FOREWORD

The Palo Verde Nuclear Generating Station (PVNGS) has developed the Updated Final Safety Analysis Report (UFSAR) in accordance with Title 10, Code of Federal Regulations (10CFR), Part 50.71, Maintenance of Records, Making of Reports, Paragraph (e). The UFSAR is analogous in content and format to the original PVNGS FSAR submitted as part of the joint application for the operation licenses for Units 1, 2, and 3, NRC Docket Nos. STN 50-528/529/530.

The original PVNGS FSAR content and format was specified by 10CFR50.34(b) and NRC Regulatory Guide 1.70, Revision 3. Content of the Updated FSAR is controlled in accordance with Regulatory Guide 1.181. Also, in accordance with NRC policy statement entitled Methods for Achieving Standardization of Nuclear Power Plants, dated March 5, 1973, appropriate sections of the Combustion Engineering Standard Safety Analysis Report (CESSAR), NRC Docket Nos. STN 50/470, were incorporated by reference.

Numerical values in the UFSAR may be nominal in nature, provided to give the reader a sense for the value of the parameter or accuracy of the measurement and should not be viewed as actual values observable in the field. Plant operation at values other than that presented in the UFSAR is acceptable provided that actual values are within established technical specifications, design bases and administrative limits.

The content and format of the UFSAR is specified by 10CFR50.71(e) and NRC Generic Letter 81-06. Pursuant to

Paragraph (4) of 10CFR50.71(e), the PVNGS UFSAR reflects changes up to 6 months prior to the required filing of the UFSAR. The UFSAR includes the effects of: approved license amendments; changes that were made to the facility or procedures as described in the FSAR that did not require a license amendment pursuant to 10 CFR 50.59(c)(1); engineering evaluations and safety analyses performed by the licensee in support of license amendments; and the analyses of new nuclear safety issues performed at the Commission's request.

No new analyses other than those originally prepared during the development and license review process of the original publication of the FSAR, or prepared and submitted pursuant to NRC requirements, have been incorporated into the UFSAR. Analyses that are provided in the UFSAR have been revised to correct known inaccuracies or errors.

The responses to NRC questions, contained in the original FSAR by appendix, are incorporated into the body of the updated FSAR as appropriate. The questions have been retained within their respective appendices, and references have been added when responses were deleted to provide direction to where the responses are incorporated.

Descriptions of physical changes to PVNGS are included in the UFSAR.

The PVNGS revision 0 UFSAR did not include identification of the subsequent supplements and amendments to the original FSAR. The 17 amendments and supplements to the original FSAR were appropriately incorporated, without identifying revision bars, into the FSAR to create a single, complete, and integral

document. Revision bars were used to identify noneditorial changes between the original FSAR, through amendment 17, and the initial UFSAR. The revision bars will preserve the history and bases of changes to the UFSAR. For the initial UFSAR, beside each revision bar is the number "0". This symbol will identify those changes incorporated into the initial UFSAR.

The UFSAR is updated in accordance with 10CFR50.71(e). Each replacement page includes both a change indicator for the area changed, e.g., a bold line vertically drawn in the margin adjacent to the portion actually changed, and page change identification (date of UFSAR revision and revision number).

1. INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

1.1 INTRODUCTION

This Final Safety Analysis Report (FSAR) is submitted in support of the joint application filed in Docket Nos. STN 50-528, 50-529, and 50-530 by Arizona Public Service Company (APS) for operating licenses for three nuclear power units to be located at Palo Verde Nuclear Generating Station (PVNGS) in Maricopa County, Arizona, west of the Phoenix metropolitan area.

The joint application for construction permits and operating licenses for PVNGS Units 1, 2, and 3 (PVNGS) was filed with the Nuclear Regulatory Commission (NRC) on July 11, 1974. Construction permits were subsequently issued for PVNGS 1, 2, and 3 on May 25, 1976, as CPPR-141, CPPR-142, and CPPR-143, respectively, in Docket Nos. STN 50-528, 50-529, and 50-530.

Each of the PVNGS units will utilize a System 80 pressurized water reactor nuclear steam supply system (NSSS) provided by Combustion Engineering, Inc., (C-E) and described in the Combustion Engineering Standard Safety Analysis Report – Final Safety Analysis Report (CESSAR).

PVNGS, including each of the three units and all property and facilities located thereat, is jointly owned or leased pursuant to sale and leaseback transactions approved by the NRC by the following seven utilities as tenants in common in PVNGS 1, 2, and 3 in the percentages indicated:

• Arizona Public Service Company	29.1
• Salt River Project Agricultural Improvement and Power District	17.49
• Southern California Edison Company	15.8
• El Paso Electric Company	15.8
• Public Service Company of New Mexico	10.2
• Southern California Public Power Authority	5.91
• Department of Water and Power of the City of Los Angeles	5.7

The rights, duties, and obligations of such utilities in respect to the construction, operation, and maintenance of PVNGS are established by the Arizona Nuclear Power Project (ANPP) Participation Agreement, dated as of August 23, 1973, as amended (a copy of which is included with the General Information accompanying the PVNGS License Application). In addition to the ownership arrangements, the provisions of the Participation Agreement that are most significant to the application are those that designate APS as the Project Manager and Operating Agent of PVNGS with full authority and responsibility to engineer, design, construct, operate, and maintain PVNGS and all related facilities other than transmission and switchyard facilities. Additionally, under the terms of the Participation Agreement, APS is responsible for obtaining all licenses, permits, and approvals required to construct, operate, and maintain PVNGS and is authorized to submit and prosecute on its own behalf and as agent for all other participants all applications therefor. Accordingly,

APS, as Project Manager and Operating Agent of PVNGS, is the applicant for permits and licenses to construct, operate, and maintain PVNGS and also is the applicant for itself and all other joint owners in PVNGS to acquire and own, or lease pursuant to sale and leaseback transactions approved by the NRC, undivided interests in said units as tenants in common in the percentages hereinabove set forth.

With respect to transmission and switchyard facilities required for PVNGS, the participants collectively are planning and coordinating transmission and interconnection arrangements suitable for the delivery to the participants of the power and energy generated by PVNGS and compatible with the transmission systems of the participants.

PVNGS, as established by the ANPP Participation Agreement, is neither a corporate entity, partnership, nor joint venture; but rather it is a jointly owned facility, consisting of all equipment, structures, nuclear fuel, and other property and rights that are or may be used or useful in the operation and maintenance of the facility, but excluding the high voltage switchyard and all transmission facilities connected thereto. Each joint owner has the sole and exclusive right to a percentage equal to its ownership interest of the generating capability of each of the PVNGS units. Accordingly, no sales of power and energy will be made by PVNGS or by APS as agent for other participants in PVNGS. Instead, all sales of power and energy from any PVNGS generating unit will be made by the various joint owners, individually, to their respective customers and to third parties separately from and independent of the ANPP Participation Agreement.

INTRODUCTION

1.1.1 TYPE OF LICENSE REQUESTED

The application is for a Class 103 license for each of the PVNGS Units 1, 2, and 3.

1.1.2 PROPOSED STATION LOCATION

PVNGS is located on a site situated in Section 34 and portions of Sections 26, 27, 28, 33, and 35 in Township One North, Range Six West of the Gila and Salt River Base and Meridian, and Section 3 and portions of Sections 2, 4, 9, and 10 in Township One South, Range Six West of the Gila and Salt River Base and Meridian, Maricopa County, Arizona.

This location is approximately 34 miles west of the nearest boundary of the city of Phoenix, Arizona. The closest population center of more than 25,000 residents is Sun City, which is approximately 34 miles east-northeast of the PVNGS site.

1.1.3 CONTAINMENT TYPE

The containment for each unit is a single containment system consisting of a steel-lined, prestressed concrete, cylindrical structure, with a hemispherical dome. The containment structures are designed by Bechtel Power Corporation (Bechtel).

1.1.4 THERMAL POWER LEVELS AND ELECTRICAL OUTPUT

NSSS rated core thermal power is 3990 MWt. Heat from nonreactor sources, primarily pump heat, is 23 MWt.

The turbine-generator electrical output for 4013 MWt (3990 MWt23 WMt) is 1411 MWe (1443 MWe valves wide open) at 3.5 inches Hg abs backpressure. The nominal net output is 1346 MWe (1378 MWe valves wide open).

