergency Generator Fuel Oil Storage and Transfer System

The controls and instrumentation for this system are discussed in paragraphs 9.5.4.3 and 9.5.4.6. The diagrams used to support the design bases are given by the following:

- Logic diagram, figure 7.4-1
- P&I diagram, 01, 02, 03-M-DFP-001

7.4.1.1.3 Class 1E AC System

This system is described in paragraph 8.3.1.1.3.

7.4.1.1.4 Essential Spray Ponds System

The controls and instrumentation for this system are discussed in paragraphs 9.2.1.6 and 9.2.1.9. The diagrams used to support the design bases are given by the following:

- Logic diagram, 01, 02, 03-M-SPP-001
- P&I diagram, figure 9.2-1

7.4.1.1.5 Essential Cooling Water System

The controls and instrumentation for this system are discussed in paragraphs 9.2.2.1.6 and 9.2.2.1.9. The diagrams used to support the design bases are given by the following:

- Logic diagram, figure 7.4-3
- P&I diagram, 01, 02, 03-M-NCP-001, -002 and -003

7.4.1.1.6 Auxiliary Feedwater System (Emergency Feedwater System) and Condensate Storage System

The safe shutdown features of these systems are discussed in subsections 10.4.9 and 9.2.6, respectively. The controls and instrumentation for the auxiliary feedwater system are discussed in paragraph 7.3.1.1.10.7. The diagram used to support the design bases are given by the following:

- Logic diagram, figure 7.4-4
- P&I diagram, 01, 02, 03-M-AFP-001 and 01, 02, 03-M-CTP-001

7.4.1.1.7 Atmospheric Dump System

The atmospheric dump valves are discussed in subsection 10.3.2. The valves are located outside the containment upstream of the main steam isolation valves.

The valves are used to remove decay heat from the steam generator in the event that the main condenser is unavailable for service for any reason, including a loss of ac power. The decay heat is dissipated by venting steam to the atmosphere. In this way, the reactor coolant system (RCS) can either be maintained at hot standby conditions or cooled down. The system instrumentation and controls for the atmospheric dump valves are described below and are shown on in engineering drawings 01, 02, 03-M-SGP-002 and -001.

A. Initiating Circuits and Logic

   There are no automatic initiating circuits for operation of the atmospheric dump valves.

The atmospheric dump valves are positioned manually by a controller (manual loading station) from either the main control room or the remote shutdown panel as part of the capability for emergency shutdown from outside the control room (see Section 7.4.1.1.10). Each valve has two separate permissive control circuits. Valve position indication is provided at each remote control station. A handwheel is also provided with the atmospheric dump valve for hand operation.

B. Bypasses, Interlocks, and Sequencing

No bypasses, interlocks, or sequencing are provided for the atmospheric dump valves.

C. Redundancy

Atmospheric dump valves are provided to maintain the reactor at hot standby or to initiate a plant cool-down. Two redundant atmospheric dump valves are provided for each steam generator, one per main steam line. However, in the event of failure of these valves, reactor decay heat will be removed through the main steam line safety valves, which will be opened when pressure in the steam generator reaches the pressure relief setpoint. Steam release will continue until the pressure is reduced to the safety valve reset pressure. The safety valves will continue to cycle in this manner as steam generator pressure rises and is relieved. The RCS will remain at hot standby conditions during this pressure relief cycling. Cooldown of the reactor coolant can be

accomplished through remote manual operation of the atmospheric dump valves. Each valve has a handwheel that can be operated locally.

D. Design Bases

1. Refer to section 10.3 for design bases for the atmospheric dump valves.

2. The two separate permissive control circuits are designed to IEEE Standards 279-1971 and 308-1974. This ensures that no single failure of the control circuits will cause a spurious opening of a valve or prevent the operation of at least one atmospheric dump valve on each steam generator.

3. The operation of the atmospheric dump valves is considered in determining the release of iodine due to steam escaping from the dumps during cooldown.

7.4.1.1.8 Shutdown Cooling System

The Shutdown Cooling System (SCS) and its interface requirements are discussed in section 5.4.7. The SCS instrumentation and control necessary to achieve cold shutdown are discussed below. The logic and piping are shown on Figure 7.4-6 and engineering drawings 01, 02, 03-M-SIP-001, -002 and -003.

7.4.1.1.8.1 Initiating Circuits And Logic. The SCS is designed to be manually initiated upon the attainment of the required Reactor Coolant System (RCS) conditions of temperature

(less than 350°F) and pressure (less than 400 psia). The SCS valve interlocks are discussed in Section 7.6; they prevent overpressurization of the low pressure portion of the system.

Control board process indication and status instrumentation is provided to enable the operator to determine system status, to evaluate system performance, and detect malfunctions. Control panel hand switches and valve position limit indication lights are provided for the isolation valves and the heat exchanger inlet, outlet, and bypass valves. Indication is provided of Low Pressure Safety Injection (LPSI) pump discharge header pressure and temperature, heat exchanger outlet temperature, and shutdown cooling injection flow and pressure. LPSI pump operating status is also indicated on the control board.

7.4.1.1.8.2 Interlocks, Sequencing And Bypasses. The SCS has overpressure protection interlocks as discussed in Section 7.6.

The system sequencing will be in approved operating procedures provided by the Applicant for the manually controlled equipment. There are no bypasses in the SCS instrumentation which would jeopardize the protection afforded by the interlocks.

7.4.1.1.8.3 Redundancy And Diversity. Each of the two SCS trains has sufficient instrumentation to assure adequate monitoring during all modes of operation. The isolation valves are discussed in Section 7.6.

7.4.1.1.8.4 Supporting Systems. The SCS has four independent power supplies for the SCS Isolation Valve Interlocks. Pumps, valves, etc. are required to be capable of being powered by the normal 1E and emergency power sources.

Also, refer to UFSAR section 7.6.1.1.1 for SCS interlocks.

7.4.1.1.9 Chemical and Volume Control System (Boron Addition Portion

The boron addition portion of the CVCS is used in the hot and cold shutdown processes. The CVCS is discussed in section 9.3.4. The system instrumentation and controls which are utilized to achieve cold shutdown are described below. The piping and logic are shown in engineering drawings 01, 02, 03-M-CHP-001, -002, -003, -004, -005 and 03-M-GHP-001.

7.4.1.1.9.1 Initiating Circuits And Logic. To aid in achieving cold shutdown the CVCS component actuation steps required are:

A. Coordinated control of the charging pumps, letdown control valves, and letdown back pressure valves to adjust and maintain the correct pressurizer water level;

B. Periodic sampling and adjustment of the boron concentration to compensate for the temperature decrease and other variables until shutdown concentration is reached.

Pressurizer level is automatically controlled during normal operation by the Pressurizer Level Control System (PLCS) as

discussed in section 7.7.1.1.3. The operation of the CVCS system is discussed in section 9.3.4. Boric acid is injected to ensure that sufficient shutdown margin is maintained as the RCS is cooled down. Control board process indication and status instrumentation is provided to enable the operator to evaluate system performance and control system operation manually.

7.4.1.1.9.2 Interlocks, Sequencing And Bypasses. The interlocks, sequence of operation, and bypasses of the CVCS are discussed in section 9.3.4.

7.4.1.1.9.3 Redundancy And Diversity. The CVCS uses multiple signals as discussed in section 9.3.4.

7.4.1.1.9.4 Supporting Systems. The major powered components of the system are required to be capable of being powered from two separate electrical buses.

7.4.1.1.10 Emergency Shutdown from Outside the Control Room

In the unlikely event that the control room should become inaccessible, sufficient instrumentation and controls are provided outside the control room to:

A. Achieve prompt hot shutdown of the reactor (hot shutdown, as used here, means the reactor is subcritical at operating pressure and temperature);

B. Maintain the unit in a safe condition during hot shutdown; and

C. Achieve cold shutdown of the reactor through the use of suitable procedures.

Postulated conditions or events resulting in control room inaccessibility are not defined; however, it is assumed these circumstances are not attended by destruction of any equipment within the control room.

See engineering drawing 13-P-OOB-003 for location of remote shutdown panels.

7.4.1.1.10.1 Hot Shutdown. Sufficient instrumentation and controls are provided external to the control room to achieve and maintain hot shutdown of the reactor should the control room become inaccessible and under the assumption that (1) the operator trips the reactor prior to evacuation from the control room, and (2) that no other adverse consequences occur in addition to the evacuation (i.e., events proceed as expected as a result of a reactor trip). For shutdown outside the control room under postulated 10CFR50, Appendix R considerations, refer to appendix 9B. Hot shutdown, as used here, means that the reactor is subcritical at normal operating pressure and temperature.

Table 7.4-1 lists the instrumentation and controls available at the remote shutdown station on PVNGS.

The atmospheric dump valve manual loading stations and the auxiliary feedwater turbine speed controller are provided with control transfer from the main control room to the remote shutdown panel.

7.4.1.1.10.2 Cold Shutdown. Cold shutdown can be achieved from outside the control room through the use of suitable procedures and by virtue of local control of the equipment listed in tables 7.4-1 and 7.1-2. No further equipment controls are needed to achieve cold shutdown.

7.4.1.2 Design Basis Information

Refer to the design bases discussion in the appropriate section of this chapter. In addition, see section 5.4.7 for discussion of SCS design basis and section 9.3.4 for CVCS design basis.

7.4.1.3 Final System Drawings

Section 1.7 includes a list of applicable electrical and instrumentation drawings and piping and instrumentation diagrams which have been provided. Furthermore, equipment location layout drawings are included in section 1.2. Logic diagrams are shown in figures 7.4-1 through 7.4-4, and 7.4-6.

7.4.2 ANALYSIS

7.4.2.1 Conformance to IEEE 279-1971

IEEE 279-1971, "Criteria For Protection Systems For Nuclear Power Generating Station," establishes minimum requirements for protection systems. The instrumentation and controls associated with the safe shutdown systems are not protection systems as defined in IEEE 279-1971; however, many criteria of IEEE 279-1971 have been incorporated in the design of the instrumentation and controls of the safe shutdown systems. Conformance of the instrumentation and controls to Section 4 of IEEE 279-1971 is discussed below.

The discussion below only pertains to those instrument and control systems and components within the CESSAR Licensing scope.

4.1 General Functional Requirements:

The instrumentation and controls of the safe shutdown systems enable the operator to:

a. Determine when a condition monitored by display instrumentation reaches a predetermined level requiring action; and

b. Manually accomplish the appropriate safety action(s).

4.2 Single Failure Criterion:

The instrumentation and controls required for safe shutdown are designed and arranged such that no single failure can prevent a safe shutdown. Single failures considered include electrical faults and physical events resulting in mechanical damage. Each system is composed of redundant trains, including instrumentation and controls which are physically separated.

4.3 Quality Control of Components:

The instrumentation and controls associated with the safe shutdown systems within the CESSAR Licensing scope are designed in accordance with The Combustion Engineering Topical Report CENPD 210A "Description of C-E Nuclear Steam Supply System Quality Assurance Program."

4.4 Equipment Qualification:

The instrumentation and controls associated with the safe shutdown systems are designed for the normal ambient conditions of the area in which they are located. Those components located in the control room, which is normally air conditioned,

are designed to operate with a loss of air conditioning for the time necessary to achieve safe shutdown.

4.5 Channel Integrity:

Section 14.2 provides description of procedure for pre-operational tests and inspections to verify that all automatic and manual controls, and sequences of the integrated systems provided for safe shutdown, accomplish the intended design function. Essential instrumentation and controls are designed as Seismic Category I to ensure their ability to operate during and following a design basis earthquake.

4.6 Channel Independence:

Safe shutdown instrumentation and control channel independence is achieved by electrical and physical separation. This independence precludes a single event causing multiple channel failures.

4.7 Control and Protection System Interaction:

This does not apply to safe shutdown systems since they are not protection systems and do not interact with protection systems.

4.8 Derivation of System Inputs:

Pressure and temperature are directly measured. Level and flow signals are derived from differential pressure signals. Valve position signals are provided by limit switches. The derivations of various other signals are discussed in the sections where the safe shutdown systems are discussed.

4.9 Capability for Sensor Check:

Sensor checking is discussed in the sections where the safe shutdown systems are discussed.

4.10 Capability for Test and Calibration:

The instrumentation and control components required for safe shutdown which are not normally in operation are capable of being periodically tested. This includes instrumentation and controls for the SCS and CVCS. All automatic and manual actuation devices are capable of being tested to verify their operability. See section 13.5 and the Technical Specifications for periodic testing.

4.11 through 4.14 Bypassing:

There are no bypasses in the instrumentation and controls for the safe shutdown systems that apply to the operation of the safe shutdown systems.

4.15 Multiple Set Points:

This does not apply to the instrumentation and controls for the safe shutdown systems.

4.16 Completion of Protective Action Once it is Initiated:

These are not protection systems and do not take protective action.

4.17 Manual Initiation:

The safe shutdown systems are manually actuated. No single failure in the instrumentation and controls for the safe shutdown systems will prevent achieving a safe shutdown.

4.18 and 4.19 Access to Setpoint Adjustment and Identification of Protective Action:

Do not apply to the instrumentation and controls for the safe shutdown systems.

4.20 Information Readouts:

All safe shutdown system monitoring and control channels have appropriate indicators to provide the operator with sufficient, accurate information to evaluate system performance and to perform necessary actions.

4.21 System Repair:

The safe shutdown systems are actuated manually; therefore, replacement or repair of instrumentation and controls components can be accomplished, in reasonable time, when the systems are not actuated. Outage of system instrumentation and controls components for replacement or repair will be limited by the Technical Specifications.

4.22 Identification:

Identification of redundant channels is as described in sections 7.1.3.16 and 8.3.1.

7.4.2.2 Conformance to IEEE 308-1971

The electrical circuitry of the instrumentation and controls conforms to the criteria of IEEE 308-1971, "IEEE Standard Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations." The instrumentation and controls

associated with systems and components not within the CESSAR Licensing scope are discussed in section 8.3.

7.4.2.3 Conformance to General Design Criterion 19

Conformance to GDC 19 is discussed in section 3.1.15. Remote instrumentation enables hot shutdown to be achieved if the control room is not habitable. Hot shutdown, as used here, means the reactor is subcritical at normal operating pressure and temperature. The reactor can be brought to cold shutdown, outside of the control room, by use of appropriate procedures. See section 6.4 for additional information.

7.4.2.4 Consideration of Selected Plant Contingencies

7.4.2.4.1 Loss of Instrument Air System

None of the essential control or monitoring instrumentation is pneumatic; therefore, loss of instrument air will not degrade instrumentation and control systems associated with systems required for shutdown of the plant.

7.4.2.4.2 Loss Of Cooling Water To Vital Equipment

None of the instrumentation and control equipment relies on cooling water for operation.

7.4.2.4.3 Plant Load Rejection, Turbine Trip, And Loss Of Offsite Power

In the event of loss of offsite power associated with plant load rejection or turbine trip, power for safe shutdown is

provided by the onsite emergency diesel generators. The emergency diesel generators will provide power for operation of pumps and valves; the batteries and emergency diesel generators via the battery chargers will provide power for operation of instrumentation and controls systems required to actuate and control essential components.

7.4.2.5 Emergency Shutdown From Outside The Control Room

Equipment and arrangements discussed in section 7.4.1 are in response to GDC 19 which requires certain functional capabilities outside of the control room, which are met as discussed below.

7.4.2.5.1 Design Capability for Prompt Hot Shutdown and to Maintain Hot Shutdown

Should the control room become inaccessible, the reactor may be manually tripped from the control room, as it is being evacuated, or from the Reactor Trip Switchgear System (RTSS).

Hot shutdown conditions can be maintained from outside the control room as described in section 7.4.1.1.10 by control of pressurizer pressure and level, feedwater flow, and atmospheric steam dump. Hot shutdown, as used here, means the reactor is subcritical at normal operating pressure and temperature.

7.4.2.5.2 Cold Shutdown

Cold shutdown of the reactor without access to the control room is possible by use of instrumentation and controls described in section 7.4.1.1.10 and applicable station procedures.

7.5 SAFETY-RELATED DISPLAY INSTRUMENTATION

7.5.1 DESCRIPTION

This section includes a description of that safety-related display instrumentation which is available to the operator to allow him to monitor conditions in the reactor, the Reactor Coolant System, containment, and safety-related process systems, throughout all operating conditions of the plant so that he may perform manual actions important to plant safety.

Display information identified on Tables 7.5-1, 7.5-2 and 1.8-1, within the Reactor Coolant System, steam generating system and the containment, provides for the remote monitoring of process variables during and following design basis events.

The safety-related display instrumentation is tabulated in the following categories:

A. Safety-Related Plant Process Display Instrumentation

   Information available to the operator for monitoring conditions in the reactor and related systems.

B. Reactor Trip System (RTS) Monitoring

   Information available to the operator for monitoring the status of the RTS.

C. Engineered Safety Feature (ESF) System Monitoring

   Information available to the operator for monitoring the status of each ESF system.

D. CEA Position Indication

Information available to the operator for monitoring the position of the CEAs.

E. Post-Accident Monitoring

Information available to the operator for monitoring the NSSS conditions following an accident.

F. Automatic Bypass Indication

Refer to section 7.5.2.6.

7.5.1.1 System Description

7.5.1.1.1 Safety-Related Plant Process Display Instrumentation

Table 7.5-2 lists the significant process instrumentation which is provided to inform the operator of the status of the reactor plant. This information which is used for the startup, operation, and shutdown of the plant, is provided in the Control Room. The information is provided in a form that is useful to the operator and may be indicated, recorded, or monitored in conjunction with a controlling function. Alternate indication and control instrumentation is provided at local stations outside the control room to allow reactor shutdown and maintenance of the reactor in a safe condition during hot shutdown should the control room become uninhabitable. (Refer to section 7.4.1.1.10). The control room layout is shown in figure 7.5-1.

7.5.1.1.2 Reactor Trip System Monitoring

Even though the RTS is automatic and does not require operator action (with the exception of a manual trip capability), sufficient information is provided to the operator in the control room to allow him to confirm that a Limiting Safety System Setting (LSSS) has been reached and a trip has taken place. This information consists of indication of; 1) process parameters which initiate reactor trip; 2) trip, pretrip, and bypass lights; 3) audible alarms; 4) Control Element Assembly (CEA) "dropped rod" information; and 5) trip switchgear circuit breaker position. Operating bypass indication as described in section 7.1.2.19 is provided on the remote modules which are located in the main control room. Individual trip channel bypass indication is provided locally at the PPS as well as on the remote modules in the main control room. (Refer to sections 7.1.2.19, 7.2, 7.5.1.1.1 and 7.5.1.1.4).

7.5.1.1.3 Engineered Safety Features Monitoring

The Engineered Safety Features Actuation System (ESFAS) continuously monitors the system input parameters and employs an actuation logic to initiate the Engineered Safety Features (ESF) Systems should these inputs reach their trip setpoints.

After automatic actuation, the ESF Systems will continue to function properly with limited operator action. When the transfer of safety injection pump suction from the Refueling Water Tank to the containment sump is required, the Recirculation Actuation Signal (RAS) will automatically actuate

this transfer. Following the RAS, timely operator action is required to close the RWT isolation valves to prevent ingress of air in the ESF pump suction piping during switchover to recirculation. Operator action is also taken to start other systems such as the Shutdown Cooling System (SCS). The RAS has to be manually overridden to allow certain SCS components to be operated for a plant cooldown.

Information is provided to the operator in the control room to allow him to monitor the operation of the ESF and related systems in the post-accident period. This information consists of valve position indication, pump operating status, tank level indication, flow indication, and indication of the process parameters which actuate Engineered Safety Feature Systems, (Refer to Table 7.5-1). In addition, four control modules provide indication of the pretrip, trip, bypass, and operating bypass condition of each of the associated actuation system input signals. Individual trip channel bypass indication is provided at the PPS cabinet as well as on the modules in the main control room.

Table 7.5-1 requires two Class 1E channels for the refueling water tank level indicators. The PVNGS design has two Class 1E channels with Class 1E level indicators on the remote shutdown panel, but only one Class 1E level indicator in the control room. The other level indicator in the control room is isolated and powered from a non-Class 1E power supply. Refer to section 1.9.

The following additional discussion relates to:

- Monitoring of equipment automatically actuated by the one-out-of-two engineered safety features actuation signal (BOP-ESFAS) (paragraph 7.1.1.3)
- Monitoring of equipment manually actuated (the containment combustible gas control system) (paragraph 7.1.1.3)
- Monitoring of equipment automatically actuated by an auxiliary feedwater actuation signal (AFAS).

Additional engineered safety features (ESF Class 1E, except as noted) information is presented in table 7.5-1.

A. Monitoring of Equipment Actuated by One-Out-of-Two ESFAS

The systems actuated by the one-out-of-two ESFAS are:

- Fuel building essential ventilation system
- Containment purge isolation system
- Control room/building essential ventilation system

The one-out-of-two ESFAS continuously monitors the system input parameters and performs actuation logic to initiate safeguards should these inputs reach their trip setpoints.

After the automatic actuation of the ESF systems, they will continue to function properly without operator action.

Information is provided in the control room to allow the operator to monitor and evaluate the operation of the active system components during system operation, including periodic tests. Table 7.5-1 lists parameters monitored in each system. In addition, the trip status of each actuation signal in each of the two channels, as well as indication of the process parameters which actuate these ESF systems, is indicated in the control room.

B. Monitoring of Manually Actuated Containment Combustible Gas Control System

Information is provided in the control room to allow the operator to monitor process conditions necessary for manual actuation of the containment combustible gas control system. Redundant analog instrument channels provide the required information.

Control room indications are provided to allow the operator to monitor and evaluate the operation of active system components during system operation, including periodic tests and the post-accident period. Table 7.5-1 lists parameters monitored in this system.

Control of the containment combustible gas control system is local and indication of system air flow and temperature is provided at the local panel.

C. Monitoring of Auxiliary Feedwater System

Refer to paragraph 7.3.1.1.10.7. Information is provided in the control room to allow the operator to monitor and evaluate the operation of the active system components during system operation including periodic tests and the post-accident period. Table 7.5-1 lists parameters monitored in this system.

7.5.1.1.4 Control Element Assembly Position Indication

Two independent CEA position indication systems provide CEA position information to the operator. The systems are the pulse counting CEA position indication system and the reed switch CEA position indication system. The pulse counting system is discussed in section 7.7.1.3.2; the reed switch system is discussed below. CEA position displays are located on the main control board.

The reed switch CEA position indication system utilizes a series of magnetically actuated reed switches (reed switch position transmitters) to provide signals representing CEA position. Two independent reed switch position transmitters (RSPT) are provided for each CEA. The RSPT provides an analog position indication signal and three physically separate discrete reed switch position signals. The analog position indication system utilizes a series of magnetically actuated reed switches spaced at 1-1/2-inch intervals along the RSPT assembly and arranged with precision resistors in a voltage divider network. The RSPT is affixed adjacent to the CEDM

pressure housing, which contains the CEA extension shaft and actuating magnet. The analog output signal is proportional to the CEA position within the reactor core. The three discrete reed switch position signals are contact closure signals from three separately located reed switches. These signals are an Upper Electrical Limit, a Lower Electrical Limit and a rod drop contact.

The analog reed switch CEA position signals are input to the DNBR/LPD Calculator System (See Section 7.2). CEA position information is provided to the Core Protection Calculators (CPCs) indirectly via a high speed communication bus connecting the CEACs and the CPCs. This analog CEA positional data is sent to the CEA Calculators (CEACs) in each safety channel via the CEA Position Processors (CPPs). Each of the two CEACs in each safety channel has its own CPP, thus supporting the concept of redundancy to increase the margin of error should an input to the CEAC fail.

The CEA Calculators display the position of each regulating, shutdown, and part-strength CEA to the operator in a numeric format on a visual display on the Operator Modules (OMs) from which the operator can address any analog position signal for display.

Additionally, this information is displayed in both graphical and numeric display on main control board CEA Position Display System (CEAPDS). The CEAPDS also displays in numerical format penalty factor, CEA deviation, and a user adjustable alarm setpoint for various CEA and CPC related functions including

deviation. The operator has the capability to select any safety channel for display or any regulating group.

In addition the displays, CEA deviation information is provided by the CEA Calculators to the CPCs and a CEA deviation alarm. The CEA deviation alarm is provided to the plant annunciator system in the event a CEA Calculator indicates that the difference between the highest and lowest CEA positions in a subgroup exceeds a predetermined allowable deviation. The CEA deviation information is used in the CPCs determination of power distribution. The power distribution is then factored into the low DNBR and high local power density trip function. Pre-trip alarms are initiated if the DNBR or Local Power Density trip limits are approached. A pre-trip alarm light is provided on the PPS control panel (both local and remote). Also, a pre-trip alarm is provided to the plant annunciator system.

The three discrete CEA position switches provide signals (contact closure signals) to the Control Element Drive Mechanism Control System (CEDMCS). The signals are utilized to provide CEA limit indication on the main control board and also to provide input to the CEA control interlocks. Each of the three discrete reed switch contacts actuates an interface relay located within the CEDMCS. These relays provide contact signals for indication and control and, in the case of the rod drop switch, an additional contact signal is provided to the Plant Monitoring System to set the pulse counting system (see section 7.7.1.3.2.3). The upper and lower electrical limits

indication appears as two separate lights on the CEDMCS control panel mounted on the main control board. The CEA drop indication appears on the core mimic display mounted on the main control board.

7.5.1.1.4.1 CEA Limit Lights Indication. A light display is provided on the control board to indicate the fully withdrawn and fully inserted position of each CEA and provides indication of a dropped CEA.

Table 7.5-1

7.5.1.1.5 Post-Accident Monitoring

The Post-Accident Monitoring (PAM) instrumentation is provided to allow the operator to assess the state of the NSSS following Design Basis Events. Most of these instruments monitor instruments or equipment, or systems which provide automatic action for the Design Basis Event.

Refer to Table 1.8-1, in addition the following are also required as post-accident monitoring instrumentation: extended range noble gas effluent radiation monitoring, containment high-range radiation monitoring, containment pressure monitoring, containment water level monitoring, and containment hydrogen monitoring. Refer to section 18.II.F.1 for TMI-related information pertaining to post-accident monitoring instrumentation.

A detailed discussion on radiation monitoring is provided in section 11.5.

A discussion on hydrogen monitoring is provided in paragraph 6.2.5.2.2.2.

7.5.1.1.6 Automatic Bypass Indication on a System Level

A status monitoring panel in the control room displays the availability of the CESSAR ESFAS, the one-out-of-two ESFAS, all the ESF systems (including the NSSS ESF systems and the containment combustible gas control system), and the automatic ESF supporting systems. The reactor protective system (RPS) has no bypasses or inoperable conditions on a system level; therefore, no RPS condition is indicated on the panel.

The number of bypass features or devices provided for operational purposes or routine testing is minimized by design, but wherever such features or devices are an integral part of the design and are used more frequently than once a year, a means of indication is provided in the main control room. Each ESF system component (such as pump, valve, or fan, including vital support system equipment) that must operate upon automatic or manual ESF actuation is monitored by a system level annunciator indicating inoperability of that ESF system. A bypass of a component in a given system by operation of a control switch, loss of control circuit power, pulling of a fuse, "racking-out" a breaker, or loss of vital supporting auxiliary systems is annunciated with an audible alarm. Any other piece of plant equipment in a system, not part of the ESF equipment, but that performs some required function in support of a piece of ESF equipment, provides a contact to annunciate the bypass status of the dependent ESF system.

Equipment rendered inoperative because of infrequent maintenance functions (performed on a frequency of once a year or less) is not specifically and automatically indicated. The capability to manually initiate a system inoperable signal is, however, included. Such maintenance activities include manual valves provided for isolation of equipment for repair, electrical cable connectors, screw terminals, motor-pump couplings, or other manual disconnects.

See figure 7.5-2 for panel layout for the safety equipment status system.

7.5.2 ANALYSIS

7.5.2.1 Analysis of Safety-Related Plant Process Display Instrumentation

Plant Process Instrumentation is provided to give the operator information to monitor conditions in the plant and perform operations important to plant safety. In addition, the information allows the operator to perform the cross-checking of Plant Protection System measurement channels to assure operational availability of these channels as discussed in section 7.2.1.1.9 and 7.3.1.1.8. The following design criteria were used in the selection of plant instrumentation:

A. Provide continuous monitoring of process parameters required by the operator;

B. Provide a permanent record of those parameters for which trend information is useful, from a safety standpoint;

C. Provide display information to the operator that is reliable, comprehensible, and timely;

D. Provide multiple channels of indication for the RPS and ESFAS process parameters to allow cross-checking of channels; and

E. Provide instrumentation display that adequately monitors the parameters over the ranges required for various conditions.

The information provided is sufficient to allow the operator to accurately assess the conditions within the reactor systems,

and in a timely manner perform those appropriate actions to maintain the reactor systems within the conditions assumed by the safety analysis in Chapter 15. In addition, the information allows the operator to perform the cross-checking of measurement channels to assure operational availability of these channels as discussed in section 7.2.1.1.9 and 7.3.1.1.8.

7.5.2.2 Analysis of Reactor Trip System Monitoring

Sufficient information is provided to the operator to allow confirmation that a trip has occurred and to determine the process parameter that has provided a trip input.

CEA insertion information can be determined by the operator after a trip by visual display bar chart information and CEA Limit Indication (refer to section 7.5.1.1.4).

Indication of neutron levels in the reactor core as well as other reactor and Reactor Coolant System information are provided for the operator.

The following design criteria were used in the selection of information that is provided to the operator:

A. System conditions requiring operator attention during routine plant operations and at the time of reactor trip are available in the control room;

B. Annunciation in the control room of all operations performed at the RPS cabinet affecting the function of the system;

C. Indication of any selected plant variables that are manually bypassed; and

D. Indication of automatic removal of a bypass.

7.5.2.3 Analysis of Engineered Safety Features Monitoring

Information is provided to the operator so that he may monitor the status of the Engineered Safety Features Systems. The following design criteria were used in the selection of information that is provided to the operator:

A. System conditions requiring operator attention or action during routine plant operators are displayed and/or controlled in the control room;

B. Annunciation is provided in the control room of all operations performed at the ESFAS cabinet affecting the function of the system;

C. Indication of any selected plant variable that is manually blocked or bypassed is provided; and

D. Indication of automatic removal of block or bypass status is provided.

Consistent with the above criteria, the information shown in Table 7.5-1 is provided for the operator's use. The information is provided to aid the operator in determining that manual actuation of an Engineered Safety Features System is required (which he may then perform) and to aid him in confirming proper system operation after automatic initiation. Input parameters used for actuation are indicated in the

control room as are positive indications that pump and valves have actuated and that flows have been established.

BOP ESFAS. Information is provided to the operator to allow monitoring of the status of the one-out-of-two ESF systems. The design criteria provided in CESSAR Section 7.5.2.3 were used in the selection of information that is provided to the operator. Consistent with these criteria, the information shown in table 7.5-1 is provided for operator use.

The display instrumentation for the containment combustible gas control system is supplied in such a manner that the operator has time to make reasoned judgment before his action is essential. Consistent with this criterion, the information shown on table 7.5-1 is provided for operator use.

The ESFAS actuation parameter displays provide information to enable the operator to assess accident conditions and to perform the necessary operation of the containment combustible gas control system. Containment hydrogen concentration monitors provide information necessary for manual combustible gas control through the use of the containment hydrogen recombiners. Refer to Table 1.8-1 and subsections 6.2.5 and 18.II.F.1.6 for further information.

7.5.2.4 Analysis of CEA Position Indication

CEA Position Indication allows the operator to easily determine the position of all of the CEAs within the reactor core. The information is presented in a form that can be assessed by the operator to easily determine that the CEAs are in the required

position, that a CEA has dropped into the core, or that the CEA positions are as required after a reactor trip.

The following design criteria were used in selection of the CEA position indication:

A. Position readouts of all CEAs may be obtained.

B. Continuous position indication of all CEAs is available.

C. A means is provided to alert the operator to deviation of CEAs within a group.

D. A permanent record may be made of the position of any or all CEAs.

E. Separate "full-in" and "full-out" indications are provided for each CEA.

F. Redundant and diverse means of indicating CEA position are provided.

7.5.2.5 Analysis of Post-Accident Monitoring Instrumentation

The Post-Accident Monitoring (PAM) instrumentation which is identified in table 1.8-1 is provided for remote monitoring of post-accident conditions within the Reactor Coolant System, steam generating system and the containment. Post-accident conditions are defined as those conditions which exist after the NSSS has reached a stable configuration following an accident.

The extensive instrumentation and controls required by table 1.8-1 provide the plant operator with long-term

monitoring and surveillance capabilities and provide redundancy and appropriate wide-range indication of post-accident conditions within the primary containment.

The requirements of IEEE 279-1971 "Criteria for Protections System for Nuclear Power Generating Station" are not completely applicable to the design of the post-accident monitoring instrumentation in that this instrumentation is not part of a protection system. However, the intent of some of the design criteria contained therein will be applied to the design of those systems used to monitor post-accident conditions to the extent appropriate as follows (heading numbers correspond to the Section numbers in IEEE 279-1971):

4.1 General Functional Requirement:

The PAM instrumentation is not designed to limit reactor fuel, fuel cladding and coolant conditions to levels within plant and fuel design limits. Each instrument's performance characteristic, response time and accuracy have been selected for compatibility with the design goal of providing the operator with long-term monitoring and surveillance capabilities after the plant has reached a stable condition.

4.2 Single Failure Criterion:

The PAM instrumentation is designed so that any single failure shall not result in the loss of the surveillance function on the system level after an incident. The wiring is arranged so that no single fault or failure, including either an open or shorted circuit will result in the loss of surveillance capability at the system level.

4.3 Quality Control of Components and Modules:

The Quality Assurance program is described in Topical Report CENPD 210A "Description of the C-E Nuclear Steam Supply System Quality Assurance Program" (Reference 1). This program includes appropriate requirements for design review, procurement, inspection and testing to ensure that PAM components shall be of a quality consistent with minimum maintenance requirements and low failure rates.

4.4 Equipment Qualifications:

The PAM instrumentation meets the equipment qualification requirements described in Section 3.10 and 3.11.

4.5 Channel Integrity:

Type testing of components, separation of sensors and channels, and qualification of cabling are utilized to ensure that the channels will maintain the functional capability required under applicable extreme conditions.

4.6 Channel Independence:

The locations of the sensors and the points at which the sensing lines are connected to the process loop have been selected to provide physical separation of the channels to the maximum extent practicable, thereby precluding a situation in which a single event could fail both PAM channels. See section 8.3.1.4 for cable routing.

4.7 Control and Protection System Interaction:

Where PAM instrumentation is also used for control purposes an isolation device shall be used to prevent any credible failure in the control portion from affecting the PAM readout.

4.8 Derivation of System Inputs:

All system inputs are derived from signals that are direct measures of the desired variables.

4.9 Capability for Sensor Checks:

Performance of the surveillance instrumentation will be verified during reactor operation subject to the following:

a. Testing will not adversely affect the safety or operability of the plant;

b. Normal system operation will be considered an acceptable method of verifying surveillance instrumentation performance if system operating parameters are similar to those anticipated following a LOCA:

c. In the event that the surveillance instrument performance cannot be verified under the conditions of a and b above, periodic testing will be performed during reactor shutdown periods.

4.10 Capability for Test and Calibration:

The PAM instrumentation can be checked from the sensor signal through the indication located in the main control room. Many of the sensors used for PAM are also used in the PPS and

therefore will be tested during PPS testing. For those sensors that are not part of the PPS, testing will be performed on a periodic basis.

4.11 Channel Bypass or Removal from Operation:

Any one of the two PAM channels may be tested, calibrated or repaired without detrimental effects on the other channel. The limitations specified in Technical Specifications should be adhered to.

4.12 Operating Bypasses:

This Section is not applicable to PAM instrumentation.

4.13 Indication of Bypasses:

This section is not applicable to PAM instrumentation.

4.14 Access to Means for Bypassing:

This section is not applicable to PAM instrumentation.

4.15 Multiple Set Points:

This section is not applicable to PAM instrumentation.

4.16 Completion of Protective Action Once it is Initiated:

This section is not applicable to PAM instrumentation.

4.17 Manual Initiation:

This section is not applicable to PAM instrumentation.

4.18 Access to Set Point Adjustments, Calibration and Test Points:

See section 13.5 for a discussion of administrative control for access to setpoint adjustments.

4.19 Identification of Protective Actions:

This section is not applicable to PAM instrumentation.

4.20 Information Readout:

Indicators capable of displaying both current reading and historical trend information are provided for each redundant post-accident monitoring (PAM) channel. Outputs are provided for continuously recording one channel of each analog variable.

4.21 System Repair:

A defective PAM channel can be detected by testing as previously discussed. Replacement or repair of one PAM channel will not affect the other channel. (Refer to Technical Specifications for limitations).

4.22 Identification:

The PAM instrumentation channels will not be uniquely identified as such. The channels will be identified to distinguish between redundant channels for the same variable. Refer to section 1.8 for a discussion of Regulatory Guide 1.97, Post Accident Monitoring Instrumentation.

7.5.2.6 Analysis of Automatic Bypass Indication on a System Level

The automatic bypass/inoperable indication status panel provides a means for the operator to easily determine the availability of ESF and ESF-supporting systems. The following design criteria were used in the design to conform to Regulatory Guide 1.47 and Branch Technical Position ICSB-21.

A. The system consists of two portions; one reporting the status of safety train A equipment, the other reporting the status of safety train B equipment. The system accepts channelized (channel A, B, C, or D) Class 1E inputs. The system is nonsafety-related, but since inputs are Class 1E, the system is powered from Class 1E 125 V-dc power supplies.

B. Status contacts continuously monitor the availability of control power and the position of circuit breakers of all automatically actuated ESF devices. A loss of control power or deliberate racking out of a breaker automatically initiates a system level indication with audible alarm, except for the containment purge refueling mode isolation valves. The circuit breakers for these valves are locked open during normal operation. An alarm is not initiated when the valve circuit breakers are locked open and the valve is in the safe position (closed). An alarm will be initiated if the valve is not in a safe position and a loss of power develops, or the valve is not in a safe position and its circuit breaker is open.

C. The capability for initiating a manual bypass indication and alarm is provided via a system level manual bypass switch used to indicate the bypass condition to the operator for those manual valves and other components which are not automatically monitored. The initiation and removal of manual bypass indication will be under administrative control.

D. All systems affected by the bypassing/inoperability of a given component that are shared by multiple systems automatically generate a bypass/inoperable audible and visual alarm in each system affected.

E. Indication and annunciation test capability is provided by simulating a trouble contact condition when the test button is depressed. The test feature generates the audible alarm and causes all windows to flash in unison. The test feature is independent for each channel.

7.6 ALL OTHER INSTRUMENTATION SYSTEMS REQUIRED FOR SAFETY

7.6.1 INTRODUCTION

This section describes the Shutdown Cooling System Suction Line Valve Interlocks and the Safety Injection Tank Isolation Valve Interlocks. The Shutdown Cooling System (SCS) is discussed in section 5.4.7; the Safety Injection System (SIS) is discussed in section 6.3.

The interlocks on the SCS and on the Safety Injection Tanks (SIT) are designed to act as permissives. The Shutdown Cooling System Suction Line Valve Interlocks permit the isolation valves to be opened below a certain pressure. The Safety Injection Tank Isolation Valve Interlocks are designed to permit the operator to isolate the SITs at low pressure and automatically open them above a certain pressure. This allows the SITs to be maintained at a given pressure when the balance of the RCS is depressurized.

Since there are no reactor coolant loop isolation valves, there will always be some flow in an idle loop so that there is no need for a cold water interlock.

The refueling interlocks are discussed in section 9.1.4.

The Shutdown Cooling System Suction Line Valve Interlocks and the Safety Injection Tank Isolation Valve Interlocks are automatically connected to the emergency busses if there should be a loss of all AC power. This is to assure that the interlocks and valves will be able to operate under all operating conditions.

7.6.1.1 System Description

7.6.1.1.1 Shutdown Cooling System suction Line valve Interlocks

The SCS is a low temperature, low pressure system used to remove decay heat from the RCS. Cooldown of the RCS is accomplished via the steam generator down to about 350°F and about 400 psia. Below these values the SCS is used to cool the RCS to refueling temperatures and to maintain these conditions for extended periods of time.

To preclude overpressurization, there are redundant, motor driven, interlocked, isolation valves on each suction line. The interlocks prevent the suction line isolation valves from being opened if RCS pressure has not decreased below 410 psia.

These interlocks are redundant so that any single failure will not cause a suction line and heat exchanger to be subjected to pressures greater than design pressure. The interlock cannot be overridden so that operator action cannot inadvertently subject the SCS to RCS pressure. In addition, no single failure can prevent the operator from aligning the valves, on at least one suction line, for shutdown cooling after RCS pressure requirements are satisfied.

Redundant relief valves are provided on the suction lines to prevent or mitigate overpressurization from pressure transients. These transients can be caused by inadvertent starting of HPSI pumps, charging pumps, inadvertent energizing of pressurizer backup heaters, or a combination of these. The

relief valves are set at 467 psig to insure the system stays below its design limits.

7.6.1.1.2 Safety Injection Tank Isolation Valve Interlocks

The SIS is designed to inject borated water into the RCS upon receipt of an SIAS (refer to Section 7.3) and to provide long term cooling in conjunction with other systems following an accident. The Safety Injection Tanks (SIT) inject borated water if system pressure drops below their internal pressure. During normal operation each tank has a motor operated isolation valve that is open and power to its motor circuit is removed to eliminate the possibility of spurious actuation. As the RCS pressure is reduced during plant shutdown, the low pressurizer pressure trip setpoint is reduced to avoid inadvertent initiation of Safety Injection, the SITs are depressurized to a value below the SCS design pressure, and the valves have their power restored and are closed.

The SIT interlocks are used to prevent the SITs from inadvertently pressurizing the SCS while maintaining SIT availability in case of a LOCA. Refer to Figure 7.6-2 for the interlock logic. The isolation valves are manually closed when RCS pressure drops below the value shown on Table 7.6-1 so that the SITs cannot cause overpressurization of the SCS, and also so that the SITs can be maintained at some pressure above atmospheric. The valves will automatically reopen when RCS pressure exceeds 515 psia; this is not a problem for the SCS since SIT pressure is less than SCS design pressure at this time. This opening of the SIT isolation valves insures that

the SITs are available for injection during plant startup. If the isolation valves are closed and an SIAS is initiated, the isolation valves will automatically open. The SIAS overrides the interlock or any manual signal.

There is an alarm associated with the SITs. The alarm will sound if the RCS pressure is increased to 700 psig and the SITs have not been repressurized. This insures that the SITs will be available for injection at the RCS pressure specified in the ECCS analysis (See section 6.3.3).

7.6.1.1.3 Class 1E Alarm System

A Class 1E alarm system is provided for a limited number of operational occurrences for which no specific automatic actuation of a safety system is required. The Class 1E alarm system alerts the operator to keep the plant operating within technical specification limits and prevent equipment damage.

The 1E alarm system consists of individual visual status indicators dedicated to each instrument channel. An audible alarm is provided for each alarm channel. The alarmed condition requires manual reset, once initiated.

The 1E alarm system is independent of the normal plant annunciation system and the redundant channels are powered from separate 1E power trains.

Operator acknowledgment of 1E alarms follows the same procedure used for the normal plant annunciator, with the exception that the audible alarms for each channel can be "silenced" with the use of a keylock switch (see 7.6.2.1.3).

7.6.1.1.3.1 Reactor Coolant Pump Cooling Water Supply Monitoring. Safety grade instrumentation is provided to detect the loss of cooling water to the reactor coolant pumps in order to ensure that the operator will have sufficient time to initiate manual tripping of the pumps to protect the pumps from seal failure. The cooling water flowrate to each pump is monitored by two redundant flow transmitters. If the cooling water flowrate is reduced below the minimum required for pump operation, a low flow signal will be initiated in each flow channel for the affected pump. The low flow signals will independently actuate their respective Class 1E redundant alarm system channels in the control room. The setpoint for alarming will be selected with sufficient margin to assure that proper operator notification is given. The alarm system utilizes a one-out-of-one logic for each channel.

7.6.1.1.3.2 Safety Injection Tank Pressure Monitoring. Safety grade instrumentation is provided to alert the operator of the unavailability of the safety injection tanks (SITs) to perform their core flooding function in the event of a LOCA.

The pressure in each SIT is independently monitored by a pressure sensor.

Reactor coolant system pressure is monitored by pressurizer pressure sensors.

If SIT pressure is reduced below that required for core flooding, a low-pressure signal will be initiated in the respective pressure channel for the affected tank.

The low-pressure signal will independently actuate its respective Class 1E redundant alarm system for channel B (tanks 1 and 2) or for channel A (tanks 3 and 4) in the control room.

The alarm for low SIT pressure is based upon an indication of pressurizer pressure above 715 psia coincident with SIT pressure below 600 psig. The alarm system utilizes a one-out-of-one logic for each SIT pressure sensor, with a one-out-of-two logic for each visual alarm window.

7.6.1.1.3.3 Auxiliary Building ESF Pump Room Level Monitoring. Safety grade instrumentation is provided to alert the operator of a leak in an auxiliary building ESF pump room (containment spray, high-pressure safety injection, and low-pressure safety injection). The level in each ESF pump room is independently monitored by a level switch mounted in the drain basin of each room. A high level signal, from the level switch, will independently actuate the respective Class 1E alarm in the control room.

7.6.1.1.4 Other Systems

7.6.1.1.4.1 Fire Protection Instrumentation and Detection System. The instrumentation utilized to detect, alarm, or mitigate the consequences of fires is discussed in subsection 9.5.1.

Table 7.6-1
SHUTDOWN COOLING (SDC) SYSTEM AND SAFETY INJECTION TANK (SIT) INTERLOCKS (Page 1 of 3)

SYSTEM	SETPOINT[a]	FUNCTION and Value[b]
Shutdown Cooling System		
SDC Suction Line Valves	≤ 385 psia	Open Permissive Interlock: prevents SDC isolation valves from opening until RCS pressure is less than the setpoint value and allows operator to open valves only when pressure is < 410 psia. Technical Specifications (TS): Verify SDC System open permissive interlock prevents the valves from being opened every 18 months with a simulated or actual RCS pressure signal ≥ 410 psia (S.R. 3.4.15.2). Test description in UFSAR section 7.6.2.2.1; 4.10
Shutdown Cooling Relief Valves	467 psig	Prevents or mitigates over-pressurization of the SCS; an LTOP design feature.
Safety Injection Tank SIT Isolation Valves	≥ 410 psia	Auto-Open Interlocks: SIT isolation valves automatically open prior to exceeding RCS pressure of 515 psia OR on a SIAS, if the valves are closed. Sends an open signal if valves are open, or closed, and overrides a closing signal.[d]

Table 7.6-1
SHUTDOWN COOLING (SDC) SYSTEM AND SAFETY INJECTION TANK (SIT) INTERLOCKS (Page 2 of 3)

SYSTEM	SETPOINT[a]	FUNCTION and Value[b]
Shutdown Cooling System		
Safety Injection Tank SIT Isolation Valves (continued)		Technical Requirements Manual (TRM): Verify that each SIT MOV opens automatically prior to actual or simulated RCS pressure exceeding 515 PSIA and upon receipt of a SIAS test signal; every 18 months. (TRM TSR 3.5.200.4) (SIAS Variable Setpoint: see Table 7.2-1 & Table 7.3-11A) Test description in USFAR section 7.6.2.2.2; 4.10
	$\leq$ 420 psia[c]	SIT Valves must be fully open when PZR pressure is $\geq$ 430 psia. Power to the MOVs must be removed when PZR pressure is $\geq$ 1500 psia. (LCO 3.5.2)
	< 405 psia	SIT Valve Closure Permissive: allows valves to be closed by the operator only when RCS pressure is less than 430 psia. (T.S. Basis for LCOs 3.5.1 and 3.5.2) With RCS pressure less than the setpoint, the SIT motor operated isolation valves may be closed to isolate the SITs from the RCS but must remain energized. This allows RCS cooldown and depressurization without discharging the SITs into the RCS or requiring depressurization of the SITs. Test description in UFSAR section 7.6.2.2.2; 4.10

Table 7.6-1
SHUTDOWN COOLING (SDC) SYSTEM AND SAFETY INJECTION TANK (SIT) INTERLOCKS
(Page 3 of 3)

SYSTEM Shutdown Cooling System	SETPOINT[a]	FUNCTION and Value[b]
Safety Injection Tank SIT Isolation Valves (continued)		TS: Verify SIT MOV power is removed every 31 days from each required SIT isolation valve operator when RCS pressure is $\geq$ 1500 psia. (SRs 3.5.1.5 and 3.5.2.5).[c] TS: Verify each required SIT isolation MOV is fully open every 12 hours when RCS pressure is $\geq$ 430 psia. (SRs 3.5.1.1 and 3.5.2.1).[c]
SIT - RCS 1E Differential Alarm	RCS > 690 psia AND SIT < 610 psig	SIT-RCS Differential pressure alarm. 1E alarm if RCS pressure is greater than 715 psia with SIT pressure less than 600 psig. (TSR 3.5.200.5)

(a) Setpoint values listed are the presently installed values determined by the applicable design calculation.

(b) Values listed with the function are from License documents such as the TRM or Technical Specifications.

(c) Acceptance criteria of $\leq$ 420 psia is used for valves open and power to MOVs removed with breakers locked open, before exceeding 430 psia.

(d) Above the SIT isolation valves auto-open interlock, the maximum pressure at which the SIAS open signal will open a closed valve is limited by the valve operator differential pressure design capability.

7.6.1.2 Design Bases

7.6.1.2.1 Shutdown Cooling System Suction Line Valve Interlocks

The SCS interlocks conform to the following design criteria:

A. Each suction line shall have at least two valves in series to provide isolation between the RCS and the SCS;

B. The isolation valves shall have interlocks to prevent opening the isolation valves while the RCS pressure is above that which would result in the allowable SCS pressure being exceeded;

C. The interlocks shall operate even after a single failure;

D. The interlocks shall not prevent achieving cold shutdown from the control room after a single failure;

E. Pressurizer pressure shall be used to provide the interlock functions;

F. Separate, physically independent sensors, located on separate pressurizer sensing nozzles, shall be provided; and

G. The interlocks must not fail so as to preclude opening of at least one SCS path (if RCS pressure permits), or closing of both suction paths after a LOCA.

7.6.1.2.2 Safety Injection Tank Isolation Valve Interlocks

The SIT Isolation Valve Interlocks are designed consistent with the balance of the SIS. Because the SIS is an ESF System, the ESF criteria take precedence over any applied to the interlocks. The interlocks conform, generally, to the SIS criteria specified in Section 6.3. The SIT interlocks meet the following criteria:

A. The SITs shall not be isolated from the RCS when RCS pressure exceeds a preset value; the interlocks shall function to automatically open the isolation valves when RCS pressure exceeds a preset value;

B. Pressurizer pressure shall provide the required function;

C. Separate, physically independent, sensors, located on separate pressurizer sensing nozzles, shall be provided;

D. Operating procedures, administrative controls, and the interlocks all insure that the isolation valves are open when pressure in the RCS is greater than a preset value;

E. When system pressure exceeds the setpoint the interlock opens the valve; the SITs must be repressurized prior to RCS pressure reaching 700 psig.

7.6.1.3 <u>Final System Drawings</u>

Refer to section 1.7 for a list of figures applicable to this section and figure 7.6-2.

7.6.2 ANALYSIS

7.6.2.1 Analysis of Design Criteria

7.6.2.1.1 Shutdown Cooling System Suction Line Valve Interlocks

A. The isolation valve interlocks are redundant in that there are two trains; train A has three valves, two receiving their signal from one pressure sensor and the third valve receives its signal from an independent sensor; train B also has three valves but using two different pressure sensors. Each path to each valve will be physically independent and separate from the others. With this degree of redundancy and independence, the interlocks can sustain a single failure and can still isolate both heat exchangers or make one available when required.

B. The interlocks and valves can be tested in accordance with General Design Criteria 1 and 21; Regulatory Guides 1.22, 1.47 and 1.68; and the appropriate sections of IEEE standards 279-1971, 336-1971 and 338-1971.

C. The method for identifying power and signal cables and cable trays dedicated to the instrumentation, control, and electrical equipment associated with the isolation valves will be as discussed in Section 7.1.3.16 and will conform to R.G 1.75 as discussed in Section 7.1.2.10.

D. The instrumentation, control, and electrical equipment associated with the SCS interlocks are seismically and environmentally qualified to operate under all required design basis events in accordance with the requirements stated in Section 3.10 and 3.11.

7.6.2.1.2 Safety Injection Tank Isolation Valve Interlocks

Because the SIS is an ESF System, the requirements of the General Design Criteria, Regulatory Guides, and IEEE standards appropriate for ESF Systems are used for all of the instrumentation and controls. The interlocks are designed to be consistent with the balance of the system and its requirements. Refer to Section 6.3 for a discussion of the SIS and Section 7.3 for a discussion of the ESFAS.

7.6.2.1.3 Class 1E Alarm System

The Class 1E alarm system utilizes two independent alarm systems, one for each channel. There are no operating bypasses for the 1E alarm system or inputs. An input signal will sound an audible alarm that can be acknowledged (muted) with a switch in the control room. Additionally, the audible alarms for each channel can be "silenced" with the use of a key which is under administrative control. The silence function disables the 1E annunciator system audible alarm which will prevent it from sounding for any new input signal until it is reset.

The instrumentation and input signals are provided in compliance with the requirements of IEEE Standard 279-1971.

7.6.2.1.3.1 Reactor Coolant Pump Cooling Water Supply Monitoring. Monitoring the cooling water flowrate to the reactor coolant pumps with two visual status alarms for each pump on low cooling water flow provides sufficient information to the operator to determine if cooling water is available to each pump and to take appropriate action in less than 30 minutes to protect the reactor coolant pump affected.

The instrumentation is provided in compliance with the requirements of IEEE Standard 279-1971.

7.6.2.1.3.2 Safety Injection Tank Pressure Monitoring. Monitoring the SIT pressure with two visual status alarms for each channel on low SIT pressure provides information to the operator to determine the unavailability of the SITs to perform their core flooding function in the event of a LOCA. The instrumentation is provided in compliance with the requirements of IEEE 279-1971.

7.6.2.1.3.3 Auxiliary Building ESF Pump Room Level Monitoring. Monitoring each ESF pump room level with one visual status alarm for each room provides sufficient information and 30 minutes of time for the operator to take appropriate action to prevent equipment flooding at a leakage rate of 50 gallons per minute. The instrumentation is provided in compliance with the requirements of IEEE 279-1971, except for the redundancy requirements. These level switches are not required to be environmentally qualified since flooding of these pump rooms will not occur as a result of an initiating event considered by the PVNGS EQ program.

7.6.2.2 Analysis of Equipment Design Criteria

7.6.2.2.1 Shutdown Cooling System Suction Line Valve Interlocks

This description is only of the interlocks. The valves and piping are discussed in Section 5.4.7. The requirements of IEEE 279-1971 are written expressly for protection systems; as such, they are not directly applicable to these interlocks. However, a discussion of the extent to which these interlocks comply with Section 4 of this standard is provided below:

4.1 General Functional Requirement:

The interlocks are designed to operate during accident environmental conditions.

4.2 Single Failure Criterion:

Any single failure leading to loss of one channel will not result in opening of all of the isolation valves installed in series in one SCS suction line. Loss of two selective interlock channels (both part of one SCS suction line) and violation of administrative controls and procedures is required to open all three isolation valves.

4.3 Quality Control of Components:

The sensors for these interlocks meet the same quality requirements imposed on the protection system sensors.

4.4 Equipment Qualification:

Type tests will be performed on the instrumentation to ensure its operation during expected environmental conditions.

4.5 Channel Integrity:

The interlocks are designed to maintain functional capability during accident environments. Failure of an interlock will not preclude opening a path or closing both paths of the SCS.

4.6 Channel Independence:

The pressure transmitters are located on separate pressurizer nozzles. Separation is maintained between channels.

4.7 Control and Protection System Interaction:

The interlocks have no non-safety control function.

4.8 Derivation of System Inputs:

Pressurizer pressure is the sensed parameter.

4.9 Capability for Sensor Check:

The operational availability of the four pressure sensing channels can be determined by comparing their outputs once pressurizer pressure has come within the range of the sensors.

4.10 Capability for Test and Calibration:

Complete testing capability of the SCS isolation valve interlock exists. The tests will be performed in conjunction with periodic in-service testing and inspection of the valves. The test will include testing of the logic, valve control circuits, and actuation of the individual valves. This testability will be equivalent to the testability required for ESF circuits. A simplified diagram of the logic circuit is shown on Figure 7.6-1.

Testing may be accomplished sequentially for each series valve by inserting a test signal to the bistables, simulating a decreased pressure condition, while holding the control switch in the open position, to the point where the valve partially opens, manually reclosing the valve, simulating an increased pressure condition and observing that the valve does not open when the hand switch is moved to open position.

4.11 Capability for Bypass or Removal from Operation:

Removal of one channel for test does not compromise system reliability. Failure of one of the remaining channels during a test outage would not create an unacceptable situation, since administrative controls (key locks) effectively preclude inadvertent opening of the valves by the operator.

4.12 through 4.14 Bypassing:

There are no bypasses.

4.15 Multiple Setpoints:

This requirement is not applicable.

4.16 Completion of Protective Action Once it is Initiated:

This requirement is not applicable.

4.17 Manual Initiation:

This requirement is not applicable.

4.18 Access to Setpoint Adjustments, Calibration and Test Points:

Access is controlled by administrative procedures.

4.19 Identification of the Protective Action:

Indication of isolation is provided by redundant valve position indication.

4.20 Information Readout:

The readout consists of four pressure indicators and position indication for four of the six valves.

4.21 System Repair:

Components are accessible for repair, one channel can be placed out of service for maintenance without jeopardizing the isolation of the SCS.

4.22 Identification:

The instrumentation and cables associated with the SCS interlocks will not be uniquely identified as such. The channels will be identified to distinguish between redundant channels of safety-related equipment (See Section 7.1.3.16).

7.6.2.2.2 Safety Injection Tank Isolation Valve Interlocks

The SIS and its design requirements are discussed in Section 6.3. The requirements of IEEE 279-1971 are written expressly for protection systems, and as such, they are not directly applicable to these interlocks. The following discussion refers to the requirements set forth in the respective items of Section 4 of IEEE 279-1971 as they relate to the SIT isolation valve interlocks:

4.1 General Function Requirement:

The interlocks have been designed to operate during accident environmental conditions.

4.2 Single Failure Criterion:

Loss of an interlock channel, at operating pressure, will not cause a valve to close since the valve motor circuit breaker is racked out. At low pressure, if the interlock should fail and an SIT starts to pressurize the RCS, the SCS is protected since the SITs are depressurized to 400 psia prior to initiation of shutdown cooling to prevent an interlock failure from causing such a problem.

4.3 Quality Control of Components:

The sensors for these interlocks meet the same quality requirements imposed on the protection system sensors.

4.4 Equipment Qualification:

Type tests will be performed on the instrumentation to ensure its operation during expected environmental conditions.

4.5 Channel Integrity:

The interlocks have been designed to maintain functional capability when exposed to accident environments. They will not preclude Safety Injection during accident conditions.

4.6 Channel Independence:

The pressure transmitters are located on separate pressurizer nozzles. Separation is maintained between channels.

4.7 Control and Protection System Interaction:

4.8 Derivation of System Inputs:

Pressurizer pressure is the sensed parameter.

4.9 Capability for Sensor Checks:

The operational availability of the two pressure sensing channels can be determined by comparing their outputs.

4.10 Capability for Test and Calibration:

Complete testing capability of the SIT isolation valve interlocks exists. The tests will be performed in conjunction with periodic in-service testing and inspection of the valves. The tests will include testing of the logic, valve control circuits, and actuation of the individual valves. A simplified diagram of the logic circuit is shown on Figure 7.6-1.

Testing may be accomplished sequentially for each valve by inserting a test signal to the bistables, simulating a decreased pressure condition while holding the control switch in the close position, to the point where the valve partially closes, and then simulating an increased pressure condition to the point where the interlock circuit causes the valve to return to the fully open position. This procedure will then be repeated to allow testing of the SIAS signal to the valve.

4.11 Capability for Bypass or Removal from Operation:

Removal of one channel for test does not compromise system reliability. Failure of one of the remaining channels during a test outage would not create an unacceptable situation, since administrative controls (key locks, racked out breakers, locked

open breakers) preclude inadvertent closing of the valves by the operator.

4.12 through 4.14 bypassing:

There are no bypasses.

4.15 Multiple Set Points:

This requirement is not applicable.

4.16 Completion of Protective Action Once Initiated:

This requirement is not applicable.

4.17 Manual Initiation:

This requirement is not applicable.

4.18 Access to Setpoint Adjustments, Calibration and Test Points:

Access is controlled by administrative procedures.

4.19 Identification of the Protective Action:

Identification of isolation is provided by redundant valve position indication.

4.20 Information Readout:

The readout consists of two pressure indicators and position indication for each valve. This provides the operator with clear, concise information.

4.21 System Repair:

The components are accessible for repair. One channel can be placed out of service without jeopardizing the availability of the SITs.

4.22 Identification:

The instrumentation and cables associated with the SIT isolation valve interlocks will not be uniquely identified as such. The channels will be identified to distinguish between channels of safety related equipment (See Section 7.1.3.16).

In addition, for periodic testing requirements, see the Technical Specifications and Technical Requirements Manual (TRM); for access procedures for setpoint adjustments, calibration, and test points, see section 13.5.

7.6.2.3 Fire Protection Instrumentation and Detection System

An analysis of the fire protection system is discussed in subsection 9.5.1.

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

Refer to paragraph 7.2.2.4.1 for additional discussion of control systems not required for safety.

7.7.1 DESCRIPTION

The control and instrumentation systems, whose functions are not essential for the safety of the plant, include plant instrumentation and control equipment not addressed in Section 7.2 through 7.6. The general description given below permits an understanding of the reactor and important subsystem control methodology.

The design reactivity feedback properties of the NSSS will inherently cause reactor power to match the total NSSS load. The resulting reactor coolant temperature at which this occurs is a controlled parameter and is adjusted by changes in total reactivity as implemented through CEA position changes or through boric acid concentration changes in the primary coolant.

The ability of the NSSS to follow turbine load changes is dependent on the ability of the control systems or operator to adjust reactivity, feedwater flow, bypass steam flow, reactor coolant inventory, and energy content of the pressurizer such that NSSS conditions remain within normal operating limits.

Except as limited by Xenon conditions, the major control systems described below provide the capability to automatically follow limited load changes. Additionally, these automatic systems provide the capability to accommodate load rejections

of any magnitude or the loss of one of two operating feedwater pumps.

7.7.1.1 Control Systems

7.7.1.1.1 Reactivity Control Systems

The reactor's reactivity is controlled by adjustments of CEAs for rapid reactivity changes or by adjustment of boric acid concentration for slow reactivity changes. The boric acid is used to compensate for such long term effects as fuel burnup and changes in fission product concentration. The boric acid concentration can be used to do some load following. Since these long term changes occur slowly, operator action is suitable for boric acid concentration control. The CEAs can either be controlled manually by the operator or automatically to maintain the programmed reactor coolant temperature and power level during boric acid concentration changes, within the limits of CEA travel.

The Reactor Regulating System (RRS) is used to automatically adjust reactor power and reactor coolant temperature to follow turbine load transients within established limits. The RRS receives a turbine load index signal (linear indication of load) and reactor coolant temperature signals (see Figure 7.7-5). The turbine load index is supplied to a reference temperature (T_{REF}) program which establishes the desired average temperature. The hot leg and cold leg temperature signals are averaged (T_{AVG}) in the RRS. The T_{REF} signal is then subtracted from the T_{AVG}, signal to provide a

temperature error signal. Power range neutron flux is subtracted from the turbine load index to provide compensation to the T_{AVG} - T_{REF} error signal generated.

This resulting error signal is fed to a CEA rate program, to determine whether the CEAs are to be moved at a high or low rate, and to a CEA status program which determines if the CEAs are to be withdrawn, inserted or held. The outputs of the rate and status programs are sent to the Control Element Drive Mechanism Control System (CEDMCS).

If the temperature error signal is very high, that is T_{AVG} is much higher than T_{REF}, an Automatic Withdrawal Prohibit (AWP) signal will be sent to the CEDMCS. Since the withdrawal of CEAs causes T_{AVG} to increase, prohibiting a withdrawal prevents an increase in the error signal.

The Control Element Drive Mechanism Control System (CEDMCS) accepts automatic CEA motion demand signals from the Reactor Regulating System or manual motion signals from the CEDMCS Operators Module and converts these signals to direct current pulses that are transmitted to the CEDM coils to cause CEA motion.

A reactor trip initiated by the Reactor Protective System causes the input motive power to be removed from the CEDMCS by the trip switchgear, which in turn causes all CEAs to be inserted by gravity. The CEDMCS is thus not required for safety. (See Figure 7.7-6).

There are four different modes of control; sequential group movement in manual and automatic control, manual group movement and manual individual CEA movement. Sequential group movement functions such that, when the moving group reaches a programmed low (high) position, the next group begins inserting (withdrawing), thus providing for overlapping motion of the regulating groups. The initial group stops upon reaching its lower (upper) limit. Applied successively to all regulating groups, the procedure allows a smooth continuous rate of change of reactivity. The CEDMCS accepts signals from the Plant Monitoring System (PMS) to effect this sequencing of regulating CEA group motion. The CEDMCS utilizes sequencing signals from the PMS that are derived from the CEDMCS up-down pulse counters. The shutdown CEAs are moved in the manual control mode only, with either individual or group-movement. A selector switch permits withdrawal of no more than one shutdown group at any time.

The part-strength CEAs may be moved manually, with either individual or group movement.

During plant startup and shutdown, and all cases where power is below 15%, manual control is used. Automatic control of the regulating CEAs by the RRS may be selected by the operator only when above 15% power. Manual control may be used to override automatic control at any time.

7.7.1.1.2 Reactor Coolant System Pressure Control System

The Pressurizer Pressure Control System (PPCS) maintains the Reactor Coolant System pressure within specified limits by the

use of pressurizer heaters and spray valves. The pressurizer provides a water/steam surge volume to minimize pressure variations due to density changes in the coolant. The pressurizer is described in Section 5.4.10.

A pressurizer pressure signal is used in a proportional controller to control the proportional heaters (see Figure 7.7-7). The heaters will be operated to maintain the pressurizer pressure as required. The operator can take manual control to regulate the pressure.

The pressurizer pressure signal is also sent to a spray valve controller. This provides a signal to the spray valves to control their opening. Since reactor coolant is somewhat cooler than the water/steam mixture, reactor coolant sprayed in will cause some steam to condense and thereby reduce the system pressure. The operator can take manual control of the spray valves to control the pressure.

If the proportional heaters are being used, and system pressure is still decreasing, the backup heaters would be automatically energized. The operator can also manually energize these backup heaters.

The control system has a low level interlock and a high pressure interlock. The low level interlock shuts off the heaters when the level falls below a setpoint.

If the pressurizer pressure reaches a high setpoint, all heaters will be deenergized; this is to ensure that the heaters will not cause the pressure to increase further.

7.7.1.1.3 Pressurizer Level Control System

The Pressurizer Level Control System (PLCS) minimizes changes in RCS coolant inventory by using the charging pumps and letdown control valves in the Chemical and Volume Control System (CVCS) discussed in Section 9.3.4. It also maintains a vapor volume in the pressurizer to accommodate surges during transients. Figure 7.7-8 shows the PLCS diagram.

During normal operations the level is programmed as a function of reactor coolant average temperature (T_{AVG}) in order to minimize charging and letdown flow requirements. The T_{AVG} goes through a level setpoint program and the setpoint program signal is compared to the actual level signal. The level error signal is sent to a level error program which is used to control the charging pumps.

If the level error program shows that the level is very high it will deenergize a normally running pump leaving only one pump (the always running pump) running. If the level is very low the level error program will cause the standby pump to start, thereby having three pumps charging the system.

The level error signal is sent to a Proportional plus Integral plus Derivative (PID) controller which generates an error signal. This signal is passed through a lag circuit which prevents rapid changes in the letdown flow. The output of the lag circuit is passed to the selected letdown valve via the auto-manual control and the letdown valve selector. The auto-manual control allows the operator to control level manually by controlling the letdown valve. The letdown valve

selector switch allows the operator to select which valve will be operated by the PLCS.

7.7.1.1.4 Feedwater Control System

The Digital Feedwater Control System (DFWCS) has a separate compound, or software control strategy, for each steam generator. The discussion of the FWCS will refer to only one steam generator. Refer to Figure 7.7-1 for the FWCS block diagram.

The DFWCS is based on a two-mode control strategy. At low power levels, the DFWCS is designed to automatically control the steam generator downcomer water level in a Single-Element mode. The DFWCS performs dynamic compensation on the level signal to generate an output signal indicative of the required feedwater flow. The output signal is used to generate the downcomer valve position demand signal. When in this control mode the economizer valve will be closed and the pump speed setpoint will be at its minimum value. Steam generator level will be controlled during 1% per minute turbine load ramps in this mode (assuming that all other control systems are operating in automatic).

The DFWCS is designed to automatically control the steam generator downcomer water level at higher levels in a Three-Element mode. The Three-Element mode continuously solves the steam generator mass balance equation to keep the feedwater input equal to the steam flow output. The level measurement acts as a trim on this mass balance and assures that the level is reset to its proper setpoint value following any system

disturbances. Thus, the three modes are level, feedwater flow, and steam flow. The gain and reset control settings are adaptively adjusted by reactor power and feedwater temperature to adjust control response for the "shrink/swell" phenomenon. Steam generator level will be controlled during the following conditions (assuming that all other control systems are operating in automatic):

A. Steady state operations;

B. 5% per minute turbine load ramps between 15 and 100% NSSS power;

C. 10% turbine load steps;

D. Loss of one of two operating feedwater pumps; and

E. Load rejection of any magnitude.

Transfer from Single-Element to Three-Element control, and back, is performed bumplessly without any need for operator balancing or other intervention. The transfer occurs automatically and is based on NSSS power. The transfer to Three-Element control occurs as soon as the stability of the steam and feedwater measurement will allow.

Panel Display Stations provide the operator interface with the DFWCS. The operator may use either interface to provide the steam generator level setpoint at the master control station or manually control the economizer and downcomer valve positions.

The signal from the master control station also goes to a high select circuit which selects the higher of the total feedwater demand signals from both feedwater systems and passes it to the

pump program. The pump program generates a pump speed setpoint signal. A panel display station provides the operator with access to the pump speed bias to allow balancing of the pumps. The operator can also manually control the pump speed at this station.

7.7.1.1.5 Steam Bypass Control System

The Turbine Bypass System consists primarily of the turbine bypass valves and the Steam Bypass Control System (SBCS). The SBCS controls the positioning of the turbine bypass valves, through which steam is bypassed around the turbine into the unit condenser, with exception of two valves which dump steam to atmosphere. These two valves are the last to open and first to close during steam bypass operation.

The system is designed to increase plant availability by making full utilization of turbine bypass capacity to remove excess NSSS thermal energy following turbine load rejections with condenser available. This is achieved by the selective use of turbine bypass valves and the controlled release of steam. This avoids unnecessary reactor trips, and prevents the opening of pressurizer or secondary safety valves.

Refer to Figure 7.7-2 for the SBCS block diagram. The Reactor Power Cutback System, discussed below, is used in conjunction with the SBCS to reduce the required turbine bypass valve capacity. Additionally, the SBCS is used during turbine loading to provide an even load on the reactor as the turbine is brought up to load. The system is also used during reactor

heatup and cooldown to remove excess NSSS energy, and control the rate of temperature change.

The following three types of valve signals are generated for each turbine bypass valve a modulation signal which controls the flow rate through the valve; a quick opening signal which causes the valve to fully open in a short time; and a valve permissive signal which is required for the preceding two signals to operate the bypass valve.

In the modulation mode a steam flow signal is sent to a program which develops a main steam header pressure program signal. At the same time the pressurizer pressure is used to generate a pressurizer pressure bias program. The two program signals and the measured main steam header pressure are compared to provide an error signal which goes to the controller. The controller demand, or a manual signal provided by the operator, is passed to an electro-pneumatic converter on each turbine bypass valve. This converts the electrical signal to an air signal which is passed through the first solenoid valve to the air actuated turbine bypass valve shown on Figure 7.7-2.

In the quick opening mode the pressurizer pressure and steam flow signals are compared and the difference signal produced is sent to a change detector. The change detector output is compared to a threshold value; if the change signal exceeds the threshold a quick opening signal is produced. The quick opening signal energizes the solenoid which then blocks the modulated air signal and applies the full air system pressure, to quick open the valve.

A permissive signal is also produced by the SBCS. This signal is provided by circuitry identical to that described above except that the output of the permissive controller is converted to a binary signal and fed into an OR gate with the permissive quick opening signal. If a permissive signal is present it will open the second solenoid valve and allow either the modulated or the quick open air signal to be applied to the pneumatically operated bypass valves. When the permissive signal is removed the control air is vented to atmosphere and the valve closes. When turbine condenser pressure exceeds a present value, the turbine bypass valves are prevented from opening.

Reactor Power Cutback demand signals are generated by the same circuitry that produces the valve quick opening signals. These redundant signals are sent to the Reactor Power Cutback System (RPCS).

7.7.1.1.6 Reactor Power Cutback System

The NSSS normally operates with minor perturbations in power and flow. These can be handled by the control systems discussed above. Certain large plant imbalances can occur however, such as a large turbine load rejection, turbine trip or loss of one of two main feedwater pumps. Under these conditions maintaining the NSSS within the control band ranges can be accomplished by rapid reduction of NSSS power at a rate which is greater than that provided by the normal high speed CEA insertion. Refer to Figure 7.7-4 for the block diagram of the Reactor Power Cutback System (RPCS).

The RPCS is a control system designed to accommodate certain types of imbalances by providing a "step" reduction in reactor power. The step reduction in reactor power is accomplished by the simultaneous dropping of one or more preselected groups of full strength regulating CEAs into the core. The CEA groups are dropped in their normal sequence of insertion. The RPCS also provides control signals to the turbine to rebalance turbine and reactor power following the initial reduction in reactor power as well as to restore steam generator water level and pressure to their normal controlled values. The system is designed to accommodate either large load rejections or the loss of one feedwater pump.

The RPCS receives two of each of the following signals; loss of feedwater pump 1, loss of feedwater pump 2 and two cutback demand signals from the SBCS. A two-out-of-two logic is required to actuate the system. The operator has the capability to manually actuate the system.

The operator inputs the CEA group drop selection through the RPCS operator's console. Input indication is provided for selection of all CEA subgroups. However, only CEA groups 4 and/or 5 (subgroups 22, 5 and/or 4) are capable of selection for drop.

The RPCS is actuated upon receiving coincident two-out-of-two sensor logic signals indicating either large turbine load rejection or loss of one main feedwater pump. The actuation initiates the dropping of the preselected pattern of CEAs. There are inhibits in the Control Element Drive Mechanisms

Control System (CEDMCS) to prevent the possibility of the RPCS dropping CEA groups which are not intended to drop for a reactor power cutback (e.g., Part-Strength groups, Shutdown Groups, etc.). Subsequent insertion of other groups either automatically by the Reactor Regulating System (RRS) or manually by the operator occurs as necessary. The actuation logic also temporarily changes plant control to a turbine follow mode by first initiating a rapid turbine power reduction to approximately 60% power, followed by a further reduction if necessary to balance turbine power with reactor power.

7.7.1.1.7 Boron Control System

Boron Concentration, via regular sampling of the reactor coolant is supplied to the operator to allow regulation and monitoring of the boron concentration in the reactor coolant. The means by which RCS boron control is accomplished is by dilution and boration. Refer to Section 9.3.4 for a discussion of the Chemical and Volume Control System (CVCS). To allow the operator to maintain the required boron concentration in the reactor coolant, the Volume Control Tank contents may be maintained at a prescribed boron concentration either manually or automatically. Additional recorders indicate reactor makeup water flow and boric acid makeup flow, which can be used to determine whether boration or dilution is occurring.

At power, the boron concentration, in addition to CEA position determines reactor coolant temperature. Because of the long time required to change the boron concentration, the boron is used for long term effects such as fuel burnup and fission

product build up. Boron concentration control can also be used for load following. By adjusting the boron concentration, the CEAs can be withdrawn to provide an adequate shutdown margin.

7.7.1.1.8 Loose Parts Monitoring System

Refer to Section 4.2.5.H.2.

A loose parts monitoring system (LPMS) is installed at PVNGS. The LPMS is designed to detect and record signals resulting from impacts occurring within the reactor coolant system. Eight transducers will be located in the areas where loose parts are most likely to become entrapped. These are:

A. Two redundant transducers clamp-mounted on the incore instrument guide tubes on the reactor vessel lower head, diametrically opposed.

B. Two redundant transducers mounted diametrically opposed on the reactor head.

C. Two redundant transducers on each steam generator. The transducers are mounted on the outer diameter in the tube sheet region.

Experience has shown that the exact location of the accelerometers is not critical since the acoustic wave that results from an impact propagates throughout the entire head. The transducers will be high temperature piezoelectric accelerometers.

A high temperature, low noise, radiation hardened, flame-retardant coaxial cable will connect the accelerometer to a

preamplifier located in a junction box outside of the biological shield. From the preamplifier the signals are sent via suitable wires, such as a twisted shielded pair, to the data acquisition panel in the control room. Cabling between redundant sensor channels from the sensor to the preamplifier located outside the secondary shield wall will be physically separated from each other.

A data acquisition panel located in the control room area contains alarm modules that continually monitor the incoming signals from the preamplifier for the presence of impacting.

The alarm level for each accelerometer is determined by a setpoint adjustment. Alarm levels were initially set above background levels established during baseline "signature" testing. Further baseline testing will be conducted from time to time and alarm levels may be adjusted to compensate for age-related noise generation at 100% power. The system sensitivity is better than 0.05 ft-lb at the sensors. Initial alarm setting is 0.5 $\pm$0.25 ft-lb. The occurrence of a loose part impacting on the inside of the structure causes bursts of signals that exceed the alarm setpoint and trigger the alarm. The data acquisition panel includes signal recording with playback and an audio monitor of live signal.

7.7.1.1.8.1 Recording. A digital recording system is provided, which includes an event analysis computer for analyzing the collected data. Signals from all channels are continually sampled. Storage time intervals are dependent upon the sampling rate and memory capacity of the analysis computer.

This computer performs data acquisition and recording and provides alarm indication on a control room annunciator to indicate a loose part event. It is capable of real-time analysis, spectrum analysis, and produces X-Y plot displays including an amplitude and frequency cursor with digital readout on an oscilloscope-type display.

7.7.1.1.8.2 Audio Monitoring. The audio monitoring shall consist of a speaker, independent volume control, and a selector switch for monitoring the loose parts channels.

7.7.1.1.8.3 Sensor Channel Functional Test. A preoperational calibration and functional test will be performed. Baseline "signatures" of each channel will be obtained to establish background levels. Provision is made for channel functional tests. System calibration shall be performed at least once each 18 months. Diagnostic procedures to confirm the presence of loose parts will make use of the baseline "signatures" to verify that recorded impact signals are above background.

7.7.1.1.8.4 Functionality for Seismic Conditions. The loose part detection system has been shown to be adequate for the OBE by test. Power is supplied from a 120 V-ac normal (nonseismically qualified) instrument bus, which has a Class 1E backup source.

All components of the system are high reliability items. They are to remain functional under normal environmental conditions of

the plant and are readily accessible for servicing (except sensors). Replacement of components, if any, at full power operation would be limited to the channel preamplifiers located outside the secondary shield wall. The preamplifiers are replaceable during full power operation. The only other components of the loose parts monitoring system located in containment are cables and the sensors. Equipment located in the control room is not subject to the environment of the containment and is readily accessible and repairable at all times.

7.7.1.1.8.5 Training Program for Plant Personnel. See paragraph 13.2.1.

7.7.1.1.9 In-Core Instrumentation System

The in-core instrumentation system is used to monitor the core power distribution.

There are 53 in-core monitoring assemblies with five self-powered Rhodium detectors in each location. The 53 assemblies are strategically distributed about the reactor core, and the five detectors are axially distributed along the length of the core at 10, 30, 50, 70 and 90% of core height. This permits representative three dimensional flux mapping of the core. The Rhodium detectors produce a delayed beta current proportional to the neutron activation of the detectors which is proportional to the neutron flux in the detector region.

The signals from the in-core detectors are converted to usable voltage signals by the In-Core Amplifier System which sends

these signals to the Plant Monitoring Systems (PMS) by way of multiplexers. The PMS converts these analog voltages to equivalent digital signals and performs the background, beta decay delay and Rhodium depletion compensation using digital signal processing routines.

The fixed in-core instrumentation system is designed to perform the following functions:

A. To determine the gross power distribution in the core during different operating conditions from 20% to 100% power;

B. To provide data to estimate fuel burn-up in each fuel assembly;

C. To provide data for the evaluation of thermal margins in the core;

The fixed in-core detectors can be used to assist in the calibration of the ex-core detectors by providing azimuthal and axial power distribution information. The ex-core system is used to provide indication of the flux power and axial distribution for the Reactor Protective System.

7.7.1.1.10 Excore Neutron Flux Monitoring System (Non-Safety Channels)

The ex-core neutron flux monitoring system includes neutron detectors located around the reactor core and signal conditioning equipment located in the control room area. Neutron flux is monitored from source levels through full power

operation and signal outputs are provided for reactor control and for information display.

Two startup channels provide source level neutron flux information to the reactor operator for use during extended shutdown periods, initial reactor startup, startups after extended shutdown periods, and following reactor refueling operations. Each channel consists of a dual section proportional counter assembly, with each section having multiple BF_3 proportional counters, one preamplifier located outside the reactor shield, and a signal processing drawer containing power supplies, a logarithmic amplifier, and test circuitry. High voltage power to the proportional counters is terminated several decades of neutron flux above the source level to extend detector life. These channels provide readout and audio count rate information but have no direct control or protective functions.

Two control channels provide neutron flux information, in the power operating range of 1% to 125%, to the Reactor Regulating System for use during automatic turbine load-following operation (see Section 7.7.1.1.1). Each control channel consists of a dual section uncompensated ionization chamber detector and a signal conditioning drawer containing power supplies, a linear amplifier, and test circuitry. The detector is operated in the current mode only. These channels are completely independent of the safety channels.

7.7.1.1.11 Boron Dilution Alarm System

Reactivity control in the reactor core is effected, in part, by soluble boron in reactor coolant system. The Boron Dilution Alarm System (Figure 7.7-11) utilizes the startup channel nuclear instrumentation signals to detect a possible inadvertent boron dilution event while in Modes 3-6. There are two redundant and independent channels in the Boron Dilution Alarm System (BDAS) to ensure detection and alarming of the event.

The BDAS contains logic which will detect a possible inadvertent boron dilution event by monitoring the startup channel neutron flux indications. When these neutron flux signals increase (during shutdown) to equal or greater than the calculated alarm setpoint, alarm signals are initiated to the Plant Annunciation System. The alarm setpoint is periodically, automatically lowered to be a fixed amount above the current neutron flux signal. The alarm setpoint will only follow decreasing or steady flux levels, not an increasing signal. The current neutron flux indication and alarm setpoint (per channel) are displayed. There is also a reset capability to allow the operator to acknowledge the alarm and initialize the system.

7.7.1.1.12 Feedwater Ultrasonic Flowmeter System.

The Feedwater Ultrasonic Flowmeter (UFM) System is an externally mounted flow measurement system utilizing an ultrasonic transit time method to measure fluid velocity and

volumetric flow rate. One externally mounted Ultrasonic Flowmeter system is installed on each Steam Generator Feedwater line to provide a measurement of Feedwater flowrate. The Ultrasonic Flowmeter Feedwater flowrate signal is then input to the Core Operating Limit Supervisory System (COLSS) software and used to calculate the secondary power calorimetric. Refer to Section 7.7.1.3.1.3.2 for discussion of the Core Power Calculations. The Feedwater flowrate signal to COLSS can be provided either by the Feedwater Ultrasonic Flowmeter, or the alternate Feedwater venturi flow meter. The Feedwater flowrate signal to COLSS is selectable via a manual switch. The primary reason that the Ultrasonic Flowmeter is preferred is that externally mounted ultrasonic flow measurement systems are not prone to the venturi fouling phenomena which causes an increase in differential pressure across venturi flow elements that is not related to an actual increase in Feedwater flow. This false increase in differential pressure for venturi flow meters results in a higher COLSS calculated mass flow and in turn a higher secondary power calorimetric.

7.7.1.2 Design Comparison

The functional design of the following, non-safety, control systems was performed by Combustion Engineering. The design differences between the control systems in the CESSAR Licensing scope and the control systems provided for the reference plant (Arkansas Nuclear One - Unit 2 - (ANO-2) NRC Docket No. 50-368) are discussed in this section.

7.7.1.2.1 Reactivity Control Systems

The RRS is functionally identical to that of the reference plant with the following changes:

A. It does not use pressurizer pressure for compensation;

B. An AMI signal is produced to prevent CEA motion whenever there is a deviation between any pair of redundant input signals; and

C. There is only one RRS instead of two.

The CEDMCS is functionally identically to that of the reference plant with the following changes:

A. The CEDMs can be deenergized in groups, by signals from the RPCS;

B. The two power buses are tied together within the CEDMCS cabinets;

C. System has a four coil, double-step CEDM instead of a five coil, single step;

D. Only one subgroup can be transferred to the hold bus at any one time;

E. The CWP is effective in all modes, and CWP can be bypassed at the Operator's Module;

F. UCL and LCL are replaced with UGS and LGS for the PLCEA; and

G. System can handle up to 97 CEAs as opposed to 81.

None of the design differences in the RRS or CEDMCS have been taken credit for in the safety analysis since they have no safety significance.

7.7.1.2.2 Reactor Coolant Pressure Control System

The PPCS is functionally identical to that used in the reference plant.

7.7.1.2.3 Pressurizer Level Control System

The PLCS is functionally identical to that used in the reference plant.

7.7.1.2.4 Feedwater Control System

The FWCS is functionally identical to the reference plant with the following exceptions:

A. This system is designed for a U-tube steam generator with an integral economizer, the reference system's U-tube steam generators do not have an economizer;

B. This system controls feedwater to the upper (downcomer) and lower (economizer) steam generator nozzles; and

C. Each nozzle has one valve to control instead of a main and bypass valve for a single nozzle.

None of these design differences discussed above have been taken credit for in the safety analysis since they have no safety significance.

7.7.1.2.5 Steam Bypass Control System

The SBCS has the following design differences from the Steam Dump and Bypass Control System (SDBCS) of the reference plant.

A. This system controls eight turbine bypass valves, the SDBCS controls three turbine bypass valves and four atmospheric dump valves;

B. Signals are provided to the RPCS upon a major load rejection.

Neither of these design differences have been taken credit for in the safety analysis since they have no safety significance.

7.7.1.2.6 Reactor Power Cutback System

The RPCS did not exist in the reference plant. It has not been taken credit for in the Safety Analysis.

7.7.1.2.7 Boron Control System

The BCS is functionally identical to that used in the reference plant.

7.7.1.2.8 In-Core Instrumentation System

The in-core instrumentation system is functionally identical to that of the reference plant with the following changes:

A. There are 53 in-core instrument assemblies being credited rather than 44; and

B. The in-core instrumentation system is designed for bottom rather than top entry.

None of these design differences have been taken credit for in the safety analysis since they have no safety significance.

7.7.1.2.9 Ex-Core Neutron Flux Monitoring System

The ex-core monitoring system is identical to the reference plant except that it uses uncompensated ion chambers instead of fission chambers for the control channel detectors. This difference has no impact on the functioning of the system and has no safety significance.

7.7.1.2.10 Boron Dilution Alarm System

The Boron Dilution Alarm System is an addition to the CESSAR design. There is no functional comparison to the reference plant.

7.7.1.3 Monitoring Systems

7.7.1.3.1 Core Operating Limit Supervisory System (COLSS)

7.7.1.3.1.1. General. The core operating limit supervisory system (COLSS) consists of process instrumentation and algorithms used to continually monitor the limiting conditions for operation on:

- Linear heat rate margin
- DNBR margin
- Total core power
- Azimuthal tilt
- Axial shape index

The COLSS continually calculates DNBR margin, linear heat rate margin, total core power, core average axial shape index, and azimuthal tilt magnitude, and compares the calculated values to the limiting condition for operation on these parameters. If a limiting condition for operation is exceeded for any of these parameters, COLSS alarms are initiated and operator action is taken as required by Technical Specifications.

The limiting safety system settings, core power operating limits, axial shape index, and the azimuthal tilt operating limit are specified such that the following criteria are met:

- No safety limit will be exceeded as a result of anticipated operational occurrences (AOOs).
- The consequences of postulated accidents will be acceptable.

The reactor protective system functions to initiate a reactor trip at the specified limiting safety system settings. The COLSS is not required for plant safety since it does not initiate any direct safety-related function during AOOs or postulated accidents. The Technical Specifications define the limiting conditions for operation (LCO) required to ensure that reactor core conditions during operation are no more severe than the initial conditions assumed in the safety analyses and in the design of the low DNBR and high LPD trips. The COLSS serves to monitor reactor core conditions in an efficient manner and provides indication and alarm functions to aid the operator in maintenance of core conditions within the LCOs given in the Technical Specifications.

The COLSS algorithms are executed in the plant monitoring system (PMS). The calculational speed and capacity of the PMS computer enable numerous separate plant operating parameters to be integrated into three easily monitored parameters: (1) margin to core power limit (based upon DNBR, linear heat rate, and power limits), (2) azimuthal tilt, and (3) axial shape index. If COLSS were not provided, maintenance of reactor core parameters within the LCOs, as defined by the Technical Specifications, would be accomplished by monitoring and alarming based on the separate nonsafety-related process parameters used in the COLSS calculations. Therefore, the essential difference in using COLSS in lieu of previous monitoring concepts is the integration of many separate process parameters into a few easily monitored parameters. The conciseness of the COLSS displays has distinct operational advantages, since the number of parameters that must be monitored by the operator is reduced.

Detailed process testing of COLSS is conducted to ensure proper system performance as described below:

A. After installation of revised COLSS software algorithms in the PMS computer, appropriate test cases are run on the computer to verify the COLSS implementation; the number of test cases may vary from 1 to approximately 43 depending on the software change(s) made. In test tests, COLSS is off-line (in the TEST mode) and sets of stored constants are substituted for live sensor inputs. These test cases are designed to test the functionality of the

module(s) containing the algorithm(s). Agreement of test case results to within round-off errors indicates that the COLSS software is functioning and implemented properly.

B. Just prior to startup from a refueling outage, new constants from a Quality Assured analysis are installed in the PMS.

C. When COLSS is on-line (in the SCHEDULED mode), a detailed report of the COLSS inputs, intermediate calculated values, and results may be printed upon request. Comparison of this information with intermediate calculated values and results from an off-line COLSS program using the same input values can provide additional assurance of proper operability of the COLSS program. Testing can be performed on an as needed basis under administrative control to assure proper performance of COLSS. Since COLSS is not required for plant safety, COLSS testing requirements are not included in the Technical Specifications (however, the Technical Specifications do include verification of certain COLSS alarms).

7.7.1.3.1.2 System Description. Sensor validity checks are performed by COLSS on those measured input parameters used in the COLSS calculations. The validity checks consist of checking sensor inputs for the following conditions:

- Sensor out-of-range

- Excessive deviation between like sensors

One of the following actions is taken for out of range sensors:

A. Automatic replacement of the failed sensor by an equivalent sensor (when available).

B. Automatic function termination when adequate process information is not available.

C. Substitution of constants for selected COLSS inputs (performed under administrative control).

If an out-of-range sensor is detected, an alarm to the operator is actuated and corrective action is automatically initiated.

A more detailed discussion of sensor validity checks is included in CEN-312, Revision 01-P.(1)

The core power distribution is continually monitored by COLSS, and the core average axial shape index is computed. Operation of the reactor with the calculated ASI within the specified axial shape index limits assures that the actual value of core average axial shape index is within the range of values used in the safety analysis. A core power operating limit based on linear heat rate is computed from the core power distribution. Operation of the reactor at or below this power operating limit assures that the peak linear heat rate is never more adverse than that postulated in the loss of coolant analyses.

Core parameters affecting the DNBR margin are continually monitored by COLSS, and a core power operating limit based on DNBR is computed. Operation of the reactor at or below this operating limit power level ensures that the most limiting DNB

transient that can result from an AOO does not result in a DNBR reduction to a value less than the DNBR SAFDL.

A core power operating limit based on licensed power level is also monitored by COLSS. When the COLSS-auctioneered reactor power exceeds the license power limit setpoint (COLSS addressable constant NKLPL), an alarm is generated. Due to normal fluctuations in the process variables used to calculate reactor power from COLSS, normal full power operation without alarm actuation requires an NKLPL setpoint > 100%. The NKLPL setpoint is determined by station procedures using a statistical analysis of COLSS calculated plant powers, with the objective to avoid nuisance alarms and still provide early warning to the operators of the need to reduce power. As required by station procedures, the Licensed Operators have the responsibility to ensure that steady state reactor power is maintained less than or equal to the licensed power limit.

Operation of the reactor at or below 100% power ensures that the total core power is never greater than that assumed as an initial condition in the safety analysis.

Axial shape index, core power, and the core power operating limits based on peak linear heat rate and DNBR are continually indicated on the control board. The margin between the core power and the lowest core power operating limit is also displayed on the control board indicator. An alarm is initiated if the COLSS calculated core power level exceeds a COLSS calculated core power operating limit or if the calculated axial shape index exceeds its limits.

In addition to the above calculations, the azimuthal flux tilt is calculated in COLSS. The azimuthal flux is not directly monitored by the plant protection system; rather an azimuthal flux tilt allowance, based on the maximum tilt anticipated to exist during normal operation, is provided as an addressable constant in the protection system. This tilt allowance is used in the low DNBR and high local power density trip calculations. The azimuthal flux tilt is continually monitored by COLSS and an alarm initiated in the event that the azimuthal flux tilt exceeds the azimuthal flux tilt allowance setting in the plant protection system.

The following are calculated by COLSS:

- Reactor coolant volumetric flowrate
- Core power as determined by:

  Reactor coolant ΔT

  Secondary system calorimetric

  Turbine first stage pressure
- Axial shape index
- Azimuthal tilt
- Linear heat rate core power operating limit
- DNBR core power operating limit
- Margin to each core power operating limit

Control board indication of the following COLSS parameters is continually available to the operator.

- Linear heat rate core power operating limit
- DNBR core power operating limit
- Total core power
- Margin between core power and lowest core power operating limit
- Axial shape index

The algorithms are executed in the PMS. Technical Specifications for the reactor core provide an alternate means of monitoring the limiting conditions for operation in the event that the PMS is out of service.

COLSS alarms are initiated if:

- Core power exceeds a core power operating limit
- Axial shape index exceeds its limits
- Azimuthal flux tilt exceeds azimuthal flux tilt limit

A description of COLSS algorithms and a discussion of the treatment of COLSS input information are included in reference 1. Table 7.7-1 provides a listing of the types, quantities, and ranges of sensors that provide input information for the COLSS algorithms.

A functional block diagram of the core operating limit supervisory system is presented in Figure 7.7-3.

7.7.1.3.1.3 <u>Description of COLSS Algorithms</u>.

7.7.1.3.1.3.1 Reactor Coolant Volumetric Flowrate. The DNBR margin is a function of the reactor coolant volumetric

flowrate. The four reactor coolant pump rotational speed signals and four RCP differential pressure instruments are monitored by COLSS and used to calculate the volumetric flowrate. The pump characteristics are determined from testing conducted at the pump manufacturer's test facility and correlations between the pump rotational speed, pump differential pressure, and the volumetric flowrate are developed. Measurement uncertainties in the pump testing and COLSS measurement channel uncertainties are factored into the calculation of the margin to a power operating limit. The four pump volumetric flowrates are summed to obtain the reactor vessel volumetric flowrate. Necessary allowances for core bypass flow, flow factors, reactor coolant temperature, etc., are factored into the value of flow used in the DNBR calculation.

7.7.1.3.1.3.2 Core Power Calculation. The reactor coolant ΔT power, turbine power, and the secondary calorimetric power are computed in COLSS. The reactor coolant ΔT power and turbine power are less complex algorithms than the secondary calorimetric power and are performed at a more frequent interval. The secondary calorimetric power is used as a standard against which reactor coolant ΔT power and turbine power are continually calibrated. The secondary calorimetric power is also used as a standard against which the Excore Safety and Control Channels are calibrated.

Table 7.7-1

COLSS MONITORED PLANT VARIABLES

Monitored Parameters	COLSS Sensors	Number of Sensors	Sensor Range
Core volumetric flow	RCP rotational speed RCP differential pressure	2 per pump 2 per pump	0 to 1,320 rpm 0 to 150 psid
Core power Primary calorimetric	Cold leg temperature	1 per cold leg	Narrow range (2) 500 to 650F Wide range (2) 0 to 600F
	Hot leg temperature	1 per hot leg	500 to 650F
Secondary calorimetric	Feedwater flow Steam flow Feedwater temperature Steam pressure	1 per generator 2 per generator 1 per generator 1 per generator	0 to 10.0×10^6 lbm/hr 0 to 5.0×10^6 lbm/hr 0 to 500F 900 to 1,300 psia
Core power distribution	In-core monitoring system	53 in-core assemblies each containing 5 axial stacked detectors	NA[a]
	CEA group position	1 per CEA group	0 to 150 inches
Reactor coolant pressure	Pressurizer pressure	2 (on pressurizer)	1,500 to 2,500 psia
Turbine power	Turbine first stage pressure	1 (on turbine)	0 to 800 psig

a. Core power distribution is provided in a graphic format.

This arrangement provides the benefits of the secondary calorimetric accuracy and the faster dynamic response characteristics of the reactor coolant ΔT power and turbine power.

The reactor coolant ΔT power is calculated based on the reactor coolant volumetric flowrate, the reactor coolant cold leg temperature, and the reactor coolant hot leg temperature. ΔT power provides a leading indication of core power changes in response to reactivity changes.

The turbine power is calculated based on turbine first stage pressure. Turbine power provides a leading indication of core power changes in response to load changes.

The secondary calorimetric power is based on measurements of feedwater flowrate, feedwater temperature, steam flow, and steam pressure. A detailed energy balance is performed for each steam generator. The energy output of the two steam generators is summed and allowances made for reactor coolant pump heat, pressurizer heaters, and primary and secondary system energy losses.

7.7.1.3.1.3.3 COLSS Determination of Power Distribution. The determination of the 3-D peaking factor, the integrated radial peaking factor, the power shape in the hottest channel, and the azimuthal tilt magnitude is performed based on in-core measurements of the flux distribution, processed by pre-programmed algorithms and stored constants. A brief description is given here of the data processing approach

employed by COLSS to yield the desired power distribution information. This analysis is repeated at least once per minute, and thus represents continual on-line monitoring.

The dynamic response characteristic of the self-powered rhodium in-core detectors is a function of both prompt and delayed components of electrical current generated in the detector and cabling. The delayed portion of the current signal is governed by the decay of isotopes of rhodium having half-lives of 0.7 minutes and 4.4 minutes. To provide the capability to compensate for the delayed portion of the signal, the COLSS power distribution determination includes a compensation algorithm for the in-core signals used as input to COLSS. The algorithm approximately represents the inverse of the in-core detector dynamic response, such that the combination of detector response and dynamic compensation produces a signal representative of the actual neutron flux response.

The capability for signal filtering is provided through selection of algorithm constants. With the capability for dynamic compensation and filtering on the in-core signals, changes in local flux level during operational load follow transients are adequately represented by the COLSS power distribution determination.

Following correction of the fixed detector signals for background and burnup, five axially distinct region-average power integrals corresponding to the five rhodium detector segments are constructed, taking into account signal-to-power conversion factors which are a function of burnup in the

surrounding fuel. The five power integrals are expanded into a forty node core average axial power distribution using a Fourier series technique.

Employing tables of factors relating power in the hot pin to the core average, the axial power profile in the hot pin is computed.

Malpositioning of a CEA or CEA group, the uncontrolled insertion or withdrawal of a CEA or CEA group, or a dropped CEA will be detected by COLSS with inputs received from the pulse-counting CEA position indicating system. Should these deviations occur, adjustments to the planar radial peaking factors are performed to ensure that the COLSS DNBR and peak linear heat rate calculations remain conservative. It is noted that COLSS only provides a monitoring function and therefore has only the function of informing the operator of such deviations. Any protective action required for the CEA-related events is provided by the RPS.

Flux tilts are detected by comparison of signals from symmetrically located sets of fixed in-core detectors, at various levels in the core. The flux tilts are included in the computation of margin to the power operating limit. In this way, postulated nonseparable asymmetric xenon shifts are identified and reflected in the power distribution assessment. Alarms are provided by COLSS when the xenon tilt exceeds the allowances for these effects carried in the core protection calculators as a penalty, or when it exceeds an absolute limit

(imposed by the Technical Specifications) indicating possible power distribution abnormality.

The possibility of nonfunctional fixed in-core detectors is allowed for by provision of redundant detector strings within each region of the core. If a nonfunctional fixed in-core detector is identified during internal consistency checks of the data, that detector is dropped from COLSS calculations prior to replacement, e.g., at a subsequent refueling.

After the inception of operation, periodic confirmation of the COLSS assessment of the power distribution, including the suitability of any updated stored constants, is obtained by comparison with a more detailed, off-line processing of an extensive in-core flux map produced by the fixed in-core instrument systems. One means of analyzing the detailed flux map is to compare it with detailed calculations of the power distribution which include computations of the flux at the instrument location. Folding this together with other analyses of the ability of the detailed calculation to estimate the local pin-by-pin power distribution enables an overall assessment of the COLSS power distribution error.

7.7.1.3.1.3.4 Core Power Operating Limit Based on Linear Heat Rate. The core power operating limit based on linear heat rate is calculated as a function of the core power distribution. The power level that results from this calculation corresponds to the limiting condition for operation of peak linear heat rate margin.

7.7.1.3.1.3.5 Core Power Operating Limit Based on DNBR. The core power operating limit based on DNBR is calculated as a function of the reactor coolant volumetric flowrate, the core power distribution, the maximum value of the four reactor coolant cold leg temperatures, and the reactor coolant system pressure. The CE-1 correlation is used in conjunction with an iterative scheme to compute the operating limit power level. (See section 4.4 for a detailed discussion of the CE-1 correlation). The power level that results from this calculation corresponds to the limiting conditions for operation on DNBR margin.

7.7.1.3.1.4 Calculation and Measurement Uncertainties. Three uncertainty penalty factors are calculated for COLSS, one which is used in calculating the linear heat rate power operating limit and two which are used in calculating the DNBR power operating limit.

The LHR adjustment accounts for the composite modeling uncertainty in the COLSS determination of the 3-D peak and for the various engineering factors. This modeling error is determined from a set of several thousand comparison cases between COLSS and design codes covering suitable ranges of power level, core burnup, CEA position, and primary system fluid properties. The overall adjustment factor accounts for the effects of fuel rod bow, poison rod bow, design code modeling uncertainty, COLSS power algorithm uncertainty, CECOR measurement uncertainty, and computer processing uncertainties.

Similarly, the DNBR adjustments account for the composite modeling uncertainty in the COLSS calculation of the power distribution and DNBR. This composite modeling error is based on the same set of comparison cases between COLSS and design codes used for the LHR uncertainty calculation. The overall adjustment factors include the effects of fuel rod bow, poison rod bow, design code modeling uncertainty, CECOR measurement uncertainty, COLSS DNB algorithm uncertainty, and computer processing uncertainties.

7.7.1.3.2 Plant Monitoring System (PMS)

The PMS is designed and configured as a general purpose facility for plant monitoring, alarming, and reporting purposes. It includes the capability of direct interaction with plant control systems to provide permissive or control inputs to these systems based upon calculational determination of plant conditions.

7.7.1.3.2.1 Application Programs. The PMS application programs, exclusive of COLSS, that provide either a reactor monitoring or Plant Protection System monitoring function are described below:

A. Power Dependent Insertion Limits (PDILs) are operating limits on allowable insertion of full-strength CEAs as a function of reactor power, PDILs are used to maintain operation consistent with shutdown margin (when the reactor is critical) and ejected CEA worth

(when the reactor is critical) constraints. PDILs utilize reactor power and CEA position signals.

B. Isolated output signals from each DNBR/LPD Calculator System channel (including calibrated ex-core neutron flux power and margin to DNBR and local power density trip setpoints) are sent to the computer. The difference between the maximum and minimum values of the four channels for each parameter is compared to a predetermined constant. An alarm is initiated if the constant is exceeded.

C. The post-trip review program monitors pre-selected process inputs at selected intervals before and after a reactor trip. This program provides a means of monitoring events before and after a plant trip.

D. The sequence-of-events program monitors PPS bistable trip units and records status of changes (channel trips) with a resolution of several milliseconds as a means of monitoring events before and after plant trip.

Each of these PMS functions is intended to assist the plant operator in supervision or analysis of plant conditions. None of these functions is required to ensure plant safety or permit plant operation.

7.7.1.3.2.2 NSSS Programs. The NSSS programs which utilize the PMS that provide input to plant control systems are described below:

A. The CEA group sequencing program provides input to the Control Element Drive Mechanism Control System (CEDMCS) in the form of permissive signals. These signals permit sequential insertion and withdrawal of regulating CEA groups by the CEDMCS, with a pre-programmed overlap between consecutive groups during Automatic Sequential and Manual Sequential modes of operation.

   The PMS monitors the following functions during sequential modes of CEA group operation: (1) withdrawal sequence which starts with group 1 and ends with the last regulating group in consecutively increasing numbers, and (2) the insertion sequence starts with the last regulating group and ends with group 1 in consecutively decreasing numbers. Proper sequencing of the group necessitates that the preceding group reach a specified limit before the next group is permitted to move. One sequential permissive contact output is initiated for each regulating group when the permissive conditions for that group have been met. In addition to sequential permissive outputs for each regulating group, one contact output for out-of-sequence alarming is provided, which does not pass through the CEDMCS Auxiliary Cabinets.

B. The PMS also provides normal CEA control limits for all FSCEAs/PSCEAs. These limits include the Upper (Lower) Group Stops for full-strength CEAs and the Upper (Lower) Group Stops for the PSCEAs. These control limits are provided to the CEDMCS to automatically terminate CEA motion upon reaching the CEA limits of travel.

Each of these functions is intended to enhance flexibility of plant operation. None are required to ensure plant safety or permit plant operation.

All other functions presently implemented in the PMS are solely for operator and administrative convenience and involve neither the Plant Protection System nor plant control. None of the PMS functions are required to ensure plant safety or permit plant operation.

7.7.1.3.2.3 Pulse Counting CEA Position Indication System. The pulse counting CEA position indication system infers each CEA position by maintaining a record of the "raise" and "lower" control pulses sent to each magnetic jack Control Element Drive Mechanism (CEDM). The pulse counting CEA position signal associated with each CEA is reset to zero whenever the rod drop contact (located within the reed switch position transmitter housing) is closed. This permits the pulse counting system to automatically reset the position to zero, whenever a reactor trip occurs or whenever a CEA is dropped into the core. This system is incorporated in the Plant Monitoring System (PMS) which feeds control board digital displays. One digital

display provides CEA group information. A second digital display provides individual CEA position information. The position of each CEA is periodically printed out for a permanent record. A printout is available, on operator demand, of selected CEA positions.

The pulse counting CEA position indication system provides position information to CEA related alarm programs and the Core Operating Limit Supervisory System (COLSS) contained in the PMS. The PMS CEA and COLSS alarms are indicated on an alarm display, which contains both audible and visible indication, and by hard copy printout on the printer. The alarms are included in the system design to provide information to the operator to assist in maintaining proper CEA control and to aid in the monitoring of CEA limits. The following alarms are provided by the pulse counting CEA position indication system:

A. Power Dependent Insertion Limits (PDILs) Alarms

   An alarm is provided on PC and CMC COLSS after CMC/COLSS upgrade, in the event CEA insertion exceeds predetermined limits required to maintain adequate shutdown margin and to ensure CEA insertion consistent with the CEA ejection analysis. Further definition of the PDIL function is provided in Paragraph 7.7.1.3.2.1.

B. Pre-Power Dependent Insertion Limits (PPDILs) Alarm

   This alarm is provided to advise the operator of an impending approach to PDILs.

C. Out of Sequence Alarm

An alarm is provided to alert the operator in the event the CEA groups are inserted in a sequence other than the pre-determined acceptable sequence.

D. CEA Deviation Alarm

An alarm is provided to alert the operator in the event the deviation in position between the highest and lowest CEA in any group exceeds a predetermined allowable deviation.

E. Core Operating Limit Supervisory System Alarms

The pulse counting CEA position indication system provides input data to COLSS. These data are used in the COLSS power distribution calculations, and alarms are initiated in the event the affected COLSS limits are reached. The basis for the COLSS alarms and the use of the pulse count CEA position information is discussed in Section 7.7.1.3.1.

7.7.2 ANALYSIS

The plant control system and equipment are designed to provide high reliability during steady state operation and anticipated transient conditions. The RPS analysis of Section 7.2.2 encompasses the failure modes of these control systems and demonstrates that these systems are not required for safety.

The safety analyses of Chapter 15.0 do not require these systems to remain functional.

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

APPENDIX 7A

QUESTION 7A.1 (NRC Question 222.01)

Loss of Non-Class 1E Instrumentation and Control Power System Bus During Power Operation (IE Bulletin 79-27)

If reactor controls and vital instruments derive power from common electrical distribution systems, the failure of such electrical distribution systems may result in an event requiring operator action concurrent with failure of important instrumentation upon which these operator actions should be based. This concern was addressed in IE Bulletin 79-27. On November 30, 1979, IE Bulletin 79-27 was sent to operating license (OL) holders, the near term OL applicants (North Anna 2, Diablo Canyon, McGuire, Salem 2, Sequoyah, and Zimmer), and other holders of construction permits (CPs), including Palo Verde. Of these recipients, the CP holders were not given explicit direction for making a submittal as part of the licensing review. However, they were informed that the issue would be addressed later.

You are requested to address this issue by taking IE Bulletin 79-27 Actions 1 through 3 under "Actions to be Taken by Licensees". Within the response time called for in the attached transmittal letter, complete the review and evaluation required by Actions 1 through 3 and provide a written response describing your reviews and actions. This report should be in the form of an amendment to your FSAR and submitted to the NRC Office of Nuclear Reactor Regulations as a licensing submittal.

RESPONSE:

The response is given in amended paragraph 7.1.2.33.

QUESTION 7A.2 (NRC Question 222.02)

If safety equipment does not remain in its emergency mode upon reset of an engineered safeguards actuation signal, system modification, design change or other protective action of the affected equipment is not compromised once the associated actuation signal is reset. This issue was addressed in IE Bulletin 80-06 (enclosed). For facilities with operating licenses as of March 13, 1980, IE Bulletin 80-06 required that reviews be conducted by the licensees to determine which, if any, safety functions might be unavailable after reset, and what changes could be implemented to correct the problem.

For facilities with a construction permit, including OL applicants, Bulletin 80-06 was issued for information only.

The NRC staff has determined that all CP holders, as a part of the OL review process are to be requested to address this issue. Accordingly, you are requested to take the actions called for in Bulletin 80-06 Actions 1 through 4 under "Actions to be Taken by Licensees". Within the response time called for in the attached transmittal letter, complete the review verifications and descriptions of corrective actions taken or planned as stated in Actions 1 through 3 and submit the report called for in Action Item 4. The report should be submitted to the NRC Office of Nuclear Regulation as a licensing submittal in the form of an FSAR amendment.

RESPONSE:

The response is given in amended paragraph 7.1.2.34.

QUESTION 7A.3 (NRC Question 222.03)

Operating reactor licensees were informed by IE Information Notice 79-22, issued September 19, 1979, that certain non-safety grade or control equipment, if subjected to the adverse environment of a high energy line break, could impact the safety analyses and the adequacy of the protection functions performed by the safety grade equipment. Enclosed is a copy of IE Information Notice 79-22, and reprinted copies of an August 20, 1979, Westinghouse letter and a September 10, 1979, Public Service Electric and Gas Company letter which address this matter. Operating reactor licensees conducted reviews to determine whether such problems could exist at operating facilities.

We are concerned that a similar potential may exist at light water facilities now under construction. You are, therefore, requested to perform a review to determine what, if any, design changes or operator actions would be necessary to assure that high energy line breaks will not cause system failures to complicate the event beyond your FSAR analysis. Provide the results of your reviews including all identified problems and the manner in which you have resolved them to NRR.

The specific "scenarios" discussed in the above referenced Westinghouse letter are to be considered as examples of the kind of interactions which might occur. Your review should include those scenarios, where applicable, but should not necessarily be limited to them. Applicants with other LWR designs should consider analogous interactions as relevant to their designs.

RESPONSE:

The response is given in amended paragraph 7.1.2.35.

QUESTION 7A.4 (NRC Question 222.04)

The analysis reported in chapter 15 of the FSAR are intended to demonstrate the adequacy of safety systems in mitigating anticipated operational occurrences and accidents.

Based on the conservative assumptions made in defining these design basis events and the detailed review of the analyses by the staff, it is likely that they adequately bound the consequences of single control system failures.

To provide assurance that the design basis event analyses adequately bound other more fundamental credible failures, you are requested to provide the following information:

1. Identify those control systems whose failure or malfunction could seriously impact plant safety.

2. Indicate which, if any, of the control systems identified in (1) receive power from common power sources. The power sources considered should include all power sources whose failure or malfunction could lead to failure or malfunction of more than one control system and should extend to the effects of cascading power losses due to the failure of higher level distribution panels and load centers.

3. Indicate which, if any, of the control systems identified in (1) receive input signals from common sensors. The sensors considered should include, but

should not necessarily be limited to, common hydraulic headers or impulse lines feeding pressure, temperature, level or other signals to two or more control systems.

4. Provide justification that any simultaneous malfunctions of the control systems identified in (2) and (3) resulting from failures or malfunctions of the applicable common power source or sensor are bounded by the analyses in chapter 15 and would not require action or response beyond the capability of operators or safety systems.

RESPONSE: Refer to Section 7.2.2.4.1 for a detailed response.

<u>QUESTION 7A.5</u> (NRC Question 492.3)[a]

CEN-251(V)-P, Revision 00 - "PVNGS-1 Cycle 1 CPC and CEAC Data Base Listing," June 1983 provides data base values for the Palo Verde, Unit 1, CPC and CEAC.