1.1.5 SCHEDULED COMPLETED AND COMMERCIAL OPERATION DATES

The scheduled completion or fuel loading dates and the scheduled commercial operation dates for PVNGS Units 1, 2, and 3 are as follows:

PVNGS Unit	Operating License Date	Commercial Operation Date[a]
1	Licensed December 31, 1984	January 28, 1986
2	Licensed December 9, 1985	September 19, 1986
3	Licensed March 25, 1987	January 8, 1988

a. ANPP terminology is firm power operation date in lieu of commercial operation date.

1.2 GENERAL PLANT DESCRIPTION

1.2.1 PRINCIPAL SITE CHARACTERISTICS

1.2.1.1 Site Location

The site is located approximately 34 miles west of the nearest boundary of the city of Phoenix in Maricopa County, Arizona. Buckeye Salome Road is north of the site and runs in a northwest to southeast direction. A paved county road, Wintersburg Road, runs north to south along the west edge of the site, and Ward Road (paved), sometimes called Elliot Road, runs east to west at the southern end of the site. A Union Pacific railroad line runs southwest to northeast 5 miles south of the power plant complex. Figure 1.2-1 shows the general site location. Figure 1.2-2 provides a general site vicinity map. Engineering drawings 13-C-ZVA-005 and 13-P-OOB-001 show the site general arrangement.

1.2.1.2 Plant Surroundings

The general area consists of a broad valley or basin surrounded by a series of intermittent hills. Relief of the Palo Verde Hills is relatively low (250-foot maximum); the basin area averages about 950 feet in elevation and the adjacent hills rise to about 1200 feet in elevation (see figure 1.2-2). The hills about 5 miles northwest of the site area are the most rugged in the area, and the highest ridges reach approximately 2100 feet above sea level. The basin floor slopes very gently (28 feet per mile) to the south and is dissected by a number of ephemeral stream channels that converge and flow toward the Gila River about 10 miles to the south.

1.2.2 SYSTEM 80 SCOPE AND DESCRIPTION

Combustion Engineering (CE) System 80 includes the NSSS and many of its auxiliary and safety systems. The original scope of design for CE System 80 systems and components is listed in Table 1.2-1 entitled "CESSAR Design Scope Systems and Equipment." The seismic category and the safety and quality classification of mechanical components within the System 80 scope are listed in Table 3.2-1 entitled "Quality Classification of Structures, Systems, and Components." Summary descriptions of the CE System 80 systems are presented below and detailed in the appropriate sections. Information related to the safe design of structures, systems and components which affect these systems, but not within the scope of CE-supplied equipment, is identified in the appropriate UFSAR sections under the heading "Interface Requirements."

NOTES

1. There is no one particular system for complete containment isolation. Containment isolation is achieved by applying acceptable common criteria to penetrations for CESSAR design scope systems and by using a containment isolation signal to actuate appropriate valves. Containment isolation is within the CESSAR scope for the lines listed under "2.b" above.
2. There is no implication that all instrumentation and controls within the CESSAR scope are safety related. The text defines what instrumentation is considered to be safety related.
3. Because of the relatively slow response of the system to changes in boron concentration, the boron control system is manual with the operator controlling boron concentration based on periodic sampling.

1.2.3 NUCLEAR STEAM SUPPLY SYSTEM

The NSSS generates power as described in section 1.1.4, producing saturated main steam. The NSSS contains two independent primary coolant loops, each of which has two reactor coolant pumps, a steam generator, a 42-inch ID outlet (hot) pipe and two 30-inch ID inlet (cold) pipes. An electrically heated pressurizer is connected to one of the loops, and safety injection lines are connected to each of the four cold legs and the two hot legs. Pressurized water circulates by means of electric-motor-driven, single-stage, centrifugal reactor coolant pumps, downward between the reactor vessel shell and the core support barrel, upward through the reactor core, through the tube side of the vertical U-tube (with an integral economizer) steam generators, and back to the reactor coolant pumps. The saturated steam produced in the steam generators is passed to the turbine.

1.2.3.1 Reactor Core

The reactor core is fueled with uranium dioxide pellets enclosed in zircaloy or zirlo tubes with welded end caps. The tubes are fabricated into assemblies in which end fittings limit axial motion and grids limit lateral motion of the tubes. The control element assemblies (CEAs) consist of Alloy 625 absorber rods, which are guided by tubes located within the fuel assembly. The core consists of 241 fuel assemblies which will be initially loaded with three different U-235 enrichments. The NSSS full-thermal output is specified in section 1.1.4. The neutron absorber is either all boron carbide (B_4C) in Feltmetal® CEAs, or a combination of B_4C and

Silver-indion-cadmium (AIC) in AIC CEAs. Only one design at a time will be used in each of the three units.

Design criteria are established to ensure the following:

A. The minimum departure from nucleate boiling ratio during normal operation and anticipated operational occurrences is not less than 1.19.

B. The maximum fuel centerline temperature evaluated at the design overpower condition is below that value which could lead to centerline fuel melting. The melting point of the UO_2 is not reached during normal operation and anticipated operational occurrences.

C. Fuel rod clad is designed to maintain cladding integrity throughout fuel life.

D. Each reactor system is designed so that any xenon transients will be adequately damped.

E. The reactor coolant system is designed and constructed to maintain its integrity throughout the expected plant life.

F. Power excursions that could result from any credible reactivity addition incident do not cause damage either by deformation or rupture of the pressure vessel, or impair operation of the engineered safety features.

G. The combined response of the fuel temperature coefficient, the moderator temperature coefficient, the moderator void coefficient, and the moderator pressure coefficient to an increase in reactor thermal power is a decrease in reactivity. In addition, reactor power transients remain

bounded and damped in response to any expected changes in any operating variable.

The reactor core is further discussed in Chapter 4.

1.2.3.2 Reactor Internals

The internal structures include the core support barrel, the lower support structure & ICI nozzle assembly, the core shroud, and the upper guide structure assembly. The core support barrel is a right circular cylinder supported by a ring flange from a ledge on the reactor vessel. It carries the entire weight of the core. The lower support structure transmits the weight of the core to the core support barrel by means of a beam structure. The core shroud surrounds the core and minimizes the amount of bypass flow. The upper guide structure provides a flow shroud for the CEA's, and limits upward motion of the fuel assemblies during pressure transients. Lateral snubbers are provided at the lower end of the core support barrel assembly.

The principal design bases for the reactor internals are to provide the vertical supports and horizontal restraints during all normal operating, upset, and faulted conditions.

The core is supported and restrained during normal operation and postulated accidents to ensure that coolant can be supplied to the coolant channels for heat removal.

Reactor internals are further discussed in Sections 3.9, 4.5, 19.1.21.B, and Table 19.5-1, Item 23B.

1.2.3.3 Reactor Coolant System (RCS)

The RCS is arranged as two closed loops connected in parallel to the reactor vessel. Each loop consists of one 42-inch ID outlet (hot) pipe, one steam generator, two 30-inch ID inlet (cold) pipes, and two pumps. An electrically heated pressurizer is connected to one of the loops, and safety injection lines are connected to each of the four cold legs and two hot legs.

The RCS operates at a nominal pressure of 2250 psia. The reactor coolant enters near the top of the reactor vessel, then flows downward between the reactor vessel shell and the core barrel, up through the core, leaves the reactor vessel, and flows through the tube side of the two vertical U-tube (with an integral economizer) steam generators where heat is transferred to the secondary system. Reactor coolant pumps return the reactor coolant to the reactor vessel.

Two steam generators, using heat generated by the reactor core and carried by the primary coolant to each steam generator, produce steam for driving the plant turbine-generator. Each steam generator is a vertical U-tube heat exchanger with an integral economizer which operates with the reactor coolant on the tube side and secondary coolant on the shell side.

Each unit is designed to transfer heat from the Reactor Coolant System to the secondary system to produce saturated steam when provided with the proper input feedwater. Moisture separators and steam driers on the shell side of the steam generator limit the moisture content of the steam during normal operation at full power.

Hot reactor coolant from the reactor vessel enters the steam generator through the inlet nozzle in the primary head. From here it flows through the U-tubes, where it gives up heat to the secondary coolant, to the outlet side of the primary head where the flow splits and leaves through the two outlet nozzles. A vertical divider plate separates the inlet and outlet plenums of the primary head. An integral economizer is employed on the cold leg of the U-tube steam generator to enhance the generator thermal effectiveness. With fixed reactor coolant conditions, the use of an economizer enables the steam generator to operate at a higher steam pressure without an increase in heating surface.

The steam generator with integral economizer is in most respects similar to earlier U-tube recirculating steam generators. The basic difference is that instead of introducing feedwater only through a sparger ring to mix with the recirculating water flow in the downcomer channel, feedwater is also introduced into a separate, but integral section of the steam generator. A semi-cylindrical section of the tube bundle, at the cold leg or exit end of the U-Tubes, is separated from the remainder of the tube bundle by vertical divider plates. Feedwater is introduced directly into this section and pre-heated before discharge into the evaporator section. Feedwater flow enters the economizer through two nozzles into the distribution box. Discharge ports in the distribution box are sized and spaced to provide a uniform rate of discharge over the full half circumference of the economizer. The flow after leaving the distribution box passes radially across the tube sheet. A flow baffle acts as the

upper boundary of this radial pass. This baffle is sized to evenly distribute flow through the axial region of the economizer. Flow passes upward through the annuli formed by the tubes and baffle plate into the axial flow region. This region is basically a counter-flow heat exchanger, with feedwater directed upward outside the tubes and primary flow directed downward inside the tubes. Feedwater then exits the economizer slightly subcooled and enters the boiling region of the steam generator.

The remainder of the steam generator differs little from previous recirculating U-tube steam generators manufactured by C-E, except that the lower portion of the evaporator section and the downcomer channel occupy only one-half of the steam generator cross-section. The effect of this non-symmetry is factored into the design of tube support structures. The steam-water mixture leaving the vertical U-tube heat transfer surface enters the separators which impart a centrifugal motion to the mixture and separate the water particles from the steam. The water exits from the perforated separator housings and recirculates through the downcomer channel to repeat the cycle. Final drying of the steam is accomplished by passage of the steam through dryers. The steam generator dryers employ a Peerless hook vane design.

An integral flow restrictor has been installed in each steam generator steam nozzle to reduce flow area.

The reactor coolant is circulated by four electric-motor-driven single-stage centrifugal pumps. The pump shafts are sealed by

mechanical seals. The seal performance is monitored by pressure and temperature sensing devices in the seal system.

The RCS is further discussed in Chapter 5.

1.2.4 ENGINEERED SAFETY FEATURES

Engineered safety features function in the highly unlikely event of an accidental release of radioactive fission products from the reactor system, particularly as the result of loss-of-coolant accidents. These safeguards function to localize, control, mitigate, or terminate such accidents to hold exposure levels below 10CFR100.

1.2.4.1 Containment System

1.2.4.1.1 Containment Building

See section 1.2.12.

1.2.4.1.2 Safety Injection System

In the highly unlikely event of a loss-of-coolant accident, the safety injection system (SIS), including high-pressure and low-pressure safety injection pumps and safety injection tanks, injects borated water into the reactor coolant system. This provides cooling to limit core damage and fission product release and ensures adequate shutdown margin. The SIS also provides continuous long-term, post-accident cooling of the core by recirculation of borated water from the containment sump.

The SIS is discussed further in Section 6.3.

1.2.4.2 Additional PVNGS Engineered Safety Features

In addition to the engineered safety features (ESF) described above, the PVNGS units are provided with the following features:

A. The essential fuel building ventilation system features redundant filter trains that are actuated by an accident signal. By maintaining the lower levels of the auxiliary building at a negative pressure, the system minimizes the offsite radiation dose following a loss-of-coolant accident (LOCA). By maintaining the fuel building at a negative pressure, the system prevents exfiltration of unfiltered air and minimizes the offsite radiation dose following a fuel handling accident in the fuel building. A more complete discussion appears in section 9.4.

B. The containment building purge (both refueling and power access) can be stopped and the containment purge inlet and exhaust lines isolated in the event of high airborne radiation. The containment purge isolation actuation signal (CPIAS) is generated to minimize the offsite radiation dose following a fuel handling accident in the containment building or a LOCA during operation.

C. Control building essential ventilation can be isolated from normal ventilation trains in the event of a high radiation signal. The control room is maintained at a positive pressure to prevent infiltration of unfiltered air and to minimize the radiation dose to

control room personnel. The control building ventilation system is discussed in sections 9.4 and 6.4.

D. The containment hydrogen control system is used to prevent the concentration of hydrogen in the containment from reaching 4% by volume following a LOCA accident. The system is comprised of two full-capacity, independent, parallel loops, each loop containing a hydrogen recombiner with the capability of keeping the containment H_2 concentration below 3.5% by volume. The hydrogen purge subsystem serves as a backup to the hydrogen recombiners. Hydrogen purge is designed to maintain the hydrogen concentration of the containment atmosphere below the flammability limit following a postulated LOCA, even without the use of either recombiner. The hydrogen control system is discussed in detail in subsection 6.2.5.

E. AC Auxiliary Power System

Engineered safety features ac loads are divided into two independent and redundant load groups. Each group consists of one 4.16 kV bus and associated 480V load centers and motor control centers. The normal plant ac loads are supplied by two 13.8 kV buses, two 4.16 kV buses, and associated 480V load centers and motor control centers.

Standby ac power is supplied by two diesel generators. Each ESF load group is supplied by a separate diesel

generator. Each diesel generator is sized to meet the maximum demand of its ESF load group. In order that the independence of these load groups not be compromised, there are no provisions for automatically transferring ESF load group buses between standby ac power supplies.

F. DC Power System

The dc power is supplied by four independent Class 1E 125 V-dc systems, one per ESF channel. The systems are adequate to ensure a constant supply of power to vital instruments and controls. Two 125V batteries provide 125 V-dc power for the nonsafety-related electric system.

G. Essential Cooling Water System

Refer to paragraph 1.2.10.3.3.1, listing A.

H. Essential Spray Pond System

Refer to paragraph 1.2.10.3.3.2.

I. Auxiliary Feedwater System

The auxiliary feedwater system (AFS) consists of one Seismic Category I motor-driven AFS pump; one Seismic Category I steam turbine-driven AFS pump; one non-Seismic Category I motor-driven AFS pump; and associated piping, controls, and instrumentation. Refer to subsection 10.4.9 for a detailed discussion.

1.2.5 INSTRUMENTATION AND CONTROL

Automatic protection systems, control systems, and interlocks are provided, along with the administrative controls of the Applicant, to assure safe operation of the plant. Sufficient instrumentation and controls are supplied to provide manual operation as a normal backup control mode on all automatic systems.

A Plant Protection System (PPS) initiates a reactor trip if the reactor approaches prescribed safety limits, or provides an actuation signal to the Engineered Safety Features Systems when a fluid system or containment parameter approaches a prescribed limit.

Sufficient redundancy is installed to permit periodic testing of the PPS so that removal from service of any one protection system component or portion of the system will not preclude reactor trip, or other protective action when required. Additionally, no single failure can preclude the PPS providing a reactor trip or other protective action when required.

The protection system and associated instrumentation is separated from the control systems and their associated instrumentation such that failure, or removal from service, of any control system, component or instrument channel will not inhibit the functioning of the protection system (see Chapter 7.0 for details).

1.2.5.1 Protection, Control, and Instrumentation Systems

1.2.5.1.1 Reactor Protective System

The controllable reactor parameters are normally maintained within acceptable operating limits by the inherent characteristics of the reactor, the Reactor Regulating System (RRS), soluble boron concentration, and the plant operating procedures.

Four independent channels of the RPS normally monitor each of the selected plant parameters. The RPS logic is designed to initiate protective action whenever the signal of any two channels of a given parameter reach the preset limit. Should this occur, the power supplied to the Control Element Drive Mechanisms (CEDM) is interrupted, releasing the Control Element Assemblies (CEA) which drop into the core to shutdown the reactor. The two-out-of-four logic can be converted to two-out-of-three logic to allow one channel to be bypassed for testing maintenance or operation. The protection system is independent of and separate from the manual and automatic control systems except for a Control Element Withdrawal Prohibit (CWP).

1.2.5.1.2 Supplementary Protection System

The Supplementary Protection System (SPS) augments reactor protection by utilizing a separate and diverse trip logic from the Reactor Protective System for initiation of reactor trip. The added equipment of the SPS provides a simple yet diverse mechanism to increase the overall reliability of the Plant

Protection Systems. The SPS will initiate a reactor trip when pressurizer pressure exceeds a predetermined value.

The SPS is provided with sensors and circuitry which are diverse from that of the RPS. The SPS design uses a selective two-out-of-four logic to interrupt the power supplied to the CEDM's and thereby cause the CEA’s to drop into the core. The SPS is independent and separate from all control systems.

1.2.5.1.3 Engineered Safety Features Actuation System

The Engineered Safety Features Actuation System (ESFAS) operates in a manner similar to the RPS to automatically actuate the Engineered Safety Features (ESF) Systems. Again, it has a selective two-out-of-four actuation logic that can be converted to a selective two-out-of-three logic. The ESFAS is completely independent of the control systems.