The data base document states that - "the purpose of this document is to specify the CPC and CEAC data base constants applicable to the PVNGS-1 Cycle 1 software described in Reference 1, the CPC Functional Design Specification, and Reference 2, the CEAC Calculator Functional Design Specification."

References 1 and 2 are the functional specifications for a CPC and CEAC for San Onofre. In addition, Reference 3 is a software modification for Waterford, although not mentioned in the text.

a. Submitted by NRC as Question 492.1

(a) Are the referenced data base constants for San Onofre applicable to Palo Verde?

(b) Why is a reference given for a Waterford modification? Does this apply to Palo Verde?

RESPONSE:

A. The references listed in CEN-251(V)-P have been reviewed, and none of the four references relates to San Onofre data base constants. Furthermore, the San Onofre data base constants are not applicable to Palo Verde.

B. The reference to a document defining the Waterford modifications was incorrect. The referenced document applies only to Waterford CPC/CEAC software. The correct Reference 3 to CEN-251(V)-P should be Reference 7A-1 to this response. Reference 7A-1 incorporates the Waterford modifications and defines additional changes that were made specifically for Palo Verde. The last complete versions of the CPC and CEAC functional descriptions submitted to the NRC were References 7A-2 and 7A-3. References 7A-1 through 7A-3 completely define the functional design for the Palo Verde CPC/CEAC software. Therefore, the first paragraph of Section 1.2 in CEN-251(V)-P should read as follows:

"The CPC/CEAC system, as functionally described in References 1 and 2 and as modified by Reference 3, is implemented in assembly language and also exists as a FORTRAN simulation. This document provides..."

In addition, Subparagraph (1) of Section 1.3 in CEN-251(V)-P should read as follows:

"(1) The CPC and CEAC protection systems described in References 1, 2, and 3."

References

7A-1 CPC/CEAC Software Modifications for System 80, Enclosure 1-P to LD-82-039, March 1982.

7A-2 Functional Design Specification for a Core Protection Calculator, CEN-147(S)-P, January 1981.

7A-3 Functional Design Specification for a Control Element Assembly Calculator, CEN-148(S)-P, January 1981.

QUESTION 7A.6 (NRC Question 492.4)[a]

CEN-251(V)-P, revision 00 - "PVNGS-1 Cycle 1 and CEAC Data Base Listing," June 1983 provides data base values for CPC and CEAC. However, the BERR values (addressable constants) are not consistent with the approved CESSAR-80 values described in Enclosure 1-P to LD-83-010, "Statistical Combination of Uncertainties Part V," January 1983. Specifically, a comparison is shown in the following table for BERR values given for Palo Verde and CESSAR-80:

____

a. Submitted by NRC as Question 492.2

	Palo Verde	CESSAR-80
BERR0	8.5	9.0
BERR1	1.065	1.099
BERR2	8.5	7.48
BERR3	1.074	1.139
BERR4	8.5	12.48

(a) Explain why the Palo Verde BERRs differ from the CESSAR-80 values and justify their acceptability.

RESPONSE:

The Palo Verde BERRs do not differ from the CESSAR-80 values. The BERR values are calculated toward the end of the CPC software testing and, therefore, are not available at the time the CPC/CEAC data base is generated. The BERR values given in CEN-251(V)-P are preliminary values. These preliminary values are required in order to generate and certify a data base for use in phase I and phase II testing. In addition, certain outputs of the CPC/CEAC software testing are required as inputs to the uncertainty analysis which determines the correct BERR values for plant power operations. Since the BERR values are addressable constants, the final values can be loaded when the software is loaded.

The BERR values given for Palo Verde are not the correct values. The values certified for power operations are the same as those given for CESSAR-80. The letter (Reference 7A-4) which transmitted the CPC/CEAC disks and software documentation also transmitted the correct BERR

values. These values are listed in Attachment 3 of the letter, which is a table of correct addressable constant values. The letter also transmitted comments on the addressable constants which include the following guidance:

> "Attachment (3) lists the addressable constants and their values. The values of some of the addressable constants in Attachment (3) are different than the values for the equivalent constants contained in the data base listing and the software data base. The values listed in Attachment (3) supersede those values listed in the data base and are to be implemented when the software is loaded."

CHAPTER 8

ELECTRIC POWER

CONTENTS

CONTENTS (cont)

TABLES

FIGURES

8. ELECTRIC POWER

8.1 INTRODUCTION

8.1.1 TRANSMISSION NETWORK DESCRIPTION

The Palo Verde Nuclear Generating Station (PVNGS), Units 1, 2, and 3, is connected to the Western Interconnection, one of the two major power grids in North America.

Eight 525 kV transmission lines connect the Palo Verde 525 kV switchyard with the RUDD, Colorado River, Westwing, Hassayampa and Delaney switchyards.

8.1.2 ONSITE POWER SYSTEM DESCRIPTION

The onsite power system for each unit is shown in engineering drawing 01, 02, 03-E-MAA-002. Six circuits supply offsite (preferred) power to the three units through secondary windings of three startup transformers (refer to engineering drawing 13-E-MAA-001). The onsite power system of each unit is divided into two separate systems: the non-Class 1E power system and the Class 1E power system which is divided into two separate load groups, also referred to as subsystems and/or trains. Power is supplied to the auxiliaries at 13.8 kV, 4.16 kV, and 480V levels. The onsite power system includes the Class 1E power system which provides auxiliary ac and dc power for equipment used to shut down the reactor safely following a design basis event. The Class 1E buses of each unit must be energized in order to provide preferred or standby power to the safety-related loads of each unit. The Class 1E power systems are designed in accordance with IEEE 308-1974. A Class 1E dc system provides four channels of 125 V-dc control power for

Class 1E switchgear, essential ac power inverters, and other engineered safety feature (ESF) equipment (refer to engineering drawing 01, 02, 03-E-PKA-001).

8.1.3 SAFETY-RELATED LOADS

The Class 1E loads supplied by the Class 1E ac systems are listed in table 8.3-1. Class 1E loads supplied by the Class 1E dc system are listed in table 8.3-6.

8.1.4 DESIGN BASES, STANDARDS, AND GUIDES

The following principal design bases are applied to the design of offsite and onsite power systems.

8.1.4.1 Offsite Power System

The offsite (preferred) power supply provides ac power from the transmission network described in subsection 8.1.1 to the 4.16 kV Class 1E buses. The following principal design bases are applied to the offsite power system:

A. Electric power to the Palo Verde 525 kV switchyard is supplied by eight physically independent transmission lines designed and located to minimize the likelihood of simultaneous failure. Refer to section 8.2 for details.

B. Three physically independent startup transformers are provided to supply the onsite electric distribution system during startup. After startup, the normal unit auxiliaries are supplied from the unit auxiliary transformer and the Class 1E equipment is supplied from

the startup transformers. Refer engineering drawing 13-E-MAA-001 for details.

C. The outage of a single startup transformer does not jeopardize continued plant operation, i.e., when loads are administratively controlled between units at least one offsite source to plant auxiliaries and ESF buses is available with a single startup transformer outage.

D. The Palo Verde 525 kV switchyard is designed with duplicate and redundant systems; i.e., two trip coils per breaker, two protective relay schemes, and two ac supplies from the 13.8 kV intermediate buses.

E. The loss of a nuclear unit or the most critical unit on the transmission network does not result in loss of offsite power to the safety-related buses.

8.1.4.2 Onsite Power System

A. The onsite Class 1E power system for each unit is split into two independent load groups, each with its own offsite and onsite power supplies, buses, transformers, loads, and associated 125 V-dc control power. Either load group is independently capable of safely shutting down the unit.

B. The onsite power system includes two redundant Class 1E electric systems for each unit. The Class 1E systems supply power at 4.16 kV ac, 480 V-ac, 120 V-ac, and 125 V-dc, as required, to plant safety-related systems.

C. One independent emergency diesel generator is provided for each Class 1E ac load group.

D. No automatic transfers are provided between redundant load groups.

E. There is complete independence of onsite electric systems between units.

F. The Class 1E power systems are designed to satisfy the single failure criterion.

G. For each protection and control channel, one independent 125 V-dc power source and one 120V vital ac power source are provided. Batteries are sized for a minimum of 2 hours of operation without support of a battery charger.

H. A separate nonsafety-related dc system is provided for nonsafety-related controls and pump motors.

I. Raceways are not shared by safety and nonsafety cables. However, the nonsafety cables that are supplied from or are derived from Class 1E sources are treated as safety-related cables up to and including the isolation device with regard to redundant system separation and identification criteria in conformance with Regulatory Guide 1.75 as qualified in section 1.8.

J. Special identification criteria apply for Class 1E equipment cabling and raceways (see paragraph 8.3.1.3).

K. Separation criteria, which establish requirements for preserving the independence of redundant Class 1E electric systems, comply with Regulatory Guide 1.75 as qualified in section 1.8.

L. Safety-related equipment is designed with the capacity to be tested periodically.

M. 10CFR50, Appendix A, is followed in the design of the electric power system.

N. A non-safety related Alternate AC (AAC) power source consisting of two redundant station blackout generators is available to provide power to cope with a 16 hour station blackout event in any one nuclear unit.

8.1.4.3 Design Criteria, Regulatory Guides, and IEEE Standards

A discussion of General Design Criteria 17 and 18 and IEEE standards is provided in paragraphs 8.3.1.2 and 8.3.2.2. Consistency of design with the recommendations of NRC Regulatory Guides 1.6, 1.9, 1.22, 1.29, 1.30, 1.32, 1.40, 1.41, 1.47, 1.53, 1.62, 1.63, 1.73, 1.75, 1.81, 1.89, 1.93, and IEEE 387-1972 are discussed in paragraphs 8.3.1.2 and 8.3.2.2. In addition, Regulatory Guides 1.100, 1.118, and 1.155 are discussed in section 1.8.

8.2 OFFSITE POWER SYSTEM

8.2.1 DESCRIPTION

Eight physically independent 525 kV transmission lines of the Western Interconnection are connected to the Palo Verde 525 kV switchyard. Three 525 kV tie lines supply power from the switchyard to three startup transformers, which supply power to six 13.8 kV intermediate buses. Two physically independent circuits supply offsite (preferred) power to the onsite power system of each unit. The offsite power system is described in this section and is depicted in figures 8.1-1 and 8.2-1.

8.2.1.1 Transmission Network

The transmission network associated with PVNGS supplies offsite (preferred) ac power at 525 kV for startup, normal operation, and safe shutdown of Units 1, 2, and 3. The eight 525 kV lines of this system that are associated with the Palo Verde 525 kV switchyard are: PVNGS to RUDD, PVNGS to Westwing I, PVNGS to Westwing II, PVNGS to Colorado River, PVNGS to Hassayampa I, PVNGS to Hassayampa II, PVNGS to Hassayampa III, and PVNGS to Delaney. They cover distances of approximately 37, 44, 44, 128, 3, 3, 3, and 15 miles, respectively.

All eight transmission lines associated with the Palo Verde 525 kV switchyard traverse relatively flat terrain and their design meets grade B requirements specified by the National Electrical Safety Code, sixth edition.

The Code specifies loading areas, wind loads for towers and conductors, and safety factors to be used. The conductors and the overhead ground wires are dampened to maintain acceptable

levels of vibration. There is a crossing of the Westwing I and Westwing II lines by a 525 kV line not associated with PVNGS, approximately 43 miles from PVNGS. There is a crossing of the Delaney line by the Colorado River line, approximately 15 miles from PVNGS.

The eight transmission lines associated with the Palo Verde 525 kV switchyard, and their rights-of-way, are designed so as to minimize line proximities that could result in simultaneous failure of more than one circuit. Based on historical transmission system data, the frequency of occurrence for breakage of the span of line that crosses the two Westwing lines is 1.1×10^{-5} per year and for the breakage of the span of the Colorado River line that crosses the Delaney line is 6.9×10^{-6} per year. In the highly unlikely event of transmission network instability resulting from simultaneous short-circuiting of both Westwing lines or simultaneous short-circuiting of the Delaney and Colorado River lines, a loss of all nonemergency AC power event could result. This design basis event is evaluated in chapter 15.

8.2.1.2 Switchyard and Connections to the Onsite Power System

The Palo Verde 525 kV switchyard utilizes a breaker-and-a-half design in which three breakers are provided for every two terminations, either line or transformers. The switchyard is connected to the eight 525 kV transmission lines discussed in Section 8.2.1.1, the 525/24 kV turbine-generator main transformers, and the 525/13.8 kV startup transformers, as shown in figure 8.2-2.

Each turbine-generator connects to the Palo Verde 525 kV switchyard through a main transformer, a 525 kV tie line, and two 525 kV switchyard breakers, as shown in figure 8.2-2. Physical connections between the units and the Palo Verde 525 kV switchyard are shown in figure 8.2-1.

The three startup transformers connect to the Palo Verde 525 kV switchyard through two 525 kV switchyard breakers each, and feed six 13.8 kV intermediate buses. These buses are arranged in three pairs, each pair feeding only one unit.

The intermediate buses for Units 1, 2, and 3 are interconnected to the startup transformers so that each unit's buses can access all three startup transformers when all startup transformers are connected to the switchyard.

The intermediate buses are connected to the onsite power system by one 13.8 kV transmission line per bus (two per unit). These lines are physically separated to minimize the possibility of simultaneous failure of the lines.

8.2.1.2.1 Switchyard and Offsite Power System Development

Figure 8.2-2 depicts the switchyard and 13.8 kV bus arrangements.

Necessary 525 kV breaker installation is accomplished during refueling, if possible, or during operation. All operating 525 kV positions are transferred to the opposite bus: thus, continuity of offsite power is maintained.

8.2.1.2.2 Water Reclamation Facility Load Shedding

The Water Reclamation Facility loads are load shed from the Unit 1 intermediate buses upon a Unit 1 BOP ESFAS Mode 1 signal concurrent with switchyard voltage at or below a value which could result in a trip of offsite power in the event of a safe shutdown or emergency event.

8.2.1.3 Compliance with Design Criteria and Standards

The following analysis demonstrates compliance with General Design Criteria 17 and 18 of 10CFR50, Appendix A, and Regulatory Guide 1.32.

8.2.1.3.1 Criterion 17 -- Electric Power Systems

In addition to the features detailed in paragraphs 8.2.1.1 and 8.2.1.2, compliance with Criterion 17 is further demonstrated by the following:

A. If one of the two 13.8 kV physically independent circuits per unit from the intermediate buses to the onsite power system is interrupted, the remaining circuit can supply offsite power to both load groups of the onsite Class 1E power system, as shown in engineering drawing 01, 02, 03-E-MAA-002.

B. The two physically independent circuits, supported on independent structures, are separated so as to avoid the possibility that the structural collapse of one will cause an outage of the other 13.8 kV circuit.

C. The 13.8 kV circuits are protected from lightning and switching surges by lightning protective equipment and by overhead static lines.

D. Design of the 125 V-dc system for the Palo Verde 525 kV switchyard consists of two independent dc systems. Each of the two systems consist of a separate 125 V-dc battery, battery charger, and distribution system. Cable separation is maintained between the two systems. A single failure caused by a malfunction of either of the two 125 V-dc systems does not affect the performance of the other system. The ability of the switchyard to supply off-site power to the plant is not affected by the loss of one of the two 125 V-dc systems.

E. Two isolated 13.8 kV supplies from the intermediate 13.8 kV buses are provided to the Palo Verde 525 kV switchyard. The ac load is divided between two power panels and loss of one feeder from the plant does not jeopardize continued operation of the switchyard equipment.

F. For reliability and operating flexibility, the Palo Verde 525 kV switchyard design includes a breaker-and-a-half arrangement for each circuit along with breaker failure backup protection. Each breaker has two trip coils on separate, isolated dc control circuits. These provisions permit the following:

1. Any transmission line can be cleared under normal or fault conditions without affecting any other transmission line.

2. Any circuit breaker can be isolated for maintenance without interrupting the power or protection to any circuit (subject to limitations of power system development paragraph 8.2.1.2.1).

3. Short circuits on a section of bus can be isolated without interrupting service to any circuit other than that connected to the faulty bus section.

G. The offsite (preferred) power supplies from the 525 kV switchyard to the startup transformers are separate and independent. The failure or structural collapse of one system or structure does not affect other offsite sources.

H. The offsite (preferred) power supplies from the startup transformers to the 13.8 kV intermediate buses NAN-S03 and NAN-S04 are independently and separately routed.

I. Two physically independent circuits are provided for offsite (preferred) power to the onsite power system for each unit. The offsite (preferred) power supply normally connected to each load group of the onsite Class 1E ac power system is immediately available to supply components important to safety following a postulated loss-of-coolant accident. Either of the

two offsite (preferred) power supplies to each load group, if available, can be connected by control switch operation in the control room. (subject to the limitations of power system development paragraph 8.2.1.2.1).

8.2.1.3.2 Criterion 18 -- Inspection and Testing of Electric Power Systems

The 13.8 kV intermediate bus circuit breakers can be inspected, maintained, and tested on a routine basis. This can be accomplished without removing the generators, transformers, or transmission lines from service (subject to limitations of power system development paragraph 8.2.1.2.1).

Transmission line protective relays can be tested on a routine basis. This can be accomplished without removing the transmission lines from service. Generator, main transformer, and startup transformer relays are tested on a routine basis when the generator is offline.

Onsite power system components will be periodically inspected and maintained as required. This can be accomplished without removing the transmission lines, generators, or transformers from service.

8.2.1.3.3 Regulatory Guide 1.32

As described in paragraph 8.2.1.3.1, listing I, an independent immediate access circuit is provided to each load group of the onsite Class 1E ac power system bus for each unit.

8.2.1.3.4 Industry Standards

The design complies with applicable standards and recommendations of:

- Institute of Electrical and Electronics Engineers, Inc. (IEEE) National Electrical Manufacturer's Association (NEMA)
- National Electrical Code (NEC)
- American Society of Civil Engineers (ASCE)
- Underwriters' Laboratory, Inc. (UL)
- American Iron and Steel Institute (AISI)

8.2.2 ANALYSIS

The transmission network is planned so that the loss of a single transmission element (i.e., line or transformer) does not result in loss of load, transmission overload, undervoltage condition, or loss of system stability. Offsite power supply reliability is determined by the performance of the eight 525 kV transmission lines associated with the Palo Verde 525 kV switchyard. The source stations for the lines all have three or more connected circuits of 230 kV and above.

Power flow studies conducted for the described system indicate that the system can reliably deliver power to all project participants using the above planning criteria. Dynamic stability studies(3) have established safe power generation levels for the generating units in the PVNGS area to ensure that the system can withstand the following disturbances without loss of system stability or loss of load:

A. A permanent 3-phase fault on the Palo Verde 525 kV switchyard bus with subsequent loss of the critical 525 kV line.

B. A sudden loss of one of the three PVNGS units with no underfrequency load shedding measures in effect.

C. The sudden loss of the largest single load in Arizona, New Mexico, Southern California, or Southern Nevada.

These studies include a 7% PVNGS generation margin.

A transmission network operating procedure controls the level of power generation in the PVNGS area to ensure that the safe levels are not exceeded.

Although these studies conclude that a PVNGS unit trip would not cause transmission network instability, certain chapter 15 accident analyses conservatively assume that offsite power is lost as a consequence of a PVNGS turbine trip. Refer to section 8.3.4 and table 15.0-0.

Transmission network availability data on 525 kV transmission lines in the area indicate an outage rate of 2.08 total outages per year per 100 line miles. Of these, 1.08 are due to planned outages and 1.00 are due to forced outages. Due to all causes, the outage ratio for 525 kV lines in the area is 0.00180.

On 230 kV transmission lines in the area, similar data indicate outage rates of 6.59 total outages per year per 100 line miles. Of these, 2.97 are due to planned outages and 3.61 are due to forced outages. Due to all causes, the outage ratio for 230 kV lines in the area is 0.0394.

These outages are most commonly attributable to lightning. Other causes are fog, contamination, flooding, other aspects of weather, falling objects, equipment failure, emergency maintenance, employee error, and, hypothetically, dust contamination. The chief constituents of dust storms are nonconducting clay dust (usually quartz) and conducting gypsum (calcium sulphate) which can contaminate the insulators. This contamination increases the probability of flashover, especially with fog or dew, by disclosing the salts to form an electrolyte.

However, dust buildup is reduced by the self-clearing action of the "V" string insulator configuration used in EHV line construction and by the abrasive action of the dust and sand. Also, any adverse conditions resulting from insulator contamination within the switchyard can be corrected by washing the insulators.

APS has never experienced a flashover in any of its EHV switchyards due strictly to dust on insulators and has found that dust storms contribute little to the outage frequency of EHV transmission lines.

Likewise, APS has not experienced any known dust-caused insulation failures at the 15 kV or 4 kV voltage levels in either open substation facilities or enclosed switchgear.

Therefore, it is felt that dust loading on the 13.8 kV system will not be a problem. The system is designed such that, with rare exceptions, forced outages do not result in loss of load.

Other forms of contamination that increase the probability of flashover in certain areas, especially near the Pacific coast,

are sea-salt deposits and industrial contaminations. The insulators can become contaminated by the salt deposits and when fogging conditions exist, flashovers are more likely to occur.

To minimize the effect of both salt and industrial contamination, the insulators are washed with demineralized water. The frequency of washing depends on the area. Some areas near the Pacific Coast require washing once a month while areas farther inland require washing every 90 days. The use of semi-conducting glazed insulators also reduces the flashover rates in areas of high contamination. No washing of insulators is anticipated in the desert regions.

8.3 ONSITE POWER SYSTEMS

8.3.1 AC POWER SYSTEMS

8.3.1.1 Description

The onsite ac power system includes a Class 1E and a non-Class 1E power system. Engineering drawings 13-E-MAA-001 and 01, 02, 03-E-MAA-002 are one-line diagrams of the ac power system.

8.3.1.1.1 Non-Class 1E AC Power System

The non-Class 1E ac power system is that part of the onsite power system outside the dotted-line enclosures indicated in engineering drawings 13-E-MAA-001 and 01, 02, 03-E-MAA-002. The non-Class 1E ac power system distributes power at 13.8 kV, 4.16 kV, 480V, and 208/120V for nonsafety-related loads. Only nonsafety-related loads are supplied by the non-Class 1E ac power system. There will be an interconnection during startup between the offsite (preferred) power supply, the non-Class 1E ac system associated with 13.8 kV buses NAN-S01 and NAN-S02 and the Class 1E ac system.

During normal plant operation, power for the onsite non-Class 1E ac power system associated with buses NAN-S01 and NAN-S02 is supplied through the unit auxiliary transformer connected to the generator isolated phase bus. Two offsite power sources are provided to meet startup, shutdown, and post-shutdown requirements of the unit. Each unit's non-Class 1E ac power system is divided into two parts arranged so that the possibility of a forced shutdown due to loss of one part will be minimized. Each of the two parts supplies a load group including approximately half of the unit auxiliaries.

Three startup transformers connected to the Palo Verde 525 kV switchyard are shared between Units 1, 2, and 3 and are connected to 13.8 kV intermediate buses of the units. Each startup transformer is capable of supplying 100% of the startup or normally operating loads of one unit simultaneously with the engineered safety feature (ESF) loads associated with two load groups of another unit. The non-Class 1E ac buses NAN-S01 and NAN-S02 normally are supplied through the unit auxiliary transformer, and the Class 1E buses normally are supplied through the startup transformers. In the event of loss of supply from the unit auxiliary transformer (except for overcurrent trip), an automatic fast transfer of 13.8 kV buses NAN-S01 and NAN-S02 to the startup transformers is initiated to provide power to the auxiliary loads. Transfers of these buses can be initiated by the operator from the control room. Engineering drawings 13-E-MAA-001 and 01, 02, 03-E-MAA-002 show connections of power supply feeders and busing arrangements of the ac power system. Offsite (preferred) power for the onsite Class 1E power system is supplied through the startup transformers, the 13.8 kV switchgear, and the 13.8 to 4.16 kV ESF transformers.

Reactor coolant pumps 1A and 2A are connected to 13.8 kV bus NAN-S01 and 1B and 2B are connected to 13.8 kV bus NAN-S02. Electrical supply for reactor coolant pumps is arranged so that the pumps will normally remain electrically connected to the turbine-generator for 20 to 30 seconds following a turbine trip should offsite power not be available. Credit is not taken for this feature.

8.3.1.1.3 Class 1E AC Power System

The Class 1E ac power system is that part of the onsite power system inside the dotted-line enclosures shown in engineering drawings 13-E-MAA-001 and 01, 02, 03-E-MAA-002.

The Class 1E ac power system distributes power at 4.16 kV, 480V, and 120V to all Class 1E loads. Also, the Class 1E ac

power system supplies power to certain selected loads that are not directly safety-related but are important to the plant. Table 8.3-1 lists the safety-related loads supplied from the Class 1E ac power system.

The Class 1E ac power system contains standby power sources (emergency diesel generators) that automatically provide the power required for safe shutdown in the event of loss of the 4.16 kV Class 1E bus voltage.

Voltage levels at the safety-related buses are optimized for the full load and minimum load conditions that are expected throughout the anticipated range of voltage variations of the power source by the adjustments of the voltage tap settings on the transformers.

An analysis was conducted and is maintained as follows. The maximum load conditions at the minimum anticipated offsite voltage are analyzed to ensure that voltages present at the terminals of the loads are above the manufacturer's minimum voltage rating. Additionally, the minimum load conditions at the maximum anticipated offsite voltage (102.0% of the switchyard voltage) are analyzed to ensure the voltages present at the terminals of the loads are below the manufacturer’s maximum voltage rating. Where this is not the case, the loads are evaluated individually and the rationale for operation is documented.

The following describes various features of the Class 1E systems.

8.3.1.1.3.1 Power Supply Feeders. Each 4.16 kV load group is supplied by two offsite (preferred) power supply feeders and one diesel generator (standby) supply feeder. Each 4.16 kV bus supplies three 750 kVA, 4.16 kV, 480V station service transformers and associated load centers. Transformers EPGAL31X and EPGBL32X have a power rating of 750/1000 kVA (AA/FA) due to the addition of fan cooling packages.

8.3.1.1.3.2 Power Feeder Cables. Power feeder cables for the Class 1E 4.16 kV power system are copper, rated at 5 kV, 3/C nonshielded armored and 1/C shielded with flame-retardant jacket. Power cables for use at 480 volts and less are rated at 600 volts. All conductors are insulated with ethylene propylene rubber or cross-linked polyethylene rated for 90C conductor temperature. All 5 kV and 600 volt cables have been designed for operation as follows:

A. Cables are suitable for installation in metal trays, in conduits, in underground duct banks, and are suitable for the environment in which they are installed as defined in Appendix A of the Equipment Qualification Program Manual.

(a) The horsepower ratings listed in this table are for reference only. The actual ratings can be found in the Electrical Equipment Database X-E-ZZI-0003. The ZZI-0003 database is controlled and lists the actual electrical equipment ratings.

B. The Class 1E and non-Class 1E cables are intended for use at a normal conductor temperature not to exceed 90°C for all area-specific ambient temperatures, at 100% relative humidity. The ambient temperature(s) may be assumed to equal the maximum (non-LOCA) temperatures for the building, area or room in which the respective cables are installed. Where the maximum design temperature is less than 40°C (104°F), the 40°C value is assumed. These "Enveloping Design Temperature" values are defined in UFSAR Table 9.4-2 and Appendix A of the Equipment Qualification Program Manual.

8.3.1.1.3.3 Bus Arrangements. The safety-related equipment is divided into two load groups per unit (load groups 1 and 2). For each unit, either one of the associated load groups is capable of providing power for safely shutting down the unit. Each ac load group consists of one 4.16 kV bus, three 480V load centers, and four 480V motor control centers (MCCs). Two non-Class 1E MCCs are connected to each load group and are tripped on a safety injection actuation signal (SIAS).

8.3.1.1.3.4 Loads Supplied From Each Bus. Refer to table 8.3-1 for a listing of Class 1E loads and to engineering drawing 01, 02, 03-E-MAA-002 for their respective buses.

8.3.1.1.3.5 Manual and Automatic Interconnections Between Buses, Buses and Loads, and Buses and Supplies. No provisions exist for automatically connecting one load group to another redundant load group or for automatically transferring loads between load groups. There are provisions for manually

connecting both ESF buses to either preferred source as shown in engineering drawing 01, 02, 03-E-MAA-002. Loss of offsite power when both buses are connected to the same preferred source results in an automatic trip of both ESF bus main breakers. Thus, failure of one breaker to trip will not result in paralleling the diesel generators. Circuit breaker interlocks are provided to prevent manually paralleling the diesel generators. During manually initiated testing, only one diesel generator at a time may be paralleled with the offsite source power.

There are provisions for manually connecting both ESF buses to a single standby power source during emergency conditions. Additionally, power can be supplied to a single ESF bus of one unit from a standby power source of another PVNGS unit. Restrictions and instructions governing the use of these two abnormal electrical lineups are given in the applicable emergency and abnormal operating procedures.

8.3.1.1.3.6 Third-of-a-Kind ESF Loads. The charging pump is third-of-a-kind ESF equipment which is supplied power from the redundant Class 1E buses. Power is supplied through a manual transfer switch. Only one breaker is available for supplying power to the third pump. When power is required to be switched to the accompanying redundant load group, the breaker previously serving the charging pump from the load group is removed and inserted in the accompanying redundant load group prior to switching the load into the source. Control power for the third charging pump is provided from the load group from which power is being supplied.

The 120V-ac Class 1E vital instrumentation and control power (PN) system train swing inverters, if implemented per DMWO 3232547, are also third-of-a-kind ESF components (power sources). They are designed as back-ups for each train of the PN system normal inverters. They are supplied power from independent channels of Class 1E DC buses (see subsection 8.2.3) and supply power to Class 1E PN distribution panels. Power is supplied through manual swing line-up switches. When power is required, a designated Class 1E DC feed breaker is manually closed and the swing line-up switch is manually aligned to the designated PN system channel. Power is then manually connected to the aligned PN distribution panel through a Manual Bypass Switch.

8.3.1.1.3.7 Interconnections Between Safety- and Nonsafety-Related Buses. There are no interconnections between the safety- and nonsafety-related buses except through the preferred power system (offsite power system).

8.3.1.1.3.8 Redundant Bus Separation. The Class 1E switchgear, load centers, and motor control centers for the redundant load groups are located in separate rooms of the control or auxiliary building in such a way as to ensure physical and electrical independence. Refer to paragraph 8.3.1.4.1 for criteria governing redundant bus separation.

8.3.1.1.3.9 Equipment Capacities. The capacities of the equipment are shown in table 8.3-2.

8.3.1.1.3.10 Automatic Loading and Load Shedding. The automatic loading sequence of the diesel generator buses is shown in table 8.3-3.

If preferred power is available to the Class 1E bus following an engineered safety features actuation signal (ESFAS), the required Class 1E loads will be started through a solid-state sequencer. However, in the event that preferred power is lost, the Class 1E system functions to shed Class 1E loads and to connect the standby power source to the Class 1E bus. The load sequencer then functions to start the required Class 1E loads in programmed time increments.

No credible sneak circuits can occur to render sensors, power supplies, or actuated devices in redundant channels or load groups inoperable through unplanned interconnections. Redundant channels and load groups are isolated and separated in accordance with Regulatory Guide 1.75 as discussed in section 1.8. Each ESF load sequencer, one for each load group, has independent sensor channels, power supplies, and actuated devices.

8.3.1.1.3.10.1 Load Sequencer Design and Testing. Each redundant ESF load sequencer system performs logic functions to generate the loss of offsite power (LOP) signal/load shed signal, the diesel generator start signal (DGSS), and the load sequencer start and permissive signals.

Each redundant ESF load sequencer system is supplied from a separate 120V vital ac distribution bus and a separate Class 1E 125 V-dc distribution bus.

The LOP signal/load shed signal logic continuously monitors the Class 1E 4.16 kV bus for an undervoltage condition using four undervoltage relays. If an undervoltage trip occurs, annunciation and indication is provided to the operator. On a two-out-of-four coincidence of undervoltage relay trips or upon manual actuation, an LOP signal and load shed pulse are generated. The LOP signal is sent to the DGSS logic. The LOP signal (maintained through a 60-second off delay) also actuates forced shutdown system loads by deenergizing actuation relays. The load shed pulse (1 second) sheds 4.16 kV and selected 480V loads from the Class 1E 4.16 kV bus and trips the 4.16 kV Class 1E bus preferred (offsite) power supply breakers by energizing actuation relays.

Table 8.3-2
EQUIPMENT CAPACITIES

Equipment	Description	Continuous Capacity	Symmetrical Fault Capacity
4160V Switchgear	Bus	1200A	58,000A RMS bracing
	Incoming breakers	1200A	33,000A RMS at 4.16kV
	Feeder breakers	1200A	33,000A RMS at 4.16kV
480V Load center	Transformers 3 phase, 60 Hz 4160/480V	750 kVA*	N/A
	Bus	1600A	55,000A RMS bracing
	Incoming breakers	1600A	50,000A RMS at 480V
	Feeder breakers	600A	30,000A RMS, 480V, with instantaneous trip
		600A	22,000A RMS 480V
480V Motor control center	Horizontal bus	600A	22,000A RMS bracing
	Vertical bus	300A	22,000A RMS bracing
	Breakers (molded case)	150,225AF	10,000/25,000 RMS minimum

Hz = Hertz
V = Volt
A = Ampere
kVA = Kilovoltampere
RMS = Root mean square
MVA = Megavoltampere

* Note: Transformers EPGAL31X and EPGBL32X have a power rating of 750/1000 kVA (AA/FA) due to the addition of fan cooling packages.

TABLE 8.3-3[(a)]
DIESEL GENERATOR LOAD SEQUENCING
(Sheet 10 of 12)

a. See ZZI-003 Electrical Equipment Database for HP, KW, or KVA rating of individual loads. See EC-MA-221 AC Distribution Calculation for DG total loading for loss of offsite power with forced shutdown and loss of offsite power with LOCA.

b. Sequencer mode 2 is a Loss of coolant accident (LOCA) and a loss of offsite power (LOP) and diesel generator breaker closed. LOCA can be either a Containment Spray Actuation Signal (CSAS) or Safety Injection Actuation Signal (SIAS). Start time is counted from the generator breaker closure instant (sequencer time 0.0) and does not include the 10 second maximum start time for the diesel generator to accelerate up to nominal voltage and frequency and the time to close the breaker. This mode begins sequencing of loads onto the diesel generator (load step 1) at .5 seconds. The .5 second delay allows initial energization of the three safety-related 4160-480 volt load center transformers (E-PGA-L31X,33X,35X, E-PGB-L32X,34X,36X). Load step 2 begins at 5 seconds, and the remaining load steps (3 through 7) occur at 5 second intervals for a total of 30 seconds. Manual loading begins after 30 seconds. One additional load step permissive occurs at 40 seconds (see note h).

c. Sequencer mode 3 is a Forced shutdown (FS) and a loss of offsite power (LOP) and diesel generator breaker closed. Forced shutdown is <u>not</u> a LOCA and is an unscheduled shutdown

TABLE 8.3-3[a]
DIESEL GENERATOR LOAD SEQUENCING
(Sheet 11 of 12)

of a unit. Start time is counted from the generator breaker closure instant and does not include the 10 second maximum start time for the diesel generator to accelerate up to nominal voltage and frequency and the time to close the breaker. This mode begins sequencing of loads onto the diesel generator (load step 1) at .5 seconds. The 5 second delay allows initial energization of the three safety-related 4160-480 volt load center transformers (E-PGA-L31X,33X,35X, E-PGB-L32X,34X,36X). Load step 2 begins at 5 seconds, and the remaining load steps (3 through 7) occur at 5 second intervals for a total of 30 seconds. Manual loading begins after 30 seconds. One additional load step occurs at 55 seconds.

d. Initial start of essential chiller is delayed 71 seconds maximum. Subsequent starts are delayed 2-1/4 minutes maximum due to chiller internal control.

e. Will be started manually at operator’s discretion.

f. These loads are not on when the diesel generator is running.

g. Non-Class IE loads fed from Class IE power through Class IE interrupting devices connected in series.

h. The load will automatically sequence on in 40 seconds for a LOCA (SIAS OR CSAS) if the following conditions are met: sequencer permissive and auto (after stop) and pressurizer level low. There is no time constraint or permissives required for manual loading.

TABLE 8.3-3[a]
DIESEL GENERATOR LOAD SEQUENCING
(Sheet 12 of 12)

i. Plant numbering system identification. Example: EPKAH11. E is the discipline designator, PK is the system designator, A is the separation group (A, B, C, and D for separation groups, E is a non-separation group but meets separation criteria, N for non-Class 1E separation group), H is the commodity or device designator, and 11 is the sequence number. See the Plant Numbering Procedure, 80DP-0CC04 for more details.

j. The motor operated valves (MOV) are modeled as constant impedance intermittent loads. These loads are included for the duration of their load sequence to model the effect of their inrush current on voltage during load sequencing.

k. Sequenced loading and steady state loading summary, which includes the distribution effects of cable and transformer losses. The actual calculations are performed by ECALC, the qualified electrical calculation software. The maximum continuous steady state load rating for the diesel generator is 5.500 MW and 4.125 MVAR (6.875 MVA).

l. EPKAH15 backs up EPKAH11 and EPKBH16 backs up EPKBH12.

N/A - Not Applicable

m. The automatic loading of E-NNN-V18 onto the Diesel Generator within 0.5 seconds is only applicable for Unit 3. E-NNN-V18 for Units 1 and 2 will remain as a manual function for Diesel Generator loading. In either case, the total steady state Diesel Generator loading has not been increased.

The DGSS logic combines the LOP, SIAS, AFAS, CSAS, and manual actuation in a logical "OR" to generate a DGSS to start the diesel generator.

The load sequencer start and permissive signal logic monitors input signals, determine the appropriate mode of operation, and generate sequentially timed start and permissive signals to ESF and forced shutdown loads as required to prevent instability of Class 1E buses. Start signals actuate devices by deenergizing actuation relays. The permissive signals, however, allow loading of devices by energizing actuation relays. The load sequencer controls only pumps, fans, and chillers, and does not control any valves or dampers.

As such, the load sequencer does not cause complete ESF system actuation. The load sequencer responds to the following conditions:

- LOCA, with or without offsite power available
- Accident other than LOCA, with or without offsite power available
- LOP with or without an accident other than LOCA, but followed at a later time by a LOCA
- LOCA that is followed at a later time by an LOP

The load sequencer has a normal mode (Mode 0) and the following four operating modes:

A. SIAS/CSAS without an LOP

B. SIAS/CSAS coincident with an LOP. Sequencing is started on a diesel generator breaker closure signal.

C. LOP without an SIAS/CSAS. Sequencing is started on a diesel generator breaker closure signal.

D. Other signals without an SIAS/CSAS and without an LOP. These signals are:

- CRVIAS or CREFAS
- FBEVAS
- AFAS-1 or AFAS-2
- Diesel generator running

Receipt of subsequent input signals requiring a change of operating mode causes the load sequencer to reset, transfer to the required mode, and initiate sequencing of the required loads.

The devices sequentially actuated through the load sequencer receive a load shed signal on bus undervoltage to trip the device load, and a load sequencer start signal to start the device at the appropriate time. Reset of the load sequencer and its actuation relays does not stop or shed actuated devices. Devices are shed only on the load shed signal.

A sequencer design demonstration test was performed to test the sequencer to assure that no credible sneak circuits or common mode failures could render both onsite and offsite power sources unavailable. The testing included approximately 130 credible scenarios combining accident situations with and without offsite power available. The test results were satisfactory and demonstrated that no sneak logic paths exist in the design that could result in failure of the sequencer to perform its required function. The test report, ESF Load

Sequencer Design Demonstration Test Report, E160972, February 1981, was submitted to the NRC (Supplier Document Register No. 13-J-104-85).

Provisions are made to permit periodic testing of the ESF load sequencer system. Tests cover the trip actions from input signals through the system and the actuation devices. System test does not interfere with the protective function of the system. Actuation of the components controlled by the ESF load sequencer system does not disturb normal plant operating conditions; therefore, the ESF load sequencer system is tested by complete actuation. Proper operation may be verified by the following:

- Checking the position of each ESF component
- Checking the actuation annunciation
- Checking the ESF component status indication
- Checking the load sequencer timing
- Checking all sequencer modes
- Checking all logic circuits

This testing will be performed as specified by the PVNGS Technical Specifications.

The ESF load sequencer for each logic train contains the necessary hardware and associated software programs stored in read-only memory to determine that each functional channel within that train will respond to field initiated input contact action and that the ESF load sequencer in the opposite train is operative.

The auto test function does not check:

A. The Cross Logic Train Actuation Signal Operation - Response times dictated by specified signal filtering bandpass limit of 30 Hz do not allow test pulses to propagate to the opposite train.

B. Actual Actuation Relay Contact Transfer - Only the relay drive current response is monitored.

C. Manually Initiated Actuation Inputs

The auto-test feature is normally off. A 24-day test interval that either manually activates the auto-test feature or performs a system test in at least one sequencer mode is sufficient to maintain the system reliability goal.

8.3.1.1.3.10.2 Module Selection and Test Scheme.

A. Address Select and Test Enable Bus

Each module has an address code associated with its position in the system (e.g., FBEVAS-01, CREFAS-02, CPIAS-03, LOP/LS-04, CRVIAS-05, DGSS-06) which is set within the module via a minidip switch unit. As the module address select signal bus (four lines) is strobed with each successive code, the selected module will admit test pulses (10 msec wide; 250 msec apart; four per test) which propagate through the logic and are sensed in such a way as to prepare a return signal to be sent back to the auto test function contained within the ESF load sequencer for interpretation. The LOP/LS module requires an additional four lines (test enable)

to interpret the module response to all possible two of four pairs.

B. Module Test Response Return Interpretation

As the modules are successively selected, the auto test features within the sequencer examines the test returns and active signals received from the modules and looks for a particular pattern based upon the system configuration, and within the time frame of the test. The auto test feature is then able to determine if the module has passed or failed a test, or if a field-related signal (actual input) has been received. In the case of a failed test or an actual input, the auto test feature will cease operation.

C. Test Failure Indication

Each module contains a test indicator lamp that illuminates in a steady-state while that module is under test. As the auto test feature strobes each module, the test indication will appear to "walk" across the face of the bin assembly containing the modules. If the auto test feature determines an erroneous response, it will cause the test indicator on the module where the failure was detected to flash. The error may or may not be within that module dependent upon the system configuration and the position of the module in the test order (e.g., if the FBEVAS module correctly responded to the test, yet a failure in the CREFAS module failed to provide its required automatic output, the auto test feature would flash the error indicator in the FBEVAS

module). Further manual tests might be required to isolate the fault. When the auto test feature terminates testing under either an error detection or receipt of an actual input, the required auto test terminate (fail) annunciator contacts will transfer to the alarm state. During auto test operation, the "auto test on" annunciator contacts are transferred.

D. Test Success Indication

As the modules are strobed into test by the module select bus (solid test indicator illumination), the test pulses propagating through the module actuation logic will cause the associated indicators to "flicker." As the module successfully completes its test, the next module in line is strobed and its actuation associated indicators "flicker," until all modules are tested, including the ESF load sequencer itself.

Refer to paragraph 8.3.1.1.4.6 for additional information on load shedding and sequencing.

8.3.1.1.3.11 Class 1E Equipment Identification. Refer to paragraph 8.3.1.3 for details regarding the physical identification of Class 1E equipment.

8.3.1.1.3.12 Instrumentation and Control Systems for the Applicable Power Systems with the Assigned Power Supply Identified. The dc control power supplies for redundant Class 1E controls are physically and electrically separate and independent so that dc subsystem A supplies Class 1E load group 1 switchgear. The battery chargers for dc subsystem A are fed

from the same load group 1 switchgear. The dc subsystem B supplies Class 1E load group 2 switchgear in a similar manner.

Each 4.16 kV bus and 480V load center bus is equipped with an undervoltage relay for annunciation in the control room. The voltage of each Class 1E 4.16 kV bus and 480V load center bus is monitored by instruments in the control room.

8.3.1.1.3.13 Electric Circuit Protection Systems. Protective relay schemes and direct-acting trip devices on primary and backup circuit breakers are provided throughout the Class 1E onsite power system to:

- Isolate faulted equipment and/or circuits from unfaulted equipment and/or circuits
- Prevent damage to equipment in abnormal operation
- Protect personnel
- Prevent system disturbances

The direct-acting trip device, installed on PVNGS Load Center breakers, is an adjustable overcurrent trip apparatus, which relies on the current flowing through the circuit breaker to provide the required tripping power in the event of circuit fault or overload. Since the unit is self-contained, no external dc or ac control power is required to support this protective trip function. The direct-acting trip device monitors the primary current flow in each phase and trips the breaker when that primary current exceeds selected current magnitudes and associated time delay(s) over the range of postulated faulted and circuit overload conditions.

The molded case circuit breakers of the Motor Control Centers, DC Control Centers and Low Voltage (AC and DC) Distribution Panels are likewise not dependent upon external control power to perform their respective protective trip function.

Major types of protection applications that are used consist of the following:

A. 4.16 kV Overcurrent Relaying

Each radial feeder into and out of the 4.16 kV buses is protected by three inverse-time phase relays and one inverse-time ground overcurrent relay. Motor protection is provided by relays that alarm in the control room on overloads set between 115 and 145% of motor full load current and trip only on heavy faults or sustained overcurrents above 145% of motor full load current.

B. Undervoltage Relaying

Each 4.16 kV switchgear bus is equipped with an undervoltage relay for load shedding, diesel generator starting, and undervoltage annunciation in the control room.

The Palo Verde design has four, 4160 volt safety-related bus induction disc loss of voltage relays, and four solid-state undervoltage relays with built-in time delays. The loss of voltage relays have a drop out voltage that varies with time, so that they will commence time out if the voltage falls below 78% for a long time or below 70% for a short time (12.6 seconds or less) (See Figure 8.3-3). The degraded voltage relays will commence a maximum 35 second time-out when the bus

voltage drops to less than 90% (nominal) of design. Recovery of the bus voltage before time-out is completed will reset the degraded voltage relays.

A fifth degraded voltage relay, on each 4160 volt safety-related bus, will provide an annunciation in the control room after bus voltage drops to less than 90% after 10 seconds.

The undervoltage monitors consist of four separate sensor signal circuits (i.e., four potential transformers across phases as follows: A-B, B-C, A-C, and A-B with the associated circuitry) for each 4.16 kV ESF bus. The undervoltage signals are redundant sensor signals within the affected train (the design for each train employs coincident logic to prevent spurious actuation and unnecessary isolation from the preferred power supply). The installation associated with each sensor includes potential transformers, voltage level monitors, trip signal isolation, bus voltage indication, set point adjustment, and trip signal annunciation output. The degraded voltage relays require 125 Vdc control power, which is provided from the same source as the breaker control power for the 4.16 kV switchgear.

The degraded voltage relays satisfy the following criteria:

1. The selection of voltage and time setpoints was determined from an analysis of the voltage requirements of the safety-related loads at all onsite system distribution levels.

2. Coincident (two-out-of-four) logic is used to preclude the spurious trip of the offsite source.

3. The time delays are such that:

   - The selected time delay minimizes the ability of short duration disturbances to reduce the availability of the offsite power source(s).

   - The allowed time duration of a degraded voltage condition at all distribution system levels does not result in failure of safety systems or components.

4. The voltage sensors will automatically initiate the disconnection of offsite power sources whenever the voltage setpoint and time delay limits have been exceeded.

5. The voltage sensors are designed to satisfy the applicable requirements of IEEE Standard 279-1971, Criteria for Protection Systems for Nuclear Power Generating Stations.

6. The Technical Specifications include limiting conditions for operation, surveillance requirements, and allowable values for the degraded voltage relay voltage and time settings.

Each 480V load center bus is equipped with an undervoltage relay for annunciation in the control room.

C. Differential Relaying

Circulating water pumps, reactor coolant pump motors, diesel generators, and transformers larger than 10 MVA are equipped with differential relays. These relays provide high speed disconnection to prevent severe damage in case of internal circuit faults.

D. 480V Load Center Protection

Each load center main feeder circuit is protected by three-phase relays and one ground overcurrent relay. Each motor control center main feeder circuit is analyzed for adequate protection or is protected by a circuit breaker and an adjustable, selective overcurrent relay. Protection for the class 1E motor is provided by three-phase relays that alarm on overload and a ground overcurrent relay that trips the breaker on ground faults.

Trip will occur only on faults or sustained overcurrents substantially greater than full load current.

E. 480V Motor Control Center Relaying

Molded-case circuit breakers provide time overcurrent and/or instantaneous short circuit protection for all connected loads. For motor circuits, the molded-case circuit breakers are equipped with instantaneous trip only. Motor overload protection is provided by heater-element trip units in the motor starter. The molded case breakers for nonmotor feeder circuits provide thermal time overcurrent protection as well as instantaneous short circuit protection. Thermal

overload protection of safety-related motors essential to safe shutdown of the plant is automatically bypassed following an ESFAS, except for the diesel generator fuel transfer pump motors [M-DFA(B)-P01] and the spray pond pump house exhaust fan motors [M-HSA(B)-J01], and the spray pond margin bypass valves [J-SPA(B)-V0075(76)].

When thermal overload protection for motor-operated valves below 1 horsepower inside the containment is bypassed, ensure adequate fault level/time characteristics for proper backup protection for the electrical penetration is provided. The bypass circuitry is designed to IEEE 279-1971 criteria.

The starter thermal overload relay contact for a motor-operated valve is bypassed by a contact of the same initiating relay that activates the motor-operated valve in the event of a LOCA. The bypass remains in effect until the initiating signal is manually reset.

The short circuit protective system is analyzed to ensure that the various adjustable devices are applied within their ratings and are set to be coordinated with each other to attain selectivity in their operation. The combination of devices and settings applied affords the selectivity necessary to isolate a faulted area quickly with a minimum of disturbance to the rest of the system.

Preoperational test of the protective devices is performed to demonstrate that they are properly calibrated and adjusted to alarm or trip as required. After the plant is in operation,

periodic tests are performed at scheduled intervals to verify the protective device calibration, setpoints, and correct operation. A random sample of molded case circuit breakers required for the protection of containment electrical penetrations will be tested periodically to verify the overcurrent trip setpoint in accordance with NEMA AB 2-1980. The PVNGS design has a combination of fuse and circuit breaker, two fuses, or two circuit breakers for circuits being fed through containment electrical penetrations.

8.3.1.1.3.14 Testing of the AC Systems During Power Operation. During periodic Class 1E system tests, subsystems of the Class 1E system such as safety injection, containment spray, and containment isolation are actuated, thereby causing appropriate circuit breaker or contactor operation. The 4.16 kV switchgear and 480V load center circuit breakers and control circuits also can be tested independently while individual equipment is shut down. The circuit breakers can be placed in the test position and exercised without operation of the associated equipment.

8.3.1.1.4 Standby Power Supply

The standby power supply for each safety-related load group consists of one diesel generator complete with its accessories and fuel storage and transfer systems. The standby power supply functions as a source of ac power for safe plant shutdown in the event of loss of preferred power and for post-accident operation of ESF loads. Each diesel generator is rated at 5500 kW at 0.8 pf for continuous operation and 6050 kW

for 2 hours out of 24 hours. There are no provisions for automatically paralleling the two diesel generators within a unit. Interlocks are provided to prevent manual paralleling of the diesel generators. There are no direct interconnections between the standby power supplies of the individual units.

Each diesel generator is normally connected to a single 4.16 kV safety features bus of a load group. However, there are provisions for connecting both ESF buses to a single diesel generator during emergency conditions. Each load group is independently capable of safely shutting down the unit or mitigating the consequences of a loss-of-coolant-accident (LOCA).

The diesel generators are physically and electrically isolated from each other. Physical separation for fire and missile protection is provided by installing the diesel generators in separate rooms in a Seismic Category I structure. Power and control cables for the diesel generators and associated switchgear are routed in separate raceways.

Ratings for the diesel generators are calculated consistent with the recommendations of NRC Regulatory Guide 1.9 (discussed in paragraph 8.3.1.2). Loads to be supplied by the diesel generator are determined on the basis of nameplate or service factor rating, pump pressure and flow conditions, pump runout conditions, and starting inrush. The loads for each diesel generator are listed in table 8.3-1. The continuous rating of the diesel generator is based on the maximum total load required at one time. The diesel generator starting and ESF bus loading sequence logic diagram is given in figure 8.3-1.

The diesel generators are controlled from the electric mimic bus panel in the main control room or from a local panel within each diesel generator control room. Controls and instrumentation are provided in both locations for starting, stopping, and for governor and excitation system adjustments. A key-locked "OFF-LOCAL-REMOTE" switch is provided at each local panel with the key removable in the OFF and REMOTE positions only. Manual control from the local panel is possible in the LOCAL position only. Manual control from the main control room is possible in the REMOTE position only. Automatic starting of the diesel generator is possible in the LOCAL and REMOTE positions of the key-locked switch. No automatic or manual start is possible in the OFF position and a DIESEL GENERATOR INOPERABLE alarm is initiated at the safety equipment status system annunciator.

Three switches are provided on the engine front panel for diesel generator testing. Two pushbutton switches are provided for emergency starts: one simulates a LOP; the other simulates a SIAS and AFAS. The third switch defeats the emergency mode interlocks, allowing the diesel generator to be taken out of the emergency mode condition, without stopping the diesel engine. This switch is used at the completion of the LOP and ESFAS tests. It is an "off-on" key-lock switch, with the key removable in “off” only (non-defeat).

The generator is driven by a turbocharged, four-cycle, 20-cylinder diesel engine. The engine produces 7670 horsepower at continuous rated output and 8437 horsepower at short-time rated output. For a discussion of the engine fuel oil system,

cooling water system, air-start system, and lube oil system, see subsections 9.5.4, 9.5.5, 9.5.6 and 9.5.7.

All components of the standby power supply system, including related controls, required to supply power to ESF and safe shutdown loads conform to the requirements of General Design Criterion 17, IEEE 308, and IEEE 279. The functional aspects of the standby power supply system are presented in the following paragraphs.

8.3.1.1.4.1 Automatic Starting Initiation Circuits. Each diesel generator is automatically started on any of the following conditions:

- Undervoltage on the 4.16 kV, Class 1E bus to which the generator is connected, loss or sustained degradation of offsite power (LOP)
- Safety injection actuation signal (SIAS)
- Auxiliary feedwater actuation signal (AFAS)
- Containment spray actuation signal (CSAS); DG starts in test mode

8.3.1.1.4.2 Diesel Generator Starting Mechanism and System. The diesel generator starting system is described in subsection 9.5.6. The design basis and analysis for diesel generator systems, controls, and instrumentation are described in section 7.3.

8.3.1.1.4.3 Tripping Devices. Devices are provided for the following protective functions for each diesel generator:

- Incomplete sequence (start failure)
- Engine overspeed
- High jacket coolant temperature
- High bearing temperature
- High crankcase pressure
- Turbocharger thrust bearing failure
- Low lube oil pressure
- Turbocharger low lube oil pressure
- Loss of field
- Generator differential
- Generator ground overcurrent
- Generator voltage restrained overcurrent
- Reverse power
- Load unbalance (negative sequence)
- Underfrequency
- Manual emergency trip

The incomplete sequence relay functions to interrupt the starting of the diesel generator if a predetermined speed is not reached.

During diesel generator starting sequences, the low lube oil pressure trips are bypassed for a predetermined period. The manual emergency trip is initiated by depressing a pushbutton at the diesel generator local control panel. An automatic or manual start is not possible unless the pushbutton is manually reset. A transparent, hinged cover is provided over the emergency trip pushbutton as protection against accidental actuation.

The critical protective devices that function to shut down the diesel generator during testing and are also retained during emergency operation consist of:

- Engine overspeed
- Low lube oil pressure (one-out-of-two-taken-twice logic)
- Generator differential
- Manual emergency trip

All other protective device trips are bypassed and annunciated during emergency (SIAS or AFAS or LOP) operation and function to shut down the diesel generator only during testing operation.

Automatic bypass is not provided around the protective devices that function during an accident because each load group is provided with one diesel generator. Therefore, should one diesel generator be tripped by a protective device, the other redundant load group is still available. Since the malfunctioning diesel generator is isolated before it can be

seriously damaged, repairs can be made while the redundant diesel generator is in operation.

The tripping devices that are in effect in both the test mode and emergency mode of operation require control air to function, except the engine over speed trip, which also shuts off combustion air to the EDG. If EDG control air is not available, the EDG can still be tripped manually to shut off the fuel racks by activating a lever on the side of the engine.

The associated DG 4.16 KV output breakers have generator protective devices in place during testing that are also bypassed during EDG emergency operations.

To provide additional reliability, shutdown due to low lube oil pressure will be initiated by one-out-of-two-taken-twice logic. That is, a false trip on one channel does not erroneously isolate the diesel generator. These protective trips and their logic conform to IEEE 279-1971.

The diesel generators are monitored from the control room and each device, when actuated, initiates an annunciator in the control room as well as locally. The alarms are set so that they provide a warning of impending trouble prior to trip of the diesel generator.