1.2.5.1.4 Reactor Control Systems

The reactor control systems are used for startup and shutdown of the reactor, and for adjustment of the reactor power in response to turbine load demand. The NSSS control systems are capable of following ramp load changes between 15% and 100% of full power at a rate of 5% per minute and a step change of 10%, except as limited by Xenon. This control is normally accomplished by automatic movement of CEAs in response to a change in reactor coolant temperature, with manual control capable of overriding the automatic signal at any time. If the reactor coolant temperature is different from a programmed value, the CEAs are adjusted until the difference is within the prescribed control band. Regulation of the reactor coolant

temperature, in accordance with this program, maintains the secondary steam pressure within operating limits and matches reactor power to load demand.

The reactor is controlled by a combination of CEA motion and dissolved boric acid in the reactor coolant. Boric acid is used for reactivity changes associated with large but gradual changes in water temperature, Xenon concentration, and fuel burnup. Addition of boric acid also provides an increased shutdown margin during the initial fuel loading and subsequent refuelings. The boric acid solution is prepared and stored at a temperature sufficient to prevent precipitation.

CEA movement provides changes in reactivity for shutdown or power changes. The CEAs are moved by CEDMs mounted on the reactor vessel head. The CEDMs are designed to permit rapid insertion of the CEAs into the reactor core by gravity. CEA motion can be initiated manually or automatically.

The pressure in the Reactor Coolant System is controlled by regulating the temperature of the coolant in the pressurizer where steam and water are held in thermal equilibrium. Steam is formed by the pressurizer heaters or condensed by the pressurizer spray to reduce variations caused by expansion and contraction of the reactor coolant due to system temperature changes.

Overpressure protection is provided by safety valves connected to the pressurizer and designed in accordance with ASME Code, Section III. The discharge from the pressurizer safety valves is released underwater in the reactor drain tank, where it is cooled and condensed. Over-pressure protection for the tank is

provided by a rupture disc which relieves to the containment. A Steam Bypass Control System (SBCS) is used to dump steam in case of a large mismatch between the power being produced by the reactor and the power being used by the turbine. This allows the reactor to remain at power instead of tripping. Each steam generator’s water level is maintained by a Feedwater Control System (FWCS). A Reactor Power Cutback System (RPCS) is used to drop selected CEAs into the core to reduce reactor power rapidly during a large loss of load. This allows the SBCS and FWCS to maintain the NSSS in a stable condition, without a reactor trip, and without lifting any safety valves during loss of large load transients with condenser available.

1.2.5.1.5 Nuclear Instrumentation

The nuclear instrumentation includes ex-core and in-core neutron flux detectors. Eight channels of ex-core instrumentation monitor the power. Two channels are provided for the startup, two channels are provided for power control, and four channels are provided for the protection channels. The control channels are used to control the reactor power during power operations. The protection channels are used to provide inputs to the overpower, logarithmic power Departure from Nuclear Boiling Rate (DNBR), and Local Power Density (LPD) trips in the RPS.

The in-core instrumentation consists of self-powered detectors, distributed throughout the core, which provide information on flux distribution within the core.

1.2.5.1.6 Monitoring Systems

The Plant Monitoring System (PMS) performs general monitoring of the NSSS and balance of plant; logging, trending, and alarming of conditions are its major functions. The PMS is not necessary for successful plant operations. Part of the PMS is the Core Operating Limit Supervisory System (COLSS).

General temperature, pressure, flow and liquid level monitoring are provided as required to keep the operating personnel informed as to plant operating conditions. Protection channels will indicate the various parameters used for protective action as well as providing trip and pre-trip alarms from the RPS. The plant liquid and gaseous effluents are monitored to assure that they are maintained within applicable radioactivity limits. A complete description of the radiation instrumentation is discussed in Chapter 11.0.

Additional instrumentation and controls are discussed in detail in chapter 7.

1.2.6 ELECTRIC SYSTEM

1.2.6.1 Transmission and Generation System

The main generator is connected by an isolated phase bus to the 24 kV side of the main step-up transformer. The other side of the main transformer is connected to 525 kV lines which carry the power to the Palo Verde 525 kV switchyard that is part of the 525 kV transmission network.

1.2.7 POWER CONVERSION SYSTEM

1.2.7.1 Turbine-Generator

The turbine-generator is an 1800 r/min, tandem compound, six-flow, 43-inch last-stage bucket reheat unit with an electrohydraulic control system.

The rated NSSS power levels, turbine generator gross outputs, and nominal net output powers for the Palo Verde Units are provided in section 1.1.4.

The generator is a direct-driven, three-phase, 60 Hz, 24,000V, 1800 r/min, conductor cooled synchronous generator rated at approximately 1559 MVA at 0.90 power factor and 75 psig hydrogen pressure.

1.2.7.2 Main Steam Supply System

The main steam supply system provides steam from the steam generators for the turbine-generator, the feedwater pump turbines, the turbine gland sealing system, condensate and feed-water heating, and main turbine reheat steam as required.

1.2.7.3 Main Condenser

Steam from the low-pressure turbine is exhausted directly downward into the condenser shells through exhaust openings in the bottom of the turbine casings and is condensed. The condenser is a multisection, multipressure condenser, each section serving one double-flow, low-pressure turbine section. The condenser also serves as a heat sink for the turbine bypass system.

1.2.7.3.1 Condenser Air Removal System (CARS)

The condenser air removal system removes air and noncondensable gases from the main condenser and exhausts them to the atmosphere via the plant vent. The CARS consists of four two-stage mechanical vacuum pumps. Three vacuum pumps are used during startup and normal operation. One additional vacuum pump serves as backup to the three pumps in operation.

1.2.7.4 Circulating Water System

The circulating water system provides the main condenser with a continuous supply of cooling water to remove the heat rejected from the turbine thermal cycle. The circulating water system consists of three circular mechanical draft cooling towers and four vertical, motor-driven pumps. The circulating water pumps circulate the cooling water from the cooling tower basins through the main condenser and then back to the cooling towers. Makeup water to compensate for drift, blowdown, and evaporative losses is supplied from the makeup water reservoirs.

1.2.7.5 Condensate and Feedwater System

Three condensate pumps take the deaerated condensate from the hotwells of the main condenser and deliver it through the low-pressure feedwater heaters to two feedwater pumps. Drains from moisture separators and reheaters, and the high-pressure feedwater heaters, are pumped into the suction stream of the feedwater pumps by two heater drain pumps, and the drains from low-pressure heaters are cascaded back to the main condenser. The feedwater pumps discharge the total feedwater flow through the high-pressure feedwater heaters to the steam generators.

1.2.7.6 Condensate Storage and Transfer System

The condensate storage and transfer system maintains the required capacity and flow of condensate for the auxiliary feedwater systems and maintains a level in the condenser hot-well. The system consists of a condensate tank, two condensate transfer pumps, and the necessary controls and instrumentation. For a detailed description of this system, see subsection 10.4.7.

1.2.8 HEATING, VENTILATING, AND AIR CONDITIONING SYSTEMS

1.2.8.1 Control Building

The control building includes the following heating, ventilating, and air conditioning systems (HVAC):

A. Control Room

The control room HVAC system is designed to provide a suitable environment for equipment and personnel. The HVAC system is divided into two subsystems, a normal HVAC system and an essential HVAC system. The system is designed to detect, limit the introduction of, and remove foreign material from the control room environment. Refer to subsection 9.4.1 for system description. The emergency system is described in section 6.4.

B. Engineered Safety Features Switchgear Rooms

Each area has its own HVAC system that consists of the following components; prefilter, high efficiency particulate filter, cooling coil, supply fan, and duct

heater. These units are located in separate fan rooms and serve ESF switchgear trains A and B, respectively. This same system supplies ESF equipment rooms and battery rooms. See subsection 9.4.1 for additional information.

C. Cable Spreading Rooms

The upper and lower cable spreading rooms HVAC systems are designed to remove heat generated in these rooms. A smoke exhaust system is also provided. The system is a part of the control building normal HVAC system. This system receives power from the normal power distribution system. See subsection 9.4.1 for additional information.

D. Computer Room

This system is combined with the control room air conditioning system as specified in subsection 9.4.1.

1.2.8.2 Containment Building

The containment building ventilation systems consist of the normal cooling, CEDM cooling, reactor cavity cooling, tendon gallery ventilation, preaccess filter, and normal purge systems. Details of these systems are discussed in subsection 9.4.6.

1.2.8.3 Turbine Building

The turbine building ventilation system is designed to provide an environment that ensures the comfort of plant personnel and the integrity of equipment and components. Evaporative cooled

outside air is supplied to the turbine building at each floor and then is drawn through the equipment areas on the floor by the exhaust systems. Turbine building ventilation systems are discussed in detail in subsection 9.4.4.

1.2.8.4 Auxiliary Building

The auxiliary building ventilation system is designed to provide a controlled environment to ensure the comfort and safety of personnel and to maintain the integrity of equipment. Conditioned outside air is distributed throughout the building.

The design of the ventilation system is such that, during normal plant operation, air is directed from areas of lower to areas of potentially higher airborne activity. Air is exhausted from the areas of high potential radioactivity, through a filter train to the plant vent. The ESF pump rooms are provided with one cooling unit per room to supply cooling to ESF pump motors. The unit consists of a fan and cooling coil that removes heat from the pump room. For additional information, refer to subsection 9.4.2.

1.2.8.5 Radwaste Building

The radwaste building ventilation system is designed to provide an environment with controlled temperature and airflow patterns. Outside air is directed to areas of low potential radioactivity and then is exhausted from areas of high potential radioactivity. The design of the ventilation system is such that, during normal plant operation, air is directed from areas of lower to areas of potentially higher airborne activity. A filtering unit processes the air before it is

released through the plant vent. A description of the system is found in subsection 9.4.3.

1.2.8.6 Fuel Building

The fuel building ventilation system provides a controlled temperature environment to ensure personnel comfort and safety and to ensure equipment integrity. Cooled outside air is distributed by the supply fan and associated ducting to areas of the building. The design of the ventilation system is such that, during normal plant operation, air is directed from areas of lower to areas of potentially higher airborne activity. The air is exhausted continuously to the plant vent.

The fuel building normal ventilation system is isolated by the closure of automatic dampers, and the fuel building essential ventilation system is started upon sensing abnormal radiation levels. See subsection 9.4.5 for a detailed description.

1.2.8.7 Diesel Generator Building

The diesel generator rooms are heated and ventilated to provide a suitable environment for operation of the diesel and its support equipment. Each diesel generator supplies power to its own exhaust fans when operational. See subsection 9.4.7 for a detailed description.

1.2.9 FUEL HANDLING AND STORAGE

1.2.9.1 Fuel Handling

Fuel handling equipment provides for the safe handling of fuel assemblies and CEAs under all specified conditions and for the

required assembly, disassembly, and storage of reactor vessel head and internals during refueling.

The major components of the system are the refueling machine, the CEA change platform, the fuel transfer system, the spent fuel handling machine, the new fuel handling crane, the cask handling crane, the transportable storage canister, the transfer cask, vertical concrete casks, and the new fuel and CEA elevators. This equipment is provided to transfer new and spent fuel between the fuel storage facility, the containment building, the fuel shipping and receiving areas, and the independent spent fuel storage installation (ISFSI) during core loading, refueling, and storage operations. Fuel is inserted and removed from the core using the refueling machine. During normal operations, irradiated fuel and CEA's are always maintained in a water environment. During interim dry storage at the ISFSI, irradiated fuel is stored in a helium environment in dry casks.

The principal design criteria specify the following:

A. Fuel is inserted, removed, and transported in a safe manner.

B. Subcriticality is maintained in all operations.

Fuel handling is discussed in section 9.1.4.

1.2.9.2 <u>Fuel Storage</u>

New fuel is stored dry in vertical racks in the fuel handling building. Room is provided to store one third of a core. The rack and fuel assembly spacing precludes criticality. Refer to subsection 9.1.1 for details.

Either new or spent fuel may be stored underwater in the intermediate storage racks inside containment. Refer to subsection 9.1.2.4 for details.

The spent fuel pool is a reinforced Seismic Category I concrete structure, stainless steel lined, which provides storage capacity for up to five and one-third cores (with expansion).

Either new or spent fuel assemblies may be stored in vertical racks in the spent fuel pool so spaced as to preclude criticality with partial credit taken for administrative controls on storage locations, and the borated pool water. Refer to subsection 9.1.2 for details.

Cooling and purification equipment is provided for both the refueling pool and spent fuel pool water, as described in paragraph 1.2.10.3.3.6.

The Independent Spent Fuel Storage Installation (ISFSI) is a Seismic Category 1X facility for interim dry storage of fuel assemblies that meet specific selection criteria. Irradiated fuel assemblies are stored in specially designed canisters and casks which provide passive cooling and shielding. Refer to subsection 9.1.2 for details.

1.2.10 AUXILIARY SYSTEMS

1.2.10.1 Shutdown Cooling System

The shutdown cooling system is used to reduce the temperature of the reactor coolant at a controlled rate from 350°F to a refueling temperature of approximately 135°F and to maintain the proper reactor coolant temperature during refueling. This system utilizes the low-pressure safety injection pumps to

circulate the reactor coolant through two shutdown heat exchangers, returning it to the reactor coolant system through the low-pressure injection header. The component cooling water system supplies cooling water for the shutdown heat exchangers.

The shutdown cooling system is further discussed in Section 5.4.7.

1.2.10.2 Chemical and Volume Control System

The Chemical and Volume Control System (CVCS) controls the purity, volume, and boric acid content of the reactor coolant.

The coolant purity level in the Reactor Coolant System is controlled by continuous purification of a bypass stream of reactor coolant. Water removed from the Reactor Coolant System is cooled in the regenerative heat exchanger. From there, the coolant flows to the letdown heat exchanger and then through a filter and a demineralizer where corrosion and fission products are removed. It is then sprayed into the volume control tank and returned by the charging pumps to the regenerative heat exchanger where it is heated prior to return to the Reactor Coolant System.

The Chemical and Volume Control System automatically adjusts the amount of reactor coolant in order to maintain a programmed level in the pressurizer. The level program partially compensates for changes in specific volume due to coolant temperature changes and reactor coolant pump controlled seal leakage. (See Section 9.3.4.2 for details.)

The CVCS controls the boric acid concentration in the coolant by a "feed and bleed" method where the purified letdown stream

is diverted to a boron recovery section and either concentrated boric acid or demineralized water is sent to the charging pumps. The diverted coolant stream is processed by ion exchange and degasification and flows to a concentrator. The concentrator bottoms are sent to the refueling water tank for reuse as boric acid solution and the distillate is first passed through an ion exchanger and then stored for reuse as demineralized water in the reactor makeup water tank.

1.2.10.3 Other Auxiliary Systems

1.2.10.3.1 Secondary Chemistry Control System

The secondary chemistry control system is designed to continuously monitor and inject chemicals into the feedwater to minimize system corrosion in the steam generator and the feed-water. The system is described in subsection 10.4.6.

1.2.10.3.2 Nuclear Sampling System

The nuclear sampling system is designed to collect samples from the reactor coolant and auxiliary systems for analysis. It permits sampling during reactor operation and cooldown without requiring access to the containment. Remote samples can be taken from equipment located in high radiation areas without personnel entering these areas. The sample lines are sized for the proper velocities to obtain representative samples and to prevent deposition. The process sampling system is described in detail in subsection 9.3.2.

1.2.10.3.3 Cooling Water Systems

1.2.10.3.3.1 Cooling Systems for Reactor Auxiliaries.

Cooling for reactor auxiliaries is provided by two systems, the safety-related essential cooling water system (ECWS) and the nonsafety-related nuclear cooling water system (NCWS). These systems are described in detail in subsection 9.2.2. A brief description of each system is provided as follows:

A. Essential Cooling Water System

The ECWS is comprised of two redundant Seismic Category I trains. These trains supply corrosion inhibited cooling water to components that are required for normal and emergency shutdown. The system also functions as an intermediate barrier between systems and equipment containing radioactive or potentially radioactive fluids and the essential spray pond system (ESPS) described in paragraph 1.2.10.3.3.2. Following a safety injection actuation signal (SIAS), cooling is supplied to the essential headers.

B. Nuclear Cooling Water System

The nonsafety-related NCWS supplies corrosion inhibited cooling water to reactor auxiliary systems and equipment during normal plant operation. The NCWS consists of one train with redundant components and acts as an intermediate barrier between systems and equipment containing radioactive or potentially radioactive fluids and the plant cooling water system.

1.2.10.3.3.2 Essential Spray Pond System. The ESPS is a safety-related, Seismic Category I system comprised of two redundant trains. The ESPS trains supply cooling water to the ECWS trains that are required to function for normal and emergency shutdown. This system is described in detail in subsection 9.2.1.