8.3.1.1.4.4 Interlocks. Diesel generator circuit breaker interlocks are provided to protect against the following:

- Automatic energizing of electrical devices during maintenance

- Automatic closing of the diesel generator breaker to an energized or faulted bus
- Automatic connection of two sources out of synchronism
- Automatic connection of the ESF loads without voltage on the associated ESF bus
- Automatically or manually paralleling the diesel generators

8.3.1.1.4.5 Permissives. A single three-position, key-locked switch is provided at each diesel generator local control panel. When this switch is in the REMOTE position, the diesel generator may be started automatically, or manually from the control room. When the switch is in the LOCAL position, the diesel generator may be started automatically, or manually from the diesel generator local control panel and a LOCAL position alarm is initiated in the control room. When the switch is in the OFF position, no automatic or manual start is possible and a DIESEL GENERATOR INOPERABLE alarm is initiated at the safety equipment status system annunciator. Blocking of automatic and manual starting of the diesel generator by the local manual emergency trip pushbutton is discussed in paragraph 8.3.1.1.4.3. A switch in the control room and a local switch are provided to allow a manual start capability in addition to the automatic start contacts. An override of a SIAS/CSAS, AFAS, or LOP is provided to allow the operator to parallel with offsite power and stop a diesel generator when offsite power is available.

During periodic diesel generator tests, permissives and interlocks are aligned to permit manual synchronization and loading of the diesel generator with the preferred power source.

8.3.1.1.4.6 Load-Shedding Circuits. Load shedding of the Class 1E, 4.16 kV bus is initiated by detection of undervoltage on this bus using a two-out-of-four coincidence logic of undervoltage relays. Paragraph 8.3.1.1.3.13, listing B, summarizes the design and setpoint criteria for these relays. The load shed signal is a single, 1-second pulse generated upon detection of an undervoltage occurrence. This pulse acts to:

A. Shed all 4.16 KV and selected 480 V loads from the Class 1E 4.16 KV bus.

B. Trip the 4.16 KV Class IE bus preferred (offsite) power supply breakers.

In conjunction with the load shed signal is the loss of offsite power signal which acts to:

C. Send a signal to start the diesel.

D. Send a signal to the sequential actuation system (refer to figure 8.3-1 for undervoltage and sequential actuation system logic).

Tripping of the offsite breakers isolates the Class 1E onsite power system, including the undervoltage relays, from the offsite power system. There is, therefore, no possibility of subsequent interaction between the load shed and the offsite power system. The return of the Class 1E, 4.16 kV bus to offsite power must be done manually. After load shedding,

tripping of the Class 1E, 4.16 kV bus offsite supply breaker, and subsequent closing of the diesel generator breaker to the Class 1E 4.16 kV bus, the undervoltage relays monitor the standby (onsite) power supply for an undervoltage occurrence. The load shed feature is blocked for 60 seconds during sequencing of ESF loads. Should an undervoltage occur after this interval, the Class 1E, 4.16 kV loads are shed and the loading sequence restarted.

As the undervoltage relays are transferred with the Class 1E 4.16 kV bus from offsite (preferred) to onsite (standby) power on a loss of offsite power, no bypass of these relays to prevent interaction of offsite power with the shed feature is required.

The sequencer, upon closure of the diesel generator breaker, will sequence the equipment in programmed steps, which prevents diesel generator instability and minimizes load accelerating time. A fast-responding exciter and voltage regulator ensures voltage recovery of the diesel generator after a load step. The generators use field flashing for voltage buildup during the start sequence.

As each generator reaches rated voltage and frequency, the generator breaker connecting it to the corresponding 4.16 kV bus closes. With the SIAS/CSAS or AFAS a diesel start is initiated; however, connection of the diesel generator to the 4.16 kV bus cannot be made unless the preferred source of power is lost. If the preferred source of power is not lost, the appropriate ESF loads will be sequenced on to the preferred powered bus and the diesel will be left running for a period of

at least 1 hour. With an SIAS or AFAS signal present and no loss of preferred power, the operator can manually override the SIAS or AFAS signal from the control room. The diesel generator can then be manually shut down from the control room or locally. In a subsequent loss of preferred power, load shedding and load sequencing will be initiated. The diesel generator will start, accelerate to at least the minimum acceptable voltage and frequency and have its output breaker close to commence accepting loads within 10 seconds of the diesel generator start signal and be completely loaded within 60 seconds after closure of the diesel generator breaker. The ESF loads required for the operation of components within the CESSAR scope in table 8.3-1 will be sequenced on within 30 seconds after closure of the generator breakers and ESF bus re-energization, as identified in table 8.3-3. Relays at the diesel generator detect generator rated voltage and frequency conditions and provide a permissive interlock for the closing of the respective generator circuit breaker. Upon loss of the preferred source of power without LOCA, the undervoltage system initiates the starting of the diesel generators and sheds all loads. The sequencer then automatically initiates the starting of the safe shutdown loads upon closure of the diesel generator breaker.

If the diesel generator is supplying power to the ESF bus, a subsequent accident signal initiates starting of the loads associated with the subsequent accident signal without shedding any operating equipment.

If offsite power is lost at some time after an accident and the required ESF equipment is running and the diesel generator is up to rated voltage and speed, the sequencer initiates restart of the safety injection pumps within 6 seconds and the auxiliary feedwater pump within 11 seconds of the closure of the diesel generator breaker such that:

A. Interrupted flow to the core is fully reestablished within 13 seconds.

B. Interrupted auxiliary feedwater flow to the steam generator(s) is fully reestablished within 23 seconds. The deviation from the CESSAR requirement of 15 seconds is acceptable to Combustion Engineering as discussed in paragraph 1.9.2.4.10.

8.3.1.1.4.7 Testability. Refer to section 14.2, and the Technical Specifications for testing requirements.

During testing, if an SIAS/CSAS or AFAS occurs while the diesel generator is paralleled to the preferred power supply with the control switch in the REMOTE or LOCAL position, the diesel generator breaker will be automatically tripped by a momentary tripping pulse. The diesel generator will continue running and automatically revert to the isochronous mode. All noncritical protective devices are bypassed. If a noncritical trip occurs during testing, the diesel generator will trip. On a subsequent SIAS/CSAS, AFAS, or LOP, the diesel generator will automatically start and run in the isochronous mode.

The LOCAL control position is selected from the local control panel for diesel generator maintenance testing. A diesel

generator LOCAL POSITION alarm will be annunciated in the control room. To prevent any starting of the diesel generator during maintenance, the OFF position is selected at the local control panel and a DIESEL GENERATOR INOPERABLE alarm is initiated at the safety equipment status system annunciator.

If the preferred power source is lost while paralleled to the diesel generator during testing, the diesel generator either trips on overcurrent or continues to run, depending upon if the resulting load is in excess of the diesel generator's load rating. If the load is excessive, the diesel generator will trip on overcurrent and the diesel generator breaker will trip automatically on a diesel generator shutdown signal. Upon detection of undervoltage on the Class 1E, 4.16 kV bus, load shedding and sequencing will be initiated as described in paragraph 8.3.1.1.4.6. If the load does not exceed the diesel generator's load rating, the diesel generator continues to run and supply the ESF bus. The operators receive indication and alarms in the control room that the preferred power source is lost.

8.3.1.1.4.8 Diesel Generator Fuel Oil Storage and Transfer Systems. Refer to subsection 9.5.4 for system description.

8.3.1.1.4.9 Cooling and Heating Systems. Refer to subsection 9.5.5 for system description.

8.3.1.1.4.10 Instrumentation and Control Systems for Standby Diesel Power Supply. Pertinent instrumentation and control systems are as follows:

A. Equipment is provided in the control room for each diesel generator for the following operations:

- Remote manual starting and stopping
- Remote manual synchronization
- Remote manual frequency and voltage regulation
- Governor and voltage droop selection
- Automatic or manual voltage regulator selection [For Units/Trains that have not installed DMWO 2859190]
- Automatic 1 or Automatic 2 voltage regulator selection [For Units/Trains that have installed DMWO 2859190]

B. Equipment is provided at each local control panel for the following operations:

- Manual starting and stopping
- Frequency and voltage regulation
- Automatic or manual regulator selection [For Units/Trains that have not installed DMWO 2859190]
- Automatic 1 or Automatic 2 voltage regulator selection [For Units/Trains that have installed DMWO 2859190]

- Exciter field removal and reset
- Manual emergency start, simulated LOP
- Manual emergency start, simulated ESFAS (SIAS/CIAS)
- Manual emergency stop
- OFF-LOCAL-REMOTE control selection
- Emergency mode interlock defeat switch

The local control operation is annunciated in the control room. The dc power source for the Class 1E diesel generator instrumentation and control system is associated with the same load group as the diesel generator.

C. Each diesel generator is equipped with the following alarms on the local control panel:

- Lube oil low pressure (engine, turbo)
- Lube oil high or low temperature
- Jacket coolant low pressure
- Jacket coolant high or low temperature (Jacket water temp. high or off normal)
- Fuel oil high level in day tank
- Fuel oil low level in day tank
- Fuel oil low level in storage tank
- Fuel oil low pressure
- Fuel oil transfer pump low discharge pressure

- Incomplete sequence (start failure)
- Generator field ground
- Generator undervoltage
- Generator overvoltage
- Generator underfrequency
- Crankcase low oil level
- Starting air solenoid or system malfunction
- Excitation bridge failure (This alarm has been removed in those units/trains where DMWO 4465038 has been implemented)
- Crankcase high pressure
- Generator overcurrent (voltage restrained overcurrent)
- Engine overspeed
- Diesel generator bypassed or inoperable (common alarm)
- Turbo thrust bearing failure
- Bearing high temperature (main and conn. rod or gen-bearing)
- Generator neutral overvoltage (ground overcurrent)
- Loss of field
- Generator differential
- Reverse power

- Fuel oil filter high differential pressure
- Fuel oil strainer differential pressure high
- Fuel oil supply to day tank high differential pressure
- Generator or high voltage cubicle space heater trouble (common alarm)
- Essential exhaust fan overload pretrip
- Annunciator ground
- Any switch not in auto (common alarm)
- Lube oil filter high differential pressure
- Generator load unbalance (negative sequence trip and pre-trip alarm)
- Starting air receiver "A" malfunction
- Starting air receiver "B" malfunction

The local annunciator provides first out indication for all alarms initiated by the diesel generator protective devices listed in paragraph 8.3.1.1.4.3.

D. The following alarms are annunciated in the control room:

- Diesel generator trip (common alarm)
- Diesel generator running
- Diesel generator differential trip
- Diesel generator overspeed trip

- Diesel generator low lube oil pressure trip
- Diesel generator emergency manual trip
- Diesel generator high priority trouble (common alarm)
- Diesel generator low priority trouble (common alarm)
- Diesel generator fuel system trouble (common alarm)
- Diesel generator in local mode

The following alarms will be annunciated on the control room safety equipment status annunciator:

- Diesel generator inoperable
- Diesel generator failed to start

The common diesel generator trip alarm is initiated only when the diesel generator is actually shutdown by a protective device. The diesel generator high priority trouble alarm is initiated by any of the protective devices listed in paragraph 8.3.1.1.4.3 whether a diesel generator shutdown results or not. The diesel generator low priority trouble alarm is initiated by any alarm condition listed in paragraph 8.3.1.1.4.10, listing C, other than the high priority and bypass, or inoperable alarms.

The diesel generator fuel system trouble alarm is initiated by any of the following:

- Diesel generator day tank low level

- Diesel generator fuel oil transfer pump low discharge pressure

The diesel generator inoperable and failed to start alarms are annunciated on a common DIESEL GENERATOR SYSTEM safety equipment status system window. This window is horizontally split, with the top half illuminated in white for an inoperable condition and the bottom half in blue for a start failure.

Conditions that render a diesel generator inoperable on an automatic start signal are:

- Low starting air pressure
- Diesel generator turning gear engaged
- Loss of dc control power
- Manual emergency trip pushbutton not reset
- Control mode selector switch in OFF position
- Emergency mode interlock defeat switch in ON position (renders LOP inoperable only)
- Generator differential lockout relay not reset
- Fuel oil supply valve closed

Low starting air pressure or turning gear engaged are indicated by a white AIR START SYSTEM indicator light. Loss of dc, selector switch in OFF, lockout relay not reset, or emergency trip switch not reset are indicated by a white START LOGIC SYSTEM indicator light. Fuel oil supply valve closed is indicated by a

white FUEL OIL SUPPLY VALVE indicator light. In addition, a DIESEL GENERATOR indicator light is provided to indicate loss of breaker control power (white) or failed to close (blue), or diesel generator failed to start (blue).

Electrical metering instruments are provided in the control room and at the local control panel for surveillance of generator voltage, current, frequency, power and reactive power. Fuel oil day tank level indicators are also provided.

8.3.1.1.4.11 Prototype Qualification Program. A start and load reliability test program was performed to certify 0.99 reliability for the diesel generators in accordance with IEEE 387-1977. A valid start and load test was defined as a start from design cold ambient conditions with loading to at least 50% of the continuous rating within the required time interval, and continued operation until temperature equilibrium is attained. At least 300 qualification tests were performed on one PVNGS diesel. The failure rate was less than 1 per 100.

A reliability testing program was performed on emergency diesel generator 2-M-DGB-H01, serial number 7183, at the manufacturer's shop during July 7, 1978 through September 10, 1978. The test period included standard shop tests to determine fuel and oil consumption, checkout, and engine break-in.

The report of the tests was provided by the manufacturer, Cooper Energy Services. Following are excerpts from that report. Included is the time-to-rated speed for the

first 24 starts. All starts reached rated speed between 5.6 and 5.9 seconds.

Requirement:

A total of at least 300 start and load tests shall be conducted to demonstrate reliability. A failure rate in excess of one per 100 will require complete retesting and a review of the system design adequacy.

A. 90% of the start and load tests will be performed with lube oil and jacket water temperatures initially at 120°F ± 10°F. The engine-generator set must achieve rated frequency and voltage within 10 seconds of the start initiation signal and be loaded to 2750 KW (resistive) min within 20 seconds of the start initiation signal. 2750 KW min load will be maintained until the engine jacket water and lube oil temperatures do not vary more than ±5F from design within a 5-minute interval. The engine will then be shut down and force cooled until jacket water and lube oil temperatures are less than 130°F at which time the next test cycle may begin.

B. 10% of the start and load tests will be performed from design hot equilibrium temperature conditions. The engine-generator set will be operated at 100% load for eight (8) hours to establish the required equilibrium condition. The engine will then be shut down.

   The engine will be started and loaded within limits outlined in (A) above. After verification that jacket

water and lube oil temperatures are within the required limits, the engine will then be shut down and the next test cycle may begin. If the engine is down for an extended period of time, the engine must be operated at 100% load to reestablish the design hot equilibrium temperature conditions.

Discussion

The test was started on August 25, 1978, and successfully completed on September 10, 1978 with a total of 303 starts.

Cooling the engine was accomplished with the engine running. To force cool the engine between starts, temporary valving was added to oil and jacket water piping to by-pass the oil and water thermostats.

During each official start and load test the thermostats were operative.

Starts No. 1 through 271 were cold starts.

Starts No. 272 through 303 were hot starts.

Before running the hot starts the engine was run for 8 hours at 100% load to establish the hot temperature conditions. During the 8-hour run the thermostats in the oil and water systems were operative.

Discussion of Starts Not Counted:

During the start and load tests the following starts were not counted because they resulted from shop facility equipment problems, operator error or from intermittent circuit operation of equipment which is by-passed when in the LOCA mode. This is in accordance with Regulatory Guide 1.108 paragraph B.2.e.2.

Between starts No. 14 and 15 a good start was made but not counted. A facility power failure in our shop caused a shutdown before the temperature stabilization run under load was completed.

Between starts No. 104 and 105 a good start was made but not counted because of an incomplete Visicorder chart. This was an operator mistake in running the Visicorder.

Between starts No. 165 and 166 a second start failure occurred with an incomplete sequence light indication on the engine panel. This was not counted as a failure as the problem was identified as the same as in the previous start failure.

Between starts No. 166 and 167 a good start was made but not counted because of an incomplete Visicorder chart. This was an operator mistake in running the Visicorder.

Between starts No. 215 and 216 a good start was made but not counted because of an operator mistake in setting up the shop facility switchgear for automatic operation. Only two steps of the three step loading came on resulting in low load during the temperature stabilization run.

During start No. 238 and through the remaining starts the voltage trace on the Visicorder chart does not appear. This is because of a failure in the recording equipment which has no effect on the engine-generator set operation.

Between starts No. 251 and 252 a good start was made but not counted because of an operator mistake in adjusting the water rheostats for the proper load. The load was too light.

<u>Investigation of Circuitry Problems:</u>

In accordance with Regulatory Guide 1.108, the following tests were made to pinpoint problem circuitry.

A. After the start failure between starts No. 155 and 156, five trial engine starts were made to see if the problem would repeat or if it was intermittent. They were all successful but were not counted because they were not continued through the loaded part of the official tests.

B. After the start failure between starts No. 165 and 166, the failures were judged to be an intermittent fiber optics component or a contact associated with 2-68B1 alarm shutdown by-pass timer and the following action taken to confirm that judgment.

   1. After all wire connections were checked for tightness, air to the engine was shut off and 32 starts simulated without starting the engine. All were good starts.

   2. Several trials were then made to show that the suspected fault would have caused the problem. This was done by removing the wire from contact 4 of 2-68B1 on some trial starts.

      1st Trial - DGS Mode - wire connected – good start.

      2nd Trial - DGS Mode - wire disconnected.

      3rd Trial - Incomplete sequence light came on

      4th Trial - and unit failed to start.

6th Trial - LOCA Mode - wire disconnected.

7th Trial - Incomplete sequence light came on and unit made a good start.

3. Instrumentation was added to the Visicorder to monitor 268B1 relay and the fiber optics components associated with this circuit in order to pinpoint the problem if any further shutdowns should occur. However, no more shutdowns occurred during the remainder of the start and load tests.

Prior to delivery to the site, the diesel generator sets are fully assembled at the supplier's factory, and each is subjected to the required factory production tests and break-in run. The following qualification tests are performed:

A. Load Capability Qualification

This test demonstrates the capability of the diesel generator set to carry the rated loads at rated power factor and to successfully reject rated load. One successful completion of the following test sequence is required:

1. Carry the continuous rated load after the time required to reach engine temperature equilibrium

2. Carry the rated short-time load for an additional 2 hours following step 1

3. Reduce load to the continuous rating. Reject continuous rated load

B. Margin Qualification

This test demonstrates the diesel generator set capability to start and carry loads that are greater than the most severe step load change within the plant design loading sequence. Two margin tests are performed using an inductive type load at least 10% greater than the most severe single inductive type step load. The margin qualification test demonstrates the following:

1. That there is sufficient engine torque available to prevent engine stall and to permit the engine speed to recover when experiencing the most severe load requirement

2. That the generator and excitation system can accept the most severe electrical inductive load without experiencing an instability that could lead to generator voltage collapse

8.3.1.1.4.12 Operation and Maintenance Program. The emergency diesel generators are operated by shift managers, control room supervisors, and Nuclear Auxiliary operators. Maintenance of these units is supervised by the section leaders and department leaders under the maintenance director. Actual maintenance is performed by plant mechanics, plant electricians, and plant instrumentation and control technicians. The level of education and minimum experience requirements for these positions are given in amended paragraph 13.1.3.1.

The emergency diesel generator operator and maintenance training program is described in amended paragraph 13.2.1. Maintenance operating and surveillance procedures for the emergency diesel generator specify the minimum qualification of personnel required to perform specific portions of these procedures. These qualifications are based on experience and the completion of specific training. Because appropriately qualified persons will be specified to operate, maintain, and test the emergency diesel generators, dedicated operators and maintenance persons are not assigned.

The design specification for the diesel generator requires that the diesel must be capable of operating at no-load for 1 hour without deterioration of the engine, generator or auxiliaries. The Palo Verde operating and surveillance procedures for the emergency diesel generators include guidance regarding the manufacturer’s recommendations for loading and unloading. This guidance is intended to apply load gradually, provide some cooldown period and limit unloaded diesel generator operation. A Safety Injection Actuation Signal without a Loss of Power is the only postulated operating event that would allow the diesel generator to run unloaded for extended time intervals. While managing the SIAS event, Operations would strive to limit the time that the diesel generator was operated unloaded. After an operating event caused the diesel generator to run unloaded for greater than 6 hours, the diesel generator will be run loaded to at least 75% of its full load value for at least 15 minutes.

Maintenance procedures for the emergency diesel generators will require investigation and correction of causes of malfunctions and will require preventive maintenance procedures tailored to

monitor performance of components discovered to have highest failure rates.

Maintenance and surveillance procedures will include post-maintenance or surveillance restoration to operability, and, in the case of the emergency diesel generators, shall specify a final equipment check. When actions have been accomplished that could affect engine operability, maintenance and surveillance procedures will include a load test prior to declaring a generator operational.

Emergency diesel generator operating, maintenance, and surveillance procedures are available onsite.

8.3.1.1.5 Control Element Drive Mechanism Power Supply

Electric power to control element drive mechanisms is supplied by two motor-generator sets operating from two separate non-Class 1E, 480V load centers.

8.3.1.1.6 Vital Instrumentation and Control Power Supply

Four independent Class 1E, 120Vac vital instrumentation and control ac power supplies are provided to supply the four channels of the reactor protective and ESF actuation systems (see engineering drawings 01, 02, 03-E-PKA-001). The power supplies are designed to regulate the steady-state voltage within +/-2% at full power output for a load power factor of 0.8 at a frequency of 60 +/-0.5 Hz. The four-bus arrangement provides a single-phase, ungrounded, electric power to each of the four protection channels of the reactor protective system that is electrically and physically isolated from the other

protection channels. Each of the four channels of vital AC instrumentation and control power supply consists of one inverter rated at 25 kVA (20 kVA if DMWO 3232547 has been implemented), a transfer switch, a backup voltage regulator, and one distribution panel. Additionally, each of the two trains of vital AC instrumentation and control power supply contains a swing inverter and swing line-up switch, if implemented per DMWO 3232547.

Currently, PVNGS Units 2 and 3 have installed an automatic static transfer switch and PVNGS Unit 1 utilizes a manual transfer switch or static transfer switch if implemented per DMWO 3232547. Normally, each distribution panel is supplied by the inverter. Each inverter is supplied by a separate Class 1E 125 V-dc subsystem as described in subsection 8.3.2. If an inverter is inoperable, its output is outside the acceptable operating range, or it is to be removed from service for maintenance or testing, a backup supply is provided from a switch. Additionally, a swing inverter and swing line-up switch, if implemented per DMWO 3232547, may be aligned as a class 1E vital supply, as well. Busing arrangements are shown in engineering drawings 01, 02, 03-E-PKA-001 and system loads are listed in table 8.3-4.

Identification of equipment, raceway, and cabling associated with the vital ac instrumentation and control power supply is as described in paragraph 8.3.1.3.

There is no manual or automatic transfer between the buses. No connection exists between the independent supplies.

There is no provision for automatic loading or load shedding of the buses.

Inverter trouble and bus undervoltage are annunciated in the control room.

In addition to the four inverter power supplies, two additional 480 volt, three-phase inverters from channel C and D batteries supply dedicated power to the shutdown cooling motor-operated valves.

8.3.1.1.7 Nonvital AC Instrumentation and Control Power Supply

The 120V nonvital ac instrumentation and control power supply furnishes power to non-Class 1E instrumentation and controls. The supply consists of four normal supply voltage regulators, four backup supply voltage regulators, auto and manual transfer switches between the supplies, and four distribution panels.

The four distribution panels are normally aligned with the normal supply voltage regulators. These voltage regulators are

non-Class 1E and are supplied by non-Class 1E power. Two are grounded and two are ungrounded.

The backup supply for the distribution panels for each unit consists of four voltage regulators (two non-Class 1E and grounded and two Class 1E and ungrounded. Each backup regulator has the capability of being supplied by the diesel. Power to the two grounded voltage regulators is tripped on an SIAS signal and can be reestablished manually after the sequential loading of the diesel generator (except for one regulator in unit three which is automatically loaded onto the Diesel Generator during a LOCA/LOP).

8.3.1.1.8 Electric Equipment Layout

The following are the general features of the electrical equipment layout:

A. Class 1E switchgear, load centers, and motor control centers of redundant load groups are located in separate rooms of the control building or the auxiliary building. Separate ventilation systems are used for the two switchgear rooms supplied from the appropriate load group.

B. Class 1E battery supplies are located in the control building. Each battery is located in a separate room, and each room is equipped with a separate ventilation system.

C. Two cable spreading rooms are provided -- one above and one below the control room. This enhances redundant cable separation. Channel A and C cables

are fed from above and channels B and D are fed from below.

D. Redundant diesel generators and associated equipment are located in separate rooms of the Seismic Category I diesel generator building.

E. The normal battery chargers, normal inverters, DC buses, AC distribution panels and line voltage regulators associated with each of the four channels of the reactor protective and ESF actuation subsystems are located in separate equipment rooms (A, B, C and D). The train (A and B) backup battery chargers are located in the A and B equipment rooms respectively. The train (A and B) swing inverter and swing line-up switches, if implemented per DMWO 3232547, are located in the C and D equipment rooms respectively.

Refer to engineering drawings 13-P-OOB-002, 13-P-OOB-003, 13-P-OOB-004 and 13-P-OOB-005 for the location of electrical equipment and main cable routes to the Class 1E switchgear, load centers, and motor control centers.

8.3.1.1.9 Design Criteria for Class 1E Equipment

Design criteria and bases for the Class 1E equipment are:

A. Motor Size

Motor size (horsepower capability) is equal to or greater than the maximum horsepower required by the driven load under normal running, runout, or discharge valve (or damper) closed condition.

B. Motor Starting Torque

The motor starting torque is capable of starting and accelerating the connected load to normal speed within sufficient time to perform its safety function for all expected operating conditions, including the design minimum terminal voltage.

C. Motor Insulation

Insulation systems are selected on the basis of the particular ambient conditions to which the insulation is exposed. For Class 1 motors located within the containment, the insulation system is selected to withstand the postulated accident environment.

D. Minimum Motor Accelerating Voltage

The electrical system is designed such that the total voltage drop on the Class 1E motor circuits is not more than 25% of the nominal motor voltage during starting. The Class 1E motors are specified with accelerating capability at 75% nominal voltage at their terminals. If analysis based on as-built conditions indicates the lowest motor terminal voltage which may exist is greater than the specified 75%, then performance evaluations may be based on the as-built minimum voltage determined. If analysis based on as-built conditions indicates the lowest motor terminal voltage is less than 75%, additional evaluations will be performed to determine if its performance is acceptable.

E. Interrupting Capacities

The interrupting capacities of the protective equipment are determined as follows:

1. Switchgear

   Switchgear interrupting capacities are greater than the maximum short circuit current available at the point of application. The magnitude of short circuit currents in high-voltage systems is determined in accordance with ANSI C37.010, 1972. The power system, diesel generator, and running motor contributions are considered in determining the fault level. High-voltage power circuit breaker interrupting capacity ratings are selected in accordance with ANSI C37.06.

2. Load Centers, Motor Control Centers, and Distribution Panels

   Load center, motor control center, and distribution panel interrupting capacities are greater than the maximum short circuit current available at the point of application. The magnitude of short circuit currents in low-voltage systems is determined in accordance with ANSI C37.13-1973, and NEMA AB1. Low-voltage power circuit breaker interrupting capacity ratings are selected in accordance with ANSI C37.16-1973. Molded-case circuit breaker interrupting capacities are determined in accordance with NEMA AB1.

F. Electric Circuit Protection

Refer to paragraph 8.3.1.1.3.13 for criteria regarding the electric circuit protection.

G. Grounding Requirements

Equipment and system grounding are designed in accordance with IEEE 80 and IEEE 142.

8.3.1.1.10 Alternate AC Power System

10 CFR Part 50.63 requires that each light water-cooled nuclear power plant be able to withstand and recover from a station blackout (SBO) of a specified duration.

The SBO 16 hour copying evaluation was submitted to the NRC in APS letter 102-05370, dated October 28, 2005. Supplemental information was provided in APS letter 102-05465, dated April 19, 2006. The NRC approved the 16-hour SBO coping evaluation in a Safety Evaluation dated October 31, 2006.

The 16 hour coping strategy analysis assumes that one of the two Station Blackout Generators (SBOG), which serves as the Alternate AC (AAC) for PVNGS, is started and loaded to E-NAN-S03 for the respective Unit during the first hour to allow the analyzed SBO loads to be powered in accordance with administrative or emergency procedures.

Should a station blackout event (SBO) occur in any one unit, i.e., a loss of offsite power coincident with the unavailability of both emergency diesel generators in that unit, an alternate AC (AAC) power source is available to provide the power necessary to cope with a SBO for a minimum of

16 hours. The PVNGS response to a SBO has been developed in accordance with Regulatory Guide 1.155 (Table 1.8-4) and NUMARC 87-00. (See exceptions to Regulatory Guide 1.155 and NUMARC 87-00 in Section 1.8).

The non-safety related AAC power source consists of two 100 percent capacity, black start station blackout generators (SBOGs) that can be connected to each unit at switchgear E-NAN-S03 via the primary winding of the ESF transformer that is normally aligned to the train A 4.16kV bus as shown in engineering drawings 01, 02, 03-E-MAA-002. One SBOG is analyzed to supply all required station blackout loads, which are located on the A train. The AAC starting system and diesel fuel oil supply is independent from the black-out unit's power systems and fuel oil supply systems, however, switchgear E-NAN-S03 at each unit is dependent upon the unit's non-safety related 125V dc power system. This dc system is energized from the AAC power source to maintain its operability during the SBO event. Any inservice fuel oil storage tank associated with the SBOGs is maintained with sufficient fuel to support full load operation of the two SBOGs for 16 hours.

The AAC power system is not normally connected to the onsite power distribution system, therefore, failure of the AAC components cannot adversly affect the class 1E power systems.

The AAC power system is physically located and physically protected so that a likely event initiating a SBO will not also affect the AAC system. Connections from the SBOGs to the units are made via cables routed through underground duct banks.

Each SBOG has a minimum continuous output rating of 3400kW at 13.8kV under worst case anticipated site environmental conditions. This rating is sufficient to provide power to the loads identified as being important for coping with the SBO.

Starting and loading of the AAC power system is performed manually; no autostart or automatic loading capability is provided.

The AAC power system has been demonstrated by test as being capable of energizing the required loads within one hour after the onset of the SBO. A study has been performed that concludes that PVNGS is capable of coping with SBO for that initial one hour period. An ongoing inspection, maintenance, and periodic test program has been implemented for the AAC power system to demonstrate system operability and provide confidence that system reliability is maintained at or above 0.95 per demand.

The normal standby configuration of the SBOGs as well as the unit electrical configuration does not change when the SBOGs are used for Shutdown Cooling Operations. The use of the SBOGs during Shutdown Cooling Operations does not change the following:

1) The power configuration to the units.

2) The electrical fault protection associated with the SBOGs.

3) The manner in which power is supplied in the event of an SBO.

4) The manner in which the SBOGs are tested.

The systems required to cope with blackout conditions with the unit in Shutdown Cooling Operation are different than the required systems in Mode 3 (blackout condition initiating with the unit at power). Even though the systems are different, the KW and KVAR loading on the SBOGs is comparable.

8.3.1.2 Analysis

8.3.1.2.1 Failure Mode and Effects Analysis

A failure mode and effects analysis for the ESF ac and dc load groups is given in table 8.3-5. Table 8.3-5 shows that no single component failure will result in the simultaneous loss of ac power to both load groups. In accordance with single failure criteria, only one failure is assumed to occur in the system following a LOCA. Refer to figure 8.3-2.

8.3.1.2.2 Compliance with Design Criteria and Guides

The following analysis demonstrates compliance with General Design Criteria 17 and 18, Regulatory Guides 1.6, 1.9, 1.22, 1.29, 1.30, 1.32, 1.40, 1.41, 1.47, 1.53, 1.62, 1.63, 1.73, 1.75, 1.81, 1.89, 1.93, and IEEE Standards 308, 317, 323, 334, 344, 383, 384, and 387.

8.3.1.2.2.1 Criterion 17, Electric Power Systems. An onsite electric power system is provided to permit functioning of structure, systems, and components important to safety. With total loss of offsite power, the onsite power system provides sufficient capacity and capability to assure that:

A. Specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary

are not exceeded as a result of anticipated operational occurrences.

B. The core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

Refer to section 3.2 for a list of structures, systems, and components required to assure these requirements are met. Refer to table 8.3-1 for a list of the loads important to safety which are supplied from the onsite electric power supplies.

The onsite electric power system includes a two-load group Class 1E system. The two load groups are redundant in that each load group, independent of the other, is capable of assuring the requirements of paragraph 8.3.1.2.2.1, listings A, and B. Sufficient independence is provided between redundant load groups to ensure that the postulated single failures affect only a single load group to the extent of total loss of that load group. The redundant load group, however, remains intact.

In the case of loss of 4.16 kV bus voltage, the affected Class 1E load group is automatically isolated from the remaining portion of the onsite power system. Under frequency relays are provided to trip the diesel generator if abnormal conditions occur while the diesel generator is synchronized to the preferred power source during a test. Also, each load group of the Class 1E power system is automatically and inherently isolated from the redundant load group. The combination of these factors minimizes the probability of

losing electric power from the onsite power supplies as a result of the loss of power generated by the nuclear unit or loss of power from the transmission network.

The turbine-generator is automatically isolated from the switchyard following a generator trip by opening the generator switchyard circuit breakers. The loss of the turbine-generator does not affect the ability of either the transmission network or the onsite power supplies to provide power to the Class 1E system. Transmission network stability studies indicate that the trip of the most critical fully-loaded generating unit would not impair the ability of the system to supply plant station service. Refer to subsection 8.2.2.

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 1 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
1	Offsite power source (any line feeding startup transformer)	Supplies power to one ESF bus of two units	Loss of power	Loss of preferred power to one redundant bus of two units (PBS-S03 or PBB-S04)	No effect – Power to the redundant bus available through one of the other two lines feeding two other startup transformers (1A or 1C). In addition diesel generator provides standby power.
2	Startup transformer	Supplies power to one ESF bus of two units	Fails to provide power	Loss of preferred power to one redundant bus of two units (PBS-S03 or PBB-S04)	No effect - Power to the redundant bus is available through one of the other startup tran-formers feeding the redundant load group. In addition standby power available from diesel generator (12)
3	Circuit breaker (NC)	Supplies power to one ESF bus under normal condi-tions, and provides protec-tion under fault conditions	Fails open	Loss of preferred power to one redundant bus	No effect - Power to the redundant bus is available through breaker 3A. In addition diesel generator provides standby power.
4	Intermediate bus	Distributes power to one ESF load group	Fault	Loss of power to one load group	No effect - Power to the redundant load group is available through intermediate bus 4A
5	Circuit breaker (NC)	Supplies power to one ESF bus.	Fails open	Loss of preferred power to one redundant bus	No effect - Breaker 5A supplies power to the redundant load group. In addition diesel generator provides standby power.

a. The FMEA is performed for one channel or one train only.

b. Identification numbers are shown on figure 8.3-2.

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 2 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
6	Bus NAN-S03 or NAN-S04	Distributes power to one ESF bus	Fault	Loss of preferred power to one redundant load group	No effect - Bus 6A is available to supply power to the redundant load group.
7	Breaker NC	Supplies power to one ESF bus	Fails open	Loss of preferred power to one redundant load group	No effect - Breaker 7A of the redundant switch-gear supplies power to the redundant load group. In addition diesel generator provides stand-by power.
8	ESF service transformer	Supplies power to one ESF bus.	Fails to provide power	Loss of power to one ESF bus	No effect - ESF transformer 8A provides power to the redundant load group.
9	Main breaker (NC)	Provides protection to ESF bus during normal operation.	Fails open	Loss of preferred power to one bus	No effect - Redundant bus (9A) is available to supply power to its ESF load group. In addition diesel generator provides standby power.
10	4.16 ESF switchgear	Distributes power to all ESF loads of one load group	Fault	Loss of power to one load group.	No effect - Redundant bus 10A provides power to its ESF load group.
11	Diesel generator breaker (NO)	Closes to connect diesel generator to the bus	Fails to close	Loss of emergency power to one of the load groups	No effect - Redundant diesel generator supplies power to its load group through breaker 11A

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 3 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
			Fails open	Loss of emergency power to one of the load group.	No effect - Redundant diesel generator supplies power to its load group through breaker 11A
			Closes on spurious signal	Loss of diesel generator, hence loss of emergency power to one of the load groups.	No effect - Redundant diesel generator supplies power to its load group through breaker 11A
12	Diesel generator	Provides standby power to ESF bus (PBA-S03 or PBB-S04)	No output	Loss of emergency power to the one ESF bus.	No effect - Redundant diesel generator 12A supplies power to the redundant load group.
13	Circuit breaker (NC)	Provides protection to 4.16 kV bus and provides power to the load center transformer	Fails opens	Loss of power to some 480 volt ESF loads of one load group	No effect - Redundant circuit breaker 13A of the redundant load group provides power to its loads.
14	Load center transformer	Provides power at 480 volts to ESF loads.	Fails to provide power	Loss of power to some 480 volt ESF loads of one load group	No effect - Redundant circuit breaker 14A of the redundant load group provides power to its loads.
15	Load center main feeder breaker	Provides protection to 480 volt bus.	Fails open	Loss of power to some 480 volt ESF loads of one load group	No effect - Redundant circuit breaker 15A of the redundant load group provides power to its loads.

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 4 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
16	Load center bus	Distributes power to 480 volt loads.	Fault	Loss of 480 volt power to loads connected to the bus.	No effect - Redundant load center 16A supplies power to its loads.
17	Load center feeder to a third of a kind load (NC)	Provides protection to the bus in case of a fault	Fails open	Loss of power to the charging pump motor	No effect - The third charging pump motor is not required to perform a safety function.
18	MCC feeder breaker (NC)	Provides protection to the bus in case of a fault	Fails open	Loss of power to some MCC loads	No effect - The corresponding MCC of the redundant load group 18A provides power to its loads.
19	MCC bus	Distributes power to MCC loads	Fault	Loss of power to one MCC	No effect - The corresponding MCC of the redundant load group (19A) provides power to its loads.
20	Third of a kind transfer switch	Transfers power from one redundant power source to the other	Fails open	Loss of power to the third charging pump	No effect - The third charging pump motor is not required to perform a safety function.
			Fault in the transfer switch	Loss of third charging pump motor	No effect - No breaker is available in breaker space 17A to affect the redundant switchgear

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 5 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
21	Feeder breaker to voltage regulator (NC)	Provides protection to the bus under fault conditions and provides power to the voltage regulator under normal conditions	Fails open	Loss of power to the voltage regulator	No effect - The voltage regulator is on standby basis in case of inverter failure.
22	Feeder breaker to battery charger (NC)	Provides protection to the bus under fault conditions and provides power to the battery charger under normal conditions	Fails open	Loss of power to one battery charger.	No effect - The battery provides power to the dc bus. In addition the standby battery charger can be connected to the dc bus.
23	Battery	Provides dc power to the bus	Fails to provide dc power	Loss of standby power to the bus	No effect - The batteries serve as the source of standby dc power to the bus. The charger provides the dc power under normal conditions
24	Battery charger	Provides dc power to the bus.	Fails to provide dc power	Loss of primary dc power.	No effect - The battery provides power to the bus and the standby charger can be connected to provide power for extended period of time.
			Impresses ac voltage on dc system	Malfunction of components in one channel.	No effect - Power is available to other three redundant channels. Potential instrument error (due to noise) on one channel. Other channel(s) available.

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 6 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
25	Battery circuit breaker	Provides protection to the battery under fault conditions and provides power to the bus under normal conditions.	Fails open	Loss of standby dc power	No effect - The battery provides standby power to the bus. The charger provides the dc power.
26	Battery charger circuit breaker (NC)	Provides protection to the charger under fault conditions and supplies power to the dc bus under normal conditions.	Fails open	Loss of dc power to the bus	No effect - The battery supplies power to the dc bus through its breaker. Standby battery charger breaker can be closed to supply power to the loads and battery.
27	DC bus	Distributes dc power to ESF loads	Fault	Loss of dc power to one channel	No effect - Power available to the other three redundant channels. No actuation of ESFAS system due to 2/4 logic.
28	Inverter feeder breaker (NC)	Provides protection to the dc bus under fault conditions and provides power to the inverter under normal conditions	Fails open	Loss of power to the inverter	No effect - Power can be provided to the vital instrumentation bus by means of regulated transformer through the transfer switch. No actuation of safety system source to the other three inverters is available (2/4 Logic).

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 7 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
29	Voltage regulator	Provides power to the vital instrumentation bus	Fails to provide power	Loss of standby ac power to the vital bus.	No effect - The voltage regulator provides standby power in case of loss of inverter power. Power to the vital bus is available through the inverter.
30	Single phase inverter	Provides precise power to vital instrumentation bus	Fails to provide power	Loss of power to one vital instrumentation channel	No effect - Power is available from voltage regulator through the transfer switch.
31	Transfer switch (Manual or Static)	Transfers power from the inverter to the voltage regulator source	Fails to transfer	Loss of power to one channel	No effect - The other three channels are provided with power from their respective inverters. No actuation of safety systems since the actuation logic is 2/4.
			Fails to conduct	Loss of power to one channel	No effect - The other three channels are provided with power from their respective inverters. No actuation of safety systems since the actuation logic is 2/4.
32	Vital instrumentation panel circuit breaker (NC)	Provides protection to the inverter in case of fault and provides power during normal conditions.	Fails open	Loss of power to the vital instrumentation bus.	No effect - Power is available to the other three redundant channels. No actuation of safety system due to 2/4 logic.

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 8 of 9)

Identification No.[b]	Component Name	Component Function	Failure Mode	Effect on Subsystem	Effect on System
33	Vital instrument bus	Distributes power to the vital instrumentation loads.	Fault	Loss of power to the vital instrument loads.	No effect - The other three channels distribute power to their redundant loads. No actuation of safety systems due to 2/4 logic.
34	Three phase inverter feeder breaker (NC)	Provides power to the three phase inverter	Fails open	Loss of power to the shutdown cooling valve.	No effect - There are three other redundant shutdown cooling valves fed from their respective channels (2 of them from MCC channels A & B). No actuation of safety systems due to 2/4 logic.
35	Three phase inverter	Provides power to the shutdown cooling valves.	Fails to provide power	Loss of power to the shutdown cooling valve	No effect - (see item 34)
36	Manual Swing Line-up Switch (when energizing swing inverter)	Aligns swing inverter to one of two channels of DC power, one of two voltage regulators and one of two train inverters	Fails to operate	Failure to align or isolate swing inverter	No effect – Power available from voltage regulator through the normal static transfer switch
			Fault in the switch	Loss of swing inverter and loss of power to the vital instrumentation bus	No effect – Power is available to the other three redundant channels. No actuation of safety system due to 2/4 logic.

Table 8.3-5

FAILURE MODE AND EFFECTS ANALYSIS[a] (Sheet 9 of 9)

37	Manual Bypass Switch (when in Bypass to Load position)	Aligns swing inverter to 120Vac vital bus via one of two train inverters	Fails to operate	Failure to align swing inverter to train inverter	No effect - Power available from voltage regulator through the normal static transfer switch
			Fault in the switch	Loss of power to the vital instrumentation bus	No effect - Power is available to the other three redundant channels. No actuation of safety system due to 2/4 logic.

8.3.1.2.2.2 Criterion 18, Inspection and Testing of Electrical Power Systems. The Class 1E system is designed to permit:

A. Periodic inspection and testing, during equipment shutdown, of wiring, insulation, connections, and relays to assess the continuity of the systems and the condition of components.

B. Periodic testing, during normal plant operation, of the operability and functional performance of onsite power supplies, circuit breakers, and associated control circuits, relays, and buses.

C. Testing, during plant shutdown, of the operability of the Class 1E system as a whole. Under conditions as close to design as practical, the full operation sequence that brings the system into operation, including operation of signals of the ESF actuation system and the transfer of power between the offsite and the onsite power system, will be tested.

D. The following switchyard systems and components have been tested and are periodically inspected and maintained as required by 10CFR50, Appendix A, Criterion 18.

   1. Systems

      a. The offsite power system (in the transfer of power among the units itself, and the onsite power system)

      b. The protection system

2. Components (including areas and features)

   a. Wiring

   b. Insulation

   c. Connections

   d. Switchboards

   e. Onsite power sources

   f. Relays

   g. Switches

   h. Buses

   The inspection and maintenance frequencies vary, depending on system and component history at Palo Verde and at other locations.

8.3.1.2.2.3 Regulatory Guide 1.6, Independence Between Redundant Standby (Onsite) Power Supplies and Between Their Distribution Systems. The Class 1E system is divided into redundant load groups so that loss of any one group does not prevent the minimum safety functions from being performed. Refer to engineering drawing 01, 02, 03-E-MAA-002. The requirements of Regulatory Guide 1.6 are met as discussed in this paragraph.

Each ac load group has connections to two preferred (offsite) power supplies and to a single diesel generator. Each diesel generator is normally connected to a single 4.16 kV load group.

The two ac load groups each incorporate a Class 1E dc power train. Each Class 1E dc power train consists of two Class 1E

dc power channels. Each Class 1E dc power channel is energized by one battery and one battery charger. The battery is exclusively associated with a single 125 V-dc bus and each battery charger is supplied by its respective ac load group. A third, redundant battery charger is also provided which can provide power to either of the two Class 1E dc power channels within the respective ac load group, but not simultaneously.

The diesel generator of one load group cannot be automatically or manually paralleled with the diesel generator of the redundant load group.

No provisions exist for connecting one load group to the redundant load group when operating from both diesel generators. However, there are provisions for connecting both load groups to a single diesel generator during emergency conditions.

No provisions exist for automatically transferring loads between redundant onsite power supplies. When "maintenance spare" equipment is used, it is connected to either load group manually.

8.3.1.2.2.4 Regulatory Guide 1.9, Selection of Diesel Generator Set Capacity for Standby Power Supplies. The continuous rating of each diesel generator is greater than the sum of the conservatively estimated loads needed to be supplied following any design basis event. See tables 8.3-1 and 8.3-3 for loading requirements.

The diesel generators conform to Regulatory Guide 1.9, Rev. 3 with the exceptions discussed in section 1.8.

8.3.1.2.2.5 Regulatory Guide 1.22, Periodic Testing of Protection System Actuation Functions. The requirements of Regulatory Guide 1.22 are met. Refer to paragraph 8.3.1.1.3.14 for compliance of the Class 1E electric system with Regulatory Guide 1.22.

8.3.1.2.2.6 Regulatory Guide 1.29, Seismic Design Classification. The requirements of Regulatory Guide 1.29 are met. The Class 1E electric system and the auxiliary systems for the diesel generators are designed to withstand the effects of the SSE. Seismic qualification of Class 1E electric equipment is discussed in section 3.10.

8.3.1.2.2.7 Regulatory Guide 1.30, Quality Assurance Requirements for the Installation, Inspection and Testing of Instrumentation and Electric Equipment. Comparison of the design with the recommendations of Regulatory Guide 1.30 is discussed in section 1.8.

8.3.1.2.2.8 Regulatory Guide 1.32, Use of IEEE Standard 308-1971. The requirements of Regulatory Guide 1.32 are met with the clarifications discussed in section 1.8.

8.3.1.2.2.9 Regulatory Guide 1.40, Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants. There are no Class 1E continuous-duty motors installed inside the containment at PVNGS.

8.3.1.2.2.10 Regulatory Guide 1.41, Preoperational Testing of Redundant Onsite Electric Power Systems to Verify Proper Load Group Assignments. The requirements of Regulatory Guide 1.41 are met. The Class 1E onsite electric power systems, designed in accordance with Regulatory Guides 1.6 and 1.32, are tested as part of the preoperational testing program and also after major modifications. The tests are performed in accordance with the procedures outlined in section 14.2.

8.3.1.2.2.11 Regulatory Guide 1.47, Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems. Comparison of the design with the recommendations of Regulatory Guide 1.47 is discussed in section 7.5.

8.3.1.2.2.12 Regulatory Guide 1.53, Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems. Comparison of the design with the recommendations of Regulatory Guide 1.53 is discussed in subsection 7.1.2.

8.3.1.2.2.13 Regulatory Guide 1.62, Manual Initiation of Protective Actions. Comparison of the design with the recommendations of Regulatory Guide 1.62 is discussed in subsection 7.1.2 and section 7.3.

8.3.1.2.2.14 Regulatory Guide 1.63, Electric Penetration Assemblies in Containment Structures for Water-Cooled Nuclear Power Plants. The electric penetration assemblies are described in paragraph 8.3.1.2.2.21 and conform to IEEE 317-1976 and Regulatory Guide 1.63 with the exceptions discussed in section 1.8.

8.3.1.2.2.15 Regulatory Guide 1.73, Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants. Refer to section 3.11 for compliance with Regulatory Guide 1.73.

8.3.1.2.2.16 Regulatory Guide 1.75, Physical Independence of Electric Systems. The separation of electrical equipment and circuits and physical independence of electric systems meets the requirements of IEEE 384-1974 and Regulatory Guide 1.75 with the clarifications and exceptions discussed in section 1.8.

8.3.1.2.2.17 Regulatory Guide 1.81, Shared Emergency and Shutdown Electric Systems for Multi-Unit Nuclear Power Plants. The requirements of Regulatory Guide 1.81 are met. Each unit has separate and independent onsite ac and dc electric systems capable of supplying minimum ESF loads and loads required for attaining a safe and orderly cold shutdown of the unit assuming a single failure and loss of offsite power. No emergency and shutdown electric systems are shared between units.

8.3.1.2.2.18 Regulatory Guide 1.89, Revision 1, Environmental Qualification of Certain Electric Equipment Important to Safety for Nuclear Power Plants. Regulatory Guide 1.89, Rev. 1, endorses IEEE Standard 323-1974, IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations. Comparison of the design with the recommendations of Regulatory Guide 1.89, Revision 1, is discussed in section 1.8.

8.3.1.2.2.19 Regulatory Guide 1.93, Availability of Electric Power Sources. The position of Regulatory Guide 1.93 is accepted (refer to the Technical Specifications Bases).

8.3.1.2.2.20 IEEE 308-1974, IEEE Standard Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations. The Class 1E ac power systems are designed to assure that any design basis event, as listed in Table 1 of IEEE 308, does not cause the following:

A. A loss of electric power to more than one load group, surveillance devices, or protection system devices sufficient to jeopardize the safety of the unit.

B. A loss of electric power to equipment that could result in a reactor power transient capable of causing significant damage to the fuel or to the reactor coolant system.

The Class 1E system is capable of performing its function when subjected to the effects of any of the design basis events.

The Class 1E loads are designed to perform their functions adequately for the design variations of voltage and frequency in the Class 1E systems.

Controls and indicators for the Class 1E, 4.16 kV bus supply breakers are provided in the control room and on the switchgear. Controls and indicators for the standby diesel generator power supplies are provided in the control room and in the diesel generator control rooms.

Class 1E equipment and associated design, operating, and maintenance documents are distinctly identified as described in paragraph 8.3.1.3.

Each type of Class 1E equipment is qualified either by analysis, by successful use under similar conditions, by actual test or by a combination of analysis and test to demonstrate its ability to perform its function under applicable design basis events.

Supplementary design criteria of IEEE 308 are addressed in the applicable sections describing specific Class 1E equipment.

The surveillance requirements of IEEE 308 are followed in the design, installation, and operation of Class 1E systems. Pre-operational tests are performed in accordance with the procedures described in section 14.2. Periodic equipment tests are performed as discussed in the Technical Specifications.

With regard to Section 7 of IEEE 308, refer to the Technical Specifications for operating alternatives under degraded Class 1E ac system conditions

With regard to Section 8 of IEEE 308, the following applies:

A. The preferred power supply has the capacity to operate the ESF on one unit and those ESF systems required for concurrent safe shutdown on the other units.

B. The Class 1E battery supplies are not shared by the units.

8.3.1.2.2.21 IEEE 317-1976, IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear-Fueled Power Generating Stations. Electric penetration assemblies are used for all electric cables that pass through the containment exterior wall. These assemblies are designed and tested in accordance with IEEE Standard 317-1976.

Principal design criteria for these assemblies include the following:

A. The mechanical design, materials, fabrication, inspection and testing of the pressure-retaining boundary of the electric penetration assembly, excluding electric compounds and gaskets, are in accordance with the requirements of the ASME Boiler and Pressure Vessel Code, Section III, Subsection NE, for Class MC components.

B. Electric penetration assemblies are designed to meet electrical requirements for the specified service environment without dielectric breakdown or overheating.

C. The electric penetration assembly is designed to have a total gas leakage rate through its pressure-retaining boundary, exclusive of the aperture seal, not greater than 1×10^{-6} standard cubic centimeters per second[a] of dry helium (or equivalent means of measurement) at the maximum specified containment design temperature and pressure as defined in subsection 6.2.1.

---

a. 20C at one atmosphere of pressure.

D. A leak test shall be performed on each penetration assembly as discussed in section 14.2.

E. The design and installation is such as to facilitate periodic individual penetration assembly gas leak rate testing after installation, including both aperture and conductor seals.

F. The penetration assembly design is qualified for the intended service within the service environment by testing and analysis.

G. DC circuits utilizing penetrations are of the low voltage control type. These circuits are self-limiting in that the circuit resistance limits the fault current to a level that does not damage the penetration.

H. PVNGS periodically tests the primary and secondary protective devices.

8.3.1.2.2.22 IEEE 323-1974, Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations. The qualification methods and documentation requirements of IEEE 323 are followed to the extent discussed in section 1.8 for Class 1E electric equipment in the Bechtel scope of supply. Qualification consists of:

A. All Class 1E BOP safety-related instrumentation, control, and electrical equipment and its associated design, operating, and maintenance documents are identified.

B. Specifications reflecting the requirements of these documents are prepared.

C. Type tests, operating experience, analysis, a combination of these, or ongoing qualification are used to demonstrate the capability of equipment meeting performance specifications under the service conditions.

D. Documentation is prepared in a manner that permits an independent evaluation of the qualification methods.

8.3.1.2.2.23 IEEE 334-1971, Type Tests of Continuous-Duty Class 1 Motors Installed Inside the Containment of Nuclear Power Generating Stations. There are no Class 1E continuous-duty motors installed inside the PVNGS containment.

8.3.1.2.2.24 IEEE 344-1975, Seismic Qualification of Class 1E Equipment for Nuclear Power Generating Stations. Seismic qualification of Class 1E electric equipment and the extent of compliance with IEEE 344 are discussed in section 3.10.

8.3.1.2.2.25 IEEE 383-1974, Standard for Type Test of Class 1E Electric Cables, Field Splices, and Connections for Nuclear Power Generation Stations. Class 1E cable, field splices, and connections are in accordance with IEEE 383-1974 requirements.

Cable assemblies for the reed switch position transmitters and fixed incore system are in accordance with IEEE 383-1974 except that following environmental qualification testing they were

tested at 750 volts ac for 5 minutes while immersed in water at room temperature. This value meets the system requirements.

8.3.1.2.2.26 IEEE 384-1974, Criteria for Separation of Class 1E Equipment and Circuits. Refer to paragraph 8.3.1.4 for compliance. Also refer to appendix 8A, Question 8A.10 response.

8.3.1.2.2.27 IEEE 387-1977, Criteria for Diesel Generator Units Applied as Standby Power Supplies for Nuclear Power Generating Stations.

A. Service Environment

Diesel engine cooling and building ventilation equipment is provided to maintain an acceptable environment within the diesel generator rooms during and after any design basis event even without support from the preferred power supply.

B. Starting and Loading

The diesel generator is capable of starting, accelerating, and accepting load as described in paragraph 8.3.1.1.3. The diesel generator automatic loading will be in accordance with Section 5.1.2(2) of IEEE 387.

C. Quality of Power

Refer to paragraphs 8.3.1.2.2.4 and 8.3.2.2.1 for frequency and voltage limits.

D. Ratings

Refer to paragraphs 8.3.1.2.2.4 and 8.3.2.2.1 for the basis of the continuous rating of the diesel generator.

E. Interactions

Refer to paragraphs 8.3.1.2.2.4 and 8.3.2.2.1 for assurance that independence is provided between the redundant Class 1E ac load groups. Mechanical and electric systems are designed so that a single failure affects the operation of only a single diesel generator.

F. Design and Application Considerations

Design conditions such as vibration, torsional vibration, and overspeed are considered in accordance with the requirements of IEEE 387.

G. Governor and Voltage Regulator Operation

The diesel can operate in the droop mode and the voltage regulator can operate in the paralleled mode during diesel generator testing. If an underfrequency condition occurs while the diesel generator is paralleled with the preferred (offsite) power supply (testing mode), the diesel generator will trip. If an SIAS signal is received while the diesel generator is being tested, the governor and voltage are automatically restored to the isochronous mode and the diesel generator breaker is automatically tripped.

Refer to figure 8.3-1 for the diesel generator logic diagram.

H. Control

Each diesel generator is provided with control systems permitting automatic and manual control. The automatic start signal is functional except when the diesel generator is in the maintenance mode. Provision is made for controlling the diesel generator from the control room and from the diesel generator room. Refer to paragraph 8.3.1.1.4.10 for further description of the control systems.

I. Surveillance

Voltage, current, frequency, and output power metering are provided in the control room to permit assessment of the operating condition of each diesel generator.

Surveillance instrumentation is provided in accordance with IEEE 387.

J. Testing

Tests as listed in paragraph 8.3.1.1.4.7 are conducted on each diesel generator in accordance with IEEE 387.

8.3.1.3 Physical Identification of Safety-Related Equipment

Each circuit and raceway is given a unique alphanumeric identification. This identification provides a means of distinguishing a circuit or raceway associated with a particular voltage or function as well as with a particular channel or load group. The identification contains the

appropriate separation group letter and is assigned on the basis of the following criteria:

Separation Group A

A Class 1E instrumentation, control, or power cable, raceway, or equipment associated with load group 1, dc subsystem A, or vital ac instrumentation and control channel A.

Separation Group B

A Class 1E instrumentation, control, or power cable, raceway, or equipment associated with load group 2, dc subsystem B, or vital ac instrumentation and control channel B.

Separation Group C

A Class 1E instrumentation, control, or power cable, raceway, or equipment associated with vital ac instrumentation and control channel C and dc subsystem C.

Separation Group D

A Class 1E instrumentation, control, or power cable, raceway, or equipment associated with vital ac instrumentation and control channel D and dc subsystem D.

Separation groups A through D are color-coded as follows:

Group A: Red

Group B: Green

Group C: Yellow

Group D: Blue

All equipment is provided with a tag number that includes the applicable separation group identification. Nameplates of color background are provided for all Class 1E cabinets.

Class 1E raceways are identified at the ends with colored nameplate stickers or stenciled markings, and along their lengths by colored diamonds or dots of separation group designation at intervals not exceeding 15 feet.

Identification is provided for safety-related field cables by color coding along the cable. Cable markers with the separation group identification are provided at each end of each cable.

Associated circuit cables are uniquely identified per section 1.8 and paragraph 7.1.3.16. In addition, interconnecting cables between the safety equipment status system (SESS) logic cabinet and the SESS status panels on the main control boards are uniquely identified as associated cables in accordance with section 1.8 and paragraph 7.1.3.16.

Power cable for the standby third-of-a-kind components is Class 1E with black jacket and is routed in conduit. This cable and conduit are assigned a separation group E identifier only for the purpose of indicating the unique separation group condition and are marked with the impacted separation group assigned color-codes (see subsection 8.3.14.3). The "E" charging pump cable and conduit are marked with red and green stripes to identify the connections to A or B redundant train power supplies. The swing inverter and swing line-up switch

cable and conduit, if implemented per DMWO 3232547, are marked to identify the connections to their independent power supplies with red and yellow stripes for A or C, respectively, and green and blue stripes for B or D, respectively.

Within control panels where more than one separation group is present, field wiring is identified by separation group color code, or, if enclosed by conduit, the conduit is identified by separation group designation and color code.

Within a cabinet or panel that is associated and identified with a single separation group, the internal wiring is exclusively associated with the same separation group, and, therefore, requires no further identification.

Design drawings provide distinct identification of Class 1E equipment. The applicable channel or load group designation is also identified.

8.3.1.4 Independence of Redundant Systems

8.3.1.4.1 Separation Criteria

This paragraph establishes the criteria and their bases for the physical separation of Class 1E circuits in preserving the independence of redundant circuits in accordance with R.G. 1.75, Rev. 1 (IEEE 384-1974).

8.3.1.4.1.1 Raceway and Cable Routing. Raceway configuration, cable routing, and barrier installation within the plant adheres to the following practices to minimize a fire in one separation group from propagating to another separation group:

A. Wherever possible, cable trays are arranged from top to bottom, with trays containing the highest voltage cables at the top and trays containing the lowest voltage cables at the bottom. Raceways are grouped by voltage levels: Medium voltage, Power and Control, Instrumentation and Communication. Individual raceways contain cables of similar voltage levels. Voltage levels are listed below:

   1. Higher medium voltage, 13.8KV (non-Class 1E only)
   2. Lower medium voltage, 4.16KV
   3. 480V load center power
   4. 480 MCC & DC power & control
   5. 120V Control and digital
   6. Instrumentation
   7. Communications

B. Cables associated with each separation group, as defined in paragraph 8.3.1.3 are run in separate conduits, cable trays, ducts, or penetrations.

C. In areas of the plant where the only source of fire is electrical and without a confirming analyses to support less stringent requirements, the following general requirements are applicable:

   1. In areas other than the main control or cable spreading rooms, Class 1E cable trays of different separation groups have a minimum:

a. Horizontal separation distance of 3 feet if no damage limiting barrier exists between redundant trays (raceways).

   In configurations where the 3 foot horizontal separation in unattainable, 1 inch minimum separation is acceptable provided redundant circuits are:

   - Contained within an enclosed raceway (i.e., conduit, tray with both solid top and bottom, or wireway, etc.),
   - Encircled within a damage limiting barrier material,
   - Separated by a damage limiting barrier extending at least 1 foot above the top of the tray (or to the ceiling) and 1 foot below the bottom of the tray (or to the floor), or,
   - A combination of the above.

b. Vertical separation distance of 5 feet if no damaging limiting barrier exists between redundant trays (raceways).

   In configurations where the 5 foot vertical separation is unattainable, 1 inch minimum separation is acceptable provided redundant circuits are:

- Contained within an enclosed raceway (i.e., conduit, tray with both solid top and bottom, wireway, etc.),
- Separated by solid bottoms on upper tray and solid tops on lower tray,
- Encircled within a damage limiting barrier material,
- Separated by a damage limiting barrier extending at least 1 foot beyond the area of unattainable separation (including tray rails), or
- A combination of the above.

2. In the main control or cable spreading rooms, cable trays of different separation groups have a minimum:

   a. Horizontal separation distance of 1 foot if no damage limiting barrier exists between redundant trays (raceways).

      In configurations where the 1 foot horizontal separation is unattainable, 1 inch minimum separation is acceptable provided redundant circuits are:

      - Contained within enclosed raceway,
      - Encircled within a damage limiting barrier material,
      - Separated by a damage limiting barrier extending at least 1 foot above the top of

the tray (or to the ceiling)and 1 foot below the bottom of the tray (or to the floor), or,

- A combination of the above.

b. Vertical separation distance of 3 feet if no damage limiting barrier exists between redundant trays (raceways).

In configurations where 3-foot vertical separation is unattainable, 1-inch minimum separation is acceptable provided redundant circuits are:

- Contained within enclosed raceway,
- Separated by solid bottoms on upper tray and solid tops of lower tray,
- Encircled within a damage limiting barrier material,
- Separated by a damage limiting barrier extending at least 1 foot beyond the area of unattainable separation (including the tray rails), or
- A combination of the above.

3. Minimum separation distances between Class 1E and exposed non-Class 1E circuits is the same as the minimum separation distances described in 1 and 2 above, while the minimum separation distance between

exposed Class 1E and enclosed non-Class 1E raceways is 1 inch.

4. Openings in the floors for vertical runs of raceways are sealed with fire resistant material. Fire stops are also provided at fire-rated wall penetrations.

5. Where it is necessary that cables of different separation groups approach the same or adjacent control panels with less than the minimum horizontal and/or vertical separation distances, isolation is maintained by installing cables of the redundant separation groups in separate enclosed raceways with 1-inch minimum separation between raceways, or by installing suitable damage limiting barriers. The raceways have a least 1 inch distance between separation groups prior to installation of the barrier.

D. Arrangement and/or protective barriers preclude locally generated forces or missiles from destroying redundant systems. In the absence of confirming analyses to support less stringent requirements, the following rules are applied:

1. In rooms or compartments containing cranes or heavy rotating machinery (such as the reactor coolant pumps) or in rooms containing high-pressure piping (such as reactor coolant piping, high-pressure feedwater piping, or high-pressure steam lines), a degree of separation commensurate with the criteria of Regulatory Guide 1.75 is provided such that the

independence of redundant Class 1E systems is maintained at an acceptable level.

2. Redundant load groups of 4.16 kV switchgear, 480V load centers, and motor control centers are separated by a protective barrier equivalent to a 6-inch thick reinforced concrete wall.

E. Non-Class 1E cables are not normally routed in Class 1E raceways. However, if a non-Class 1E cable is routed in a Class 1E raceway, it is considered an associated cable and treated as if it were a Class 1E cable of the same separation group as the raceway.

F. Load group 1 and protection channels A and C and load group 2 and protection channels B and D cables are routed through separate cable chases and cable spreading rooms. The former circuits enter the upper cable spreading room, while the latter circuits enter the lower cable spreading room.

G. Specific circuits (cables and wiring) have been analyzed on a case by case basis (per IEEE 384-1974, sections 4.5, 4.6.2, and 5.1.1.2) in Engineering Study 13-ES-A041[1] and identified as being low energy circuits. As such, these circuits are incapable of degrading redundant circuits within their vicinity. Circuits analyzed as low energy circuits are not applicable to Reg. Guide 1.75 separation requirements are as follows:

Non-Class 1E

- Fiber optic circuits

- Fire detection Protectowire circuits
- Fire detection circuits within panels
- Radiation monitoring system computer signal and information circuits
- Plant telephone system circuits
- Plant paging system circuits
- Main Steam and Feedwater Isolation System (MSFIS) trouble alarm circuits
- RCP temperature sensor monitoring system (Spec. 13-JM-111) circuits
- RCP temperature recording system (Spec. 13-JM-304) circuits
- RCP shaft speed sensing system circuits
- Radio system coaxial cable
- RCP vibration monitoring system (Spec. 13-JM-803) circuits
- Valve vibration monitoring system (Spec. 13-JM-366) circuits
- Containment sump level transmitter and converter circuits
- Fire Protection system dampers (Specs 13-MM-652 and 13-MM-658) circuits
- Fuel Building Air Filtration Units (AFU) temperature elements (Spec. 13-MM-721B) circuits

- Non-Class 1E run time meter circuits[(2)]

Class 1E cables

- Radiation monitoring system detector circuits
- RCP shaft speed sensing system circuits
- Reed Switch Position Transmitter (RSPT) system power supply circuits
- Class 1E instrument AC power system Inverter alarm circuitry[(1)]

H. Exposed non-class 1E festoons, pendants, bus bar feeder rails, etc. supplies with cranes, monorail hoists, and the refueling machine may not meet the separation requirements of Regulatory Guide 1.75, depending on crane position. When unattended, this equipment shall be de-energized by means of a disconnect device or feeder circuit breaker whenever Regulatory Guide 1.75 compliance cannot be satisfied. The cranes may be energized as needed for plant or crane maintenance activities as applicable, and locally controlled. The crane operator would detect any crane malfunction.

I. Outside the PKA-F11 battery room is a permanently mounted Non-Class 1E battery charger used to charge spare battery cells for the Class 1E batteries. The spare cells sit in the PKA-F11 battery racks. The Non-Class cables that feed the spare cells do not meet the cable separation requirements of 8.3.1.4.1.1.C.1 with respect to the Class 1E battery cables. These cables however, meet the separation requirements of IEEE 384 1992 and Reg.

Guide 1.75 Revision 3. The reduced separation required distances are 6 inches horizontal and 12 inches vertical as per IEEE 384 1992 Section 6.1.4.

8.3.1.4.1.2 Control Board and Other Panels. Single control devices to which different separation groups are connected are avoided. Within the main control boards, non-Class 1E wiring is run separated from Class 1E wiring. Harnesses of different separation groups are separated physically by a minimum distance of 6 inches, or where physical separation is impractical, barriers (metal barriers, metallic conduit, metallic gutter, or wire duct) with 1-inch air gap are used for maintenance of independence. Where 1-inch air gap cannot be maintained, ceramic fiber insulation equivalent to a 1-inch air gap is used.

A. A 6-inch minimum physical separation is maintained between field cables of different separation groups entering an enclosure (main control boards, switchboards, equipment cabinets, panels, and termination cabinets) between any of these cables and internal wiring of the separation groups within the enclosure and between the internal wiring of different separation groups within the enclosure. Where a 6-inch minimum physical separation between two separation groups cannot be maintained, one of the following is performed:

    1. The cables or cable conductors of redundant safety-related separation groups are installed in separate enclosed raceway (rigid steel conduit,

flexible conduit, EMT, or enclosed metallic gutter) maintaining a 1-inch minimum separation between enclosed raceways. The enclosed raceways are installed over the entire length of the cables or cable conductors from/to the point where a 6-inch minimum separation distance can be established.

2. A metal barrier is erected between the cabling, terminal boxes, or components of the separation groups, and a 1-inch air gap is maintained between the barrier and the separation group component.

B. Non-Class 1E circuits within Class 1E enclosures (switchboards, equipment cabinets, panels and termination boxes, etc.) or devices, which contain non-Class 1E instrumentation and/or control wiring (field cabling or internal wiring) and wiring (field or internal wiring) of only a single Class 1E separation group, are considered as associated circuits and are treated as Class 1E wiring if minimum separation between the Class 1E devices and wiring and the non-Class 1E devices and wiring cannot be maintained.

C. When non-Class 1E cables enter an enclosure containing Class 1E wiring (field or internal wiring), a 6-inch minimum physical separation is maintained between the non-Class 1E cables and any Class 1E wiring. Where a 6-inch separation cannot be maintained, the

non-Class 1E cables are installed in enclosed raceways (rigid steel conduit, flex conduit, EMT, or enclosed metallic gutter) and a minimum of 1-inch separation is maintained between the non-Class 1E enclosed raceways and the Class 1E cables.

D. Within the main control board only, in the event a 6-inch separation cannot be maintained, either the non-Class 1E cables will be enclosed and separated as noted in listing C above or the Class 1E cables will be installed in enclosed raceways (rigid steel conduit, flex conduit, EMT, or enclosed metallic gutter) and a minimum of 1-inch separation is maintained between the enclosed Class 1E raceway and the nonenclosed non-Class 1E cables. When the Class 1E cables of a particular separation group are enclosed in a raceway group, then the non-Class 1E cables that are routed within 6 inches of that given Class 1E separation group shall not be routed within 6 inches of any other Class 1E separation group.

E. Six-inch separation between separation groups for control and instrument circuits within the plant protection system cabinet is not provided. Justification for this exception was provided by a letter from Mr. E. E. Van Brunt, Jr., APS, to Mr. G. W. Knighton, NRC, ANPP-31526, dated December 18, 1984.

8.3.1.4.1.3 Reactor Containment Penetration Areas. Four separate penetration areas are provided for all cables that

must pass through the containment wall. The two southeast penetration areas contain cable for separation groups B and D at two levels, each located in a separate area. The two southwest penetration areas contain cable for separation groups A and C, at two levels each located in a separate area. Raceway separation criteria, as described in this section, apply in routing cable through the penetration areas. Non-safety-related penetration assemblies are located in each of the four areas.

8.3.1.4.2 Administrative Responsibilities and Controls for Assuring Separation Criteria

The cable and raceway channel identification described in paragraph 8.3.1.3 facilitates and ensures the maintenance of separation in the routing of cables and the connection of control boards and panels. At the time of the cable routing assignment during design, those responsible for cable and raceway scheduling check to ensure that the separation group designation in the cable number is compatible with a single-line diagram load group designation. Extensive use of computer facilities assists in ensuring separation. Each cable and raceway is identified in the computer program, and the identification includes the applicable separation group designation. Auxiliary programs are made available specifically to ensure that cables of a particular separation group are routed through the appropriate raceways. The routing is also confirmed by inspection personnel during installation to be consistent with the design document. Color

identification of equipment and cabling (refer to paragraph 8.3.1.3) assists field personnel in this effort.

8.3.1.4.3 Cable and Raceway Installation

Information pertinent to cable and raceway installation is as follows:

A. Cable Derating and Cable Tray Fill

To limit cable temperatures to 90°C, cable ampacity ratings and group derating factors are generally in accordance with ICEA P-46-426 for cables in conduit, ducts, or maintained spacing trays and to ICEA P-54-440 for cables in randomly filled trays.

In trays containing:

- Power cables rated 5kV and 15kV, cables are generally spaced in the tray with a one cable diameter spacing maintained.
- Power cables rated 600 volts and below, tray fill is generally limited to a calculated tray depth of 1.15 inches.
- Control or instrumentation cables only or a mixture of low voltage power, control, and/or communication cables; cables are installed with a 40% fill limitation applied.

Trays not meeting the above requirements are reviewed by Design (Electrical) Engineering on a case-by-case basis for adequacy of design and acceptability, and

documented in PDMS (Plant Data Management System) as an override.

To ensure 90°C cable ratings are not exceeded, the sizing of power cables in electrical raceways is based on all cables being fully loaded simultaneously to their rated ampacity with correction factors for ambient temperatures other than 40C incorporated in accordance with ICEA Publication P-54-440. When this conservative approach indicates cable temperatures exceeding 90°C, a more detailed method based on plant 'As Built' conditions is utilized to ensure the 90°C criteria is not exceeded.

Cables installed in Class 1E and non-Class 1E trays are further required to meet, as a minimum, the 70,000 BTU/hr IEEE 383 flame test. There are 27 cables installed at PVNGS that do not meet the IEEE 383 flame test. These 27 cables have been evaluated, for both electrical and fire protection properties, and "Accepted-As-Is" by Material Engineering Evaluation (MEE) 02480.

Conduit fill is in compliance with the provisions of Chapter 9 of the National Electrical Code (1975). In cases where this condition is exceeded, a design engineer reviews each individual case for adequacy of design.

B. Cable Routing in Congested Areas and Hostile Environment

Separation or barriers are provided as described in paragraph 8.3.1.4.1 to ensure adequate independence of redundant cable routings in congested and hostile areas.

C. Sharing of Cable Trays

Raceways are not shared by Class 1E cables and non-Class 1E cables except where a non-Class 1E is supplied from a Class 1E bus. In this case, the circuit from the bus to the terminal or isolation device is installed as if it were a Class 1E circuit of the associated separation group.

D. Fire Detection and Protection

Adequate fire detection and protection are provided in areas where cables are installed as described in subsection 9.5.1.

E. Cable and Cable Tray Markings

Color identification is used for trays and cables as described in paragraph 8.3.1.3.

F. Spacing of Wiring and Components in Control Boards, Panels, and Relay Racks

Physical separation or installation of barriers or conduit provides adequate independence of wiring and components in panels as described in paragraph 8.3.1.4.1.2.

G. Fire Barriers and Separation Between Redundant Groups

Refer to paragraph 8.3.1.4.1 for information regarding utilization of fire barriers and separation between redundant cable trays.

Fire barriers in the upper cable spreading room floor will be MCT (multicable transit). Fire barriers in other areas shall consist of Kaowool, silicone foam, or material of similar construction.

8.3.2 DC POWER SYSTEMS

8.3.2.1 Description

The Class 1E 125 Volt direct current (dc) systems for each unit is located in the control building and is made up of two trains (A & B) of four independent channels (A, B, C & D). Channels A & C are designated as Load Group 1 or Train A; Channels B & D are designated as Load Group 2 or Train B. The Class 1E dc trains and channels are identified on plant drawing 01, 02, 03-E-PKA-001. Channels A & B provide control power to ac load groups 1 (Train A) & 2 (Train B), to vital instrumentation and control power for Channels A & B of the reactor protective and engineered safety feature (ESF) systems and diesel generators A & B. Channels C & D also provide instrumentation and control power to the reactor protective and ESF systems and other safety related loads. Each channel contains a battery bank, hereby referred to as a battery, a battery charger, a control center, a distribution panel, and is supplied with Class 1E 480 V-ac power from a different Motor Control Center (MCC) within its associated load group. Each load group or train

additionally contains a back-up battery charger aligned to their respective A and B dc train which can be manually connected to channels A or C for Load Group 1 and channels B or D for Load Group 2 (see drawing 01, 02, 03-E-PKA-001). The Class 1E back-up chargers are mechanically interlocked to prevent channels A or C and B or D from being simultaneously connected. Four inverters, supplied from the dc channel provide four independent 120 V-ac vital instrumentation and control power for the four channels of the reactor protective and ESF systems.

Non-Class 1E dc loads are not fed from Class 1E dc buses.

The non-Class 1E loads for the station are supplied by a separate dc system. The non-Class 1E dc system consists of two 125V batteries, two dc control centers, three battery chargers, and four dc distribution panels for control and power loads. A spare battery charger is provided as a backup to primary battery chargers. The spare charger shall not provide power to both systems simultaneously. The non-Class 1E DC system is identified on plant drawings 01, 03, 03-E-NKA-001.

8.3.2.1.1 Safety-Related DC Loads

Table 8.3-6 identifies loads related to each Class 1E 125 V-dc channel.

8.3.2.1.2 Class 1E Station Batteries and Battery Chargers

8.3.2.1.2.1 Battery Capacity. Each Class 1E battery has sufficient capacity to independently supply the required loads as shown in table 8.3-6 for 2 hours. The sizing of the batteries is based on a minimum temperature of 60F in the

battery room for the 2-hour service period. In accordance with IEEE Standard 450-2002 battery replacement criteria, initial battery capacity is at least 25% greater than required. This margin allows a battery replacement criterion of 80% rated capacity. The battery sizing calculation includes factors for design margin and temperature as well as an additional 5% margin reserved for the uncertainties related to using 2 amps of float current as the designation that the battery is at least 95% charged.

Total loads on bus D			101(d)	89(d)

Notes:

(a) Intermittent loads, which may occur randomly several times during the 2-hour period.

(b) Random loads and the second DG field flash are assumed to occur at 119-120 minutes. For “A” channel, the 119-120 (last) minute loads are conservatively enveloped in 6-120 minute column. For ‘B’ channel, these loads are shown in 119–120 minute column. (Ref. Calculation 01-EC-PK-0207, Rev. 06, section 3.2.3, and 3.2.4)

(c) These loads are not expected to operate during the 2-hour period. Fractional amperes represent control circuit load only.

(d) These values are taken from “Battery Load Profiles” (Calculation 01-EC-PK-207, Rev. 06, which is representative of all three units). This calculation models the DC system network and switching operations during LOCA in much greater detail than is depicted in this Table. The Table reflects only the peak loadings during a specific switching mode of operation which may occur for one second only and is not the total of all the loads occurring for the entire one minute. Therefore, the net battery loading does not equate to the sum of the individual load currents, but is derived more precisely in the calculation. Load amperes are rounded to one decimal place only. Numeric values in this table are nominal in nature, provided to give the reader a sense of the value of the parameter and should not be viewed as actual value in the field as discussed in the FOREWORD to the UFSAR.

(e) Only the major loads are shown on this table. Smaller loads or the details of the loads are reflected in the calculation 01-EC-PK-0207, Rev. 06.

(f) Above table is based on 2 hours of LOCA event consistent with the applicable safety analyses in UFSAR chapter 6,15 and 8.3.2.1.2.1.

(g) Thermal overload protection is automatically bypassed upon receipt of an ESFAS actuation.

8.3.2.1.2.2 Battery Charger Capacity. The capacity of each Class 1E battery charger is based on the largest combined demand of all the steady-state loads and the charging current required to restore the battery from the design minimum charge state to the fully charged state within 12 hours regardless of the status of the plant during which these demands occur. This is in accordance with Regulatory Guide 1.32. The float voltage is maintained at or above the manufacturers recommended value and is periodically verified in accordance with the battery maintenance program. For the GNB NCN-33 cells this is 2.17 volts per cell.

8.3.2.1.2.3 Inspection, Maintenance, and Testing. Testing of the dc power system was performed prior to plant operation in accordance with IEEE 450-1972 as described in section 14.2. Subsequent tests and inspections are as described in the Technical Specifications or the battery maintenance program.

8.3.2.1.3 Separation and Ventilation

The Class 1E batteries, chargers, and dc switchgear are located in separate rooms of the Seismic Category I control building, as described in paragraph 8.3.1.1.8.

Each battery room is provided with separate and independent exhaust fans. The ventilation system is designed to preclude the possibility of hydrogen accumulation. Refer to paragraph 8.3.1.1.8 and section 9.4 for details regarding the battery room ventilation system.

8.3.2.2 Analysis

8.3.2.2.1 Compliance with Design Criteria and Guides

The analysis in this section demonstrates compliance of the Class 1E dc power system with General Design Criteria 17 and 18, Regulatory Guides 1.6, 1.22, 1.29, 1.30, 1.32, 1.40, 1.41, 1.47, 1.53, 1.75, 1.81, 1.89, 1.93, and IEEE Standards 308, 323, 344, 383, 384, and 450.

8.3.2.2.1.1 General Design Criterion 17, Electric Power Systems. Consideration of Criterion 17 leads to the inclusion of the following factors in the design of the dc power system:

A. Separate Class 1E 125 V-dc trains supply control power for each of the two Class 1E ac load groups.

B. The ac power for the battery chargers in each of these dc trains is supplied from the same ac load group for which the dc trains supplies the control power.

C. The Class 1E dc channels, including batteries, chargers, dc switchgear and distribution equipment, are physically separate and independent.

D. Sufficient capacity, capability, independence, redundancy, and testability are provided in the Class 1E dc channels, ensuring the performance of safety functions assuming a single failure.

8.3.2.2.1.2 General Design Criterion 18, Inspection and Testing of Electric Power Systems. Each of the four Class 1E 125 V-dc channels is designed to permit the following:

A. Inspection and testing, during equipment shutdown, of wiring, insulation, and connections to assess the continuity of the subsystem and condition of its components.

B. Periodic testing, during normal plant operation, of the operability and functional performance of the subsystem, by isolating the subsystem.

As described in paragraph 8.3.2.1.2.3, the battery and charger of each Class 1E 125 V-dc subsystem is periodically inspected and tested to assess the condition of battery cells and other components. Moreover, all important system components can be tested during service to detect faults. Abnormal conditions of important system parameters are annunciated in the unit control room. Refer to paragraph 8.3.2.2.1.7 for preoperational testing.

8.3.2.2.1.3 Regulatory Guide 1.6, Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems. The requirements of Regulatory Guide 1.6 are met. Two of the four separate Class 1E 125 V-dc channels, one per each load group, supply control power for their respective Class 1E ac load groups. Complete loss of either one of these channels does not prevent the minimum safety functions from being performed.

Each of the four dc channels is energized by one battery and one battery charger. Each battery is exclusively associated with a single 125 V-dc bus. The battery and the battery charger exclusively associated with one of these four 125 V-dc channels cannot be interconnected with any other 125 V-dc

channel. The battery chargers are supplied from the same ac load group for which the associated dc channel supplies the control power. No provision exists for transferring loads between redundant 125 V-dc channels. Thus, sufficient independence and redundancy exist between the 125 V-dc subsystems to ensure performance of minimum safety functions assuming a single failure.

8.3.2.2.1.4 Regulatory Guide 1.22, Periodic Testing of Protection System Actuation Functions. The requirements of Regulatory Guide 1.22 are met. Refer to paragraph 8.3.1.1.3.14 for compliance of the Class 1E electrical system with Regulatory Guide 1.22.

8.3.2.2.1.5 Regulatory Guide 1.29, Seismic Design Classification. Refer to section 3.10 for a discussion of compliance with Regulatory Guide 1.29.

8.3.2.2.1.6 Regulatory Guide 1.30, Quality Assurance Requirements for the Installation, Inspection and Testing of Instrumentation and Electric Equipment. Comparison of the design with the recommendations of Regulatory Guide 1.30 is discussed in section 1.8.

8.3.2.2.1.7 Regulatory Guide 1.32, Use of IEEE Standard 308-1971, Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations. Refer to section 1.8.

8.3.2.2.1.8 Regulatory Guide 1.40, Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of

Water-Cooled Nuclear Power Plants. There are no Class 1E continuous-duty motors installed inside the containment.

8.3.2.2.1.9 Regulatory Guide 1.41, Preoperational Testing of Redundant Onsite Electric Power Systems to Verify Proper Load Group Assignments. In compliance with this regulatory guide, the Class 1E 125 V-dc channels designed in accordance with Regulatory Guides 1.6 and 1.32 are tested as described in section 14.2.

8.3.2.2.1.10 Regulatory Guide 1.47, Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems. Comparison of the design with the recommendations of Regulatory Guide 1.47 is discussed in section 7.5.

8.3.2.2.1.11 Regulatory Guide 1.53, Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems. Comparison of the design with the recommendations of Regulatory Guide 1.53 is discussed in subsection 7.1.2.

8.3.2.2.1.12 Regulatory Guide 1.75, Physical Independence of Electrical Systems. Refer to paragraph 8.3.1.2.2.16.

8.3.2.2.1.13 Regulatory Guide 1.81, Shared Emergency and Shutdown Electric Systems for Multi-Unit Nuclear Power Plants. The requirements of Regulatory Guide 1.81 are met. Each unit has separate and independent onsite ac and dc electric systems capable of supplying minimum ESF loads and loads required for attaining a safe and orderly cold shutdown of the unit assuming

a single failure and loss of offsite power. No emergency and shutdown electric systems are shared between units.

8.3.2.2.1.14 Regulatory Guide 1.89, Revision 1, Environmental Qualification of Certain Electric Equipment Important to Safety for Nuclear Power Plants. Regulatory Guide 1.89, Rev. 1 endorses IEEE Standard 323-1974, IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations. Comparison of the design with the recommendations of Regulatory Guide 1.89, Revision 1, is discussed in section 1.8.

8.3.2.2.1.15 Regulatory Guide 1.93, Availability of Electric Power Sources. The position of Regulatory Guide 1.93 is accepted (refer to the Technical Specifications Bases).

8.3.2.2.1.16 IEEE 308-1974, IEEE Standard Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations. The Class 1E dc system provides dc electric power to the Class 1E dc loads and for control and switching of the Class 1E systems. Physical separation, electrical isolation, and redundancy are provided to prevent the occurrence of common failure modes. Design of the Class 1E dc system includes the following:

A. The dc system is separated into two load groups (trains) broken into four independent channels.

B. The safety actions by each group of loads are independent of the safety actions provided by its redundant counterpart.

C. Each dc subsystem includes power supplies that consist of one battery and one battery charger.

D. The batteries are not interconnected between channels.

E. The redundant batteries cannot be made inoperative by a single design basis event.

Each Class 1E distribution circuit is capable of transmitting sufficient energy to start and operate all required loads in that circuit. Distribution circuits to redundant equipment are independent of each other. The distribution system is monitored to the extent that it is shown to be ready to perform its intended function. The dc auxiliary devices required to operate equipment of a specific ac load group are supplied from the same load group.

Some nonsafety-related circuits may be supplied from the safety-related dc buses. When this is done, those circuits are treated as safety-related up to the equipment terminations or isolation devices.

Each battery supply is continuously available during normal operations and following the loss of power from the ac system to start and operate all required loads.

Control room instrumentation is provided to monitor the status of the battery supply as follows:

- DC bus undervoltage alarm[a]
- Battery current indication
- DC voltage indication
- DC ground indication

a. Via alarm typewriter, alarm displays, and plant annunciator.

- Battery breaker open alarm[a]

The plant monitoring system (PMS) provides a common dc system trouble annunciator.

The batteries are maintained in a fully-charged condition and have sufficient stored energy to operate all necessary circuit breakers and to provide an adequate amount of energy for all required emergency loads for 2 hours after loss of ac power.

Each Class 1E battery charger has sufficient capacity to restore the battery from the design minimum charge to its fully-charged state while supplying the maximum demand of the steady-state loads. The battery charger of one subsystem is independent of the battery charger for the redundant subsystem. Instrumentation is provided to monitor the status of the battery charger as follows:

A. Output voltage at the charger and in the control room

B. Output current at the charger and in the control room

C. AC and dc breaker position indications at the charger

D. Charger malfunction alarm in control room, including input ac undervoltage, dc undervoltage, dc overvoltage, and output breaker open

Each battery charger has an input ac and output dc circuit breaker for isolation of the charger. Each battery charger power supply is designed to prevent the ac supply from becoming a load on the battery due to a power feedback as the result of

---

a. Via alarm typewriter, alarm displays, and plant annunciator.

the loss of ac power to the chargers. Battery chargers are provided with built-in overvoltage shutdown protection that is capable of tripping the ac input breaker in the event of dc overvoltage.

Equipment of the Class 1E dc system is protected and isolated by fuses or circuit breakers in case of short circuit or overload conditions. Indication is provided to identify equipment that is made unavailable (refer to table 8.3-7).

The Class 1E 125 V-dc subsystem is designed to meet Seismic Category I requirements as stated in section 3.10. The batteries, battery chargers, inverters, and other components of dc subsystem are housed in the control building, which is a Seismic Category I structure

The periodic testing and surveillance requirements for the Class 1E batteries are detailed in the Technical Specifications.

Table 8.3-7

CLASS 1E DC SYSTEM EQUIPMENT FAILURE AND INDICATION

Event	Available Indication[a]
Battery charger ac input breaker trip	Charger trouble alarm
Battery charger dc output breaker open	Charger trouble alarm
Battery breaker trip or open	Breaker trip/open alarm
Loss of 125 V-dc bus voltage	Bus undervoltage alarm
125 V-dc distribution panel supply breaker trip	Breaker trip alarm
Inverter dc supply breaker trip	Inverter trouble alarm

a. Via alarm typewriter, alarm displays, and plant annunciator.

8.3.2.2.1.17 IEEE 323-1974, Standard for Quality Class 1E Equipment for Nuclear Power Generating Stations. Refer to paragraph 8.3.1.2.2.22.

8.3.2.2.1.18 IEEE 344-1975, Seismic Qualification of Class 1E Equipment for Nuclear Power Generating Stations. Seismic qualification of Class 1E electric equipment and the extent of compliance with IEEE 344 are discussed in section 3.10.

8.3.2.2.1.19 IEEE 383-1974, Standard for Type Test of Class 1E Electric Cables, Field Splices, and Connections for Nuclear Power Generation Stations. Class 1E cable, field splices, and connections are in accordance with IEEE 383-1974.

Cable assemblies for the reed switch position transmitters and fixed incore system are in accordance with IEEE 383-1974 except that following environmental qualification testing they were tested at 750 volts ac for 5 minutes while immersed in water at room temperature. This value meets the system requirements.

8.3.2.2.1.20 IEEE 384-1974, Criteria for Separation of Class 1E Equipment and Circuits. Refer to paragraph 8.3.1.4 for compliance. Also refer to appendix 8A, Question 8A.10 response.

8.3.2.2.1.21 IEEE 450-2002, Recommended Practice for Maintenance, Testing, Replacement of Large Stationary Type Power Plant and Substation Lead Storage Batteries. Recommended practices of IEEE 450 for maintenance, testing, and replacement of batteries are implemented as follows:

A. Maintenance and inspections are carried out on a regularly scheduled basis to comply with the requirements of IEEE 450-2002 (refer to the Technical Specifications and battery maintenance program).

B. Performance discharge tests are carried out as discussed in the Technical Specifications.

C. The rating of the battery is at least 25% greater than that required to supply the emergency load requirements.

D. An acceptance test of battery capacity is performed at the factory to determine if it meets the specified discharge rate and duration.

E. A performance test of the battery capacity is performed within the first 2 years of service to determine if it meets the specified discharge rate and duration.

F. Records of the data obtained from inspections and tests are kept along with test procedures to comply with the requirements.

G. Whenever any cell’s electrolyte level reaches the low level mark, water will be added to increase the level to approximately the midpoint between the high and low electrolyte level marks.

8.3.2.3 Physical Identification of Safety-Related Equipment

Refer to paragraph 8.3.1.3 for physical identification of Class 1E equipment.

8.3.2.4 Independence of Redundant Systems

The general considerations for the independence of Class 1E dc power subsystems are described in paragraph 8.3.1.4.

8.3.3 FIRE PROTECTION FOR CABLE SYSTEMS

Refer to subsection 9.5.1. In addition, for a discussion of cable derating and cable tray fill, refer to paragraph 8.3.1.4.3. Fire barriers and separation between redundant trays are discussed in paragraph 8.3.1.4.1.

8.3.4 CESSAR INTERFACES

The following NSSS interface requirements are repeated from CESSAR Section 8.3.1.

1. Following a turbine or reactor trip, power shall be provided to the auxiliary loads as specified in Table 8.3.1-3.

2. Standby, onsite power shall be provided by two or more independent standby generators. Each standby generator shall supply equipment in one ESF train. This insures that the loss of one standby generator would only affect one ESF train. These standby generators shall be designed to attain rated voltage and speed within 12 seconds following either a loss of offsite power to the ESF bus, or initiation of the CSAS, SIAS, or AFAS of the ESFAS.

3. The design of automatic sequencing features for loading the standby generators shall be consistent with the following requirements:

   a. If the standby generators are the only source of power to the ESF bus when an ESFAS is generated the ESF loads which are appropriate to the particular ESFAS shall be automatically sequenced on, see Table 8.3.1-4.

   b. In the event that offsite power is unavailable and the standby generators are not yet up to rated voltage and speed at the time that an ESFAS is generated, there can be a delay of up to 12 seconds before the standby generator output breakers close and power is supplied to the ESF buses. After the generators are supplying the ESF buses, the ESF loads which are appropriate to

the particular ESFAS shall be automatically sequenced on, see Table 8.3.1-4.

c. If a standby generator is supplying power to an ESF bus (offsite power not available) and appropriate ESF equipment is operating on that bus, the operating ESF equipment shall not be shed if another ESFAS is generated. The ESF loads associated with the second ESFAS shall have no additional sequencing imposed but shall be sequenced if that is the normal way that the components are operated.

d. If offsite power is lost at some time after the standby generators are up to rated voltage and speed, and after the required ESF equipment is running following one or more ESFAS, the following requirements shall be met:

    1) Interrupted ECCS flow to the core shall be fully reestablished within thirteen seconds.

    2) Interrupted auxiliary feedwater flow to the steam generator(s) shall be fully reestablished within fifteen seconds.

e. If offsite power is available and the standby generators are started on an ESFAS initiated by a plant condition actually requiring operation of the ESF loads appropriate to the ESFAS, the standby generators shall be left running for a period of at least one hour.

f. If offsite power is the source of power to an emergency bus when an ESFAS is generated, the ESF loads which are appropriate to the particular ESFAS shall be started by sequencing, on the offsite powered emergency bus. See Table 8.3.1-4.

4. Four physically and electrically independent 120 volt, 60 Hz, single phase, ungrounded vital instrument sources are required to provide power to NSSS instrumentation used for protection. The output frequency shall be 60 ± 0.5 Hz and the output voltage shall be regulated to within ±2% at full output for a load power factor greater than 0.8 (towards unity).

5. The Engineered Safety Features electric system shall be designed on a two independent train basis. Each train shall be capable of furnishing power to equipment load groups of the ESF Systems. The ESF buses and associated cabling shall be physically separated and electrically isolated to allow for redundancy.

6. When redundant "third of a kind" components are included as part of the safety system design, it is required that these components be capable of receiving power from either of the redundant emergency buses. The transfer from one redundant source to another shall be capable of being accomplished manually. This transfer (if required) would be necessary within approximately two hours after a loss of offsite power.

7. The consequences of frequency decays of up to 3 Hz/sec (with bus voltage at its nominal value and with all RCPs connected to their buses) on the Reactor Coolant Pump buses are not more severe than the consequences of loss of flow of the four RCPs due to loss of power. The Applicant's RCP buses, therefore, shall not subject the RCPs to sustained frequency decays of greater than 3 Hz/sec.

8. The following tables provide electrical data for the safety-related equipment which is generally supplied by Combustion Engineering. Complete tables and responsibilities for supply will be provided in the Applicant's Safety Analysis Report.

   a. Table 8.3.1-1 Power Requirements for CESSAR Design Scope Safety-Related Equipment.

   b. Table 8.3.1-2 Power Requirements for CESSAR Design Scope Safety-Related Equipment at Various Operating Conditions.

   c. Table 8.3.1-3 Power Requirements for CESSAR Design Scope Safety-Related Electrical Equipment During Emergency Operation.

   d. Table 8.3.1-4 Required Standby Generator Loads

9. The vital instrument buses shall be designed such that the maximum voltage fault shall not exceed 480 VAC + 10% or 325 VDC + 10%.

10. Cabling shall meet the requirements specified in Sections 7.1.3, 7.2.3, and 7.3.3 for separation and

independence so that no credible fault in one channel can be propagated.

The following NSSS interface requirement is derived from CESSAR Sections 15.3.3, 15.3.4, and 15.6.3.2.

11. Offsite power shall be available for at least 3 seconds following a turbine trip resulting from a RCP rotor seizure, RCP shaft break, or steam generator tube rupture.

8.3.5 CESSAR INTERFACE EVALUATION

Interface design requirements in CESSAR Section 8.3.1 are applicable but do not contain all requirements for the onsite power system. The onsite power system design meets the CESSAR interface requirements presented in subsection 8.3.4 as discussed in the following sections corresponding to the interface requirements.

1. Refer to paragraph 8.3.1.1.3 and table 8.3-1.
2. Refer to paragraph 8.3.1.1.3, 8.3.1.1.4, and 8.3.1.1.4.6.
3. Refer to paragraph 8.3.1.1.3.10, 8.3.1.1.4.6 table 8.3-3, and figure 8.3-1.
4. Refer to paragraph 8.3.1.1.6.
5. Refer to paragraph 8.3.1.1.3.3 and 8.3.1.1.3.8.
6. Refer to paragraph 8.3.1.1.3.6.
7. The reactor coolant pump electrical power supply, which is part of the 13.8 kV non-Class 1E onsite power system, is normally electronically connected through

the unit main and auxiliary transformer to the transmission network. The electrical characteristics of the transmission network are classified as such that underfrequency transient perturbations are anticipated operational occurrences that will affect the reactor coolant pumps. The rate of frequency decay of these perturbations, based on presently available information, is calculated not to exceed 1.5 Hz. The transmission network frequency decay rate allowable by low DNBR and fuel damage considerations as given in CESSAR is 3 Hz at nominal bus voltage with all reactor coolant pumps running. Consequently, the expected rate of 1.5 Hz will not cause a more severe effect on coolant flow than would be caused by a complete loss of electric power to the pumps starting at 100% flow. Therefore, the assumptions of CESSAR Section 7.2.1.1.2.4 are satisfied and are applicable to the PVNGS plant and transmission network. In view of the preceding analysis, disconnection of the reactor coolant pumps on underfrequency is not required.

8. Refer to tables 8.3-1, 8.3-3, 8.3-4, 8.3-6, engineering drawing 01, 02, 03-E-MAA-002, and paragraph 7.4.1.1.1.

   Loads indicated as requiring emergency power in CESSAR Table 8.3.1-1 are included in table 8.3-1. Also, Class 1E loads not supplied by C-E have been added. CESSAR Tables 8.3.1-2 and 8.3.1-3 are applicable but do not contain all requirements for Class 1E ac system

loads. Loads from CESSAR Tables 8.3.1-2 and 8.3.1-3 are included in table 8.3-1.

Loads from CESSAR Table 8.3.1-2 are also included in UFSAR Table 8.3-3. This CESSAR table lists power requirements for four scenarios: startup, shutdown, refueling, and normal. UFSAR table 8.3-3 provides the load requirements for forced shutdown and LOCA shutdown. Forced shutdown loads provides the worst case loading of the four scenarios and thus envelopes the other three.

CESSAR Table 8.3.1-4 is used as a guide for preparation of table 8.3-3. CESSAR Figure 8.3.1-1 is not applicable in detail and is replaced by figure 8.3-2. Loading of buses in figure 8.3-2 is similar to the CESSAR figure.

9. The vital instrument buses are described in paragraph 8.3.1.1.6. The maximum voltage fault values given (480 VAC + 10% and 325 VDC + 10%) come from the specifications given by CE for the Plant Protection System (PPS) Cabinets. It is an isolation/separation requirement between channels to comply with IEEE 279, 379, and 384. They are worst case postulated high energy fault values. The cabinets were analyzed and tested showing that these values applied to a channel cannot affect another channel.

   The only potential sources for these fault voltages are the 125 Vdc supply to the vital ac inverter and the 480 Vac supply to the vital ac regulator. The dc power

system cannot physically generate 325 Vdc +10%. Paragraph 8.3.1.1.3 describes voltage optimization requirements that are within the 480 Vac +10%. Therefore, the design of the vital ac bus and its supply power sources meet the criterion.

10. Refer to paragraph 8.3.1.4.

11. Following a turbine trip resulting from a design basis accident, offsite power remains available for at least 3 seconds. During this time, the unit auxiliary transformer continues to supply offsite power to the non-Class 1E distribution system. Refer to section 8.2.2, 10.2.2.4, and table 15.0-0.

APPENDIX 8A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

CONTENTS (Cont.)

<u>QUESTION 8A.1</u> (NRC Question 430.1) (8.3)

Provide a detail discussion (or plan) of the level of training proposed for your operators, maintenance crew, quality assurance, and supervisory personnel responsible for the operation and maintenance of the emergency diesel generators. Identify the number and type of personnel that will be dedicated to the operations and maintenance of the emergency diesel generators and the number and type that will be assigned from your general plant operations and maintenance groups to assist when needed.

In your discussion identify the amount and kind of training that will be received by each of the above categories and the type of ongoing training program planned to assure optimum availability of the emergency generators.

Also discuss the level of education and minimum experience requirements for the various categories of operations and maintenance personnel associated with the emergency diesel generators.

RESPONSE: The response is given in paragraph 8.3.1.1.4.12.

<u>QUESTION 8A.2</u> (NRC Question 430.2) (8.3)

Periodic testing and test loading of an emergency diesel generator in a nuclear power plant is a necessary function to demonstrate the operability, capability and availability of the unit on demand. Periodic testing coupled with good preventive maintenance practices will assure optimum equipment readiness and availability on demand. This is the desired goal.

To achieve this optimum equipment readiness status the following requirements should be met:

1. The equipment should be tested with a minimum loading of 25% of rated load. No load or light load operation will cause incomplete combustion of fuel resulting in the formation of gum and varnish deposits on the cylinder walls, intake and exhaust valves, pistons and piston rings, etc., and accumulation of unburned fuel in the turbocharger and exhaust system. The consequences of no load or light load operation are potential equipment failure due to the gum and varnish deposits and fire in the engine exhaust system.

2. Periodic surveillance testing should be performed in accordance with the applicable NRC guidelines (R.G. 1.108), and with the recommendations of the engine manufacturer. Conflicts between any such recommendations and the NRC guidelines, particularly with respect to test frequency, loading and duration, should be identified and justified.

3. Preventive maintenance should go beyond the normal routine adjustments, servicing and repair of components when a malfunction occurs. Preventive maintenance should encompass investigative testing of components which have a history of repeated malfunctioning and require constant attention and repair. In such cases consideration should be given to replacement of those components with other products which have a record of demonstrated reliability, rather than repetitive repair and maintenance of the existing components. Testing of the unit after adjustments or repairs have been made only confirms that the equipment is

operable and does not necessarily mean that the root cause of the problem has been eliminated or alleviated.

4. Upon completion of repairs or maintenance and prior to an actual start, run, and load test a final equipment check should be made to assure that all electrical circuits are functional, i.e., fuses are in place, switches and circuit breakers are in their proper position, no loose wires, all test loads have been removed, and all valves are in the proper position to permit a manual start of the equipment. After the unit has been satisfactorily started and load tested, return the unit to ready automatic standby service and under the control of the control room operator.

Provide a discussion of how the above requirements have been implemented in the emergency diesel generator system design and how they will be considered when the plant is in commercial operation, i.e., by what means will the above requirements be enforced.

RESPONSE:

1. The response is given in paragraph 8.3.1.1.4.12.
2. Periodic surveillance testing of the emergency diesel generators will be conducted in accordance with the recommendations of Regulatory Guide 1.108 as interpreted by section 1.8, and with the recommendations of the engine manufacturer. The engine manufacturer's recommendations for periodic testing do not conflict with Regulatory Guide 1.108 as interpreted.
3. The response is given in paragraph 8.3.1.1.4.12.

4. The response is given in paragraph 8.3.1.1.4.12.

QUESTION 8A.3 (NRC Question 430.3) (8.3)

The availability on demand of an emergency diesel generator is dependent upon, among other things, the proper functioning of its controls and monitoring instrumentation. This equipment is generally panel mounted and in some instances the panels are mounted directly on the diesel generator skid. Major diesel engine damage has occurred at some operating plants from vibration induced wear on skid mounted control and monitoring instrumentation. This sensitive instrumentation is not made to withstand and function accurately for prolonged periods under continuous vibrational stresses normally encountered with internal combustion engines. Operation of sensitive instrumentation under this environment rapidly deteriorates calibration, accuracy and control signal output.

Therefore, except for sensors and other equipment that must be directly mounted on the engine or associated piping, the controls and monitoring instrumentation should be installed on a free standing floor mounted panel separate from the engine skids, and located on a vibration free floor area. If the floor is not vibration free, the panel shall be equipped with vibration mounts.

Confirm your compliance with the above requirement or provide justification for noncompliance.

RESPONSE: Controls and monitoring equipment are located on the floor, separate from the engine foundation, to eliminate engine vibration effects. Refer to engineering

drawings 13-P-ZGL-701 and -702 (diesel generator control room).

QUESTION 8A.4 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Final approval of the overall offsite power system is withheld pending receipt of the following additional information:

1. A discussion of transmission line rights-of-way, height, as well as spacing, between transmission towers, etc.
2. Physical layout drawings of the circuits that connect the onsite distribution system to the offsite power system.
3. A description of the instrumentation provided for monitoring and indicating the status of the offsite power system and switchyard batteries.

RESPONSE:

Item 1. The following drawings have been provided to the NRC in response to this request:

1. Overall map showing the transmission system 500 kV lines
2. Drawing K-675-503, Palo Verde/Kyrene line route map
3. Bechtel drawings 13-E-ZYP-012, ZVU-009, and 13-C-ZVA-001 showing line routing on the plant property.
4. Typical tower, pole, and double tower right-of-way usage.

The plan and profile sheets for the Palo Verde/Kyrene line show the double right-of-way obtained for a portion of the line length for a future Saguaro line. Right-of-way acquisition beyond this common corridor has not yet been acquired.

Item 2. The circuits connecting the onsite distribution system to the offsite power system are shown in drawings 13-E-ZYP-012 (Rev. 3) and 13-E-ZVU-009 (Rev. 10), which have been provided to the NRC.

Item 3. The instrumentation provided for monitoring and indicating status of the offsite power system is presented in the following drawings, which have been provided to the NRC:

A. Bechtel drawings -- 13-E-MAA-001 Rev. 4
01-E-NAA-001 Rev. 3
01-E-NAA-002 Rev. 3
02-E-NAA-001 Rev. 2
02-E-NAA-002 Rev. 3
03-E-NAA-001 Rev. 2
13-E-NAA-002 Rev. 3
13-E-NAA-003 Rev. 3
13-E-PBA-001 Rev. 3
13-E-PBA-002 Rev. 3

B. Vendor drawings -- J200-205

J200-265

<u>QUESTION 8A.5</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Revise the FSAR to include switchyard components for testing and perform periodic inspection and maintenance on all the switchyard and onsite power components.

RESPONSE: The response is given in paragraph 8.3.1.2.2.2, listing D.

<u>QUESTION 8A.6</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Provide the transmission load flow diagram associated with the transient stability cases assumed in the FSAR.

RESPONSE: The load flow diagram has been submitted to the NRC under separate cover (see section 8.2.2 for current load flow analysis).

<u>QUESTION 8A.7</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

We require that new diesel generator designs to be used in nuclear power plant service undergo a reliability establishment testing program in accordance with IEEE 387. The applicant should submit the results of the reliability testing program for our review.

RESPONSE: The response is given in paragraph 8.3.1.1.4.11.

<u>QUESTION 8A.8</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Local and control room alarms are provided for each diesel generator. The local annunciator provides first out indication for all alarms initiated by the diesel generator protective devices; this conforms with the guidance of Regulatory Guide 1.9, Position C.8, and is acceptable. The control room annunciation consists of single input alarms and common alarms. In addition the following alarms are annunciated on the control room safety equipment status annunciator for each diesel generator:

1. Diesel generator inoperable.
2. Diesel generator failed to start.

The applicant should provide additional information in this area.

RESPONSE: The response is given in amended paragraph 8.3.1.1.4.10.

<u>QUESTION 8A.9</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Revise the separation criteria in the following areas:

a. Where cable of different separation groups approach the same or adjacent control panels with less than the minimum horizontal and vertical separation distance, isolation is maintained by installing cables of one of the separation groups in metallic conduit. This is inconsistent with the recommendations of IEEE 384 and

is unacceptable. Therefore, we require that cables of both separation groups be installed in metallic conduit or a barrier be installed between separation groups.

b. If a 6-inch minimum physical separation between two separation groups inside the control boards or other panels cannot be maintained, the cables of at least one of the separation groups is installed in an enclosed raceway. This is inconsistent with the recommendations of IEEE 384 and is unacceptable. Therefore, we require that 1) cables of both separation groups be installed in enclosed raceways or, 2) a barrier be installed between separation groups, or, 3) provide an analysis to justify that the separation is adequate.

Also, the applicant should document the interval at which these cables and raceways are marked for physical identification.

RESPONSE: The response is given in amended paragraphs 8.3.1.3, 8.3.1.4.1.1, and 8.3.1.4.1.2.

QUESTION 8A.10 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Based on our evaluation of the information provided by the applicant, we conclude that in order to accept current limiting transformers as isolation devices we require a clear demonstration that these transformers are current limiting under faulted conditions and their limiting current will not compromise the remainder of the Class 1E system. In addition, we also require the applicant to provide a discussion of those

non-Class 1E circuits that are connected to the Class 1E batteries.

RESPONSE: IEEE 384, Section 6.1.2.3, states "devices which will limit the input current to an acceptable value under faulted conditions of the output qualify as isolation devices .... Note: Devices in this category may include inverters, regulating transformers, "... etc. Voltage regulators used in PVNGS utilize a ferro-resonant transformer, which operates at saturated (magnetic core) condition and has current limiting characteristics in the overload region.

The transformer supplier has stated that "the current on the primary when a bolted short is applied to output is less than the high line full load primary current." This statement is based on supplier's review of test data sheets for this equipment.

Refer to paragraph 8.3.2.1 for a discussion on Class 1E dc loads.

QUESTION 8A.11 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Part A

It is stated in the FSAR that separate control power is not required for these breakers. We disagree with this statement and require that control power from separate sources be provided to the load feeder breakers and bus feeder breakers so

that failure of either source will not violate the single failure criterion.

RESPONSE: The statement in the FSAR is correct in that load center breaker overcurrent trip is independent of the 125 V-dc (control) power. Breaker trip units are direct acting, i.e., "breaker latch release is powered by the line overcurrent." Additional response is given in paragraph 8.3.1.1.3.13.

Part B

For circuits fed from motor control centers, the load feeder breaker is coordinated with, and backed up by, the bus feeder breaker, control power of bus feeder breakers is separate from that of load feeder breakers.

The low-voltage control systems, power circuits and high energy level control circuits use self-fusing characteristics of field cables to ensure that under all circumstances the penetration maintain its integrity. We have informed the applicant that this is unacceptable; we do not permit self-fusing of cables as backup protection. Subsequently, the applicant committed to provide two breakers in series for each control circuit that passes through a containment penetration.

We have reviewed the above information and conclude that the applicant has not provided enough information on this subject for us to make an evaluation, therefore, we would require the applicant to provide the following additional information on this subject.

1. A discussion of (1) the direct current circuits and (2) circuits that are required for short periods of time during startup refueling or a maintenance shutdown that pass through the containment penetrations and describe how these circuits meet the guidance of Regulatory Guide 1.63, Position 1.
2. Submit time-current characteristic curves of protective devices provided for each size of penetration to demonstrate that adequate time-current coordination exists between the motor primary and backup protection devices and the penetration itself.
3. A commitment to periodically test the primary and secondary protective devices.

RESPONSE: Refer to amended section 1.8, describing PVNGS compliance with Regulatory Guide 1.63.

Item 1(1)

The response is given in paragraph 8.3.1.2.2.21, listing G.

Item 1(2)

Circuits that are required for short periods of time during startup, refueling or maintenance shutdown that pass through the containment penetrations and are permanently installed meet the guidance of Regulatory Guide 1.63 (Position 1) with exceptions as stated in section 1.8.

Item 2

Thirty-three time-current characteristic curves were submitted to the NRC under separate cover.

Item 3

The response is given in paragraph 8.3.1.2.2.21, listing H.

QUESTION 8A.12 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

The Palo Verde station design motor-operated valves activated by a safety injection signal in the event of a LOCA have their respective thermal overload protection devices bypassed during accident conditions. This conforms with the guidance of Regulatory Guide 1.106, Positions C.1 and C.2, and is acceptable. However, to complete our evaluation and verification of this design feature, the applicant should provide a description and drawings indicating how this is accomplished.

RESPONSE: The response is given in paragraph 8.3.1.1.3.13. Drawings 13-E-SIB-012, -020, and -022, which have been provided to the NRC, indicate how thermal overload devices are bypassed during accident condition.

QUESTION 8A.13 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

It is not clear from the information provided in the FSAR how the Palo Verde design meets the guidelines of Branch Technical Position ICSB 18 (PSB) concerning power lockout to selected ESF valve actuators as means of designing against a single failure that might cause an undesirable valve motion in the fluid system. In addition, this position requires that all such valves be listed in the Technical Specifications and that the

position indication for these valves meet the single failure criterion. We therefore, require the applicant to provide the following specific information on this item.

1. A list in the Technical Specifications of all valves that require power lockout in order to meet the single failure criterion in the fluid system.

2. A description of (1) the design feature for locking out control power to these valves, (2) how electrical power can be restored to the valves from the control room if valve repositioning is required at a later time, and (3) the testability of the power lockout feature. In addition, provide the associated schematic diagrams showing these design features.

3. Redundant and independent valve position indication in the control room which meets the single failure criterion.

RESPONSE:

The response is given in paragraph 6.3.1.4 (including valve list) and PVNGS Technical Specifications, that specifies power removal to the valves.