1.2.10.3.3.3 Ultimate Heat Sink. One ultimate heat sink is provided for each generating unit. The ultimate heat sink consists of two Seismic Category I essential spray ponds. The ultimate heat sink is utilized for normal and emergency shutdown in conjunction with the ESPS and the ECWS. The ultimate heat sink has a storage capacity that enables the associated ESPS trains to operate continuously for 26 days without any makeup water supply. However, normal makeup to replace evaporative loss from the ultimate heat sink is provided from the domestic water system or makeup water reservoir. Refer to subsection 9.2.5 for a detailed description of the ultimate heat sink.

1.2.10.3.3.4 Plant Cooling Water System. During normal operation, the plant cooling water system (PCWS) is utilized to remove heat from the NCWS and the turbine cooling water system (TCWS).

The PCWS rejects heat to the circulating water system. Redundant heat exchangers and pumps are provided. The PCWS is described in detail in subsection 9.2.10.

1.2.10.3.3.5 Turbine Cooling Water System. The TCWS is a nonsafety-related cooling system that provides treated demineralized cooling water to components in the turbine plant and acts as an intermediate system between turbine plant components and the PCWS. A detailed description of the TCWS is provided in subsection 9.2.8.

1.2.10.3.3.6 Spent Fuel Pool Cooling and Cleanup System. The spent fuel pool cooling system provides forced cooling of the pool water as required under normal and emergency (loss of offsite power) operating conditions. During normal operation, the fuel pool heat exchangers are supplied with cooling water by the NCWS. In the event of loss of offsite power, cooling water is available from the ECWS. The fuel pool and the fuel pool cooling system are Seismic Category I systems. The shutdown cooling system described in UFSAR Section 1.2.10.1 can also be used to augment fuel pool cooling. See Section 9.1.3.2.1.1

The purification loop is used to maintain the purity and clarity of water in the fuel transfer canal, the spent fuel pool, and refueling pool. The loop has a filter and demineralizer for purifying the water.

These systems are described in detail in subsection 9.1.3.

1.2.10.3.3.7 Evaporation Ponds. Evaporation ponds were added incrementally as the units were brought on line. They are earth embankments, lined with an artificial liner to limit seepage. The ponds store and evaporate cooling tower blowdown water and wastewater. Pond No. 1, pond No. 2 and pond No. 3

are lined with a composite liner that is described in paragraph 2.4.8.2.3.

1.2.10.3.4 Plant Fire Protection System

The fire protection water system provides water to any plant area where fire protection may be required. Units 1, 2, and 3 share a common fire protection water system. Water is taken from its two fire water/well water reserve tanks. The system consists of one electric-driven pump, two diesel engine driven pumps, one jockey pump, and the associated piping, valves, hydrants, and hose stations.

Chemical, carbon dioxide, and Halon 1301 firefighting systems also are provided in addition to the water fire protection system.

Necessary instrumentation and controls are provided for proper operation of the fire protection system. The fire protection system is described in subsection 9.5.1

1.2.10.3.5 Communications Systems

A communication system is provided with multiple redundancy to ensure safety, ease of operation, and maintenance. The system provides onsite, intraplant, interplant, and plant-to-offsite communications. The communication system is normally ac powered with a backup dc supply. The system description is given in subsection 9.5.2.

1.2.10.3.6 Lighting System

The three lighting systems provided are described as follows:

A. Normal Lighting

The normal lighting system provides illumination for the entire plant. The lighting load is distributed between two non-Class 1E lighting transformers.

B. Essential Lighting

The essential lighting system is connected to ESF buses. In general, the essential lighting system is designed to provide sufficient illumination to allow safe personnel access/egress throughout the plant in the event of a loss of normal lighting. It is also designed to provide sufficient illumination for the local manual operation of safe shutdown equipment in the event of fire. It provides 100% lighting in the control room area and remote shutdown room.

C. Emergency Lighting

The emergency lighting system is provided in areas used during shutdown or emergency. These areas include the control room, the local control stations required to shut down and maintain the plant in a hot shutdown condition from outside the control room, and the emergency exit routes. All emergency lighting is served by either self-contained battery units or battery backed UPS systems.

The lighting systems are described in detail in subsection 9.5.3.

1.2.10.3.7 Demineralized Water System

The demineralized water system furnishes demineralized water to each unit. Water from the reverse osmosis subsystem of the domestic water system is used to supply the demineralized water makeup system. The demineralizers consist of three mixed bed demineralizer units. Any two demineralizer beds operate in series to form a makeup train. A condensate tank, a demineralized water tank, and a reactor makeup tank are used at each unit to maintain the required demineralized water storage. The system is described in subsection 9.2.3.

1.2.10.3.8 Domestic Water System

The domestic water system provides necessary potable water to each unit for the consumptive use of plant personnel and water for other general plant uses. Well water is filtered, processed, and chlorinated prior to distribution throughout the plant. The domestic water system is described in subsection 9.2.4.

1.2.10.3.9 Alternate AC Power System

The station blackout gas turbine generation system is available to provide ac power to station loads that have been identified as important to the mitigation of a station blackout in any one unit of PVNGS. Two redundant 100 percent capacity Station Blackout Generators (SBOGs) are available for providing power to one of the safety related 4.16kV busses in each unit. The system is described in Section 8.3.1.1.10.

The SBOGs are also available during modes 5 & 6 to provide emergency power for shutdown cooling operations under conditions addressed in station abnormal and emergency operating procedures.

Having the SBOGs available to support a shutdown unit in the event of a SBO, does not impact their ability to support a unit that is at full power.

1.2.11 RADIOACTIVE WASTE MANAGEMENT SYSTEMS

The radioactive waste management system is designed to safely control potentially radioactive liquid, gaseous, and solid wastes. The system includes three principal subsystems:

- Liquid radwaste system (LRS)
- Gaseous radwaste system (GRS)
- Solid radwaste system (SRS)

The LRS is designed so that during normal operation there is no offsite release of radioactive liquids of plant origin from the plant site. The design of all radwaste systems ensures that all radioactive releases are as low as is reasonably achievable (ALARA).

1.2.11.1 Liquid Radwaste System

The LRS recovers radioactive or chemical liquid wastes for solidification. The system can accommodate liquid wastes generated at maximum anticipated rates, including demineralizer resin chemical regenerants from the condensate demineralizers,

and can segregate waste on the basis of total dissolved solids (TDS) for optimal economic treatment.

Particulate and ionic impurities in low TDS waste are removed by filters and ion exchangers. High or low TDS liquid wastes are concentrated by the LRS evaporator and are solidified. Evaporator condensate flows through ion exchangers prior to being recycled as reactor makeup water or condensate makeup. See section 11.2 for a detailed description of the LRS.

1.2.11.2 Gaseous Radwaste System

The GRS has two separate process paths based on the activity and/or hydrogen content of the waste gas. High-activity, hydrogen rich gases from the reactor coolant are collected, compressed, and stored in tanks to allow for radioactive decay. Low activity, aerated gases are removed by exhaust systems and are released through the plant vent. After decay, contents of the waste gas decay tanks are discharged to the plant ventilation system for dilution and are released with the low activity gases. All waste gases are filtered and monitored prior to environmental release. See section 11.3 for a detailed description of the GRS.

1.2.11.3 Solid Radwaste System

The SRS originally designed for the station is abandoned. The waste solidification process is described in section 11.4.

1.2.12 MAJOR STRUCTURES AND EQUIPMENT ARRANGEMENTS

Major Seismic Category I structures are described in the following sections. Engineering drawings 13-C-ZVA-005 and

13-P-OOB-001 provide a plot plan and engineering drawings 13-P-OOB-002 through -011 provide the general arrangements for the PVNGS units.

1.2.12.1 Containment Building

The containment building is a prestressed concrete cylinder with a hemispherical dome. The basemat is a flat, circular slab of reinforced concrete. The interior of the structure is lined with a continuous, welded steel plate 1/4 inch thick. Approximate dimensions of the structure are:

Structure Characteristic	Dimensions (ft)
Inside diameter	146
Inside height	206.5
Vertical wall thickness	4
Dome thickness at apex	3.5
Basemat diameter	161
Basemat thickness	10.5
Net Free Volume	2.62×10^6 ft^3

The Containment building is designed for a maximum internal pressure of 60 psig and a maximum, accident condition inner surface temperature of 300 degrees F. Housed within the containment building and supported by the basemat are the reinforced concrete and structural steel internal structures that support the reactor and reactor coolant system.

Under the most severe of postulated loading conditions -- including the combined effects of permanent loads, design basis LOCA loads, and either the safe shutdown earthquake or tornado

loads -- the containment building is designed to maintain its structural and leaktight integrity. This design permits a predictable response of the containment structure to allow operation of engineered safety features equipment for mitigation of accident consequences. Together with isolation valves, penetration assemblies, and its continuous, welded-steel liner, the structure contains the released fission products and maintains a leak rate below the design leak rate levels. The containment is designed to provide long-term control of fission products following a postulated accident.

1.2.12.2 Auxiliary Building

The auxiliary building is a multistory, reinforced concrete structure approximately 139 by 194 feet. It is located adjacent to the containment building but is physically separated from it. It has a two-level basement extending approximately 60 feet below grade. The building rises to about 56 feet above grade at its highest point. The auxiliary building primarily houses the ESF and CVCS equipment, and the power block controlled access facility.

1.2.12.3 Control Building

The control building is approximately 86 by 114 feet and is a four-story reinforced concrete structure. It is located adjacent to the radwaste and auxiliary buildings but is physically separated from them. It has a full basement below grade and rises to about 80 feet above grade at its highest point. The control building primarily houses the control room, computer room, upper and lower cable spreading rooms, battery

rooms, electrical equipment rooms, and ventilation equipment rooms.

1.2.12.4 Fuel Building

The fuel building is a reinforced concrete structure approximately 88 by 124 feet, rising to about 94 feet at its highest point. It is located adjacent to the containment and auxiliary building but is physically separated from them. The fuel building primarily houses the spent fuel pool, new fuel storage area, the dry spent fuel storage system loading and transfer equipment, and the spent fuel pool cooling heat exchangers and pumps.

1.2.12.5 Essential Spray Ponds

Two identical essential spray ponds (ESPs) are provided per unit. The combined water capacity of both ESPs is sufficient for 26 days continuous operation without makeup. The ESPs are approximately 172 by 345 feet. The perimeter walls are 17.5 feet high and 2 feet thick. See subsection 9.2.5 for a detailed description of the ESP.

1.2.12.6 Diesel Generator Building

The diesel generator building is a reinforced concrete structure located adjacent to the control building but is physically separated from it. The building is approximately 80 by 60 feet and has a maximum height of approximately 48 feet above grade.

1.3 COMPARISON TABLES

1.3.1 COMPARISONS WITH SIMILAR FACILITY DESIGNS

Tables 1.3-1 and 1.3-2 present a summary of the characteristics of the Palo Verde Nuclear Generating Station for Unit 1 Cycle 1 (the reference cycle for the three PVNGS units). Table 1.3-1 presents similar reactor core and coolant system data for Pilgrim Station Unit 2 and San Onofre Units 2 and 3.
Table 1.3-2 presents similar containment system, engineered safety features, and electrical components data for Farley Units 1 and 2, Calvert Cliffs 1 and 2, and San Onofre Units 2 and 3. The values presented in these tables were valid at the time the operating licenses were issued, and are not updated.

The Pilgrim Station Unit 2 and San Onofre Units 2 and 3 designs were selected for comparison in table 1.3-1 because of the basic similarity of the reactor core and coolant systems. In addition, San Onofre was selected for comparison because this reactor is nearing completion of its operating license application review with the NRC.

1.3.2 COMPARISON OF FINAL AND PRELIMINARY INFORMATION

Table 1.3-3 contains a discussion of significant changes that have been made in plant design since submittal of the PVNGS 1, 2, and 3 PSAR and amendments 1 through 20. These changes were applicable at the time the operating licenses were issued. Any subsequent changes are not documented in Table 1.3-3.

Table 1.3-1

REACTOR CORE AND COOLANT SYSTEM PARAMETERS (Sheet 1 of 9)

Item	Palo Verde	Reference Section	Pilgrim Station Unit 2	San Onofre Units 2 and 3

On site storage:							
High level solidification	42-80 ft^3 drums or 294-55 gal drums	20-50 ft^3 drums	175-55 gal drums				
Low level solidification baling station	50-55 gal drums	25-55 gal drums	400-55 gal drums				
Shipping containers used	55-gal drums and 80 ft^3 drums	55 gal drums and 50 ft^3 drums	55 gal drums				

COMPARISON TABLES

Table 1.3-3

SIGNIFICANT DESIGN CHANGES

Items	System Described in FSAR Section	Reason for Change
Containment spray	6.1	The containment spray additive was eliminated based on analyses that demonstrate acceptable consequences following a small or large break LOCA using borated refueling water as spray. The Iodine Removal System (IRS) has been disconnected from the Containment Spray System (CCS) and abandoned in place. Hydrazine is caustic and hazardous to work with. Elimination of the IRS reduces both personnel and property hazards from leaking seals, pumps, and valves, and significantly reduces cleanup requirements in the event of an inadvertent CSS actuation. Elimination of the IRS increases CSS System reliability by removing active components subject to potential failure.
Condensate storage tank	3.8	Changed from steel tank with concrete missile barrier to concrete, Seismic Category I structure with stainless steel liner.
Refueling water tank	3.8	Changed from steel tank with concrete missile barrier to concrete, Seismic Category I structure with stainless steel liner.
Atmospheric dump valves	10.3.2	Changed to safety grade controls.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

1.4.1 ENGINEER

Bechtel Power Corporation (BPC) entered into separate contracts with Arizona Public Service Company (APS) for the engineering and construction of Palo Verde Nuclear Generating Station (PVNGS) in 1973.

In 1984, the construction contract was assigned to Bechtel Construction, Inc. (BCI) which is responsible for the construction of PVNGS, and in 1986, the engineering and procurement services were subcontracted to Bechtel Western Power Corporation (BWPC).

BWPC, as agent for APS, is responsible for all procurement and manages procurement contracts, including the nuclear steam supply system (NSSS), turbine-generator and other designated contracts entered into by APS.

BWPC and BCI are responsible for implementing the Bechtel quality assurance program within the scope of their respective contracts. BWPC is obligated to conduct a quality assurance program, including audits of its own work, BCI, and all of its subcontractors.

1.4.2 NUCLEAR STEAM SUPPLY SYSTEM SUPPLIER

APS has contracted with Combustion Engineering, Inc. (C-E), located in Windsor, Connecticut, to design, manufacture, and deliver an NSSS for each unit and nuclear fuel for the initial core and first reload batch of each NSSS. In addition, C-E furnishes technical direction for erection, initial fuel

loading, testing, and initial startup of each NSSS. C-E is further obligated to conduct a quality assurance program, including audits, of its own work and all its subcontractors and suppliers, in a manner which complies with 10CFR50, Appendix B.

1.4.3 TURBINE-GENERATOR SUPPLIER

The turbine-generator (TG) is manufactured by the General Electric Company (GE). Design of the TG is under the direction of the Large Steam Turbine-Generator Products Division located in Schenectady, New York. General Electric furnishes technical direction during erection testing and startup of the TG.

1.4.4 PRINCIPAL CONSULTANTS

1.4.4.1 NUS/ERTEC Western

NUS Corporation of Rockville, Maryland, along with its geotechnical consultant, ERTEC Western, Inc. (formerly FUGRO) of Long Beach, California, has performed site selection and environmental studies and has provided appropriate input to the FSAR and Environmental Report-Operating License Stage (ER-OL). NUS and ERTEC are obligated to conduct a quality assurance program, including audits of their own work and all their subcontractors and suppliers, as appropriate, in a manner which complies with 10CFR50, Appendix B.

1.4.4.2 S. M. Stoller Corporation

The S. M. Stoller Corporation, located in New York City, has acted as a general nuclear consultant, providing technical assistance as required.

1.4.5 DIVISION OF RESPONSIBILITY

1.4.5.1 Design Stage

Combustion Engineering, Inc. and Bechtel are delegated the responsibility for design of the NSSS and the balance of the plant, respectively. All parties (APS, Bechtel, C-E, and NUS/Fugro) participated in the preparation and review of design bases and philosophies for both systems and structures by reviews of the design. General Electric and C-E are responsible to review Bechtel's balance of plant design to assure proper interface with their supply.

1.4.5.2 Procurement of Safety-Related Equipment

1.4.5.2.1 Combustion Engineering, Inc. Scope of Supply

Procurement procedures are established for safety-related equipment under the C-E scope of supply. These require both APS and Bechtel to review bidders' lists and specifications. All bidders meet the quality assurance requirements described in CESSAR Section 17.0. Combustion Engineering, Inc. prepares specifications, issues requests for proposals, evaluates proposals, advises Bechtel and APS of prospective suppliers, and issues purchase orders to suppliers.