<u>QUESTION 8A.14</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

In order to accept the use of a single load sequencer for both offsite and onsite power sources, the applicant should provide a detailed analyses to assure that there are no credible sneak circuits or common mode failures in the sequencer design that

could render both onsite and offsite power sources unavailable. Furthermore, we would require the applicant to provide the following additional information:

1. A full description of the load sequencer design feature in the FSAR. This should include sequencer power supplies, test features and alarms.
2. A reliability study on the sequencer.

RESPONSE:

Item 1: The response is given in paragraph 8.3.1.1.3.10.1.

Item 2: The response is given in the submitted report, Reliability Analysis Report for Balance of Plant Engineered Safety Features Actuation System, E-115-751 (Rev.), January 1979 (Supplier Document Number J104-52-3).

QUESTION 8A.15 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

The analytical techniques and assumptions used in the voltage analyses must be verified by actual measurement. The verification and test should be performed prior to initial full power reactor operation on all sources of offsite power by:

a. Loading the station distribution buses, including all Class 1E buses down to the 120/208V level, at least 30%
b. Recording the existing grid and Class 1E bus voltages and bus loading down to the 120/208 volt level at steady-state conditions and during the starting of both a large Class 1E and non-Class 1E motor (not concurrently)

NOTE: To minimize the number of instrumented locations (recorders) during the motor starting transient test, the bus voltages and loading need only be recorded on that string of buses which previously showed the lowest analyzed voltages from item above.

RESPONSE: PVNGS will measure the station distribution buses including Class 1E buses unloaded and record voltages. PVNGS will also measure and record the station distribution buses, including Class 1E buses, upon loading the bus to at least 30%. This will occur prior to completion of the initial test program. CATS RCTS 035303 closed 11/18/87, letter ANPP-34491.

PVNGS will measure and record grid and Class 1E bus voltages and bus loading during the startup of a large Class 1E motor and also during the starting of a large non-Class 1E motor. The above information will be reviewed to verify analytic data. CATS RCTS 031430 closed 9/6/84, letter ANPP-18670-P26.

QUESTION 8A.16 (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

Part 1

Provide the time delay settings for the two 4160 volt safety related bus undervoltage relays.

RESPONSE: The response is given in paragraph 8.3.1.1.3.13.

Part 2

Submit the following information: the voltage levels at the safety-related buses optimized for the maximum and minimum load conditions that are expected throughout the anticipated range of voltage variations of the offsite power sources by appropriate adjustment of the voltage tap settings of the intervening transformers. The tap settings selected should be based on an analysis of the voltage at the terminals of the Class 1E loads. The analyses performed to determine minimum operating voltages should typically consider maximum unit steady state and transient loads for events such as a unit trip, loss of coolant accident, startup or shutdown; with the offsite power supply (grid) at minimum anticipated voltage and only the offsite source being considered available. Maximum voltages should be analyzed with the offsite power supply (grid) at maximum expected voltage concurrent with minimum unit loads (e.g., cold shutdown, refueling). A separate set of the above analyses should be performed for each available connection to the offsite power supply.

RESPONSE: The response is given in paragraph 8.3.1.1.3.

<u>QUESTION 8A.17</u> (Letter from R. L. Tedesco of June 17, 1981 on AC Power)

One of the CESSAR interface requirements is to provide 480 volt power supply to the six shutdown cooling isolation valves such that no single failure of power supply can open the valves to connect the reactor coolant system and shutdown cooling system inadvertently, nor can a single failure of power supply prevent

opening all the valves of, at least, one section line during initiation of shutdown cooling. The Palo Verde design provides 480 volt power to four of these valves only. The other two valves are not included in table 8.3-1 of the FSAR. This is unacceptable. Therefore, we require that the remaining valves be included in this table. In addition, the following additional information on this subject shall be provided for our review:

1. A description of how the power supply to these valves meet the single failure criterion to prevent over-pressurization of the low-pressure system piping and achieve cold shutdown.
2. A sketch that shows how the power supply to the three series shutdown cooling isolation valves in each train is arranged.

RESPONSE: The two remaining cooling isolation valves, having tag numbers J-SIC-UV-653 and J-SID-UV-654, are shown in table 8.3-6.

Additional response is given in section 5.4.7.2. PVNGS meets the single failure criterion.

9. AUXILIARY SYSTEMS

9.1 FUEL STORAGE AND HANDLING

9.1.1 NEW FUEL STORAGE

9.1.1.1 Design Bases

The following design bases are imposed on the storage of new fuel:

A. Accidental criticality shall be prevented for the most reactive arrangement of new fuel stored, with optimum moderation, by assuring that K_{eff} is less than 0.98. This design basis shall be met under any normal or accident conditions.

B. The requirements of Regulatory Guide 1.13 shall be met.

C. The storage racks and facilities shall be qualified as Seismic Category 1.

D. Storage shall be provided for at least one-third core of new fuel.

9.1.1.2 Facilities Description

The rack assemblies are made up of individual racks similar to those shown in figure 9.1-1. A minimum edge-to-edge spacing between fuel assemblies, as required by paragraph 9.1.1.3.1, is maintained between assemblies in adjacent rows. These spacings are the minimum values after allowances are made for rack fabrication tolerances and the predicted deflections resulting from postulated accident conditions, discussed in paragraph 9.1.1.3.1.

The specific location of the new fuel racks in the fuel building is shown in engineering drawings 13-P-OOB-004, 13-P-OOB-005, 13-P-OOB-010 and figure 9.1-2.

The stainless steel construction of the storage racks is compatible with water and zirconium clad fuel.

The top structure of the racks is designed such that there is no opening between adjacent fuel cavities that is as large as the cross-section of the fuel bundle. In addition, the outer structure of the racks precludes the inadvertent placement of a bundle against the rack closer than the prescribed edge-to-edge spacing.

9.1.1.3 Safety Evaluation

The new fuel storage rack design and location, discussed in paragraph 9.1.1.2, ensures that the design bases of paragraph 9.1.1.1 are met. The capability of PVNGS new fuel storage is described below.

9.1.1.3.1 Criticality Safety

The following postulated accidents were considered in the design of the new fuel storage racks:

A. Flooding; complete immersion of the entire storage array in pure, unborated, room temperature water.

B. Envelopment of the entire array in a uniform density aqueous foam or mist of optimum density that maximizes the reactivity of the finite array as described in listing D of the criticality safety assumptions. It is

postulated that these conditions could be present as a result of fire fighting.

C. A fuel assembly dropped from a height of 4-1/2 feet onto the rack which then falls horizontally across the top of the rack.

D. Tensile load on the rack of 5000 pounds (limited by adjustment of the motor stall torque or load limiting device of the crane used to load fuel into the racks.)

Although the above accident conditions have been postulated, the fuel handling equipment, new fuel racks, and the building arrangement are designed to minimize the possibility of these accidents or the effects resulting from these accidents by:

A. Providing positive hoist travel limits and interlocks to ensure proper equipment operation and sequencing.

B. Limiting the crane loads when installing fuel into or removing fuel from the fuel rack.

C. Designing the new fuel racks for SSE conditions and dropped fuel bundle conditions.

D. Maintaining K_{eff} less than 0.95 in the event the fuel area becomes flooded.

E. Designing the new fuel handling crane to preclude the new fuel handling crane, or any part thereof, from falling into the new fuel handling area.

The following assumptions are made in evaluating criticality safety:

A. Under postulated conditions of complete flooding by unborated room temperature water, the storage array is treated as described in item D.

B. Under postulated conditions of envelopment by aqueous foam or mist, a range of foam or mist densities is examined to ensure that the maximum reactivity of the array is established. The foam or mist is assumed to be pure water.

C. For the analyses presented here, the poisoning effects of rack structure have been included in a conservative manner by assuming the box wall thickness to be less than the minimum wall thickness shown in figure 9.1-1. It is also assumed that no supplemental fixed poisons are utilized in the storage array.

D. Two concrete storage cavities are utilized for new fuel storage. Each cavity is approximately 8 feet by 23 feet and contains 45 fuel assemblies with an active fuel length of 150 inches. Three racks (figure 9.1-1) are installed in each cavity forming a 3 x 15 array of fuel assemblies.

   The 3 x 15 array is assumed to be surrounded on all six faces by a 1-foot thick close-fitting reflector of concrete with reflective boundary conditions applied to the outside of each the six faces. This assumption is conservative since the concrete walls are several inches away from the outer rows of fuel assemblies, the

floor is several inches below the bottom of the active fuel, and the materials above the active fuel provide a substantially poorer reflector than the assumed thick concrete reflector. Calculations indicate that the assumption of concrete reflectors is conservative relative to the assumption of thick water reflectors.

E. The rack is assumed to be filled to capacity with fuel assemblies.

F. No burnable poison shims or other supplemental neutron poisons (e.g., control element assemblies) are assumed to be present in the fuel assemblies.

Criticality safety margins are maintained by:

A. Limiting the size of the array to 90 assemblies.

B. Defining an overall array configuration as shown in figure 9.1-1.

C. Providing adequate mechanical separation of fuel assemblies in the array, even under postulated accident conditions.

The mechanical separation provided is discussed in paragraph 9.1.1.2.

In evaluating criticality safety, neutron cross-section data for representative fuel rod cells, and material between and around assemblies, is from the updated 44 group ENDF/B-5 neutron cross section library[1]. Spatial calculations are performed using the three-dimensional Monte Carlo code KENO-Va[1] to quantify the multiplication factor for the storage racks for the range of water densities from flooded to mist conditions

assuming thick concrete reflectors on all faces of the storage array.

Maximum K_{eff} values have been calculated for radially averaged enrichments up to 4.80 w/o U-235. For all conditions, i.e., normal and accident, the K_{eff} values are less than 0.95.

These k_{eff} values are substantially below the limiting values allowed by ANSI Standard N18.2 and provide adequate margin for calculation uncertainty.

The rack structure provides at least 10 inches between the top of the active fuel and the top of the rack to preclude criticality in the event a fuel assembly is dropped into a horizontal position on the top of the rack.

The new fuel storage area is protected from the effects of missiles or natural phenomena as discussed in section 3.5.

9.1.1.3.2 Compliance with Regulatory Guide 1.13

New fuel storage complies with Regulatory Guide 1.13.

9.1.1.3.3 Seismic Classification

New fuel storage racks and facilities are qualified as Seismic Category I.

9.1.1.3.4 Storage Capacity

Storage is provided for at least one-third of a core of new fuel.

9.1.2 SPENT FUEL STORAGE

9.1.2.1 Design Bases

9.1.2.1.1 Spent Fuel Pool

The following design bases are imposed on the storage of fuel within the spent fuel pool:

A. Accidental criticality shall be prevented by assuring the K_{eff} remains less than 1.0 with full density unborated water under normal conditions, and by assuring that K_{eff} remains less than or equal to 0.95 taking credit for 900 ppm soluble boron in the water under any normal or accident conditions. These K_{eff} limits include an allowance for biases and uncertainties, including methodology and temperature biases, and enrichment, stack density, steel thickness, storage cell pitch, assembly position, calculational, and 95/95 confidence level uncertainties.

B. The requirements of Regulatory Guide 1.13 shall be met.

C. The storage racks and facilities shall be Seismic Category I.

D. Storage shall be provided for up to 1329 fuel assemblies.

E. The storage racks and spent fuel pool facilities shall prevent extensive bulk boiling in the fuel racks and prevent fuel assembly peak clad temperatures from exceeding 650F.

F. Shielding of spent fuel shall be adequate to ensure that the radiation zone criteria of section 12.3 are met.

9.1.2.1.2 Independent Spent Fuel Storage Installation (ISFSI)

The principle design bases of the ISFSI are prescribed in the NAC-UMS® Certificate of Compliance (CoC) and FSAR (Docket no. 72-1015). Refer to the ISFSI 72.212 Evaluation Report for additional details regarding dry fuel storage system design bases.

9.1.2.2 Facility Description

9.1.2.2.1 Spent Fuel Pool

For the purpose of compliance with NAC-UMS Technical Specifications, the spent fuel pool consists of the spent fuel pool and/or the cask loading pit; however, the Seismic Category I boundary varies depending on configuration of the gates, PCN-V-118, and the quick closure device.

During normal operations, the spent fuel pool Seismic Category I physical boundary is defined as the inner gate located between the spent fuel pool and the cask loading pit and the quick operating closure device on the containment side of the transfer tube in combination with the spent fuel pool liner drain valves.

During scheduled refueling operation, the Seismic Category I physical boundary of the spent fuel pool is defined as the inner gate located between the spent fuel pool and the cask loading pit and the valve PCN-V-118 on the fuel building side

of the transfer tube in combination with the spent fuel pool liner and drain valves.

During transfer of spent fuel assemblies to support dry fuel storage loading operations, the Seismic Category I physical boundary of the spent fuel pool is defined as the outer gate located between the cask loading pit and the cask wash down area and the quick closure device on the containment side of the transfer tube in combination with the spent fuel pool liner and drain valves.

During movement of heavy loads with the cask handling crane, the spent fuel pool Seismic Category I physical boundary is the same as that defined for normal operations.

The fuel pool transfer canal, cask loading pit and cask washdown area gate seals are designed as Class Q, Seismic Category I. These seals are designed to remain functional during and after accident conditions.

9.1.2.2.2 Spent Fuel Pool Storage Racks

The spent fuel pool storage racks are made up of individual modules. A module is an array of fuel storage cells similar to that shown in figure 9.1-3. The storage racks are comprised of 17 modules: twelve 8 by 9 and four 8 by 12 arrays, and one 9 by 9 array. The storage racks are stainless steel honeycomb structures with rectangular fuel storage cells. The stainless steel construction of the racks is compatible with fuel assembly materials and the spent fuel borated water environment. The fuel assembly spacings of a nominal 9.5 inches center-to-center distance between adjacent storage

cell locations are minimum values after allowances are made for rack fabrication tolerances and predicted deflections resulting from a safe shutdown earthquake (SSE)

The spent fuel pool was originally designed and approved by the NRC to store up to 1329 new or spent fuel assemblies in a borated fuel storage mode, up to 665 assemblies in a checkerboard storage mode, or between 665 and 1329 assemblies in a mixed mode.

In September 1994, the NRC approved Technical Specification amendments 82, 69, and 54 for Units 1, 2, and 3, respectively, to allow credit to be taken for burnup of spent fuel assemblies in establishing storage locations within the spent fuel pool in three distinct storage regions.

In March 2000, the NRC approved Technical Specification amendment 125 for Units 1, 2, and 3 to increase the storage capacity of the spent fuel pools by taking credit for burnup, decay time, and soluble boron in establishing storage locations with the spent fuel pool in four storage regions. These storage regions are shown in Figures 9.1-7 and 9.1-7A. Fuel is placed in the appropriate region based on the initial enrichment, actual burnup, and actual decay time as designated in Table 9.1-1. Core operating conditions, such as temperature and boron concentration, influence plutonium production and may increase the discharged fuel reactivity which could impact those numbers. Curves corresponding to the data in Table 9.1-1 are shown in Technical Specification LCO 3.7.17, and Regions 1, 2, 3, and 4 are described in Sections 9.1.2.2.2.1 through 9.1.2.2.2.4.

The spent fuel pool criticality analysis of record allows 1209 fuel assemblies to be stored in the four region configuration. However, since the design basis for the spent fuel cooling system assures adequate cooling for only 1205 fuel assemblies (Section 9.1.3), four additional cells are required to be blocked to satisfy both the criticality analysis and the spent fuel cooling system design basis. As shown in Figures 9.1-7 and 9.1-7A, cells A-22, A-23, A-24, and HH-26 have been specified as the additional four cells required to be blocked.

The spent fuel pool incorporates L-inserts as shown in Figure 9.1-4 in every other storage rack location. The change to the spent fuel pool made as a result of the September 1994 Technical Specification changes did not install L-inserts in the available storage cells where L-inserts were not previously installed. The safety analysis submitted for that Technical Specification change justified not installing the additional L-inserts.

NOTE 1: Minimum assembly burnup for fuel with initial radially averaged enrichment other than the weight percents shown should be linearly interpolated.
NOTE 2: Minimum assembly burnup for fuel with actual decay time other than the values shown should be linearly interpolated.
NOTE 3: Credit for decay time greater than 0 years does not apply to Region 2.

9.1.2.2.2.1 Region 1. Fresh fuel assemblies with a maximum radially averaged enrichment equal to 4.80 weight percent U-235 will be stored in a checkerboard (two-out-of-four) storage pattern. Fuel assembly blocking devices are used in rack cells that are not within the acceptable checkerboard storage pattern (see figures 9.1-5, 9.1-7, and 9.1-7A). This prevents accidental insertion of a fuel assembly into an interstitial position so as to preclude criticality. Fuel that qualifies to be stored in Regions 1, 2, 3, or 4 may be stored in Region 1. Fresh fuel assemblies may only be stored in Region 1. Storage for up to 119 fuel assemblies can be provided in Region 1.

9.1.2.2.2.2 Region 2. Fuel will be stored in a repeating three-by-four storage pattern in which Region 2 (two-out-of-twelve) and Region 4 (ten-out-of-twelve) locations are mixed as shown in Figures 9.1-7 and 9.1-7A. Fuel that qualifies to be stored in Regions 2, 3, or 4 may be stored in Region 2. Fuel that only qualifies to be stored in Region 1 may not be stored in Region 2. Storage for up to 131 fuel assemblies can be provided in Region 2 in Units 2 and 3. Storage for up to 119 fuel assemblies can be provided in Region 2 in Unit 1.

9.1.2.2.2.3 Region 3. Fuel will be stored in a four-out-of-four storage pattern. Fuel that qualifies to be stored in Regions 3 or 4 may be stored in Region 3. Fuel that only qualifies to be stored in Regions 1 or 2 may not be stored in Region 3. Storage for up to 297 fuel assemblies can be provided in Region 3 in Units 2 and 3. Storage for up to 369 fuel assemblies can be provided in Region 3 in Unit 1.

9.1.2.2.2.4 Region 4. Fuel will be stored in a repeating three-by-four storage pattern in which Region 2 (two-out-of-twelve) and Region 4 (ten-out-of-twelve) locations are mixed as shown in Figures 9.1-7 and 9.1-7A. Only fuel that qualifies to be stored in Region 4 will be stored in Region 4. Storage for up to 658 fuel assemblies can be provided in Region 4 in units 2 and 3. Storage for up to 598 fuel assemblies can be provided in Region 4 in Unit 1.

9.1.2.2.3 Independent Spent Fuel Storage Installation (ISFSI)

The ISFSI is a 20-acre facility located Northeast of the Palo Verde 525 kV switchyard. The ISFSI provides a location for interim dry storage of spent nuclear fuel prior to shipment off-site for permanent storage. The ISFSI consists of 12 Seismic Category IX reinforced concrete pads arranged in a 3 x 4 array. Each pad is 285′ x 35′ x 30″ and is capable of storing 28 vertical concrete casks arranged in a 2 x 14 array. The 2 rows of each array are 15′ center to center with individual casks in each row spaced a minimum of 15′ center to center. This spacing provides sufficient room for maneuvering of the cask transporter and also assures the casks will be stored in a subcritical array. Each cask is loaded with up to 24 spent fuel assemblies. The 336 total casks that the ISFSI is designed to store are sufficient to contain all anticipated spent fuel assemblies that will be generated by PVNGS for the duration of its current license.

While on the storage pad, the VCC outlet temperatures are monitored and compared to ambient temperature using the temperature monitoring system (TMS). The temperature

monitoring system relays data form each VCC to the Unit 1 control room for performance of NAC-UMS® Technical Specification Surveillances. Performance of these Surveillances provides assurance that the VCC heat removal system remains Operable (i.e., air inlets and outlets are not blocked).

The ISFSI is secured in a protected area that is separate from the 10CFR50 reactor facility protected area. Refer to the PVNGS security plan for additional details.

The ISFSI is surrounded on three sides by an earthen berm. The earthen berm is designed to provide radiation shielding to maintain personnel dose ALARA and to meet the requirements of 10CFR72.104 and 10CFR72.106. There is no active radiation monitoring or alarm system at the ISFSI. Radiation is monitored by use of strategically located TLD's.

9.1.2.3 Safety Evaluation

The spent fuel pool storage rack design and location, discussed in paragraph 9.1.2.2, provides assurance that design bases of paragraph 9.1.2.1 are met as noted in the following sections.

9.1.2.3.1 Criticality Safety

The following postulated accidents were considered in the design of the spent fuel pool storage racks.

A. A fuel assembly dropped from a height of 2 feet above the rack onto the rack with the assembly then falling horizontally across the top of the rack or falling

between the rack and surrounding spent fuel pool walls or falling into a blocked-off fuel storage cavity.

B. Tensile load on the rack of 5000 pounds.

Although the above accident conditions have been postulated, the fuel handling equipment, fuel racks, and building arrangement are designed to minimize the possibility of these accidents or the effects resulting from these accidents by:

A. Providing positive mechanical travel hoist limits and interlocks to ensure proper equipment operation and sequence.

B. Limiting the crane loads when installing fuel into or removing fuel from the fuel rack.

C. Designing the fuel racks for SSE conditions and dropped fuel bundle conditions.

D. Designing the fuel handling machine as Seismic Category I to preclude the fuel handling machine, or any part thereof, from falling into the spent fuel pool.

The following assumptions are made in evaluating criticality safety:

A. No control element assemblies (CEAs) are assumed to be present in the fuel assemblies.

B. The rack is assumed to be filled to capacity (as defined by Section 9.1.2.2.2) with fuel assemblies of the type whose criticality safety was evaluated with the pool filled with water.

C. For normal operation, no credit is assumed for the soluble boron contained in the spent fuel pool water (K_{eff} < 1.0). For operation with the most limiting single fuel misloading, credit is taken for 900 ppm of the soluble boron contained in the spent fuel pool water (which is normally at $\geq$ 2150 ppm) to assure that K_{eff} remains less than or equal to 0.95 at all times. For the flooded spent fuel pool criticality analysis, a conservative temperature is assumed for the water moderator.

D. Intentionally left blank.

E. Only one fuel assembly is assumed to be dropped in a fuel handling accident, and only one fuel assembly is assumed to misloaded in a fuel misloading event.

Criticality safety margins are assured by:

A. Not crediting the neutron absorption effects associated with the soluble boron concentration in excess of 900 ppm contained in the spent fuel pool water.

B. Qualifying a fuel assembly to be stored in Regions 1, 2, 3, or 4 based upon the initial enrichment, burnup, and decay time of the fuel assembly.

In evaluating criticality safety, neutron cross-section data for representative fuel rod cells, and material between and around assemblies, is from the updated 44 group ENDF/B-5 neutron cross section library[1]. Spatial calculations are performed using the three-dimensional Monte Carlo code KENO-Va[1] to quantify the multiplication factor for the storage rack as a

whole as well as the sub-region infinite multiplication factors.

Maximum K_{eff} values have been calculated for radially averaged enrichments up to 4.80 w/o U-235.

For all conditions, i.e., normal and accident, K_{eff} is less than 0.95 given partial credit for soluble boron contained in the spent fuel pool water. The K_{eff} values are less than or equal to the values allowed by 10CFR50, Appendix A, Criterion 62, "Prevention of Criticality in Fuel Storage and Handling".

The spent fuel storage area is protected from the effects of missiles or natural phenomena as discussed in section 3.5.

9.1.2.3.2 Deleted

9.1.2.3.3 Seismic Classification

The PVNGS spent fuel pool storage racks and facilities are Seismic Category I.

9.1.2.3.4 Storage Capacity

Storage is provided for up to 1329 fuel assemblies.

9.1.2.3.5 Fuel Assembly Cooling

The PVNGS spent fuel pool storage racks are designed to prevent extensive bulk boiling in the racks as well as maintain fuel cladding temperatures well below 650F for the following collective conditions:

A. Natural convection water circulation within the spent fuel pool

B. Maximum pool water temperature of 180F at the fuel rack inlet flow passages

C. Maximum fuel pool heat load as described in subsection 9.1.3.

9.1.2.3.6 Shielding

Concrete and water shielding are provided as shown in engineering drawings 13-P-OOB-003 through –005, 13-P-OOB-007 and 13-P-OOB-010. This shielding attenuates radiation from the maximum design loading of stored fuel assemblies such that the radiation zone criteria of section 12.3 are met.

9.1.2.4 Design Bases for Containment Fuel Storage Racks

The following design bases are imposed on the storage of fuel within the containment fuel rack:

A. Accident criticality shall be prevented for the most reactive arrangement of fuel stored in unborated water by designing to a k_{eff} less than 0.95. This design basis shall be met under any normal or accident conditions.

B. The requirements of Regulatory Guide 1.13 shall be met as described in Section 1.8.

C. The storage racks and facilities shall be Seismic Category 1.

D. Storage shall be provided for up to four fuel assemblies having a maximum radially averaged U-235 enrichment of 4.80 weight percent.

E. The refueling canal facilities shall prevent extensive bulk boiling in the fuel racks and prevent fuel assembly peak clad temperatures from exceeding 650F.

F. Shielding of spent fuel shall be adequate to ensure that the radiation zone criteria of section 12.3 are met.

9.1.2.4.1 Description of Containment Fuel Storage Racks

The four-cavity containment fuel storage rack is designed as an intermediate storage location for fuel bundles during a refueling.

The rack consists of four cavities for storage of fuel. Each cavity is a stainless steel can 8.69 inches on a side. The cavities are separated by a minimum fuel edge-to-edge distance of 9.4 inches. Each of the cavities is open at the bottom to provide thermal cooling for a worst case fuel bundle. The rack's structure is designed to maintain k_{eff} of less than 0.95 by assuring that under all normal and accident conditions, which includes SSE, the minimum edge distance is not violated and also that a fuel bundle cannot violate the 12-inch minimum stand-off distance around the cavities. The rack is located adjacent to the core support barrel laydown area, which provides access to the refueling machine for insertion and removal of fuel bundles.

9.1.2.4.2 Safety Evaluation

The containment fuel storage rack design and location, discussed in paragraph 9.1.2.4.1, provides assurance that design bases of paragraph 9.1.2.4 are met as noted in the following paragraphs.

9.1.2.4.2.1 Criticality Safety. The following assumptions are made in evaluating criticality safety:

A. No CEAs are assumed to be present in the fuel assemblies.

B. The rack is assumed to be filled to capacity with fuel assemblies of the type whose criticality safety is being evaluated.

C. For normal operation, no credit is assumed for the boron normally found in the refueling pool water.

D. An infinitely long fuel assembly is assumed.

Criticality safety margins are assured by:

A. Neglecting the neutron absorption effects associated with the boron normally in the refueling pool water during refueling operations.

B. When fuel is stored in the rack, no credit is taken for the neutron absorption affects of the rack structure.

C. No credit is taken for burnable shims or other supplemental neutron poisons (e.g., CEAs).

In evaluating criticality safety, neutron cross-section data for representative fuel rod cells, and material between and around assemblies, is from the updated 44 group ENDF/B-5

neutron cross section library[1]. Spatial calculations are performed using the three-dimensional Monte Carlo code KENO-Va[1] to quantify the multiplication factor for the storage racks.

Maximum K_{eff} values have been calculated for radially averaged enrichments up to 4.80 w/o U-235.

For all conditions, i.e., normal and accident, K_{eff} is less than 0.95. The K_{eff} values are substantially below the limiting values allowed by ANSI Standard N18.2 and provide adequate margin for calculation uncertainty.

9.1.3 SPENT FUEL POOL COOLING AND CLEANUP SYSTEM

9.1.3.1 Design Basis

9.1.3.1.1 Fuel Pool Cooling Design Bases

The following design bases are imposed on spent fuel pool cooling:

A. Two independent, 100% capacity spent pool cooling systems are provided to cool the spent fuel pool and prevent damage to spent fuel assemblies stored therein under normal plant operation. Spent fuel pool cooling system capacity requirement vary significantly during refueling and accident conditions. During these modes of operation, the shutdown cooling system may be used to augment pool cooling. The combination of these systems provide the flexibility required to maintain spent fuel cooled while maintenance tasks are performed during refueling outages. The simultaneous operation of two PC pumps and one LPSI or one CS pump is administratively prohibited due to the

potential for air entrainment into the suction line. Table 9.1-2 and sections 9.1.3.2.1.1 and 9.1.3.3.1.1 provide a minimum number of systems required to be available based on maximum decay heat generated from the spent fuel assemblies. However, minimum systems in operation could be less if bulk water temperature in the spent fuel pool can be maintained to values stated in section 9.1.3.3.1.1. Also, these requirements are only applicable if decay heat is present in the spent fuel pool and decay heat loads are comparable to values listed in table 9.1-2. System requirements are usually less restrictive and are time dependent due to reduction of decay heat as a function of time.

B. Each of the spent fuel pool cooling system trains must reject heat to an ultimate heat sink qualified under the provisions of Regulatory Guide 1.27.

C. Two makeup water sources, one of which is Seismic Category I, shall be available for use.

D. All equipment and instrumentation necessary to meet the design bases of this section shall be provided with reliable power source and capability of being loaded on Class 1E electrical power if needed.

E. Spent fuel pool cooling systems, in conjunction with shutdown cooling systems when needed, shall provide adequate cooling to the spent fuel during all operating conditions for up to 1205 spent fuel assemblies.

9.1.3.1.2 Spent Fuel Pool Cleanup Design Bases

The following design bases are imposed on spent fuel pool cleanup:

A. Fuel pool water clarity shall be maintained.

B. A level of decontamination of the spent fuel pool water during normal operation and refueling shall be maintained such that dose rates above the pool at the refueling machine platform are maintained less than 2.5 mrem/h event when considering direct shine due to fuel assemblies.

C. The fuel pool cleanup system shall be designed to tolerate the following water chemistry:

1.	pH (at 77F)	3.8 to 10.2
2.	Boric acid, max weight percent	2.5
3.	Ammonia, maximum ppm	50
4.	Lithium, maximum ppm	0.5
5.	Dissolved air, maximum	Saturated
6.	Chloride, maximum ppm	0.15
7.	Fluoride, maximum ppm	0.1

9.1.3.2 System Description

9.1.3.2.1 Spent Fuel Pool Cooling and Cleanup System

Engineering drawings 01, 02, 03-M-PCP-001 is a piping and instrumentation diagram of the spent fuel pool cooling and cleanup system. As this system has two different functions, the system description is in two parts. Refer to

paragraph 9.1.3.2.1.1 for the spent fuel pool cooling subsystem and to paragraph 9.1.3.2.1.2 for the spent fuel pool cleanup subsystem.

9.1.3.2.1.1 Spent Fuel Pool Cooling. The spent fuel pool cooling system is manually operated from a local control panel. The pool high temperature alarm, the water level alarms, and local control panel trouble alarm are annunciated in the main control room via a common trouble alarm.

The spent fuel pool cooling system consists of two spent fuel pool cooling pumps, each powered from the Class 1E electrical system, and two fuel pool heat exchangers. The fuel pool cooling pumps are connected to a common suction header and return header. The system is also provided with appropriate valves, piping, and instrumentation. Spent fuel pool water is circulated by the fuel pool pumps through the fuel pool heat exchangers, where it is cooled by the nuclear cooling water system or by the essential cooling water system and ultimate heat sink. The following is a summary of analyzed plant condition (also refer to sections 9.1.3.1.1 and 9.1.3.3.1).

1- Normal plant condition: One or two trains of the spent fuel pool cooling system provide cooling of the spent fuel pool. During this mode of operation, heat exchangers are cooled by the nuclear cooling water system. If the nuclear cooling water system is unavailable, the essential cooling water system can be used.

2- Emergency plant condition: The spent fuel pool cooling system can be aligned manually with the essential cooling water system and ultimate heat sink system during any event

described in chapter 15 which would result in loss of offsite power. See section 9.2 for details of these auxiliary systems.

3- Scheduled normal refueling condition (includes full core off load/reload, fuel off load initiated 100 hours after shutdown): The spent fuel pool cooling system is normally cooled by one or two trains of the pool cooling system and the nuclear cooling water system. If the nuclear cooling water system is unavailable, the essential cooling water system can be used. The shutdown cooling system (using either the LPSI or containment spray pump) can also be used to augment spent fuel pool cooling as needed. The system description for the shutdown cooling system is presented in section 5.4.7.

4- Emergency condition during a scheduled normal refueling (loss of offsite power): One train of the spent fuel pool cooling system augmented by one train of the shutdown cooling system (using either the LPSI or containment spray pump). These systems are cooled by essential cooling water in conjunction with the ultimate heat sink (spray pond).

5- Emergency condition during fuel transition mode (loss of offsite power); During this mode of operation when the core is being off loaded or re-loaded, the spent fuel pool cooling system may be augmented by one train of shutdown cooling (using either the LPSI or containment spray pump) and associated auxiliaries. The shutdown cooling train in service is aligned such that it would provide cooling to both the reactor core and the spent fuel pool.

6- Emergency core off load condition: When the core is fully off loaded, during an unscheduled outage for emergency maintenance, the spent fuel pool can be cooled by one train of the fuel pool cooling system cooled by the nuclear cooling water system, augmented by one train of the shutdown cooling system cooled by the essential cooling water system.

Instrumentation is provided which monitors the temperature of both the refueling and spent fuel pools and the water level in both pools. Spent fuel pool alarms are annunciated locally and in the main control room via a common trouble alarm. Refueling pool computer alarms are annunciated in the main control room only. Additional instrumentation and a thermowell on the heat exchanger inlet, monitored locally, is provided to check inlet and outlet temperatures on the heat exchangers, and to determine the pressure of the cooling pump discharge. Sight gauges are provided on the heat exchangers and the cooling pump drain lines.

Table 9.1-2 provides the principal design parameters of the cooling loop.

9.1.3.2.1.2 Spent Fuel Pool Cleanup. The spent fuel pool cleanup system consists of two trains, each having a strainer, a pump, a filter, and an ion exchanger. Either one or both trains may be aligned to clean the water in the spent fuel pool or the refueling water tank continuously (if required). During refueling, this system can be aligned with the refueling pool if all fuel assemblies are in the reactor vessel or in the spent fuel pool and valve PCN-V-118 is closed, or

administrative procedures are in place to ensure timely identification and isolation of a breach of spent fuel pool cleanup system boundary as result of a seismic event or pipe break. The spent fuel pool clean up system is aligned with the pool drain system only for a short duration of time during the refueling operation for fill and drain operation. The system is under procedural control during these evolutions.

The cleanup loops are normally run from a local panel when required by the water conditions from the various sources. It is possible to operate each loop independently and with either the ion exchanger or filter bypassed by means of manually operated valves. Local samples permit analysis of ion exchanger and filter efficiency. A small fraction of the purification flow is drawn through the surface skimmers.

The spent fuel pool and refueling pools are continuously monitored by detectors XJ-SQA-RU-31 and XJ-SQA-RU-33 (refer to table 11.5-1). Additionally, sampling is provided by a batch method as shown in engineering drawing 13-N-997-184.

The fuel pool cleanup system has differential pressure transducers on the cleanup filters, the ion exchangers, and the cleanup strainers. Sight gauges are provided on the cleanup pumps and filters.

The principal design parameters of the cleanup loop are listed in table 9.1-3.

9.1.3.3 Safety Evaluation

9.1.3.3.1 Fuel Pool Cooling

Each unit has continuous, independent, ESF grade, fuel pool cooling systems designed to ensure safe spent fuel handling and storage as described below.

9.1.3.3.1.1 Safety Design Bases. There are four provisions for cooling discharged fuel:

- Spent fuel pool cooling train A
- Spent fuel pool cooling train B
- Shutdown cooling system train A (LPSI or Containment spray pump)
- Shutdown cooling system train B (LPSI or Containment spray pump)

Each cooling system can itself be cooled by the essential cooling water (ECW) system. However, spent fuel pool cooling is normally cooled by the nuclear cooling water system (reference sections 1.2.10.3.3.1, 1.2.10.3.3.6, 9.2.2.1 and 9.2.2.2). The ECW system heat exchangers are serviced by the ultimate heat sink (spray pond). In the event that the spent fuel pool temperature rises above 125F, alarms are annunciated locally and in the main control room. If the nuclear cooling water system is out of service, the cooling water for the PC heat exchangers can be switched to the ECW system. The following summarizes different plant conditions

Table 9.1-2
COOLING SYSTEM DESIGN PARAMETERS (Sheet 1 of 4)

Parameter	Value
Minimum Analyzed Heat Removal Capability, Btu/hr	
1 - Normal plant condition 2 trains of PC cooled by NC	9.9E+6/train or 19.8E+6 total
2 - Emergency plant condition 1 train of PC cooled by EW	12.6E+6
3 - Scheduled Normal refueling plant condition 1 train of PC cooled by NC augmented by 1 train of SDC	 9.9E+6 37.6E+6
Total	47.5E+6
4 - Emergency plant condition during a scheduled refueling. 1 train of PC cooled by EW augmented by 1 train of SDC	 16.4E+6 63.6E+6
Total	80.0E+6
5 - Emergency plant condition during fuel transition mode (off load/ reload). 1 trains of PC cooled by EW augmented by 1 train of SDC	 16.4E+6 32.6E+6
Total	49.0E+6
6 - Emergency core off load during an unscheduled outage. 1 train of PC cooled by NC augmented by 1 train of SDC	 9.9E+6 45.0E+6
Total	54.9E+6
Spent Fuel Decay Heat[1], Btu/Hr	
1 - Design heat load power operation	12.6E+6 Administrative limit conservatively based on the SFP cooling capability given in Condition 2.
2 - Design heat load during emergency plant condition (accident)	12.6E+6 Administrative limit based on maximum heat removal capability of 1 train of PC cooled by EW (plant condition 2 above) following a design basis accident, concurrent with a LOP.
3, 4, and 5 - Design normal/emergency refueling heat load	47.0E+6 Full core offload beginning at 100 hours after shutdown plus 964 assemblies from the 12 previous annual refuelings.

1. Decay heat assumptions
   Method of calculation: Branch Technical Position 9-2, 1975
   Maximum duration of fuel cycle: 13,200 hr/cycle, irradiated 3 full cycles
   Plant capacity factor: 100%/cycle
   Plant power level: 3990 MWt
   For Cases 3, 4, 5, and 6: Fuel management practices limit total number of fuel assemblies in spent fuel pool as a function of time following reactor trip to maintain margin to spent fuel pool cooling system design capacity.

Table 9.1-2
COOLING SYSTEM DESIGN PARAMETERS (Sheet 2 of 4)

Parameter	Value
6 - Design Maximum heat load during emergency core offload	47.0E+06 Full core offload beginning at 100 hours after shutdown plus 1/3 core offload 90 days before the full core offload plus 884 assemblies from the 12 previous annual refuelings.

COOLING SYSTEM DESIGN PARAMETERS (Sheet 4 of 4)

Parameter	Value	
Shell side, nuclear cooling water (NCW) / essential cooling water (ECW)	NCW	ECW
Flow per heat exchanger, gal/min	2500	1340
Nominal Inlet temperature, °F	105	105
Nominal Outlet temperature, °F	113	117

1- Normal plant condition: Two trains of the spent fuel pool cooling system are available. One or two spent fuel pool cooling pumps would be in operation to keep the pool temperature below 125F. In the event of failure of one train of spent fuel pool cooling, a single train is sufficient to maintain the spent fuel pool temperature below 145F. The heat removal capability of the spent fuel pool cooling system with two pool cooling trains available (PC cooled by NC) is 9.9E+6 Btu /hr/train, and the maximum decay heat generated in the spent fuel pool is administratively controlled to 12.6E+6 Btu/hr. (Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

2- Emergency plant condition: The spent fuel pool cooling system would be available within 8 hours from the initiating event by manually aligning it with the essential cooling water system and ultimate heat sink system (this scenario is applicable to any event described in chapter 15 which would result in loss of offsite power). During this scenario, spent fuel pool temperature would be limited to 167F. The heat removal capability of one train of the spent fuel cooling system under this condition is 12.6E+6 Btu /hr, and the maximum decay heat generated in the spent fuel pool is administratively controlled to 12.6E+6 Btu/hr. (Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

3- Scheduled normal refueling condition (includes full core off load/reload, beginning at 100 hours after shutdown with fuel management practices limiting total number of fuel

assemblies in spent fuel pool as a function of time following reactor trip to maintain margin to spent fuel pool cooling system design capacity): The spent fuel pool cooling system is normally cooled by one or two trains of the spent fuel pool cooling system (PC cooled by NC). The shutdown cooling system (LPSI or containment spray pump) can also be used to augment spent fuel pool cooling as needed. The spent fuel pool temperature during this mode of operation is maintained below 125F. The combined heat removal capability of the spent fuel cooling system and shutdown cooling system under this condition (1 train of PC/NC augmented by 1 train SDC) is 47.5E+6 Btu /hr, and the maximum calculated decay heat generated in the spent fuel pool is 47.0E+6 Btu/hr for a core power of 3990 MWt. (Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

4- Emergency condition during a scheduled normal refueling (loss of offsite power and mechanical single failure): One train of the spent fuel pool cooling system augmented by one train of the shutdown cooling system (LPSI or containment spray pump). These systems are cooled by essential cooling water in conjunction with the ultimate heat sink (spray pond). During this scenario, the spent fuel pool temperature would be limited to 145F. The combined heat removal capability of one train of the spent fuel cooling system and one train of the shutdown cooling system under this condition is 80.0E+6 Btu/hr, and the maximum calculated decay heat generated in the spent fuel pool is 47.0E+6 Btu/hr for a core power of 3990 MWt.

(Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

5- Emergency condition during fuel transition mode (loss of offsite power and a mechanical single failure): During this mode of operation when the core is being off loaded or re-loaded one train of the fuel pool cooling system could be augmented by one train of the shutdown cooling (LPSI or containment spray pump) and associated auxiliaries. The shutdown cooling train in service is aligned such that it would provide cooling to both the reactor core and spent fuel pool. The maximum pool temperature during this condition would be limited to 145F. The combined heat removal capability of one train of the spent fuel cooling system and one train of the shutdown cooling system under this condition is 49.0E+6 Btu/hr, and the maximum calculated decay heat generated in the spent fuel pool is 47.0E+6 Btu/hr for a core power of 3990 MWt. (Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

6- Emergency core off load condition: One train of fuel pool cooling and one train of shutdown cooling can maintain and limit the maximum spent fuel pool temperature to less than 125F. Fuel pool decay heat for this event is a full core off load (beginning at 100 hours after shutdown with fuel management practices limiting total number of fuel assemblies in spent fuel pool as a function of time following reactor trip to maintain margin to spent fuel pool cooling system design capacity) plus 1/3 core offload 90 days before the full core offload plus 884 assemblies

from the 12 previous annual refuelings. This same temperature limit will apply even with a mechanical single failure, as there is a spare train available for each system. The combined heat removal capability of one train of the spent fuel cooling system and one train of the shutdown cooling system under these conditions is 54.9E+6 Btu/hr, and the maximum calculated decay heat generated in the spent fuel pool is 47.0E+6 Btu/hr for core power of 3990 MWt. (Refer to sections 9.1.3.1.1 and 9.1.3.2.1.1 for design bases and system descriptions.)

9.1.3.3.1.1.1 Minimum Water Level Requirement. If the spent fuel pool levels fall below a setpoint of 137 feet 6 inches an alarm is sounded locally and in the control room. The low level alarm is provided to ensure that assumptions made in chapter 15.7.4 would be maintained during movement of spent fuel or a heavy load over the pool area. The spent fuel pool cooling system includes inherently safe design features which would prohibit loss of pool cooling during event such as:

- Pipe break in the non-quality portion of cooling/cleanup loops by providing siphon holes.
- Component failure - such as pump seals by providing redundant make-up capabilities.
- Loss of source water - by providing sufficient reserved inventory and makeup capabilities.

If a pipe break were to occur in the Seismic Category I/quality portion of the system, pool cooling could be lost. However,

the event would be self-limiting as all pipe penetrations through the pool wall are at or above the minimum required water levels for spent fuel shielding of 10 ft as required by Regulatory Guide 1.13. All pipes extending down into the pool have siphon breaker holes at or above the minimum required water level. Under these conditions, sufficient time (longer than 30 minutes) is available to isolate the break and recover the minimum level required for start of the pool cooling system. If the spent fuel pool clean up system is aligned with the refueling pool (drain valves), administrative procedures are in place to identify, locate and isolate a pipe break within the containment in a timely manner.

9.1.3.3.1.2 Ultimate Heat Sink. The spray ponds (refer to subsection 9.2.5) qualify as the ultimate heat sink for spent fuel cooling under the provisions of Regulatory Guide 1.27. During normal operation, the fuel pool heat exchangers are supplied with cooling water by the nuclear cooling water system which is in turn supplied by plant cooling water. During abnormal operation (e.g., loss of offsite power), the fuel pool heat exchangers are supplied with cooling water from the essential cooling water system. (Refer to section 1.2.10.3.3, Cooling Water Systems)

Table 9.1-3
CLEANUP SYSTEM DESIGN PARAMETERS (Sheet 1 of 4)

Parameter	Value
General system data	
Normal cooling flowrate, gal/min	4000
Normal purification flowrate, °F gal/min	300
Normal fuel pool temperature, °F	125
Fuel loading	1329 assemblies
Pool boron concentration, ppm	zero to 4400
Fuel pool cleanup strainers	
Quantity	2
Type	Basket
Screen size, perforated, in	1/8
Design pressure, psig	200
Design temperature, °F	250
Flow, gal/min	150
Clean pressure drop, psi at gal/min	0.5 at 150
Fluid, boric acid solution, wt%	2-1/2
Materials in contact with fluid	Stainless steel
Maximum WP across element, psi	30
Fuel pool cleanup pumps	
Quantity	2
Type	Centrifugal, mechanical seals

Materials in contact with fluid	Stainless steel
Fluid, boric acid solution, wt%	2-1/2

9.1.3.3.1.3 Makeup Water. Normal makeup water for the pool is drawn from the refueling water tank (Seismic Category I source including lines). The RWT makeup water is the only Borated water source. Backup makeup water can be obtained from the liquid radwaste system (LRS) recycle monitor tank or the condensate tank. If makeup is the result of evaporation losses, then the LRS makeup water source is used in order to minimize waste and maintain proper spent fuel boron concentration. A minimum of 9 feet 5 inches of water is maintained over the active portion of the fuel assemblies during fuel movement (reference UFSAR sections 9.1.4.3.4, 9.1.4.6 and 9.1.4.7). Technical Specifications require at least 23 feet of water over the top of irradiated fuel assemblies seated in the storage racks.

9.1.3.3.1.4 Electrical Power. Normal and Class 1E electrical power is supplied to necessary components of the spent fuel cooling system.

9.1.3.3.1.5 Storage Capacity. Storage and cooling for 1329 spent fuel elements (5-1/3 cores) is provided as described in subsection 9.1.2 and paragraph 9.1.3.2.

9.1.3.3.2 Fuel Pool Cleanup

None of the design bases listed in paragraph 9.1.3.1.2 is safety-related. However, the design bases are met as follows:

A. The fuel pool cleanup system will maintain fuel pool water clarity.

B. Dose rates above the surface of the spent pool are less than 2.5 mrem/h.

C. The fuel pool cleanup system will accommodate the water chemistry limits of paragraph 9.1.3.1.2, listing C.

9.1.3.4 Inspection and Testing Requirements

Fuel pool cooling lines and components will be inspected in accordance with ASME Section XI, Subsection IWD. Fuel pool cleanup lines are ANSI class lines and do not require inservice inspection.

Instrumentation will be recalibrated at regular intervals as part of normal plant maintenance in accordance with the PVNGS preventive maintenance program. Chemical analysis downstream of the filters and ion exchangers is done via batch sampling only. These samples, as a minimum, are to be taken at 1 week intervals.

Decontamination factors or radiation levels are the criteria used to determine replacement of the resin bed for the ion exchangers. The cleanup filters are provided with pressure differential indicator switches which gave local indication of pressure drop across the filters and alarm to the local panel on high pressure drop.

The fuel pool cleanup filter cartridges will be replaced when the pressure drop across the filters exceeds 25 psid during operation of the system or the gamma radiation reading on the outside of the filter housing exceeds a reading to be determined when normal system radiation levels have been measured in order to maintain radiation exposures ALARA.

Fuel pool cleanup ion exchanger performance will be monitored by determining a decontamination factor from ion exchange inlet to outlet samples for gross activity and gross iodine. Ion exchanger resin will be replaced when the decontamination factor drops below a minimum efficiency level, as determined by examining initial operating decontamination factors, for three consecutive samples taken 2 hours apart or when the gamma radiation readings on the outside of the filter housing exceed a reading to be determined when normal system radiation levels have been measured in order to maintain radiation exposures ALARA. Water chemistry will be sampled and analyzed as necessary.

9.1.4 FUEL HANDLING SYSTEM

9.1.4.1 Design Bases

9.1.4.1.1 System

The fuel handling system is designed for the handling and storage of fuel assemblies and control element assemblies (CEAs). Associated with the fuel handling system is the equipment used for assembly, disassembly and storage of the reactor closure head and internals. As appropriate, the fuel handling equipment included interlocks, travel limiting features, and other protective devices to minimize the possibility of mishandling or equipment malfunction that could result in inadvertent damage to a fuel assembly and potential fission product release.

The refueling water provides the coolant medium during spent fuel transfer. The spent fuel pool is provided with a pool cooling and purification system.

All spent fuel transfer and storage operations except dry cask storage operations are designed to be conducted underwater to insure adequate shielding. Dry cask storage canisters and casks contain integral shielding.

The primary function of the cask load pit is to support dry cask storage operations. The cask load pit may remain filled with borated water since it has a liner plate leak detection system. Long-term borated water storage in the cask load pit is permitted to support dry cask storage, refueling outages or other normal operational maneuvers.

The arrangement of the fuel handling system is shown in engineering drawings 13-P-OOB-0003 through –0005, 13-P-OOB-0007 and 13-P-OOB-0010. Also refer to figure 9.1-2 for crane travel limits in the fuel building.

9.1.4.1.2 Fuel Handling Equipment

The principle design criteria for the dry fuel storage system fuel handling equipment is discussed in the NAC-UMS® CoC and FSAR.

The principle design criteria for the fuel and CEA handling equipment (refueling machine, fuel transfer equipment, spent fuel handling machine, CEA change platform and new fuel and CEA elevators) are as follows:

A. For non-seismic operating conditions, the bridges, trolleys, hoist units, hoisting cable, grapples and hooks conform to the requirements of Crane Manufacturing Association of America Specification #70.

B. For seismic design, the combined dead loads, live loads and seismic loads do not cause any portion of the equipment to disengage from its supports and fall into the pool.

C. Grapples and mechanical latches that carry fuel assemblies or CEAs are mechanically interlocked against inadvertent opening.

D. Equipment is provided with locking devices or restraints to prevent parts, fasteners, or limit switch actuators from becoming loose. In those cases where loosened parts or fasteners can drop into, or are not separated by a barrier from, or whose rotary motion will propel it into the water of the refueling pool or spent fuel pool, these parts and fasteners are lockwired or otherwise positively captured.

E. A positive mechanical stop is provided to prevent the fuel from being lifted above the minimum safe water cover depth and shall not cause damage or distortion to the fuel or the refueling machine when engaged at full operating hoist speed.

F. The fuel hoists are provided with load measuring devices and interlocks to interrupt hoisting if the load increases above the overload set point and interrupts lowering if the load decreases below the underload set point. The PLC will generate the normal operational load weighing interlocks.

G. In the event of loss of power, the equipment, and its load remain in a safe condition.

H. Equipment remaining within the containment is capable of withstanding, without damage, the internal building test pressure.

Electrical interlocks are provided to ensure the reliability of system components, to simplify the performance of sequential operations, and to limit travel and loads such that design conditions will not be exceeded. In no case will they be utilized to prevent inadvertent criticality or the reduction of the minimum water coverage for personnel protection. In addition to electrical interlocks, visual load indication is provided at the controls such that the operator can monitor the load. In the event an interlock fails to stop the hoist, the operator can take action to stop hoist movement. Load indications exceeding interlock setpoints would subsequently necessitate evaluation of the fuel handling equipment and fuel assemblies involved.

In addition, the new fuel handling crane design bases are described as follows:

A. Design Basis A

The new fuel handling crane shall be designed to prevent operation over the spent fuel pool except by the use of a key-operated interlock override.

B. Design Basis B

Hoisting load lift force shall be restricted to 5000 pounds when fuel assemblies are being lifted.

C. Design Basis C

The new fuel handling crane shall be restrained and supported such that it does not become a hazard, in the event of an SSE, to safety grade components, systems, or structures.

9.1.4.1.3 Cask Handling Crane and Containment Polar Crane

The design bases for the cask handling crane and the containment polar crane are as follows:

A. Design Basis A

The cask handling crane shall be designed to meet the guidelines of NUREG-0612, Section 5.1.6 (Single Failure – Proof Handling Systems).

B. Design Basis B

The cask handling crane shall be designed to restrict operation over the main body of the spent fuel pool.

C. Design Basis C

The cask handling crane shall be restrained and supported such that in an OBE or SSE event, it does not become a hazard to safety grade components, systems, or structures.

D. Design Basis D

The containment polar crane shall be designed not to lift any object higher than 40 feet above the reactor vessel flange, while the crane hook is over the reactor vessel flange, except through the use of an administratively controlled key-operated bypass switch.

E. Design Basis E

The containment polar crane shall be equipped with an interlock designed to prevent the trolley from carrying loads over the reactor vessel. The interlock is designed to prevent the trolley from moving within the 15 foot exclusion zone when the reactor vessel contains fuel. This interlock can be bypassed by an administratively controlled key-operated bypass switch to allow for removal and replacement of the Upper Guide Structure and Reactor Vessel Head and for movement of loads located in the area above the reactor vessel.

9.1.4.1.4 Codes and Standards

Codes and standards that apply wholly or in part to the design of the fuel handling system include:

- General Design Criteria 61 and 62 of 10CFR50, Appendix A, as discussed in section 3.1
- Regulatory Guides 1.13, 1.29, and 1.65 as discussed in section 1.8
- 29CFR1910
- 10CFR71

- NUREG-0612, Control of Heavy Loads at Nuclear Power Plants
- NUREG-0554, Single-Failure-Proof Cranes for Nuclear Power Plants
- ASME NOG-1, Rules for Construction of Overhead and Gantry Cranes
- CMAA Specification #70, Specifications for Top Running Bridge and Gantry Type Multiple Girder Electric Overhead Traveling Cranes

9.1.4.2 System Description

9.1.4.2.1 System

The fuel handling system is an integrated system of equipment, tools and procedures for refueling the reactor. The system provides for handling and storage of fuel assemblies from receipt of new fuel to shipment of spent fuel. The equipment is designed to handle the spent fuel underwater from the time it leaves the reactor until it is placed in a canister for storage at the ISFSI or cask for shipment from the site. Underwater transfer of spent fuel provides a transparent radiation shield, as well as a cooling medium for removal of decay heat. Boric acid is added to the water in the quantity required to assure subcritical conditions during refueling. The dry cask storage system provides passive cooling, shielding and criticality control. See the NAC-UMS® Certificate of Compliance (CoC) and FSAR for details.

The major components of the system are the refueling machine, the CEA change platform, the fuel transfer system, the spent fuel handling machine, the cask handling crane, the transfer cask, and the new fuel elevator and new fuel handling crane. The refueling machine moves fuel assemblies into and out of the core and between the core and the transfer system. The CEA change platform is used to move the CEAs within the Upper Guide Structure or between the UGS and the CEA elevator and new fuel handling crane. The CEA elevator is used to introduce new CEAs into the refueling pool and may be used to hold the spent CEAs while they are being disassembled for disposal. The fuel transfer system moves the fuel between the containment building to the fuel building through the transfer tube. The spent fuel handling machine handles fuel between the transfer system, the spent fuel storage racks, the new fuel elevator and the NAC-UMS® transportable storage canister in the cask loading pit. The new fuel elevator and new fuel handling crane are used to introduce new fuel into the spent fuel pool so that it can be moved to the transfer system by the spent fuel-handling machine. The NAC-UMS® transfer cask provides shielding and a means of transferring the transportable storage canister to and from the vertical concrete cask. The cask handling crane is used to move the transfer cask, transportable storage canister and other heavy loads.

Special tools and lifting rigs are also used for disassembly of reactor components.

In the design of this equipment, mechanical stops and positive locks have been provided to prevent damage to or dropping of

the fuel assemblies. In the design of the refueling machine, positive locking between the grapple and the fuel assemblies is provided by the engagement of the actuator arm in vertical channels in the hoist assembly so that relative rotational movement and uncoupling is not possible, even with inadvertent initiation of an uncoupling signal to the actuator assembly. Therefore, failure of an electrical interlock will not result in the dropping of a fuel assembly.

The following list identifies and defines the function of the interlocks contained in the fuel handling equipment. Typically, no method has been provided to directly inform the operator that an interlock is inoperative. However, in most cases a redundant device has been provided to perform the same function as the interlock or to present information to the operator allowing him to deduce that an interlock has malfunctioned.

The fuel handling and CEA machines do not fully fall within the framework of an overhead or gantry crane as described in OSHA subpart N, Materials Handling and Storage, of 29 CFR 1910.179. However, it has been used for guidance. More than 95% of the fuel-handling machine does conform to the OSHA regulations. In each case, additional features to protect the safety of the operator and facility have been installed and are part of appropriate operational procedures.

9.1.4.2.1.1 Refueling Machine. The following identifies and describes the functions of the interlocks that are contained in the refueling machine. The PLC will generate the normal operational load weighing interlocks. The load cell output

will be fed to the control system and displayed on the control console. This allows monitoring of overloads, underloads, and slack cable.

A. Refueling Machine Hoist Interlock (Overload)

Interrupts hoisting of a fuel assembly if the load increases above the overload set point. The hoisting load is visually displayed so that the operator can manually terminate the withdrawal operation if an overload occurs and the hoist continues to operate. In the event load indications exceed the setpoint, evaluation of the fuel handling equipment and fuel assemblies involved would be performed.

B. Refueling Machine Hoist Interlock (Up Limit)

Interrupt hoisting of a fuel assembly when the correct (full up) vertical elevation is reached. A mechanical up stop has also been provided to physically restrain the hoisting of a fuel assembly above the elevation which would result in less than the minimum shielding water coverage.

C. Refueling Machine Hoist Interlock (Underload)

Interrupts insertion of a fuel assembly if the load decreases below the underload setpoint. The load is visually displayed so that the operator can manually terminate the insertion operation if an underload occurs and the hoist continues to operate. In the event load indications exceed the setpoint value, evaluation of the fuel handling equipment and fuel assemblies involved would be performed.

D. Refueling Machine Hoist Interlock (Cable Slack)

Interrupts lowering of the hoist under a no-load condition. An independent slack cable switch that also terminates lowering under a no-load condition backs up the weighing system interlock.

E. Refueling Machine Translation Interlock

Denies translation of the bridge and trolley while the fuel hoist is operating.

F. Refueling Machine Hoist Interlock (Bridge/Trolley Interlock - BTI)

Hoisting is denied during translation of the bridge and/or trolley. No backup or additional circuitry is provided for this interlock.

G. Refueling Machine Translation Interlock (Spreader Extended)

Denies translation of the bridge and/or trolley with the spreader extended. An underwater TV system can be used by the operator to determine whether the spreader has been raised, and icons on the control console indicate whether it is withdrawn or extended.

H. Refueling Machine Mast Anti-collision Interlock

Stops translation of the bridge and/or trolley when the collision ring on the mast is contacted and deflected.

Redundant switches are provided to minimize the possibility of this interlock becoming inoperative. Slow bridge speeds are provided for movement of the

refueling machine in areas other than its normal travel route that might contain obstructions. Travel limits are also provided to prevent machine contact with obstructions within the pool area.

I. Refueling Machine Hoist Speed Interlock

Provides restriction on maximum hoisting speed when the fuel is within the core. During insertion and withdrawal the change in hoist speed can be monitored by observation of the hoist vertical position indicator.

J. Refueling Machine Hoist Interlock (Maximum Overload)

Interrupts hoisting of a fuel assembly if the load increases above the maximum overload set point.

9.1.4.2.1.2 Transfer System. The following identifies and describes the functions of the interlocks that will be contained in the transfer system.

A. Transfer System Winch Interlock

Terminates movement of the fuel carriage through the transfer tube if the load increases above the overload setpoint.

An overload is indicated by a light on the control panel and by an audible alarm.

B. Transfer System Winch Interlock

Prevents the winch from attempting to pull the fuel carriage through the transfer tube with an upender in a vertical position. If this interlock fails and a transfer signal is initiated, winching will be

terminated when the load increases above the overload setpoint.

C. Transfer System Upender Interlock

Rotation of the upender is denied while the refueling machine and SFHM are at their upender stations and the hoist is not at full up. Failure of this interlock while the machines are at the upending station will allow the transfer equipment operator to initiate rotation of the fuel carrier.

D. Transfer System Upender Interlock

Rotation of the upender is denied unless the fuel carrier is correctly located for upending. Failure of this interlock will: (1) with the fuel carrier in the transfer tube allow the upender to rotate with no effect on the carrier or fuel bundle, and (2) with the fuel carrier partially in the upender, attempt to but not be successful in, rotating the carrier since a mechanical lock prevents premature carrier rotation.

9.1.4.2.1.3 Spent Fuel Handling Machine. The following identifies and describes the functions of the interlocks that will be a part of the spent fuel handling machine:

A. Spent Fuel Handling Machine Hoist Interlock (Overload)

Interrupts hoisting if the load increases above the overload setpoint.

Since the operator manually controls the tool, failure of the tool to move or reduction in tool speed as a

result of an overload can be sensed by the operator if the interlock becomes inoperative. The hoist load is displayed on the control console so that the operator can manually terminate the withdrawal operation if an overload occurs and the hoist continues to operate. In the event load exceeds the setpoint, evaluation of the fuel handling equipment and fuel assemblies involved would be performed.

B. Spent Fuel Handling Machine Hoist Interlock (Underload)

Interrupts lowering if the load decreases below the underload setpoint. Since the operator manually controls the tool, failure of the tool to move downward or reduction in cable tension as a result of an underload can be sensed by the operator if the underload interlock becomes inoperative. The hoist load is displayed on the control console so that the operator can manually terminate the withdrawal operation if and overload occurs and the hoist continues to operate. In the event load exceeds the setpoint, evaluation of the fuel handling equipment and fuel assemblies involved would be performed.

C. Spent Fuel Handling Machine Hoist Interlock (Cable Slack)

Interrupts hoisting if the load decreases to cable slack.

Since the tool is manually controlled, a slack cable condition can be visually determined by the operator and hoisting terminated.

D. Spent Fuel Handling Machine Translation Interlock

Provides speed restriction on bridge and trolley translation unless the load is in the full up position, at which time fast speed is allowed.

If this interlock fails, the mandatory slow speed restriction is removed. However, since the translation speed controls are infinitely variable, the operator can run at slow speed when the interlock malfunction is recognized.

E. Spent Fuel Handling Machine Translation Interlock

A dual redundant encoder positioning system protects against running the load into walls or the gate of the storage area. The operator has direct vision of the tool and the attached load so that translation can be terminated if an interlock fails to operate.

F. Spent Fuel Handling Machine Hoist Interlock (Maximum Overload)

Interrupts Hoisting of a Fuel Assembly if the load increases above the maximum overload set point.

9.1.4.2.1.4 New Fuel Elevator. The following identifies and describes the functions of the interlocks that are part of the new fuel elevator.

A. New Fuel Elevator Hoist Interlock

Stops the elevator motor should the cable become slack.

If this interlock fails, the operator can stop the elevator motion from the spent fuel handling machine console.

B. New Fuel Elevator Hoist Interlock

Prevents raising of the elevator with a fuel assembly in the elevator box. This interlock is a backup for the administrative control, which precludes the placement of a spent fuel assembly in the new fuel elevator. A key operated bypass switch is provided to allow raising of dummy or new fuel assemblies should it become necessary.

9.1.4.2.2 Components

9.1.4.2.2.1 Refueling Machine. The refueling machine is a traveling bridge and trolley which is located above the refueling pool and rides on rails set in the concrete on each side of the refueling pool. Motors on the bridge and trolley position the machine over each fuel assembly location within the reactor core or fuel transfer carrier. The controls for the refueling machine are mounted on a console that is located on the refueling machine trolley. Coordinate location of the bridge and trolley is indicated at the console by digital readout devices that are driven by encoders coupled to the guide rails through rack and pinion gears. During withdrawal or insertion of a fuel assembly, the load on the hoist cable is monitored at the console to assure that movement is not being restricted. Limits are such that damage to the assembly is prevented.

Locking between the grapple and the fuel assembly is provided by the engagement of the grapple actuator arm in axial channels running the length of the fuel hoist assembly. Therefore, it is not possible to uncouple even with inadvertent initiation of an uncoupling signal to the actuator assembly. The drives for both the bridge and the trolley provide close control for accurate positioning, and brakes are provided to maintain the position once achieved. In addition, interlocks are installed so that movement of the refueling machine is not possible when the hoist is withdrawing or inserting an assembly. PLC interlocks are provided that deny translation of the bridge and trolley while the fuel hoist is in operation and translation of the hoist while the bridge and trolley are in operation.

For operations above the core, the bottom of the hoist assembly is equipped with a spreading device to align the surrounding fuel assemblies to their normal core spacing to assure clearance for fuel assemblies being installed or removed. An anti-collision device at the bottom of the mast assembly prevents damage should the mast be inadvertently driven into an obstruction. A positive mechanical up stop is provided to prevent the fuel from being lifted above the minimum safe water cover depth. A system of pointers and scales serves as a backup for the remote positioning readout equipment.

Manually operated handwheels are provided for bridge, trolley and winch motions in the event of a power loss. Manual operation of the grappling device is also possible in the event that air pressure is lost.

The refueling machine hoist box is equipped with the necessary manifolds, tubing, and fittings to allow for wet sipping of fuel assemblies. See Sections 9.1.4.2.2.23 and 9.1.4.2.3.4 for a description of the wet sipping system components and operation.

9.1.4.2.2.2 Transfer System. The major components of the transfer system are one carriage with carrier, two upenders, and two hydraulic power packages as described below.

A. Transfer Carriage

A transfer carriage conveys the fuel assemblies through the transfer tube. Two fuel assembly cavities are provided in the fuel carriage. Fuel assemblies are placed on the transfer carriage in a vertical position, lowered to the horizontal position, moved through the fuel transfer tube on the transfer carriage, and then restored to the vertical position. Only one irradiated fuel assembly is permitted to be transferred through the transfer tube at a time.

Wheels support the carriage and allow it to roll on tracks within the transfer tube. The track sections at both ends of the transfer tube are mounted on the upending machines to permit the carriage to be properly positioned at the limits of its travel. The carriage is driven by steel cables connected to the carriage and through sheaves to its driving winch mounted on the operating floor.

The load in the transfer cables is displayed at the master control console. An overload will interrupt the transfer operation. Manual override of the overload cutout allows completion of the transfer. The supports for the replaceable rails on which the transfer carriage rides are welded to the 36-inch diameter transfer tube. The rail assemblies are fabricated to a length that will allow them to be lowered for installation in the transfer tube. No rails need be installed in the valve on the spent fuel pool side of the transfer tube.

B. Upending Machine

An upending machine is provided at each end of the transfer tube. Each machine consists of a structural support base from which is pivoted an upending straddle frame that engages the two-pocket fuel carrier. When the carriage with its fuel carrier is in position within the upending frame, the pivots for the fuel carrier and the upending frame are coincident. Hydraulic cylinders, attached to both the upending frame and the support base, rotate the fuel carrier between the vertical and horizontal position as required by the fuel transfer procedure. Each hydraulic cylinder can perform the upending operation alone and can be isolated in the event of its failure. A long tool is also provided to allow manual rotation of the fuel carrier in the event that both cylinders fail or hydraulic power is lost.

C. Hydraulic Power Unit

The hydraulic power unit provides the motive force for raising and lowering the upender with the fuel carrier. It consists of a stand containing a motor coupled to a hydraulic pump, a pump reservoir, valves and the necessary hoses to connect the power package to the hydraulic cylinders on the upender. The valves can be aligned to actuate either or both upender cylinders. The hydraulic fluid is distilled water.

9.1.4.2.2.3 Fuel Transfer Tube and Valve. A fuel transfer tube extends through the containment wall. During reactor operation, the transfer tube is sealed by means of a remotely operated quick operating closure device (QOCD) located inside the containment. Prior to filling the refueling pool, the closure cover plate is removed. After a common water level is reached between the refueling pool and the spent fuel pool, the transfer tube valve is opened.

The procedure is reversed after refueling is completed.

The transfer tube arrangement consists of a 36-inch diameter transfer tube contained within a penetration which is sealed to the containment. The transfer tube and penetration sleeves are sealed to each other by welding rings and bellow-type expansion joints to allow for horizontal movement to the tube and valve. During reactor operation, the containment side of the fuel transfer tube is contained within a tube, one end of which is welded to the pool liner and the other end equipped with a quick operating closure device. The closure device reducing ring is permanently bolted to the tube and sealing is

accomplished through two sealing rings. The closure plate that attaches to the reducing ring is also sealed with two sealing rings. Both sets can be checked for adequacy by pressurizing the annulus between the seals. In this arrangement, the transfer tube never sees containment pressure during reactor operation. Other arrangements are acceptable provided containment integrity is maintained during reactor operation.

9.1.4.2.2.4 CEA Change Platform. The CEA change platform is positioned above the upper guide structure after it has been placed in the storage area and the UGS lifting rig removed. The platform is mounted on the same rails as is the refueling machine. The platform locates the operator over the CEA to be moved. The CEA handling tool, attached to an overhead crane, is then lowered, grappled to the CEA and the CEA relocated, as required. The platform is also utilized during the handling of ICIs and during trash can movements.

9.1.4.2.2.5 Fuel Handling Tools. Two fuel handling tools are used to move fuel assemblies in the spent fuel pool area. A new fuel tool is provided for dry transfer of new fuel, and a spent fuel tool is provided for underwater handling of both spent and new fuel in the spent fuel pool. The tools are operated manually from the new fuel handling crane and from the trolley on the spent fuel handling machine respectively. An additional fuel handling tool is used to move fuel assemblies, trash cans and dummy fuel assemblies within the refueling pool. The New Fuel Handling Crane is also used to support tools used to perform spent fuel reconstitution and recaging.

9.1.4.2.2.6 Reactor Vessel Head Lifting Rig. The reactor vessel head lifting rig consists of three (3) lifting legs which extend from the reactor vessel closure head lifting lugs to the ring girder elevation at the top of the simplified head assembly air cooling shroud. The legs are located external to the simplified head assembly lower cooling shroud/radiation shield and upper shroud assembly.

9.1.4.2.2.7 Reactor Internals Handling Equipment. The reactor internals lift rig is a structure used to remove either the upper guide structure assembly or the core support structure from the reactor vessel.

The upper clevis assembly is a tripod-shaped structure connecting the lifting rig to the containment crane lifting hook. The lifting rig includes a spreader beam providing three attachment points that are bolted to the core support barrel flange. Correct positioning of the lifting rig is assured by attached guide bushings that mate to the reactor vessel guide pins. With the lift rig in the configuration provided for removal of the upper guide structure, the spreader beam supports three columns, providing attachment points to the upper guide structure assembly. Attachment to the upper guide structure assembly is accomplished manually from the working platform. Correct positioning is assured by attached bushings that mate to the reactor vessel guide pins.

The clevis assembly, tie rod assembly, and spreader beam assembly which are common to this and the core support structure lifting rig, are installed prior to lifting of the structure by the crane hook. The working platform also

incorporates the holding fixtures for the extension shafts and CEAs after the CEAs have been withdrawn into the upper guide structure. The holding fixtures that latch the extension shafts (with the CEAs) to the work platform are positive locking in that the extension shafts have to be raised before the fixtures can be disengaged.

9.1.4.2.2.8 Spent Fuel Handling Machine. The spent fuel handling machine is a traveling bridge and trolley which rides on rails over the spent fuel pool, refueling canal, and cask storage area. Motors on the bridge and trolley position the machine over the spent fuel assembly storage racks, the new fuel elevator and the upending machine. An auxiliary crane is used to transfer new fuel from the new fuel storage racks to the new fuel elevator.

The spent fuel handling machine hoist assembly supports a grappling tool which, when rotated by the operator, engages the fuel assembly to be moved. Once the fuel assembly is grappled, the hoist raises the fuel assembly and the machine then transports the fuel assembly from the new fuel elevator to the upending machine or spent fuel storage racks (new fuel), from the upender to the spent fuel storage racks or from the spent fuel storage racks, to the spent fuel cask.

The controls for the spent fuel handling machine are mounted on a console that is located on the spent fuel handling machine trolley.

Coordinate location of the bridge and trolley position is indicated by a pointer and target system. Dual encoders are

also installed and the location of the bridge and trolley will be displayed on the console.

During withdrawal or insertion of a fuel assembly, the load on the hoist cable is displayed on the console and is monitored to assure that movement is not being restricted. Set points are such that damage to the assembly is prevented.

Positive locking is provided between the grappling device and the fuel assembly to prevent inadvertent uncoupling. The drives for both the bridge and the trolley provide close control for accurate positioning, and brakes are provided to maintain the position once achieved. In addition, interlocks are installed so that movement of the spent fuel handling machine is not possible when the hoist is withdrawing or inserting an assembly.

Manually operated handwheels are provided for bridge, trolley and winch motions in the event of a power loss.

9.1.4.2.2.9 New Fuel Elevator. A fuel elevator is utilized to lower new fuel from the operating floor to the bottom of the pool where it is grappled by the spent fuel handling tool. The elevator is powered by a cable winch and fuel is contained in a simple support structure whose sliding pads are captured in two rails. New fuel is loaded into the elevator by means of the new fuel handling crane hoist and the new fuel handling tool.

A manually operated handwheel is provided for elevator operation in the event of a power loss.

9.1.4.2.2.10 Underwater Television. A closed circuit television system is available to monitor the fuel handling operations inside the containment. The camera is an operator aid and is not required for refueling machine operation.

9.1.4.2.2.11 Dry Sipping Equipment. Refer to FSAR paragraph 1.9.2.4.19.

9.1.4.2.2.12 Transport Container. The Transport Container is used to store and move cut up pieces of spent CEAs and In-core Instruments (ICIs). The container has the same nominal outside dimensions as a fuel bundle and is provided with top fitting to mate with the fuel grapple so it can be moved by the fuel handling equipment.

9.1.4.2.2.13 Refueling Pool Seal. The temporary refueling pool seal which was installed and removed for each refueling outage has been replaced by a Permanent Reactor Cavity/Refueling Pool Seal (PRCRPS). The PRCRPS is an annular ring approximately 23 feet OD, 6.5 inches high, and 3 feet wide. The PRCRPS is designed to perform two basic functions. First, the PRCRPS provides a seal for the reactor vessel cavity during refueling operations. Second, the PRCRPS is designed to allow the free flow of cooling air in the reactor vessel cavity during plant operation. The function is accomplished with access openings in the PRCRPS. These openings are covered and sealed during refueling operations. The covers may be removed and conveniently stored during plant operation. The covers can also be removed for access to excore nuclear instrumentation.

The PRCRPS is designed to accommodate the hydrostatic loads (nominally 26 ft.) of the refueling pool water and allow unrestricted reactor vessel thermal and seismic movement as per the original reactor coolant system design. These requirements are met by providing a flexible seal membrane and a separate rigid structure in the PRCRPS. The sealing function is accomplished with a thin, flexible membrane which is welded to the reactor vessel seal ledge, covers the support structure, and is also welded to the refueling pool embedment ring. The structural function is accomplished by a separate structure used to support hydrostatic loads which rests on the reactor vessel seal ledge and refueling pool embedment ring under the seal membrane.

9.1.4.2.2.14 In-Core Instrumentation and CEA Cutters. A portable underwater hydraulic cutter is provided to cut the expended CEAs into lengths necessary to permit transfer to the spent fuel building in the fuel carrier. A second cutter is used for disposal of the incore instrumentation leads.

9.1.4.2.2.15 Gripper Operating Tool. This tool is approximately seventeen feet long and consists of two concentric tubes with a funnel at the end to facilitate engagement with the CEA extension shafts. When installed, pins attached to the outer tube are engaged with the extension shaft. The inner tube of the tool is then lifted and rotated relative to the outer tube which compresses a spring allowing the gripper to release, thus separating the extension shaft from the control element assembly.

9.1.4.2.2.16 Cask Handling Crane. The cask handling crane is designed to transfer dry fuel storage system components and other heavy loads in the fuel building. The crane maximum critical load (MCL) and design rated load (DRL) are 150 tons. This capacity is sufficient to fulfill the design function of handling the SAFLIFT^{tm}, and a transfer cask containing a transportable storage canister loaded with 24 spent fuel assemblies and water in the canister.

The cask handling crane main hoist critical load bearing components are classified as Seismic Category I, Quality Class Q (Reg. Guide 1.13 and 1.29). All other components including the auxiliary hoist are classified as Seismic Category IX, Quality Augmented.

Since the crane handles spent fuel and also operates in the vicinity of spent fuel and safe shutdown equipment, it is designed to meet the guidelines of NUREG-0612, Section 5.1.6 (Single-Failure-Proof Handling Systems), NUREG-0612, Appendix C (Modification of Existing Cranes) and NUREG-0554 (Single-Failure-Proof Cranes for Nuclear Power Plants). Special lifting devices and other rigging used to handle heavy loads must meet the applicable guidelines of NUREG 0612 and ANSI N14.6. The cask handling crane has an auxiliary hoist with an MCL and DRL of 15 tons, which is designed to be single failure proof. Use of single failure proof hoisting systems makes it unnecessary to analyze the effects of postulated load drops because the probability of occurrence is extremely small.

For an item by item evaluation of NUREG-0554 compliance, refer to the single-failure-proof trolley final safety analysis report.

Mechanical antiderailment devices, mounted on the wheel axles of the overhead crane bridge and trolley, prevent the crane from being dislodged from the rail due to horizontal motion during an earthquake. The crane is designed so that vertical acceleration resulting from an earthquake is not large enough to overcome the downward load of gravity. The crane complies with the requirements of 29CFR1910, OSHA Subpart N, Section 1910.179.

Mechanical stops on the crane rails, shown on figure 9.1-2, prevent crane movement such that the crane hook cannot travel east of the cask pit centerline. The stops react on the crane bridge via buffers, and prevent crane movement over the main body of the spent fuel pool and the new fuel storage areas.

Limit switches on the crane rail normally interrupt the crane drives before the stop is contacted.

When handling spent fuel in dry fuel storage system transportable storage canisters (TSC), the cask handling crane uses the SAFLIFT^{tm}, which is an under the hook special lifting device designed to handle the TSC and the transfer cask (TFR). The SAFLIFT^{tm} incorporates a lifting beam with load hooks that support the TFR, and an underhung hoist and grapple that support the TSC. The MCL of the lifting beam and load hooks is 125 tons, while the MCL of the canister hoist and grapple is 50 tons. The SAFLIFT^{tm} weighs approximately 22 tons, so

lifting its MCL of 125 tons will not result in overloading the cask handling crane.

The SAFLIFT^{tm} critical load bearing components are classified as Seismic Category I, Quality Class Q (Reg. Guide 1.13 and 1.29). All other components are classified as Seismic Category IX, Quality Augmented.

Since the SAFLIFT^{tm} handles spent fuel and also handles heavy loads in the vicinity of safe shutdown equipment, it is designed to be used in single failure proof applications in accordance with NUREG-0612, NUREG-0554, CMAA-70 and ANSI N14.6.

9.1.4.2.2.17 New Fuel Handling Crane. The new fuel handling crane transfers new fuel assemblies between the transportation carrier, new fuel inspection station, new fuel storage facility, and new fuel elevator. This crane is a 10-ton bridge crane. The New Fuel Handling Crane is also used to perform activities associated with spent fuel reconstitution and recaging.

Drives for the crane provide close control for accurate positioning and brakes to maintain the position once achieved.

During withdrawal (or insertion) of a new fuel assembly in the new fuel storage facility, the hoisting load is limited to 5000 pounds and monitored by load cell readout to ensure that vertical movement of the fuel assembly is not being obstructed. The load cell operates an electrical trip circuit at the 5000-pound load. This interrupts the hoist drive. If loads larger than 5000 pounds need to be lifted in areas other than

over the spent fuel pool, the load interlock can be overridden by utilization of a key under administrative control.

Electrical interlocks on the crane long travel and cross travel motions prevent the crane hook from being traversed over the spent fuel pool. A key-operated interlock override is used to allow crane operation over the spent fuel. The key is under administrative control. In addition, electrical interlocks are provided to prevent movement of the crane when the hoist is withdrawing (or inserting) a new fuel assembly in its storage position. However, those interlocks may be bypassed using an administratively-controlled key, allowing crane long and cross travel with the hook below its upper travel limit. In the event of a power loss, the hand release feature of the spring set brake provides maneuverability to move the bridge, and the self-excited, eddy-current brake alternator generates adequate power to allow a controlled, safe lowering of the load. The new fuel handling crane and its rails are designed to withstand a safe shutdown earthquake without becoming dislodged and causing the loss of function of component systems or structures that must remain functional.

The new fuel handling crane is the only crane that can traverse the spent fuel pool.

9.1.4.2.2.18 Containment Polar Crane. Refer to Section 9.1.4.3.3 for the handling of the reactor vessel closure head.

The containment polar crane is used during the construction phase for installation of the heavy equipment items inside the containment. Thereafter it is used during refueling operations. It also may be used for maintenance operations for

the lifting and removal of major items of equipment if required. An administratively controlled key-operated limit switch prevents the crane from lifting the reactor closure head more than 40 feet above the reactor vessel flange while over the reactor vessel.

Reference to the reactor vessel closure head assembly raised height of 18 feet in CESSAR Interface Evaluation section 9.1.4.7 is no longer applicable to PVNGS. Refer to section 9.1.4.3.5 for closure head lift height evaluation.

9.1.4.2.2.19 Intermediate Storage Rack. The intermediate storage rack is used for the temporary storage of new fuel assemblies, spent fuel assemblies, and CEAs. It is located in the containment building on the refueling canal wall adjacent to the core support barrel laydown area and has four storage cavities (refer to paragraph 9.1.2.4).

9.1.4.2.2.20 Transportable Storage Container (TSC) The TSC is a component of the NAC-UMS dry cask storage system as described in the NAC-UMS Certificate of Compliance (CoC) and FSAR (Docket no. 72-1015). The TSC is designed for storage of 24 spent fuel assemblies. The TSC contains a fuel basket, which is a stainless steel lattice that provides criticality control by maintaining the fuel in a sub-critical array. The fuel basket contains BORAL sheets between the cells to assure the array remains subcritical with full density moderator intrusion. Once the TSC is loaded, confinement of the fuel is achieved by sealing the canister with a shield lid and structural lid, both of which are welded in place. The loaded

TSC is backfilled with helium to facilitate heat transfer and protect against corrosion.

9.1.4.2.2.21 Transfer Cask (TFR) The TFR is a component of the NAC-UMS dry cask storage system as described in the NAC-UMS Certificate of Compliance (CoC) and FSAR (Docket no. 72-1015). The TFR provides shielding during loading operations until the TSC is placed in the VCC. The TFR is fabricated primarily from lead for gamma shielding, NS-4-FR for neutron shielding, and low alloy steel for structural support. The transfer cask is a special lifting device designed in accordance with NUREG-0612 and ANSI N14.6 for use in single failure proof applications.

9.1.4.2.2.22 Vertical Concrete Cask (VCC) The VCC is a component of the NAC-UMS dry cask storage system as described in the NAC-UMS Certificate of Compliance (CoC) and FSAR (Docket no. 72-1015). The VCC is the storage overpack for the TSC. The VCC is a reinforced concrete structure with a structural steel inner liner. The VCC provides structural support, shielding, protection from environmental conditions, and natural convection cooling of the canister during storage. The lifting lugs on the VCC are designed to meet the guidelines of NUREG-0612 for single failure proof handling systems.

9.1.4.2.2.23 Telescope Fuel Sipping Equipment. The Telescope fuel sipping equipment is used when wet sipping is implemented during fuel handling evolutions to identify cladding failures by detection of leaking gaseous and water soluble fission products. The Telescope fuel sipping equipment is skid mounted and portable, and it is only in place on the refueling machine

bridge when being used. After Telescope fuel sipping is completed, the skid-mounted equipment is disconnected and removed. Refer to paragraph 9.1.4.2.3.4 for a description of the fuel sipping system operation.

9.1.4.2.2.24 Rod Storage Basket (RSB) and Rod Capture Tube (RCT). The RSB is used to store and move fuel rods with identified cladding defects or rods removed from fuel assemblies. The storage basket has the same nominal outside dimensions as a fuel assembly and is provided with a removable top fitting to mate with the fuel grapple so it can be moved by the fueling handling equipment. The RCT is used to capture fuel rods or pieces of fuel rods that may have separated during reconstitution or appear to have a high potential for separation. The RCT's are sized to be stored within the RSB.

9.1.4.2.3 System Operation

9.1.4.2.3.1 New Fuel Transfer. After arrival of the new fuel shipping containers, the container covers are removed and the fuel assembly strongback raised to the vertical position and locked. The new fuel handling tool, attached to the overhead crane, is then locked to the fuel assembly, the fuel assembly clamping fixtures are removed and the fuel assembly is removed from the shipping container. Next, the fuel assembly is moved over to the new fuel storage racks where it is placed into its designated cavity. (The fuel may also be moved directly to the new fuel elevator and placed in its designated spent fuel storage rack location.) The tool is unlocked from

the assembly and the operation repeated until all assemblies have been placed in the racks.

Prior to or during reactor refueling operations, the new fuel is removed from the new fuel storage racks and transferred to the new fuel elevator by using the overhead crane and the short fuel handling tool.

The new fuel elevator lowers the fuel assembly into the pool to allow the spent fuel handling machine to transfer the fuel assembly to the upending mechanism or storage location.

9.1.4.2.3.2 Dry Fuel Storage Refer to the NAC-UMS® FSAR for detailed description of the fuel basket, transportable storage container (TSC), vertical concrete cask (VCC), and the handling of these components. Refer to ISFSI 72.212 Evaluation Report for additional details regarding system operation. The principle design bases of the ISFSI are prescribed in the NAC-UMS Certificate of Compliance (CoC) and FSAR (Docket no. 72-1015).

With the spent fuel pool (SFP) gate installed, a transfer cask (TFR) containing a TSC is placed on the alignment stand in the cask loading pit (CLP). The single failure proof cask handling crane and the SAFLIFT are used to handle this heavy load. The CLP water level is equalized with the SFP level by transferring borated water from the RWT. When CLP and SFP water levels are equalized, the gate is removed. Spent fuel is loaded into the TSC using the spent fuel handling machine.

When fuel loading is complete, the SFP gate is reinstalled, and the shield lid is installed on the TSC using the cask handling

crane and the shield lid lift rig (SLLR). Once the shield lid is in position, the water level in the CLP can be lowered. The shield lid is welded, then the canister is drained, dried, and backfilled with helium. The water and air removed from the TSC using a vacuum drying skid is discharged into the SFP via temporary spargers. This process is necessary to assure there is no moisture remaining in the canister that could cause corrosion during storage. The helium is also necessary to maintain the heat transfer properties assumed in the NAC accident analyses. The canister is pneumatically tested and helium leak tested as part of the loading process to verify integrity of the confinement boundary. The structural lid is then installed and welded in place.

There are two temporary modifications that, when installed, support the dry cask loading process; 1) the Annulus Flush System (AFS) and 2) spargers connected to a vacuum drying skid. The temporary AFS provides positive pressure of filtered CLP water to the annulus between the TSC and the TFR. The AFS provides supplemental CLP water cleanup to reduce contamination levels on the TSC. Supply water comes from the CLP that it is processed through an ion exchange vessel and discharged into the TFR annulus. When installed, the ion exchangers are located on the 140’ elevation of the Fuel Building. A chiller and heat exchanger are provided for use if necessary to reduce CLP temperature during loading operations.

The TSC is then placed in the VCC using the cask handling crane, the SAFLIFT, and the TFR. The loaded VCC is then transported to the ISFSI along specifically designated transportation paths. The VCC is transported to the ISFSI

using a specially designed railcar and railcar mover. Once at the ISFSI, the VCC is removed from the railcar at the unloading pad and placed on its designated location on the storage pads. Transportation of the VCC at the ISFSI is performed using a hydraulic mobile lifting frame.

Once on the storage pad, the VCC air inlet and outlet temperatures are monitored by the temperature monitoring system. The temperature differential is surveilled as a means of determining OPERABILITY of the concrete cask heat removal system. This information is routed to the Unit 1 control room through the ISFSI interface shed. The interface shed provides a controlled environment to house the ISFSI security and environmental monitoring components.

9.1.4.2.3.3 Refueling Procedure. The following information provides a general description of the refueling activities. It is not intended to be totally inclusive of all activities, nor is it intended to be utilized as a procedure. Some of the evolutions described below may be performed in parallel with other refueling operations.

During cooldown of the reactor coolant system, preparations are begun for the refueling operation. The control element drive mechanisms (CEDMs) are disengaged from the control element assemblies extension shafts by de-energizing the CEDM electromagnets. The CEDM cabling is then disconnected in preparation for removal of the reactor vessel head. Refueling operations are initiated when the missile shield is removed from over the reactor vessel. The cable support structure, reactor vessel head vent line, nuclear cooling line, CEDM

ventilation ducts and reactor vessel head insulation are removed and stored in the appropriate laydown areas. The multiple stud tensioner (MST) is then set into place around the reactor vessel head. The MST then tensions the reactor vessel head studs such that the nuts may be removed. Once the nuts are removed, the MST stud handling vehicles are then utilized to remove the studs. Plugs and two guide pins are installed into the stud holes to prevent water from filling the stud holes once the reactor cavity is flooded for fuel movement. Openings in the reactor cavity pool seal are closed and leak tested. The ICI detectors are disconnected and withdrawn from the core region to allow the fuel assemblies to be moved. The Quick Operating Closure Device (QOCD) is removed to allow the fuel assemblies to be transported to and from the fuel building. The reactor vessel head delta beam is then installed on the reactor vessel head assembly. The reactor vessel head assembly is then lifted by the polar crane and transported to the head laydown stand. The refueling pool is partially filled while the head assembly is being transported to the head stand.

The upper guide structure (UGS) lift rig is installed on, and bolted to, the upper guide structure. The CEA extension shafts are then latched to the UGS lift rig working platform. The working platform is raised, withdrawing the CEAs from the reactor core into the UGS. As the working platform is raised, refueling pool water level is also increased until the normal water level for fuel movement is achieved. The UGS is then removed from the reactor vessel and transported to the UGS laydown area in the refueling pool. If CEAs are to be replaced or inspected, the extension shafts are uncoupled from the CEAs

and the UGS lift rig, with the CEA extension shafts, is moved to the UGS lift rig storage stand.

After correct water level in the refueling pool has been established and the UGS has been stored, the spent fuel pool to transfer canal gate is removed and the transfer tube gate valve is opened. These actions allow fuel assemblies to be moved between the reactor vessel and the spent fuel pool.

Refueling the reactor vessel now takes place. The reactor core may be entirely off-loaded to the spent fuel pool, or a fuel shuffle may take place. If the reactor core is to be off-loaded, each fuel assembly is removed from the reactor vessel by the refueling machine and placed into the transfer machine. The transfer machine transfers the fuel assembly to the fuel building, where it is removed from the transfer machine by the spent fuel handling machine. The spent fuel handling machine then places the fuel assembly into a storage location within the spent fuel pool. If a core shuffle is performed, approximately one-third of the fuel assemblies are removed from the reactor vessel and stored in the spent fuel pool. The remaining fuel assemblies are shuffled to accommodate the new core design as new fuel is transported and loaded into the reactor vessel. The fuel handling sequence is briefly described in the following paragraphs.

Once conditions for fuel movement are established, the refueling machine (RFM) is positioned over the desired core location. Alignment of the RFM to the desired fuel assembly is accomplished by verifying correct bridge and trolley position via a digital positioning readout system. After the hoist

grapple is positioned on the fuel assembly, the operator actuates the grapple actuator which rotates the hoist grapple such that it engages the fuel assembly. The fuel assembly is then hoisted into the RFM hoist box which protects the fuel assembly during transportation.

Once the fuel assembly has been hoisted to the correct elevation, the fuel assembly may then be transported to a different core location, the fuel transfer machine baskets or to a temporary storage rack. If the assembly is transported to a different core location or to a temporary storage rack, then the RFM is positioned over the desired location and the RFM position is verified via the digital positioning readout. The fuel assembly is then lowered into position. When correct positioning of the fuel assembly has been verified, the RFM operator will actuate the grapple actuator to disengage the grapple from the fuel assembly. The RFM hoist is then raised to allow safe movement of the RFM.

If it is desired to transfer the fuel assembly to the spent fuel pool, the RFM operator will position the RFM over the fuel transfer machine carriage baskets. The fuel assembly is then lowered into an empty basket and ungrappled from the RFM. If a core shuffle is in progress, the other basket may contain a replacement fuel assembly. The RFM operator will reposition the RFM over the replacement fuel assembly and remove it from the basket. The replacement fuel assembly will be inserted into the reactor vessel while the spent fuel assembly is transported to the fuel building by the fuel transfer system.

The fuel transfer system moves the fuel baskets to the horizontal position. Once the baskets are horizontal, the carriage drive actuates to transport the transfer carriage on tracks through the transfer tube to the fuel building. The fuel transfer baskets are then upended to the vertical position. If a core shuffle is in progress, the spent fuel handling machine (SFHM) may place a replacement fuel assembly in an empty fuel transfer basket. The spent fuel assembly is removed from the other fuel transfer basket by the SFHM and placed in an appropriate spent fuel pool storage location.

Removal and cutup of spent ICI detectors may take place during the refueling operation. This activity is not performed during each refueling outage - ICI detector replacement is dictated by the life of the ICI detectors.

If necessary, CEAs may be relocated or replaced within the UGS. This activity may occur simultaneously with fuel movement operations. The CEAs are moved using specialized tooling and the CEA change platform. Expanded CEAs are moved to the CEA elevator or other disposal location where the CEA fingers are cut and placed into a transport container. Remnant pieces of the CEA fingers, locking nuts and spiders are then removed from the refueling pool, disassembled and loaded into a disposal container. The transport container, with the cut CEA fingers in it, is transferred to the spent fuel pool using the fuel handling system where they will be stored or disposed of. New CEA fingers, spiders and locking nuts are assembled outside of the refueling pool and placed in the CEA elevator or are assembled in the CEA elevator. The new CEA assembly is then re-installed in the UGS.

Inspection of the fuel assemblies for leaks may be performed during fuel handling evolutions. The lower end of the fuel assembly is placed into the ultrasonic test, or other inspection, machine. The fuel assembly is then scanned to determine if any of the fuel pins are leaking. When the scan is complete, the fuel is removed from the machine and placed into the appropriate fuel location.

At the completion of fuel handling activities, the spent fuel pool to transfer canal gate is reinstalled and the transfer tube gate valve is closed. The UGS is reinserted into the reactor vessel. The refueling pool level is lowered and the CEAs are lowered into position. The reactor vessel head assembly is then placed on the reactor vessel and bolted into place. The remaining water in the deep ends of the refueling pool is drained and the QOCD is reinstalled. The refueling cavity pool seal hatches are opened. The ICI detectors are reinserted into the core region and reconnected. The cable support structure, reactor vessel head vent line, nuclear cooling line, CEDM ventilation ducts and reactor head insulation are installed. Placing the missile shield into position concludes the refueling operations.

References to the temporary pool seal in the section of the CESSAR are no longer applicable to PVNGS. Refer to PVNGS UFSAR Section 9.1.4.2.2.13 for a description of the permanent reactor cavity/refueling pool seal (PRCRPS) now used.

References to installing the pool seal and air testing for leak tightness in the CESSAR shall now be interpreted to mean the

closure and air testing of the access/air flow hatches on the PRCRPS.

References in the CESSAR to the removal of the refueling pool seal following fuel reload shall now be interpreted to mean the opening of the PRCRPS access/air flow hatches if desired at that time. (All six hatches must be removed prior to plant heat up.)

9.1.4.2.3.4 Telescope Fuel Sipping. Telescope fuel sipping may be implemented during fuel handling evolutions to identify cladding failures by detection of leaking gaseous and water soluble fission products. Sipping of fuel assemblies is performed during the initial de-fueling process in the refueling outage while the assemblies are being moved via the refueling machine between the reactor core and the transfer system. As the fuel assembly is raised from the reactor by the grapple, a reduced pressure condition is created in the water around the fuel assembly, resulting in a release of fission product gases into the water in the hoist box. A skid-mounted portable fuel sipping station located on the refueling machine bridge is connected to the hoist box fittings and draws water from a position close to the top of the fuel bundle. The sipping station separates the fission gases from the water and then circulates the fission gases through a sensitive Beta detector that measures the activity level as an indicator of cladding failure. The sampled water and gas are discharged back to the refueling pool.

9.1.4.3 Safety Evaluation

9.1.4.3.1 Cask Handling Crane

The cask handling crane is designed to transfer dry cask storage system components in the fuel building. The capacity of the crane is based on lifting the SAFLIFT^{tm}, and a transfer cask containing a fully loaded transportable storage canister including water.

The cask-handling crane is upgraded to meet the guidelines for single failure proof hoisting systems contained in NUREG-0612 Section 5.1.6, NUREG-0612 Appendix C, and NUREG 0554. The maximum critical load (MCL) and design rated load (DRL) of the main hoist on the upgraded crane are both 150 tons. The MCL and DRL of the auxiliary hoist are 15 tons.

The SAFLIFT^{tm} is designed to handle the dry fuel storage system transfer cask (TFR) with a transportable storage canister (TSC) containing 24 spent fuel assemblies. The SAFLIFT^{tm} is designed to meet the applicable guidelines for single failure proof special hoisting systems contained in NUREG-0612 Section 5.1.6, ANSI N14.6, and NUREG 0554. The MCL of the SAFLIFT^{tm} lift beam is 125-ton including the 50-ton MCL of the canister hoist and grapple.

The crane and lifting devices are designed such that a single failure of a critical component will not result in the loss of the capability to safely retain the load. Where redundant features are not practical the design safety factor has been doubled as recommended in NUREG-0612, ANSI-N14.6, and NUREG-0554 in order to provide enhanced safety. By designing

the crane and lifting devices to be single failure proof, it is not necessary to analyze the effects of postulated events involving loss of the load, which in turn cause a direct or indirect release of radioactivity. Similarly, it is also not necessary to analyze the effects of postulated events in which the loss of the load adversely affects the ability to mitigate the consequences of an accident.

The design of the fuel building structure, the runway and the crane bridge is not affected by the new single failure proof trolley since the existing bridge analysis bounds the new trolley weight. Therefore, there is no need to re-perform the structural analysis of the crane bridge girders, end ties, trolley rails, end trucks, crane runway, runway rails, and rail clips. As a result, seismic analyses are only performed for the new single failure proof trolley.

Since the existing bridges will not be modified, critical welds on the bridges are identified, nondestructively examined and repaired if required in accordance with UFSAR section 17.2 and AWS D1.1.

Components that are subject to wear are designed to carry a load approximately 15% higher than the MCL. This provides a margin in the crane’s load handling ability before it drops below its MCL capacity. See the single failure proof cask handling crane safety analysis report for details of the affected components and the specific design load.

The trolley is designed to operate at temperatures between 40 °F and 104 °F; however, the operating temperature of the

crane is limited to the fuel building licensing basis temperatures between 50 °F and 104 °F (Ref. UFSAR table 9.4-2).

The occurrence of a bridge girder brittle fracture failure is not credible. Brittle fracture is typically a concern with members whose thickness exceeds 5/8”, areas in tension with a stress riser present, and a relatively low temperature of structural steel member. The only primary load-carrying member of the existing bridge box girders whose thickness exceeds 5/8” is the top flange, which is 7/8” thick. Under normal operating loads, the top flange of the girder will be in compression only. Therefore, brittle fracture is not a concern for the existing bridge box girders.

The bridge, trolley and hoist motions are controlled by flux vector variable frequency drives that provide for smooth slow speed positioning and gradual acceleration and deceleration. These drives also provide dynamic braking.

Electrical controls are incorporated in the design to mitigate design basis events due to inadvertent operator action, component or sub-component malfunction, and/or site conditions that may occur during load handling. Design features on the main and auxiliary hoists include, overspeed and uncommanded motion detection, weight overload protection, redundant upper and lower limits, two-block protection, wire rope level wind limits, and unbalanced load detection. The bridge and trolley motions are provided with end of travel limit switches. There are emergency stop buttons located both in the cab and on the radio control transmitter.

Should the crane become immobilized with a critical load suspended, repairs, replacement or adjustment of failed or malfunctioning components may be made without affecting the ability of the crane to hold the load. The crane also has provisions for manual operation in the event of loss of electrical power. These provisions allow a suspended load to be transferred to a specific laydown area and safely lowered.

Both the main and auxiliary hoists are dual rope reeved with the load balanced between head and load blocks through the configuration of the ropes and rope equalizers. The design of the reeving limits the load experienced by the wire rope with the MCL attached to less than 10% of the manufacturer's published breaking strength. In the case of a broken rope, the design of the equalizer system limits the load on the intact reeving system to less than 40% of the breaking strength of the rope, including the dynamic effects of load transfer caused by the broken rope condition.

The main hoist sister hook and the auxiliary hook have been designed with a 10:1 safety factor to compensate for a single attaching point. NUREG-0612, Appendix C allows the use of a single attachment point for existing cranes if the hook height is limited by building height. If a single attachment point is employed, NUREG-0612 states that increasing the safety factor to 10:1 compensates for the loss of the single failure proof feature, and equals the total safety factor of the wire rope.

Two diverse limit switches are supplied to prevent two blocking. The lower limit switch is a geared type that counts drum rotations. The upper limit switch is a paddle type that

is actuated by contact of the lower block with the actuating arm if the low limit fails. Should both limits fail, protection against two blocking is provided by a mechanical slip clutch located between the gearbox and the motor, and by sizing of mechanical and structural components with the required strength to maintain integrity.

The wire rope is protected from side loads by limit switches that detect excessive unbalanced loading of the equalizer. The rope is also protected against jumping grooves on the drum by photoelectric sensors that are focused across the outside diameter of wire rope laying in the grooves. Should the rope jump grooves, it will break the beam during drum rotation and activate the switch.

Dynamic braking of both the main and auxiliary hoists is provided by the flux vector drive. Both hoists have primary and secondary holding brakes, which are single failure proof. On the main hoist, the gearbox is not of dual design since the secondary holding break system is mounted on the hoisting drum which provides single failure proof design. The auxiliary hoist has dual gearboxes to account for single failure proof design since they are mounted between the drum and the secondary holding brakes. The brakes are all sized with sufficient capacity to stop the full load of the respective hoist. Each of the breaking systems are designed for fail safe operation.

Trolley and bridge dynamic braking is provided by the flux vector variable frequency drive system. This system also provides overspeed protection and torque limiting. Both the

dynamic brakes and the holding brakes are rated at greater than 100% of the maximum driving torque at the point of application. The holding brakes for both the trolley and bridge are fail safe with manual release provided. They are electrically actuated during normal operation and cannot be used as slow-down brakes.

The crane can be operated from the cab or by radio control. Selecting one mode of operation disables the other.

Critical load bearing components of the crane (main hoist, trolley frame, and bridge girders) and SAFLIFT^{tm} (Lift Beam, Cask hooks, 50-ton hoist, 50-ton Grapper, and Canister Ring) are classified as Seismic Category I, Quality Class Q since the crane and SAFLIFT^{tm} will be handling TSCs containing irradiated nuclear fuel. Critical load bearing components are designed to remain functional during and after SSE or OBE events.

9.1.4.3.2 New Fuel Handling Crane

The new fuel handling crane is designed so that through the use of interlock and operating procedures the hoisting load is limited to 5000 pounds and a key-operated interlock override is used to allow crane operation over the spent fuel pool. Additional design details are discussed in paragraph 9.1.4.2.2.17.

9.1.4.3.3 Containment Polar Crane

The operation of the containment polar crane during lifting and lowering the reactor vessel closure head is described as follows:

In preparation for refueling, the crane lifts the closure head, transports it to the laydown area of the refueling floor where the closure head is temporarily stored. The crane is then used for other lifting functions during the refueling operation. The main hoist raise circuit limit switch is equipped with an administratively controlled key operated bypass switch that enables override of the 40 ft limit. The bypass switch is used for lifts other than the reactor vessel closure head under administrative controls.

The trolley travel exclusion zone interlock circuit is also administratively controlled by a key operated switch that can be bypassed when fuel is present for removal and replacement of the Reactor Vessel Head and the Upper Guide Structure and for movement of loads located in the area above the reactor vessel.

9.1.4.3.4 Fuel Handling

A failure mode analysis is described in Table 9.1-4.

Direct communication between the control room and the refueling machine console is available whenever changes in core geometry are taking place. This provision allows the control room operator to inform the refueling machine operator of any impending unsafe condition detected from the main control board indicators during fuel movement.

Functionality of the fuel handling equipment including the bridge and trolley, the lifting mechanisms, the upending machines, the transfer carriage, and the associated instrumentation and controls is assured through the implementation of pre-operational tests and routines. In

addition to the interlocks described in section 9.1.4.2.1, the equipment has the following special features:

A. The major systems of the fuel handling system are electrically interlocked with each other to assist the operator in properly conducting the fuel handling operation. Failure of any of these interlocks in the event of operator error will not result in damage to more than one fuel assembly.

B. Miscellaneous special design features which facilitate handling operations include: backup hand operation of the refueling machine hoist and transverse drives in the event of power failure; backup hand operation of the CEA change platform traverse drives in the event of power failure. A two speed transmission is installed on the transfer machine winch skid to permit applying an increased pull on the transfer carriage in the event it becomes stuck; a viewing port in the refueling machine trolley deck to provide visual access to the reactor for the operator; electronic and visual indication of the refueling machine position over the core; a protective shroud into which the fuel assembly is drawn by the refueling machine; transfer system upenders manual operation by a special tool in the event that the hydraulic system becomes inoperative.

C. The fuel transfer tube is sufficiently large to provide natural circulation cooling of one irradiated fuel assembly in the unlikely event that the transfer carriage should be stopped in the tube.

D. The manual operator for the fuel transfer tube valve extends from the valve to the operating deck. Also, the valve operator has enough flexibility to allow for operation of the valve even with thermal expansion of the fuel transfer tube.

E. Travel stops in both the refueling and spent fuel handling machines restrict withdrawal of the spent fuel assemblies. This results in the maintenance of a minimum water cover of 9 feet 5 inches over the active portion of the fuel assembly resulting in a radiation level of 2.5 mr/hr or less at the surface of the water. The depth of water surrounding the fuel transfer canal, transfer tube and spent fuel storage pool is sufficient to limit the maximum continuous radiation levels in working areas to 2.5 mr/hr.

9.1.4.3.5 Reactor Vessel Closure Head Handling

The reactor vessel closure head is a heavy load that by necessity must be transported above irradiated fuel in the vessel in order to perform core off-load and reactor reassembly operations. Since the containment polar crane is not single-failure proof, a reactor head drop is a credible event that may damage fuel resulting in significant offsite exposures. Per the guidance in NUREG-0612 and NEI 08-05, the effects of a postulated load drop event have been analyzed using realistic calculation to demonstrate that the potential consequences are acceptable.

Operating experience shows that special lifting devices such as the head lift rig are extremely reliable, and problems tend to

be self-revealing at an early stage in the lift sequence. Consequently, malfunction of the polar crane or operator error are the only credible failure mechanisms that may result in a dropped head. To analyze this event, the assumed drop weight accounts for the reactor head, the lifting rig, and the remainder of the head assembly. The weight of the crane hook or load block need not be included because they cannot impact simultaneously with the head if dropped. Failures in the handling system are postulated to occur directly above the head’s center of gravity and so impart no significant rotational movement to the head. The result is a flat drop which conservatively transfers more load to vessel internal components than the case where the head rotates as impact. Because drops beyond the outer radius of the vessel flange would likely transfer substantial energy to structures other than the reactor vessel, a concentric orientation is more limiting than an offset drop. Load drops form locations prohibited by interlock or procedures were not considered credible because they would require either an interlock malfunction or a human error in combination with an additional crane failure, which would exceed the single failure criterion.

The analysis considers the flat, concentric drop of a head assembly weighing 400,000 pounds from a height of 40 feet. Since the refueling pool may or may not contain water during head movement, the head is assumed to fall through air; no credit is taken for water to slow the head descent or otherwise dissipate the impact energy. The head is conservatively assumed to be perfectly rigid because plastic deformation of the head would reduce the energy deposited in the system. The

head drop calculations utilize a hybrid approach involving both classical lumped mass-spring models of assemblies and also three-dimensional finite element modeling of critical components. Static and dynamic, non-linear, elastic-plastic analyses were performed using codes approved for safety related applications in accordance with the methodology provided in NEI 08-05 with minor exceptions as described below.

The reactor coolant system evaluation used a lumped mass and stick model similar to that shown in Figure 3.7-9B. This model, developed previously for seismic and LOCA blowdown analysis, is suitable for an impact transient but was modified to account for the locally high, non-linear, elastic-plastic effects. All major system components, including supports and a simplified representation of the reactor internals and fuel, were incorporated to more accurately model the distribution of vibration energy in a coupled system. The effective spring stiffnesses of the reactor of the reactor vessel support columns were computed based on an elastic-plastic analysis of the columns and a static finite element analysis of the primary biological shield structure using ANSYS (refer to Section 3.9.1.2.1.8). Piping branch connections with negligible contribution to the dynamic response were omitted. The transient analysis is initiated when the head weight is allowed to dynamically impact the reactor vessel with the velocity determined from the kinetic energy of the fall. Time-varying stress intensities were calculated using ANSYS and compared to the Level D services limits in Appendix F of ASME Boiler and Pressure Vessel Code. The 1983 code year was selected over the original construction code because it

provided more appropriate criteria for the analysis. The initial results showed that the bolts that anchor the reactor vessel support column base plates to the biological shield structure fail during rebound. The event was re-analyzed assuming that the bolts break at the moment of peak tensile stress, and thereafter the vessel support columns were modeled as only proving compressive restraint (no upward vertical stiffness). With the bolts either intact or failed, the structural integrity of the vessel and main loop piping was sufficient to maintain shutdown cooling.

The effect of the head drop impact on the primary bioshield structure supporting the reactor vessel was also considered. The relevant portions of the reactor vessel support structure and the containment base mat were represented in a simplified 3-D finite element model using ANSYS that included all openings that could significantly influence the overall structural response. Property data were taken from project design specifications and the construction codes as applicable. Credit was taken for the increase in compressive strength of concrete due to aging based on actual 91-day test results, and an additional increase for dynamic loads events was also considered. Although 28-day data were not used for aging as described in NEI 08-05, the 91-day data are representative of the installed properties and thus consistent with a realistic evaluation of the transient. The primary shield concrete structural dynamic response was analyzed with ANSYS using the interface force and moment time-histories developed from the reactor coolant system analysis for cases where the vessel support column anchor bolts failed or remained intact.

Resultant stresses in critical areas were compared to the inelastic limits in ACI 349-06 for concrete (with amendments per Regulatory Guide 1.142) and AISC N690 for steel. Use of the 2006 edition of ACI 349 instead of the 1997 edition described in NEI 08-05 has negligible impact on the analysis. The impact load response of the primary shield structure region that bridges over the in-core instrument chase lies in the inelastic range. Energy balance methods were used to determine the inelastic response ductilities for comparison with code allowables. The structural response to the impact attenuates rapidly away from the vessel support column base plate region where the maximum loading occurs. Although some crushing of concrete may occur immediately below the base plates, this minor and localized damage has a negligible effect on the overall structural integrity of the vessel support system.

The reactor vessel internals were modeled using a lumped mass and stick model considering vertical displacements only. A stick representation similar to the seismic model shown in Figure 3.7.40-8 was expanded to include the effects of the vessel supports, and non-linear spring elements were added to account for energy dissipation due to plastic deformation, friction, and hydrodynamic interaction. Initial displacements due to the deadweight of the internal components were determined using STATIC. Then they dynamic response and peak forces in the elements resulting form the impact were calculated by CESHOCK (refer to Section 3.9.1.2.3.5). The upper guide structure (UGS) flange is indirectly supported by the vessel flange via the holdown ring and the core support barrel. In a postulated head drop, the head first contacts the

UGS, which would be transmitted to the reactor vessel flange, forcing the vessel downward, compressing the vessel supports, and rebounding. The peak loads experienced during the transient analysis were compared to Level D service limits in Appendix F of the 1974 ASME Code with no addenda. For critical members subject to bending, elastic-plastic finite element static analyses with solid 3-D elements were performed using ANSYS to determine the load-deflection behavior. The results indicate the fuel is not damaged, and the vessel and internals experience limited deformation that does not prevent adequate core cooling.

As a heavy load, the reactor head is moved using the administrative controls described in NUREG-0612 and Regulatory Guide 1.160, Revision 3, which serve to reduce the probability of a dropped load. The analyses above demonstrate that the postulated drop of the reactor vessel head will not result in damage to irradiated fuel directly due to the impact or indirectly through loss of core cooling capability. Minor deviations from the guidance in NEI 08-05 had minor effects on the results that were small in comparison with the overall uncertainty of the analysis. Additionally, head removal and installation with fuel in the vessel are performed with “containment closure” as defined in the Technical Specification Bases to provide further defense in depth for the reduction of potential radioactive release consequences. These programmatic controls ensure that the overall risk from reactor head movement remains at an acceptably low level.

9.1.4.4 Testing and Inspection Requirements

During manufacture of the fuel and CEA Handling Equipment at the vendor's plant, various in-process inspections and checks are required including certification of materials and heat treating, and liquid-penetrate or magnetic-particle inspection of critical welds. Following completion of manufacture, compliance with design and specification requirements is determined by assembling and testing the equipment in the vendor's shop. Utilizing a dummy fuel assembly having the same weight, center of gravity, exterior size and end geometry as an actual assembly, all equipment is run through several complete operational cycles. All traversing mechanisms are tested for speed and positioning accuracy. All hoisting equipment is tested for vertical functions and controls, rotation, and load misalignment.

Hoisting equipment is also tested to 125 percent of specified hoist capacity. Set points are determined and adjusted and the adjustment limits are verified. Equipment interlock functions, and backup systems operations are checked.

Those functions having manual operation capability are exercised manually. During these tests, the various operating parameters such as motor speed, voltage, and current, hydraulic system pressures and load measuring accuracy and set points are recorded. At the completion of these tests the equipment is checked for cleanliness and the locking of fasteners by lockwire or other means is verified.

Equipment installation and testing at the plant site is controlled by approved installation procedures and

pre-operational test procedures designed to verify conformance with procurement specifications. Each component is inspected and cleaned prior to installation into the system. Recommended maintenance, including any necessary adjustments and calibration, is performed prior to equipment operation. Preoperational tests also include checks of all control circuits including interlocks and alarm functions.

9.1.4.5 Instrumentation Requirements

The refueling system instrumentation and controls are described in Paragraph 9.1.4.2. No credit is taken for instrumentation or interlocks on components of the fuel handling equipment to either prevent or mitigate the consequences of the postulated accident. Thus, safety-related interlocks are not provided.

9.1.4.6 CESSAR Interface Requirements

Below are detailed the interface requirements that reactor vessel closure head lifting and the fuel handling system places on certain aspects of the BOP, listed by categories. Additionally, refer to subsection 4.2.1 for additional containment polar crane interface requirements.

A. Power

   1. At least 24.0 kVA shall be provided to power the fuel handling system.

   2. Instrument air and power shall be provided for the refueling equipment.

B. Protection from Natural Phenomena

1. Protection shall be provided in accordance with Criterion 2 of 10CFR50, Appendix A.

C. Protection from Pipe Failure

Not Applicable

D. Missiles

Not Applicable

E. Separation

Not Applicable

F. Independence

Not Applicable

G. Thermal Limitations

Not Applicable

H. Monitoring

Not Applicable

I. Operational/Controls

1. If a single failure can cause the reactor vessel closure head assembly to drop on the reactor vessel flange, the reactor vessel closure head assembly shall not be raised to a height greater than 17 feet while above the reactor vessel flange.

2. Equipment design and building arrangement shall be such that during all phases of expended fuel handling and storage minimum water coverage of

9 feet above the active portion of the fuel assembly shall be maintained to provide adequate shielding for the protection of operating personnel. A nominal 2-foot pool freeboard should be employed.

Equipment shall be provided for moving reactor vessel surveillance specimens, neutron sources, expended CEAs and expended ICIs through the transfer tube and to allow handling or storage of these items in the fuel storage building.

J. Inspection and Testing

Not Applicable

K. Chemistry/Sampling

Not Applicable

L. Materials

Not Applicable

M. System/Component Arrangement

1. The depth of the spent fuel pool shall be such that a fuel rod assembly lying horizontally on the top of the fuel racks shall be covered by a water depth of at least 23 feet.

N. Radiological Waste

Not Applicable

O. Overpressure Protection

Not Applicable

P. Related Services

1. Refueling Pool

   a. Within the pool, embedment and foundation supports shall be designed to accommodate the design loads from the equipment installed for refueling.

   b. Adequate underwater areas shall be provided for storage of the internals and tools without interfering with the refueling operation.

2. Spent Fuel Pool

   a. Within the pool, embedment and foundation supports shall be designed to accommodate the design loads from the equipment installed for refueling.

   b. Adequate underwater areas shall be provided for storage of tools and equipment without interfering with the refueling operation.

   c. Drains, permanently connected systems, and other features of the spent fuel pool shall be designed so that neither maloperation nor failure can result in loss of coolant that would uncover the stored fuel.

   d. Spent fuel pool cooling shall be capable of removing the decay heat generated from all spent fuel placed in the pool.

3. During reactor operation, the tools and equipment on Table 9.1-1 shall be stored in such a manner as to maintain the tools in a safe condition and to prevent them from damaging safety class equipment during a seismic excursion.

4. Motion between the fuel transfer tube support points shall be limited to 3/4 inch.

   a. Supports for the transfer tube shall be provided to allow for thermal expansion and for seismic loadings.

5. A fire protection system shall be provided to protect the fuel handling system consistent with the requirements of GDC 3, and shall include, as a minimum, the following features:

   a. Facilities for fire detection and alarming.

   b. Facilities or methods to minimize the probability of fire and its associated effects.

   c. Facilities for fire extinguishment.

   d. Methods of fire prevention such as use of fire resistant and noncombustible materials whenever practical, and minimizing exposure of combustible materials to fire hazards.

   e. Assurance that fire protection systems do not adversely affect the functional and structural integrity of safety related structures, systems, and components.

f. Care should be exercised to ensure fire protection systems are designed to assure that their rupture or inadvertent operation does not significantly impair the capability of safety-related structures, systems, and components.

Q. Environmental

1. Containment Ventilation Requirements

a. During refueling operations, the containment ventilation system must be capable of maintaining the ambient temperature within the range of 60F - 120F.

9.1.4.7 CESSAR Interface Evaluation

CESSAR interface requirements listed in paragraph 9.1.4.6 are met by PVNGS design as follows and, in addition, refer to subsection 4.2.6 for the evaluation of additional containment polar crane interface requirements.

A. Power

1. At least 24 kVA is provided to power the fuel handling system.

2. Instrument air and power are provided for the refueling equipment.

Table 9.1-4
(Sheet 1 of 2)
FAILURE MODE ANALYSIS OF FUEL HANDLING EQUIPMENT

Component Identification	Failure Mode	Detrimental Effect on System	Corrective Action	Remarks
R. M. Fuel Hoist weight system	Electrical Overload Trip fails	None	Continue refueling, repair on non-interfering basis	Use visual presentation load on meter.
Fuel carrier	Wheels lock in transfer Tube	Transfer Operation can be completed	Move carriage in opposite direction. If carriage does not move, then use handwheel at lower gear ratio to move carriage in both directions.	Power Sufficient to move fuel carrier with all wheels locked.
Hydraulic Power supply for upender	Line to cylinder on upender ruptures	None	Valve off defective line	Upender has two cylinders, each of which is capable of raising upender.
	Loss of hydraulic power	Process can continue on slower basis	Upend manually	Use tool provided.
Brake on R.M. fuel hoist	Does not provide required brake load	None	Continue, repair on noninterfering basis	Redundant brake system provided
Fuel Carrier Cable	Cable parts	Delays refueling	Move fuel carrier to safe position with manual tool	Remove fuel prior to repair
R. M. Hoist Motor	Power Failure	Delays refueling	Repair	Hoist using manual handwheel

Table 9.1-4
(Sheet 2 of 2)
FAILURE MODE ANALYSIS OF FUEL HANDLING EQUIPMENT

Component Identification	Failure Mode	Detrimental Effect on System	Corrective Action	Remarks
Bridge Drive Motor	Power Failure	Delays refueling	Repair	Drive using manual hand-wheel
RFM electronic hoist position indication	Electrical Failure	None	Repair	Redundant indicators are provided
Fuel Carrier Position Sensing System	Electrical Failure	None	Repair	
Refueling Machine	Loss of air pressure	None	Repair	Continue, using manual mode
Refueling Machine TV Camera	Electrical Failure	None	Repair on noninterfering basis	Non-mandatory for fuel handling
Refueling Machine Electronic hoist position indication	Electrical Failure	None	Repair on noninterfering basis	Redundant mechanical counter provided
Reactor Vessel Closure Head Assembly Lift Rig	Mechanical Failure	Possible local damage to vessel head assembly and internals.	Repair	Core maintained in a coolable array

B. Protection from Natural Phenomena

1. All safety-related pumps and components are located in Seismic Category I structures. The protection of Seismic Category I structures against natural phenomena is presented in subsections 3.3.4 and 3.4.4.

C. Protection from Pipe Failure

Not Applicable

D. Missiles

Not Applicable

E. Separation

Not Applicable

F. Independence

Not Applicable

G. Thermal Limitations

Not Applicable

H. Monitoring

Not Applicable

I. Operational/Controls

1. The reactor vessel closure head assembly will not be raised to a height greater than 18 feet above the reactor vessel flange while over the reactor vessel.

References to the reactor vessel closure head assembly raised height of 18 feet are no longer

applicable to PVNGS. Refer to section 9.1.4.3.5 for closure head lift height evaluation.

2. Water shielding in excess of 9 feet can be obtained with 27 inches of freeboard. Equipment is provided to move reactor vessel surveillance specimens, neutron sources, and expended ICIs through the transfer tube and to allow handling or storage in the fuel building.

J. Inspection and Testing

Not Applicable

K. Chemistry/Sampling

Not Applicable

L. Materials

Not Applicable

M. System/Component Arrangement

1. The depth of the spent fuel pool will be such that a fuel rod assembly lying horizontally on top of the fuel racks will be covered by a water depth of at least 22 feet and 6 inches. Refer to sections 1.9 and 15.7.4.1.3.C.

N. Radiological Waste

Not Applicable

O. Overpressure Protection

Not Applicable

P. Related Services

1. Refueling Pool

   a. Within the pool, embedment, and foundation supports are designed to accommodate the design loads from the equipment installed for refueling.

   b. Adequate underwater areas are provided for storage of the internals and tools without interfering with the refueling operation.

2. Spent Fuel Pool

   a. Within the pool, embedment and foundation supports are designed to accommodate the design loads from the equipment installed for refueling.

   b. Adequate underwater areas are provided for storage of tools and equipment without interfering with the refueling operation.

   c. Drains, permanently connected systems, and other features of spent fuel pool have been designed so that neither malfunction nor failure can result in loss of coolant that would uncover the stored fuel.

   d. Spent fuel pool cooling capability is sufficient to remove the decay heat generated from all spent fuel placed in the pools.

3. During reactor operation, the tools and equipment noted on CESSAR Table 9.1-1 are stored in such a manner as to maintain the tools in a safe condition and to prevent them from damaging safety class equipment during a seismic excursion.

4. Motion of fuel transfer tube supports due to seismic building movements will be less than ¾ inch. The transfer tube supports are designed to accommodate seismic and thermal expansion movements and loads.

5. Fire protection for the fuel handling system is discussed in subsection 9.5.1.

Q. Environmental

The containment ventilation system is capable of maintaining the ambient temperature within the range of 70 to 100F.

9.1.5 OVERHEAD HEAVY LOAD HANDLING SYSTEMS (OHLHS)

9.1.5.1 Program Requirements

A Heavy Loads Program is established to implement the guidelines of NUREG-0612 (Control of Heavy Loads at Nuclear Power Plants). These guidelines provide defense in depth against load handling accidents that could result in the release of radioactivity in excess of 10CFR100 limits.

A heavy load is defined as a load whose weight is greater than the combined weight of a single spent fuel assembly, CEA, and

its associated handling tool. The handling of a single spent fuel assembly has been reviewed in the original licensing review or in the Generic Issue “Fuel Handling Accident Inside Containment.” The heavy load for PVNGS is 1480 pounds for the spent fuel assembly and 760 pounds for the handling tool, for a combined weight of 2240 pounds. For convenience and conservatism, PVNGS considers loads in excess of 2000 pounds as heavy loads.

The NRC has established seven general guidelines in NUREG-0612 that must be met in order to provide the defense-in-depth approach for the handling of heavy loads. These seven guidelines should be satisfied for all overhead handling systems that handle heavy loads in the vicinity of the reactor vessel, near spent fuel in the spent-fuel pool, or in other areas where a load drop may damage safe shutdown systems. The following guidelines from Section 5.1.1 (Phase 1) of NUREG-0612 should be satisfied for all heavy load handling unless other alternative measures are taken:

1. Safe load paths
2. Procedures
3. Crane operators
4. Special lifting devices
5. Lifting devices that are not specially designed
6. Crane (inspection, testing and maintenance)
7. Crane (design)

Alternative measures may be taken to compensate for deficiencies in safe load paths, mechanical stops, or

electrical interlocks. These alternative measures can include: increasing crane reliability; restricting crane operations over the spent fuel pool until fuel has decayed sufficiently to limit offsite doses to acceptable levels; or, analyzing the effects of postulated load drops to show that the consequences are within acceptable limits. These alternative guidelines are described in detail in Section 5.1.2 through 5.1.6 (Phase II) of NUREG-0612.

NUREG-0612 Phase II guidelines have been implemented as an alternative means of compensating for deficiencies in safe load paths associated with: spent fuel in the transportable storage canister (TSC); handling of the loaded canister; and, handling of heavy loads in the vicinity of the fuel building essential air filtration units. The Phase II guidelines have been met for the cask handling crane and associated lifting devices by implementation of NUREG-0612, Section 5.1.6 (Single-Failure-Proof Handling Systems).

9.1.5.2 References

All references regarding Heavy Loads, NUREG 0612, and the Reactor Vessel Closure Head (RVCH) drop analysis, including the licensing correspondence previously contained in the section, have been consolidated in Section 9.1.6.

9.1.5.3 Applicability

The cranes and special lifting devices that are used to handle heavy loads in accordance with the heavy loads program are identified in table 9.1.5-1.

9.1.5.4 Compliance with Guidelines

9.1.5.4.1 Safe Load Paths

NUREG-0612 requires that the safe load path be painted on the floor. APS instead identifies the safe load paths in procedures and work documents. In certain cases, exclusion zones may be established in lieu of safe load paths to prevent heavy loads from encroaching on either spent fuel or safe shutdown equipment. In this case, handling of heavy loads may take place in areas outside the exclusion zone, but safe load paths or other compensatory measures must be established if carrying a heavy load within the exclusion zone. A signal person is required to verify the safe load path prior to lifting the load.

General guidelines for establishing safe load paths are contained in the rigging control procedure. Deviations from approved safe load paths require an approved engineering evaluation and changes to the appropriate procedures. Plant Safety Review Board approval is not required as detailed in NUREG-0612 guideline 5.1.1(1).

The fuel building cask handling cranes are single failure proof in accordance with NUREG-0612 Appendix C, and NUREG-0554. Heavy loads handled with this crane may deviate from established safe load paths/exclusion zones only when necessary. Approval for deviations from safe load paths/exclusion zones may be justified based upon the fact that the increased reliability of the crane and associated lifting devices makes the probability of a load handling accident extremely small.

9.1.5.4.2 Procedures

Procedures are established to cover load-handling operations for heavy loads that are or could be handled over or in proximity to irradiated fuel or safe shutdown equipment. These procedures should include:

- identification required plant conditions and equipment that are prerequisites for performing these lifts
- inspection, tests, and acceptance criteria required before movement of loads
- verifications and oversight required for movement of loads
- qualifications and training of riggers and crane operators
- the steps and proper sequence to be followed in handling the load
- defining the safe load paths
- maintenance requirements for rigging and cranes, and
- other special precautions

These controls may be contained in either administrative or technical procedures as appropriate.

Heavy load lifts during outages are controlled by the appropriate procedures. Heavy load lifts are evaluated as maintenance activities using the maintenance rule risk assessment procedures in compliance with Regulatory Guide 1.160 as described in Section 1.8.

Heavy load lifts by both the polar crane and pedestal crane are allowed to occur simultaneously through defense-in-depth

approach. Crane design and administrative controls that mitigate common cause failure are:

- different crane designs
- both cranes are designed to maintain structural integrity with load during an SSE
- both cranes are designed to not drop a load on loss of power
- rigging meets the appropriate standard design requirements
- rigging used for heavy loads is engineered with at least a 15% safety margin
- independent rigging crews and operators are used for the cranes
- rigging crews and operators must attend a high risk evolution briefing for heavy loads lifts
- safe load path verification is performed prior to lift
- rigging is checked by different qualified individual prior to lift

9.1.5.4.3 Crane Operators

Procedures are established to assure that individuals operating OHLHS are trained and qualified in accordance with applicable sections of ANSI B30.2, Overhead and Gantry Cranes. These procedures provide assurance that individuals certified as crane operators have the necessary knowledge level, proficiency level and physical capabilities commensurate with the importance to safety of the duties they perform.

9.1.5.4.4 Special Lifting Devices

Special lifting devices are listed in Table 9.1.5-1.

NUREG-0612 states that special lifting devices should satisfy the guidelines of ANSI N14.6, Standard for Special Lifting Devices for shipping Containers Weighing 10000 Pounds (4500kg) or More for Nuclear Materials with the exception that the stress design factor should be based on the combined maximum static and dynamic loads that could be imparted on the handling device based on the characteristics of the crane that will be used.

Special lifting devices used in single failure proof applications meet the augmented requirements of NUREG-0612, Section 5.1.6(1)(a). These devices either employ dual load paths or are designed with twice the design safety factor as is required for special lifting devices.

The special lifting devices that are designated for use with the containment polar crane were designed to ANSI N14.6 unless otherwise noted in Table 9.1.5-1. The special lifting devices designed by C-E or Westinghouse have been analyzed for potential load drops and the effects have been found acceptable. Administrative controls require all new special lifting devices to be designed in accordance with NUREG-0612 Section 5.1.1 or 5.1.6 as applicable.

The special lifting devices designed by CE that are designated for use with the containment polar crane are subject to different testing and inspection criteria than recommended in ANSI N14.6. These devices are subject to the following testing and inspection:

a) Performance of a visual inspection on the special lifting devices at the beginning of each refueling outage, prior to the returning the device to service. Dimensional testing shall be performed if indications from the visual inspections warrant it. Every third refueling outage ($\pm$ one refueling outage) the inspections shall be performed, in accordance with item b) or c).

b) Performance of a complete visual inspection with applicable NDE tests (magnetic particle testing and liquid penetrant testing) at all major load-carrying welds and critical areas defined in EER 87-ZC-072. NDE of the Reactor Vessel Head Lift Rig may be performed with the lift rig removed from the Containment Building during the operating cycle. Dimensional testing shall be performed if indications from either the visual inspections or NDE testing warrant further inspection, or

c) Performance of a 125% minimum load test followed by a complete visual inspection. Perform dimensional testing, if required, as a result of the load test or visual inspection.

Testing and inspection of all other special lifting devices shall be performed in accordance with applicable guidelines of ANSI N14.6.

9.1.5.4.5 Lifting Devices That Are Not Specially Designed

These devices include slings, shackles, rigging eyes, and other “off the shelf” type devices. NUREG-0612 requires these devices to be sized in accordance with ASME B30.9, Slings,

except that the load used in selecting the device must be based on the combined maximum static and dynamic loads that could be imparted on the device based on the characteristics of the crane that will be used.

Devices used in single failure proof applications meet the augmented requirements of NUREG-0612, Section 5.1.6(1)(b). The devices either employ dual load paths or are selected based on twice the load as is required for other devices used to handle heavy loads.

The lifting device designed by Bechtel (SLD 4 of Table 9.1.5-1) is maintained, tested and inspected in accordance with 9.1.5.4.4 a) through 9.1.5.4.4 b). All other lifting devices that are not specifically designed are tested and inspected in accordance with ASME B30.9 – slings.

9.1.5.4.6 Crane Inspection, Testing, and Maintenance

Administrative controls are established to perform inspection, testing, and maintenance of OHLHS overhead cranes in accordance with chapter 2-2 of ASME B30.2.

9.1.5.4.7 Crane Design

OHLHS cranes and hoists are designed and fabricated in accordance with applicable sections of ASME B30.2, CMAA Specification 70, and CMAA Specification 74.

9.1.5.4.7.1 Single Failure Proof Crane Design

OHLHS Cranes that are required to handle heavy loads in the vicinity of spent fuel or safe shutdown equipment, are either

analyzed for postulated load drops, or are designed with increased reliability to make the probability of postulated load handling accidents extremely small. NUREG-0612, Section 5.1.6 and Appendix C, and NUREG-0554 contain guidelines for crane design to provide increased reliability through the use of dual load paths or increased design stress factors. It is not necessary to analyze the effects of postulated load drops for single failure proof cranes, since the probability of occurrence is extremely small.

The cask handling cranes are upgraded to meet the guidelines of NUREG-0612, Section 5.1.6. The trolleys on the upgraded cranes meet the guidelines of NUREG-0554 (Single-Failure-Proof Cranes) and NUREG-0612, Appendix C (Modification of Existing Cranes). To comply with guidelines for prevention of brittle fracture of the girders, operation of the cask handling cranes are restricted to temperatures between 50°F and 104°F, inclusive (ref. UFSAR Table 9.4-2).

9.2 WATER SYSTEMS

9.2.1 STATION SERVICE WATER SYSTEM (ESPS)

The station service water system, referred to as the essential spray pond system (ESPS), removes heat from engineered safety features (ESF) and safety-related components and dissipates it to the atmosphere via the essential spray ponds (ultimate heat sink).

The ESF and safety-related components served by the ESPS are:

- Standby diesel generator cooling systems
- Essential cooling water system (ECWS) heat exchangers

The ESPS includes safety-related components and components used for ESPS water cleanup and chemistry control. It is operated in an emergency situation and in conjunction with a normal reactor shutdown. During normal plant operation, the ESPS may be operated in support of several auxiliary systems including emergency diesel generators, shutdown cooling, essential chillers, fuel pool cooling, and nuclear cooling water priority loads, as well as for chemistry control, and testing. The system is also actuated each time the standby diesel generators are started and on loss of offsite power.

Each generating unit is provided with two redundant, safety-related ESPS trains. There are no interconnections or cross connections with any other PVNGS unit's ESPS.

The ESPS provides the cooling water needed for those components that must operate following a loss-of-coolant accident (LOCA) and that are essential to a safe reactor shutdown.

The ESPS is shown in engineering drawings 01, 02, 03-M-SPP-001. Table 9.2-1 lists the safety-related component heat loads and associated water requirements for the ESPS and the ECWS.

In addition, table 9.2-1 cross-references the sections covering the related systems that include the safety-related components listed.

The ESPS will be operated in accordance with Technical Specifications.

9.2.1.1 Safety Design Bases

Safety design bases pertinent to the ESPS are as follows:

A. Safety Design Basis One

The ESPS, in conjunction with the ultimate heat sink and the ECWS, shall be capable of removing sufficient heat to ensure a safe reactor shutdown coincident with a loss of offsite power.

B. Safety Design Basis Two

The ESPS, in conjunction with the ultimate heat sink, shall be capable of maintaining the ECWS temperature to the essential chiller at 135°F or less following the design basis LOCA under the most adverse historical meteorological conditions consistent with the requirements of Regulatory Guide 1.27.

C. Safety Design Basis Three

A single failure of any component in the ESPS will not impair the ability of the ESPS to meet its design

requirements because two 100% redundant trains are provided.

D. Safety Design Basis Four

Adverse environmental occurrences will not impair the ability of the ESPS to meet its functional requirements.

E. Safety Design Basis Five

The ESPS shall be designed to detect leakage of pond water from the ESPS.

F. Safety Design Basis Six

The ESPS shall be designed to minimize the effects of long-term corrosion and organic fouling.

G. Safety Design Basis Seven

The ESPS shall be designed to withstand the effects of a safe shutdown earthquake (SSE).

H. Safety Design Basis Eight

All components of the ESPS shall be capable of being fully tested during normal plant operation. In addition, all parts and components shall be accessible for inspection at any time.

I. Safety Design Basis Nine

The ESPS, in conjunction with the ultimate heat sink and the ECWS, provides cooling capability for the spent fuel pool when the spent fuel pool normal cooling system is not available.

Table 9.2-1
TABULATION--HEAT LOADS AND WATER REQUIREMENTS
ESSENTIAL SPRAY POND SYSTEM AND ESSENTIAL COOLING WATER SYSTEMS (Sheet 1 of 2)

Component	Related System	FSAR Section Reference	Heat Load (10^6 Btu/h) Note 11			Water Flow (gal/min)		
			3.5 h After Shutdown	27.5 h After Shutdown	LOCA	Normal	LOCA	Basis
ESPS								
Diesel generator cooling system train A	Diesel generator cooling water system	9.5.5	12.4	12.4	12.4	--	1,500	Note 1 & 10
	Diesel generator lubrication system	9.5.7						
	Diesel generator combustion air system	9.5.8						
Diesel generator cooling system train B	Diesel generator cooling water system	9.5.5	12.4	12.4	12.4	--	1,500	Note 1 & 10
	Diesel generator lubrication system	9.5.7						
	Diesel generator combustion air system	9.5.8						
Essential cooling water system heat exchanger (tube side) train A	ECWS	9.2.2.1	247.5	88.4	Note 6	14,420	14,000	Note 2 & 9
Essential cooling water system heat exchanger (tube side) train B	ECWS	9.2.2.1	247.5	88.4	Note 6	14,420	14,000	Note 2 & 9

Notes:

1. Actual heat to be rejected by a 5500 kW diesel generator Unit.
2. Summation of individual heat loads on train for a single train cooldown.
3. Also see subsection 9.2.7 for heat loads and flowrates.
4. Condenser heat rejection for 100% air conditioning load on levels 100 and 140 feet of the control building.
5. During normal operation cooling is provided from the NCWS.
6. Heat load is variable and is discussed in subsection 6.2.1.
7. Heat load and water flow requirements are placed on the ECWS when the NCWS is not available, but not during post-LOCA operation. Only one train of the ECWS services these components at any given time.
8. Heat load is variable. The "LOCA" spent fuel heat load to be rejected is a combination of the maximum decay heat in the pool at the end of a cycle (constant equal to 4.0E+6 Btu/h) and the sensible heat of the pool at the time of manual alignment to ECWS.
9. The LOCA flow rates shown in the Table are those chosen for and are specific to the Design Bases scenario evaluated for the Ultimate Heat Sink (UHS) thermal performance analyses. The “Normal” flow rates represent values that are selected for use in analyses of other assumed events that require a normal unit shutdown.

Table 9.2-1
TABULATION--HEAT LOADS AND WATER REQUIREMENTS
ESSENTIAL SPRAY POND SYSTEM AND ESSENTIAL COOLING WATER SYSTEMS (Sheet 2 of 2)

Component	Related System	FSAR Section Reference	Heat Load (10^6 Btu/h) Note 11			Water Flow (gal/min)

Normal chiller	Normal chilled water system	9.2.9	12.9	12.9	--	--	2,500	Note 7
Reactor coolant pumps (seals and motor)	Reactor coolant system	5.1	12.4	--	--	2,044	2,044	Note 7
CEDM air coolers	Reactor	9.4	5.0	--	--	400	400	Note 7

Notes (continued):

10. The minimum cooling water flow rate required for each diesel generator is based on the maximum spray pond water temperature and permissible plugging in the heat exchangers. The diesel generator fuel oil cooler is not required for diesel engine operation. (Note 13) Therefore, the fuel oil coolers of all six emergency diesel generators have been functionally abandoned.
11. Heat Loads are bounding for core power up to 3990 MWt.
12. See Table 6.2.1-7 for EW flow ranges used and evaluated in the Containment Peak Pressure Analysis.
13. In units where DEC-00649 has been implemented, the diesel generator fuel oil coolers cooling function has been permanently retired.

J. Safety Design Basis Ten

Design and arrangement of the ESPS is such that its functional operation is unaffected by any missile effects.

9.2.1.2 Power Generation Design Bases

Pertinent power generation design bases are as follows:

A. Power Generation Design Basis One

The ESPS, in conjunction with the ultimate heat sink and the ECWS, is designed to cool the reactor from 350F to 125F within 27-1/2 hours during normal shutdown utilizing two trains of ESPS and ECWS. The cooling rate of the reactor coolant does not exceed 75F per hour.

B. Power Generation Design Basis Two

The ESPS, in conjunction with the ultimate heat sink and the ECWS, is designed to provide a maximum cooling water temperature of 105F to the shutdown cooling heat exchanger 27-1/2 hours after normal shutdown utilizing two trains of ESPS and ECWS.

9.2.1.3 Codes and Standards

The ESPS and associated components are designed in accordance with codes and standards described in section 3.2 and specified in table 3.2-1.

9.2.1.4 System Description

The ESPS consists of two separate, redundant trains, each train comprised of an ESPS pump (rated at 16,300 gpm, at 120 ft. TDH, 600 hp), pump structure, piping, valves, instrumentation, and controls required to provide cooling water to the nuclear safety-related components listed in table 9.2-1, in conjunction with the ultimate heat sink. The rated flow and head are the conditions for which the pumps were originally purchased. The performance requirements (as validated by surveillance tests) are established by the system hydraulic and thermal performance analyses. The ultimate heat sink (essential spray ponds) is discussed in subsection 9.2.5.

Each ESPS train, in conjunction with the ultimate heat sink, is capable of supporting alone 100% of the cooling functions required for a safe reactor shutdown or following a LOCA.

The ESPS operates at a higher pressure than the ECWS as protection against leakage into the ESPS from the ECWS in case of tube leakage in the ECWS heat exchanger. Analysis of postulated cracks in moderate-energy piping is discussed in section 3.6.

9.2.1.5 ESPS Components

9.2.1.5.1 Essential Spray Pond Pump Intake Structures and Sumps

The ESP pump intake structures and sumps are Seismic Category I structures, 6 feet deeper than the ponds to satisfy NPSH requirements.

9.2.1.5.2 Essential Spray Pond System Pumps

Each of the redundant ESPS trains includes a water pump (ESPS pump). Each pump is sized for full emergency load capacity and provides the flow needed to remove the heat following a LOCA from the components listed in table 9.2-1. These pumps are Seismic Category I and are furnished with onsite power when offsite power is not available. Each pump is powered from a separate ESF bus. The pump arrangement as shown in figure 9.2-1 (sheet 1 of 2) is such that pump performance is not affected by high and low pond water levels. Refer to section 3.9 for a discussion of qualification testing of these pumps.

9.2.1.5.3 Essential Spray Pond System Valves

Valves are used for control of the ESPS and for isolation of components in the ESPS. These valves are furnished in conformance with ASME Code, Section III, Class 3. These valves are operated manually.

9.2.1.5.4 Essential Spray Pond System Piping

Essential spray pond system water service piping inside the spray ponds is made of 316L austenitic stainless steel. Epoxy-lined carbon steel is used for water service piping outside the spray ponds. Piping external to the pond is installed underground.

Piping is corrosion protected or of corrosion-resistant material.

The supply and return piping to and from system components in a train are separated physically from the supply and return lines in the redundant train, except for a short section of piping within the instrumentation vault. Physical separation of the trains is designed to mitigate the consequences of a fire or pipe rupture. The probability of a fire inside the vault is considered to be insignificant. A calculation on the section of piping within the vault showed that a moderate energy line break is not a credible accident. Therefore, physical separation inside the vault is not required. Holes are provided in selected risers in the spray piping of each spray pond to drain standing water, in the exposed piping, to preclude freezing.

9.2.1.5.5 Instrumentation and Controls

Refer to paragraph 7.4.1.1.4 for the ESPS pump control logic. (Refer to paragraph 9.2.1.9 for instrumentation and control applications to the ESPS.)

9.2.1.5.6 Chemical Control Equipment

Chemical Control equipment is indicated in Table 9.2-2. Other equipment in addition to the listed equipment may be installed as needed (such as equipment needed for the addition of corrosion inhibitors and biocides).

9.2.1.6 System Operation

During emergency operations, the ESPS provides cooling water directly to the cooling systems of the diesel generators and to the ECWS indirectly through the ECWS heat exchangers. Cooling

water for the ESPS is supplied from the ultimate heat sink as described in subsection 9.2.5. Return flow from components serviced by the ESPS is returned to the ESPS spray cooling subsystem and to the ultimate heat sink for reuse.

The ESPS will operate for 26 days following a postulated LOCA without requiring any makeup water to the ultimate heat sink and without requiring any blowdown from the spray ponds for dissolved solids control. Provisions for makeup water and spray pond blowdown for the time period following 26 days are discussed in subsection 9.2.5. The combined water inventory of both essential spray ponds is needed for a 26-day operation without makeup.

The ESPS has two redundant and separate trains. During the early stages of a LOCA, when heat removal demands are highest, spray pond flow rate is controlled by a combination of a flow orifice and bypass valve in the spray pond return line. Later into the accident, when heat removal demands are lower, the bypass valve will be closed. This increases thermal performance margin while maintaining the 26 day inventory requirement described in Section 9.2.5. In Unit 1 and 3 Train B installations, DMWO 3304346 has not been fully implemented on the spray pond return piping, and therefore, the spray pond bypass valves remain in the closed position during a postulated LOCA event until completion of DMWO 3304346.[1] Each train alone, in conjunction with the ultimate heat sink, has a full 100% heat dissipation capacity for a safe shutdown. Although

(1) DMWO 3304346 adds the capability to vary SP flow rates. This note applies to units and trains where this DMWO has been installed.

an emergency reactor shutdown is accomplished by initial (first 24 hours) operation of both ESPS trains, shutdown and cooldown over an extended period of time is possible with the use of a single train.

The ESPS operational logic and the associated initiation and actuation controls and instrumentation are summarized in the following paragraphs.

Both trains of the ESPS and the ECWS (see paragraph 9.2.2.1) are operationally actuated by any single or any combination of the following signals or operations:

- Safety injection actuation signal (SIAS)
- Containment spray actuation signal (CSAS)
- Control room ventilation and isolation actuation signal (CRVIAS)
- Control room essential filtration actuation signal (CREFAS)
- Auxiliary feedwater actuation signal (AFAS-1 or AFAS-2)Diesel generator start signal (DGSS)
- Loss of offsite power signal (LOP)
- Manual start by control room operator

Manual start and stop actuation from the control room overrides the automatic mode. Manual start and stop controls are also provided for each of the two ESPS trains and two ECWS trains. This individual control feature permits the removal of a train from operation after the automatic operation actuation if it is not required.

The only components that are actuated in any of the trains, either automatically or by manual control room operator initiation in lieu of automatic actuation, are the ESPS pumps. Essential spray pond system and ECWS valves are manually and locally operated. Valves in the supply lines from the pumps and in the return lines to the essential spray ponds or to the ECWS and diesel generator heat exchangers are locked open. In Unit 1 and 3 Train B installations of the spray pond return line, DMWO 3304346 has not been fully implemented, and therefore, the spray pond margin bypass valves remain in the locked closed position.

9.2.1.7 Safety Evaluations

Safety evaluations, numbered to conform to the safety design bases, are as follows:

A. Safety Evaluation One

The ESPS, in conjunction with the ultimate heat sink, has the capability to dissipate within the safe reactor shutdown time frame all imposed heat loads.

Loss of offsite power results in the shutdown and restarting of the ESPS in accordance with the diesel generator load sequencing. The diesel generator load capacity and sequencing times, as described in section 8.3, are commensurate with ESPS requirements. Thus, safe reactor shutdown is supported by the ESPS.

B. Safety Evaluation Two

The ESPS, in conjunction with the ultimate heat sink, maintains the ECW heat exchanger outlet temperature at or below 135F for the design basis LOCA.

C. Safety Evaluation Three

The ESPS is comprised of two physically separate, independent, full capacity trains, each of which is powered from a separate ESF bus and a separate diesel generator. This ensures that a single failure does not impair system effectiveness. Refer to table 9.2-3 for the single failure analysis. A short section of ESPS piping within the instrumentation vault does not have physical separation. Separation of trains is designed to mitigate the consequences of a fire or pipe rupture. The probability of a fire inside the vault is considered to be insignificant. A calculation on the section of piping within the vault showed that a moderate energy line break is not a credible accident.

Table 9.2-2
EQUIPMENT LIST ESSENTIAL SPRAY POND CHEMICAL CONTROL (PER UNIT)

Component Description	Quantity	Type	Design Flow (gal/min)
Sulfuric Acid Metering Pump	2	Positive Displacement	0 - 0.1
Hypochlorite Metering	2	Flow Orifice	0.25
Hypochlorite Metering	2	Flow Orifice	0.5

Table 9.2-3
ESSENTIAL SPRAY POND SYSTEM SINGLE FAILURE ANALYSIS

Components	Failure Mode/Cause	Effect on System	Method of Detection	Inherent Compensating Provision
ESP pumps	One pump inoperable/ mechanical or electrical failure	None--Redundant loop is available	Motor status and flow indicated in the control room	Two redundant loops are provided. Either loop is capable of providing 100% of heat removal require-ments under normal or accident condition.
ESP spray nozzle header	Spray nozzle header loss	None--Redundant spray nozzle header is available	Temperature indication in the control room	Two redundant spray loops are available. Each loop is capable of 100% heat removal.
Check valve in pump discharge	Check valve stays closed	None—Redundant loop is available	Pressure is indicated locally and in the control room	Two redundant loops are provided.
Piping	Loss of pump discharge header	None--Redundant loop is available	Flow and pressure indications are indicated in the control room	Two redundant loops are provided.
	Loss of return header	None--Redundant loop is available	Flow and pressure are indicated in the control room	Each loop will be capable of satisfying the heat requirements.
ESP return line flow orifice bypass valve (1)	Valve stays open Valve remains locked closed - Unit 1B & 3B	None--Redundant loop is available	Valve position indication locally at MCC	Two redundant loops are provided.

(1) DMWO 3304346 adds the capability to vary SP flow rates. This note applies to units and trains where this DMWO has been installed.

Therefore, physical separation inside the vault is not required.

D. Safety Evaluation Four

The ESPS pumps are located in Seismic Category I pump structures that protect the pumps against the adverse environmental occurrences outlined in chapters 2 and 3. Other required portions of the ESPS are either installed underground or are located in buildings that also protect against adverse environmental conditions described in chapters 2 and 3. Holes are provided in selected risers in the spray piping of each spray pond to drain standing water, in the exposed piping, to preclude freezing.

E. Safety Evaluation Five

Flow differential is monitored between ESPS pump discharges and the return lines to the essential spray ponds for detecting large system leaks/pipe breaks. Since the ESPS operates at a higher pressure than the ECWS, leakage of potentially radioactive water from the ECWS into the ESPS is precluded.

F. Safety Evaluation Six

Wetted surfaces in the ESPS are of materials compatible with the cooling water chemistry. Organic fouling and inorganic buildups are controlled by proper water treatment. (Refer to subsection 9.2.5).

G. Safety Evaluation Seven

The ESPS is Seismic Category I in accordance with requirements presented in chapter 3.

H. Safety Evaluation Eight

During normal plant operation, the ESPS may be operated in support of several auxiliary systems including emergency diesel generators, shutdown cooling, essential chillers, fuel pool cooling, and nuclear cooling water priority loads, as well as for chemistry control, and testing. The redundant features of the ESPS allow testing of one train without violation of technical specifications.

I. Safety Evaluation Nine

The capacity of the ESPS, in conjunction with the ultimate heat sink and the ECWS, is sufficient to dissipate the heat loads of the fuel pool in the event the normal fuel pool cooling system is unavailable.

J. Safety Evaluation Ten

Components of the ESPS outside of buildings or structures, except for spray pond nozzles, are located below grade such that missiles from any source would not prevent the system performing its design function. Each ESPS train is separated from the other ESPS train. For additional information on the effect of tornado missiles on the spray nozzles see section 3.5.1.4 and 9.2.5.4(B).

9.2.1.8 Tests and Inspections

Preoperational testing is performed in accordance with the test descriptions of section 14.2. Periodic surveillance testing is described in the Technical Specifications.

9.2.1.9 Instrument Application

The ESPS instrumentation facilitates automatic operation, remote control, and continuous indication of system parameters (ESP water temperature, ESPS pump flow, ESP inlet flow, ESP water level) both locally and in the control room.

Controls and instrumentation necessary for operation of the ESPS pumps are located in the control room. Local instrumentation and controls also are provided at ESPS pumps and ECWS heat exchangers for maintenance, testing, and performance evaluation.

Specifically, control room process indication and alarm is provided to enable the operator to evaluate the ESPS performance and to detect malfunctions. Essential spray pond system pump discharge pressure is displayed and alarmed to detect an abnormally low pressure (pump failure, piping break) or abnormally high pressure (piping blockage, closed valves). Spray pond levels and temperatures are indicated to show a low or high level condition or a high temperature condition in a spray pond.

Control conditions of level and temperatures are also alarmed in the control room. The ESPS water discharge temperatures from the ECWS heat exchangers are indicated in the control room. A high temperature condition is alarmed to indicate either a reduced water flow to the exchanger or an abnormal heat input to the exchanger from the ECWS. ESPS chemistry is monitored by grab samples (table 9.3-3). Out-of-specification chemistry readings may indicate a buildup of dissolved solids level in the water and a need for pond blowdown with makeup to maintain the safe water inventory of the pond.

Differential flow between the ESPS pump discharge and the spray header is indicated in the control room to identify a significant line break or a large system leak. Local pressure or temperature indicators are provided on the cooling water discharge lines of various heat exchangers or cooling systems served by the ESPS.

9.2.2 COOLING SYSTEMS FOR REACTOR AUXILIARIES

Two separate, independent cooling systems for reactor auxiliaries are provided. Each of the systems provides for the indirect cooling, through heat exchangers, of those reactor auxiliaries that carry radioactive or potentially radioactive fluids. The ECWS serves the safety-related and normal shutdown components. The nuclear cooling water system (NCWS) serves the nonsafety-related (normal operating) components.

Paragraph 9.2.2.1 discusses the ECWS and paragraph 9.2.2.2 discusses the NCWS. Equipment locations for the ECWS are shown in engineering drawings 13-P-OOB-002 through -004.

9.2.2.1 Essential Cooling Water System

The ECWS is shown in engineering drawings 01, 02, 03-M-EWP-001. Table 9.2-1 lists the safety-related nuclear component heat loads and associated water requirements for the ECWS. Cross-references to sections covering the related systems also are included in table 9.2-1. Table 9.2-4 lists the ECWS major equipment items and their design specifications.

9.2.2.1.1 Safety Design Bases

Safety design bases applicable to the ECWS are:

A. Safety Design Basis One

The ECWS, in conjunction with the ESPS (including the ultimate heat sink), shall be capable of removing sufficient heat to ensure a safe reactor shutdown coincident with a loss of offsite power.

B. Safety Design Basis Two

The ECWS, in conjunction with the ESPS, shall be capable of maintaining the outlet temperature of the ECWS heat exchanger from exceeding 135F during a postulated LOCA with loss of offsite power.

C. Safety Design Basis Three

A single failure of any component in the ECWS will not impair the ability of the ECWS to meet its functional requirements.

D. Safety Design Basis Four

Adverse environmental occurrences will not impair the ability of the ECWS to meet its functional requirements.

E. Safety Design Basis Five

The ECWS shall be designed to detect leakage of radioactive water into the ECWS, and to detect leakage from the ECWS.

F. Safety Design Basis Six

The ECWS shall be designed to minimize the effects of long-term corrosion.

Table 9.2-4

EQUIPMENT LIST ESSENTIAL COOLING WATER SYSTEM

Component Description	Quantity	Type	Rated Head (ft)	Rated Flow (gal/min)	Motor (hp)	Design Pressure (psig)	Water Capacity (gal)	Material	Service Side
ECWS pump	2	Centrifugal	138	16,650	800	150	--	Carbon steel	--
Surge Tank	2	Vertical Cylindrical	--	--	--	15	1,000	Carbon steel	--
Chemical addition tank	2	Ball feeder	--	--	--	200	11.3	Carbon steel	--
ECWS heat exchanger	2	Shell & tube; Refer to Table 9.2-1	--	--	--	150	--	--	ESPS

G. Safety Design Basis Seven

The ECWS shall be designed to withstand the effects of an SSE.

H. Safety Design Basis Eight

Components of the ECWS shall be capable of being fully tested during normal plant operation. In addition, parts and components shall be accessible for inspection at any time.

I. Safety Design Basis Nine

The ECWS, in conjunction with the ESPS, shall provide cooling capability for the fuel pool when the fuel pool normal cooling system is not available.

J. Safety Design Basis Ten

The design and arrangement of the ECWS shall be such that its functional operation is unaffected by any missiles.

9.2.2.1.2 Power Generation Design Bases

Power generation design bases pertinent to the ECWS are as follows:

A. Power Generation Design Basis One

The ECWS, in conjunction with the ESPS, is designed to cool the reactor coolant from 350F to 125F within 27-1/2 hours during normal shutdown utilizing two trains of ECWS and ESPS. The cooling rate of the reactor coolant does not exceed 75F per hour.

B. Power Generation Design Basis Two

The ECWS, in conjunction with the ESPS, is designed to provide a maximum cooling water temperature of 105F to the shutdown heat exchanger 27-1/2 hours after normal shutdown utilizing two trains of ESPS and ECWS.

C. Power Generation Design Basis Three

The ECWS, in conjunction with the ESPS, is designed to provide cooling water to the reactor coolant pumps, control element drive mechanism (CEDM) coolers, nuclear sample coolers, and normal chillers by manual valve realignment in the event of a loss of offsite power.

9.2.2.1.3 Codes and Standards

The ECWS and associated components are designed in accordance with codes and standards described in section 3.2 and specified in table 3.2-1.

9.2.2.1.4 System Description

The ECWS consists of two separate, independent, redundant, closed loop, safety-related trains. Either train of the ECWS is capable of supporting 100% of the cooling functions required for a safe reactor shutdown or following a LOCA.

The ECWS operates at a lower pressure than the ESPS as protection against leakage into the ESPS from the ECWS in case of tube leakage in the ECWS heat exchanger.

Each train of the ECWS includes a heat exchanger, surge tank, pump, chemical addition tank, piping, valves, controls, and instrumentation.

The ECWS provides cooling water to the safety-related components listed in paragraph 9.2.2.1.6.

The makeup water line to the ECWS is connected to the demineralized water system. A backup makeup water line of Seismic Category I construction is provided from the condensate tank. A makeup line is also provided from the cooling water holdup tank. Additionally a connection is provided to hook up a fire hose to the makeup line. Normal makeup is supplied from the demineralized water system. When the normal makeup is not available, the other sources listed may be used as necessary, if available. For details on makeup from the condensate storage facility, refer to Section 9.2.6.

In case of a major leak in one of the ECWS trains, that train is removed from service and the other train is used.

The ECWS equipment is located in the auxiliary building and control building.

The chemistry control program applicable to the ECWS is established in accordance with the EPRI Closed Cooling Water Chemistry Guideline. The ECWS chemistry control program is an objective based program and the water quality control parameters are designed to minimize corrosion, organic and inorganic fouling and microbiological growth. Table 9.2-6 lists Seismic Category I valves in the ECWS.

9.2.2.1.5 Component Description

Table 9.2-4 lists the major ECWS components and their design specifications.

9.2.2.1.5.1 ECWS Heat Exchangers. The ECWS heat exchanger in each train has a 100% heat dissipation capacity. The heat exchangers are of the shell and tube type. The tube side is furnished with cooling water from the ESPS at a higher operating pressure than the shell side as noted in paragraph 9.2.2.1.4.

The shell side carries the ECWS cooling water. This closed-loop, shell-side water is initially supplied with demineralized water from the demineralized water system as discussed in subsection 9.2.3.

9.2.2.1.5.2 ECWS Pumps. One ECWS pump is provided for each ECWS train. Each pump has the flow capacity to move sufficient flow to remove 100% of the heat dissipated. The pumps are of the horizontal centrifugal type and are installed at an elevation below the ECWS surge tank to ensure flooded suction and maintain a constant pressure at the suction side of the pump. Pump motors are connected to separate Class 1E buses. Each motor can be supplied by its related emergency diesel generator (standby) power supply. In the event offsite (preferred) power is lost, the pumps are stopped and restarted in accordance with the emergency diesel generator load sequencing. Refer to section 3.9 for a detailed discussion of ECWS pump qualification testing.

9.2.2.1.5.3 ECWS Surge Tanks. One surge tank is provided in each ECWS train to automatically accommodate the closed loop water expansion and contraction due to thermal changes in the system. Level controls in each tank signal a demineralized

water makeup line control valve that then actuates to maintain the water required in the ECWS. The surge tanks are installed on the suction side of the ECWS pumps.

9.2.2.1.5.4 Safety-Related Equipment Heat Exchangers. Table 9.2-1 lists the safety-related equipment, associated heat loads, and their water requirements. Descriptions of these items are included in the applicable sections as noted on the table.

9.2.2.1.5.5 Piping, Valves, and Fittings. Piping from and to the ECWS heat exchangers is of carbon steel. Piping, valves, and fittings are supplied in accordance with ASME Code, Section III, Class 3.

Piping is corrosion protected. The supply and return piping to and from system components in a train is physically separated from the supply and return lines in the redundant train.

9.2.2.1.5.6 Instrumentation and Controls. The discussion of the operational logic and the associated initiation and actuation controls and instrumentation of the ECWS and the ESPS is covered jointly in paragraph 9.2.1.6.

Refer to paragraph 9.2.2.1.9 for instrumentation and control applications to the ECWS.

9.2.2.1.6 System Operation

The ECWS has two redundant and separate trains. Each train is connected to its corresponding ESPS train through the ECWS heat

exchanger that serves as a pressure-thermal barrier between the ESPS and the ECWS.

Although either train has a 100% heat dissipation capacity (through heat transfer from the shell side to the tube side of the ECWS heat exchanger and the dissipation of the transferred heat load by the ESPS to the atmosphere), an emergency reactor shutdown is normally accomplished by initial operation of both trains of the ECWS and ESPS.

Shutdown and cooldown by only one train over an extended period of time is possible. The discussion of operations of the ECWS and ESPS are given in paragraph 9.2.1.6.

Each train of the ECWS provides cooling for the following redundant safety-related components:

- Shutdown cooling heat exchangers (one per train)
- Essential chillers (one per train)
- Fuel pool heat exchangers (one per train) if NCWS is not available

Each train can also provide cooling for the following non-safety-related components:

- Reactor coolant pump assemblies (four pumps on one train at a time) if NCWS is not available
- Control element drive mechanism coolers (one on one train at a time) if NCWS is not available
- Normal chillers (one on one train at a time) if NCWS is not available

- Nuclear sample coolers if NCWS is not available

In the event the NCWS becomes inoperable the operator has the option of valving in either train A or train B of the ECWS (never both) to the above nonsafety-related components.

In the event of an LOP, the operator can open the train A NCWS crosstie valves from the control room, permitting the ECWS train A to supply cooling water to the reactor coolant pump assemblies, CEDM coolers, normal chillers, and nuclear sample coolers. If train A fails, the operator must manually open the train B NCWS crosstie valves and shut the train A crosstie valves to permit the same function.

9.2.2.1.7 Safety Evaluations

Safety evaluations are numbered to conform to the safety design bases and are as follows:

A. Safety Evaluation One

   The ECWS has the capability to dissipate within the safe reactor shutdown time frame the imposed heat loads.

   Loss of offsite power results in the shutdown and restarting of the ECWS in accordance with the diesel generator load sequencing. The diesel generator load capacity and sequencing times, as described in section 8.3, are commensurate with ECWS requirements. Thus, safe reactor shutdown is supported by the ECWS.

B. Safety Evaluation Two

   The required cooling water flow is listed in table 9.2-1. This flow and associated heat transfer

capability are compatible with providing the required ESF system cooling water from exceeding 135F during a postulated LOCA.

C. Safety Evaluation Three

The ECWS is comprised of two physically separate, independent, full-capacity trains, each of which is powered from a separate ESF bus and a separate diesel generator. This ensures that a single failure does not impair system effectiveness. Refer to table 9.2-7 for the single failure analysis.

D. Safety Evaluation Four

Components of the ECWS are installed in buildings that protect against adverse environmental conditions described in chapters 2 and 3.

E. Safety Evaluation Five

To detect leakage into or out of the ECWS, high and low level signals at the surge tank will alarm in the control room. Radiation monitors indicate leakage of radioactive fluids into the ECWS. Finally, each system being served by the ECWS is monitored for inleakage.

F. Safety Evaluation Six

Wetted surfaces in the ECWS are of materials compatible with the cooling water chemistry. Organic fouling and inorganic buildups are controlled by proper water treatment. The use of demineralized water and corrosion inhibitors for this system minimizes this problem.

The water in the loop is sampled for quality on a scheduled basis and the pH is adjusted if required by the addition of treatment chemicals.

G. Safety Evaluation Seven

The ECWS is Seismic Category I in accordance with requirements presented in chapter 3.

H. Safety Evaluation Eight

During normal plant operation, the ECWS is not operating. The redundant features of the ECWS allow testing of one train without violation of technical specifications.

I. Safety Evaluation Nine

The capacity of the ECWS, in conjunction with the ESPS, is sufficient to dissipate the heat loads from the fuel pool in the event that the normal fuel pool cooling system is unavailable. In the event that the NCWS becomes inoperable, the fuel pool heat exchangers must be supplied cooling water by the ECWS. Each fuel pool heat exchanger is supplied water separately by each train of the ECWS; i.e., one heat exchanger by train A and the other heat exchanger by train B.

Valves associated with switching service from the NCWS to the ECWS are manually operated, Seismic I, and Safety Class 3. These valves are also used to isolate the ECWS from the NCWS. They are located in the auxiliary building.

Table 9.2-7

ESSENTIAL COOLING WATER SYSTEM SINGLE FAILURE ANALYSIS

Components	Failure Mode/Cause	Effect on System	Method of Detection	Inherent Compensating Provision
ECWS pumps	One pump inoperable/ mechanical or electrical failure	Loss of flow in one loop None--redundant loop is available	Motor status and flow indication in the control room	Redundant loops are provided. One operable loop is capable of providing 100% of heat removal requirements under normal and accident conditions.
ECWS heat exchangers	One heat exchanger malfunction Leaking tubes or blockage	Loss of heat sink None--redundant loop is available	Temperature indication in the control room	Heat exchanger in redundant loop will provide 100% of heat removal
ECWS surge tank	One surge tank malfunction Tank leaking	Loss of water level None--redundant loop is available	Low level alarm in the control room	Redundant loops are provided.
Butterfly valves	Butterfly valve in the pump suction stays closed/operator error	None--redundant loop is available	Flow indication and pressure alarm in the control room	Redundant loops are provided.
Piping (pipe breaks)	Loss of pump discharge header/ linebreak or mechanical damage Loss of return header/linebreak or mechanical damage	None--redundant loop is available	Flow indication and pressure alarm in the control room	Redundant loops are provided.

Sufficient time would be available for the operator to access the auxiliary building to manually actuate these valves since the fuel pool does not require continuous cooling.

J. Safety Evaluation Ten

Components of the ECWS are located such that missiles from any source would not impair the system's functional requirements. The two trains of the ECWS are physically separated and are routed such as to be protected from missiles that could be potentially generated from other sources. Refer to section 3.5 for a discussion of missile protection.

9.2.2.1.8 Tests and Inspections

Preoperational testing is performed in accordance with the test descriptions of section 14.2. Periodic surveillance testing is described in the Technical Specifications.

In response to Generic Letter 89-13, Palo Verde will conduct heat exchanger thermal performance testing on the Essential Cooling Water (EW) heat exchangers in accordance with site Heat Exchanger Program Procedure developed in accordance with Electric Power Research Institute (EPRI) guidelines.

9.2.2.1.9 Instrument Application

Refer to paragraph 9.2.1.9 for a presentation of the ECWS interfaces to the ESPS.

The ECWS instrumentation facilitates automatic operation, remote control, and continuous indication of system parameters

locally and in the control room. Controls and instrumentation necessary for operation of the ECWS pumps are located in the control room. Local instrumentation and controls also are provided at the ECWS pumps and at the various safety-related nuclear component heat exchangers for maintenance, testing, and performance evaluation.

Specifically, control room process indication and alarm is provided to enable the operator to evaluate the ECWS performance and to detect malfunctions. Essential cooling water system pump discharge pressures and temperatures at the inlets and outlets of the ECWS heat exchangers are locally displayed. Essential cooling water system pump discharge pressures are alarmed to detect a pump failure, return piping blockage, or pipe breaks. Essential cooling water system pump discharge temperature is indicated and alarmed in the control room for detection of ECWS heat exchanger malfunction.

Surge tank is provided with level gauge glass to show low or high level condition in the closed loop. Critical conditions of tank level and pressure are alarmed in the control room for leak detection.

As discussed in paragraph 9.2.1.9, the ESPS water discharge temperature from the ECWS heat exchangers are indicated in the control room. A high temperature condition of ESPS water discharge is alarmed to indicate either a reduced ESPS flow to the exchanger or an abnormal heat input to the exchanger from a component in the ECWS closed loop.

Relief valves are provided, as required, for personnel and equipment protection.

9.2.2.2 Nuclear Cooling Water System

The NCWS is shown in engineering drawings 01, 02, 03-M-NCP-001, -002 and -003. Table 9.2-8 lists the components served by the NCWS, their required heat load cooling requirements and their associated cooling water flows.

9.2.2.2.1 Safety Design Bases

The safety design basis applicable to the NCWS is that the dose consequences resulting from an interfacing system component failure (i.e. heat exchanger tube rupture) shall be maintained below 10CFR20.1-20.601 and 10CFR100 limits.

9.2.2.2.2 Power Generation Design Bases

The power generation design basis pertinent to the NCWS is as follows:

A. Power Generation Design Basis One

   The NCWS, in conjunction with the plant cooling water system (PCWS), is designed to provide an adequate supply of cooling water to the nonsafety-related components listed in table 9.2-8.

9.2.2.2.3 Codes and Standards

The NCWS and associated components are designed in accordance with codes and standards described in table 3.2-1.

9.2.2.2.4 System Description

The NCWS equipment required for the cooling of nonsafety-related components includes heat exchangers, surge tank, chemical water treatment components, pumps, piping, valves, controls, and instrumentation. The NCWS equipment items are located in the auxiliary building, the radwaste building, the turbine building, the containment building, the fuel building, and outside areas.

The NCWS consists of one closed loop flow train of full unit capacity. This loop includes redundant 100% capacity pumps and redundant 100% heat exchangers. The tube sides of the heat exchangers are furnished with cooling water from the plant cooling towers via the PCWS. The shell side of the heat exchangers is part of the closed cooling loop that includes the pumps, surge tank, and nonsafety-related reactor auxiliaries listed in table 9.2-8.

The water quality parameters applicable to the NCWS are the same as those itemized for the ECWS in paragraph 9.2.2.1.4. Makeup water for the closed loop is supplied to the surge tank from the demineralized water system as discussed in subsection 9.2.3.