1.4.5.2.2 Bechtel Scope of Supply

Procurement procedures are established for the safety-related equipment under the Bechtel scope of supply. These require both APS and Bechtel participation. Bechtel prepares the specifications and lists of qualified bidders and transmits them to APS for review and comment. After review by APS and resolution of any comments by Bechtel, Bechtel has the responsibility for issuing specifications to the bidders for proposals in accordance with the approved bidders' list. All bidders meet the quality assurance requirements described in chapter 17. After reviewing the proposals, Bechtel prepares a technical and commercial evaluation and forwards a recommendation for purchase to APS. After review by APS, Bechtel is advised of the selected supplier. Bechtel then prepares purchase order documents for execution by APS. Bechtel then manages these purchase orders for APS.

1.4.5.3 Construction

Bechtel provides primary construction activities and overall construction management for PVNGS. Certain portions of the construction activities have been subcontracted subject to the concurrence of APS. Independent testing agencies are utilized, as necessary, to perform special tests and to provide expertise in the interpretation of test results.

1.4.5.4 Operation

APS has the responsibility for the operation of PVNGS as described in chapter 13.

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

This section lists a number of development programs. Table 1.5-1 lists those programs and identifies where results are documented.

1.5.1 TOPICAL PROGRAM SUMMARY

References 1 through 5 present descriptions of safety related Research and Development programs which are being carried out by, or in conjunction with Combustion Engineering, Inc., and which are applicable to C-E pressurized water reactors (PWR). This type of report is updated annually.

For each program summarized in these reports, the objectives are first introduced, followed, where appropriate, by background information. This is followed by a description of each program relative to the stated objectives and a presentation of pertinent, up-to-date results. Finally, conclusions are made where appropriate and future work plans are discussed relative to past performance and findings of the program. New programs, which include existing programs which become safety related for licensing purposes will be described in future versions of this report. Descriptions of programs or parts of programs are phased out of versions of this report as they are completed and documented.

1.5.2 SYSTEM 80 - 16 x 16 ASSEMBLY TEST PROGRAM

Since fuel fabrication for System 80 reactors is not scheduled to start for some time, the development schedule is compatible with the project schedules having System 80 designs such that

definite results will be available before each plant design is complete and/or in time to consider a backup position in the program or changes in the design should the program results not verify expectations.

1.5.2.1 Components Testing

Component test programs have been conducted in support of all C-E PWR designs. The tests subject a full-scale reactor core module comprising fuel assemblies, control element assembly, control element drive mechanism, and reactor vessel internals components to the hydraulic environment of the reactor under all normal operating conditions. The program is a continuing series of tests wherein components introduced as part of a particular design are tested in C-E TF-2 hot loop test facility at Windsor, Connecticut. The Tests are designed to proof and life test the integrated fuel assembly and control element drive mechanism under a variety of simulated operating conditions to evaluate component fretting and wear characteristics, scram performance, and fuel assembly uplift and pressure drop. Information and a description of the testing is provided in Section 4.4.4.2.

1.5.2.2 Fuel Assembly Seismic Testing

The program can be divided into three areas - spacer grid tests, fuel assembly static tests and fuel assembly dynamic tests. The results are utilized in developing the seismic models of the fuel described in Section 3.7.3.14 and Section 4.2.

1.5.2.3 Reactor Flow Model Testing

A scale flow model of the C-E System 80 reactor vessel and internals has been tested. A detailed discussion of the flow model and test facility appears in Section 4.4.4.2. The purpose of these tests is to establish or verify design hydraulic parameters. In particular, core inlet flow distributions and pressure losses along the flow path segments within the reactor vessel have been measured for operating configurations.

1.5.2.4 DNB Improvement

A substantial test program has been undertaken to verify the thermal performance capability of the System 80 fuel assembly. The test program is an extension of the experimental studies conducted with rod bundles representative of the C-E 14 x 14 fuel assembly. Those studies are described in more detail in Section 4.4.4.5 and are used in System 80 analyses.

1.5.2.5 Fuel Development Programs

Combustion Engineering has in progress several company-sponsored fuel irradiation programs. In addition, several cooperative fuel development programs are being performed with Kraftwerk Union as part of a technical agreement. Also, Combustion Engineering has access to all data and results of Kraftwerk Union's company-sponsored fuel development programs.

A complete description of the programs and the results obtained is provided in Section 4.2.

1.5.3 SYSTEM 80 STEAM GENERATOR DEVELOPMENT PROGRAMS

C-E's System 80 Steam Generator is a vertical U tube component. The current Palo Verde steam generators from Ansaldo-Camozzi energy special SPA represent the next evolution of the System 80 steam generator. A complete description of the steam generator is given in Section 5.4.2. Development efforts were conducted to confirm the structural integrity of the steam generator during thermal, MSLB and FWLB transients.

1.6 REFERENCED MATERIAL

1.6.1 GENERAL REFERENCES

General references are not considered part of the FSAR, but are intended to provide background information or additional detail that the reader may refer to in order to learn more about particular material presented in the FSAR. These may be texts, environmental studies or technical reports, as well as PVNGS controlled documents such as operating or maintenance procedures, calculation manuals, etc. References to such information may be located at specific points in the FSAR, or they may be listed at the end of FSAR chapters or in introductory sections.

The basic reference document for the PVNGS FSAR is the Combustion Engineering Standard Safety Analysis Report (CESSAR). The use of the CESSAR is described in section 1.9.

Referenced Bechtel Power Corporation (BPC) topical reports are listed in Table 1.6-1. These topical reports have been approved by the NRC as shown in Table 1.6-2. Referenced Combustion Engineering Topical Reports are listed in Table 1.6-3. The revision/supplement/addendum level indicated in these tables represents the revision/supplement/addendum that is referenced. Additional references may be included at the end of each FSAR section or chapter.

1.6.2 INCORPORATION BY REFERENCE

Information that is appropriate to include in the FSAR, that is also part of a separate PVNGS controlled document or technical

report, may be incorporated by reference. "Incorporation by reference" refers to a method by which all or part of a separate source document can be made part of the FSAR without duplicating the desired information in the FSAR.

For PVNGS information to be incorporated by reference, the information must be publicly available (i.e., it must have been submitted to the NRC) unless there exists an explicit NRC requirement to maintain the information on site. Furthermore, information incorporated by reference into the FSAR is subject to the update and reporting requirements of 10 CFR 50.71(e) and change controls of 10 CFR 50.59 unless a separate NRC change control requirement applies (e.g., 10 CFR 50.54(a)). References should be as clear as possible as to the extent of the information incorporated by reference and thus considered part of the FSAR.

A list of PVNGS documents incorporated by reference are listed in Table 1.6-4.

1.7 DRAWINGS AND OTHER DETAILED INFORMATION

1.7.1 ELECTRICAL, INSTRUMENTATION, AND CONTROL DRAWINGS

Table 1.7-1 lists nonproprietary electrical, instrumentation, and control (EI&C) drawings which are necessary to evaluate the safety-related features described in chapters 7 and 8. When appropriate, reference is made to the specific sections which discuss the drawing. There are no proprietary EI&C drawings. Engineering drawings 01, 02, 03-J-ZZL-010 and 01, 02, 03-J-ZZL-012 illustrate the legend and symbols used on control logic diagrams referenced in this section.

1.7.2 PIPING AND INSTRUMENTATION DIAGRAMS

Table 1.7-2 lists piping and instrumentation diagrams (P&IDs) which have been incorporated by reference into this UFSAR. Engineering drawings 13-M-ZZP-001 through –004 illustrate the legend and symbols utilized on the listed P&IDs.

1.7.3 OTHER DETAILED INFORMATION

Other detailed information which has been provided separately to the NRC staff is itemized below.

A. PVNGS onsite hourly meteorological data have been provided on magnetic tape utilizing the recommended NRC format, for the 5-year period from August 13, 1973 to August 13, 1978.

1.8 CONFORMANCE TO NRC REGULATORY GUIDES

This section discusses the conformance of plant design with the guidelines presented in the NRC regulatory guides. A reference to the FSAR section in which the applicable design feature is described is also provided.

Where the design deviates from the regulatory guide, or where conformance to the guide has been qualified by an interpretation of the guide, these variances are discussed in detail in this section.

This section presents the applicant's position with respect to the regulatory guides. Refer to CESSAR Section 1.8 for C-E's response to the regulatory guides in CESSAR scope. Regulatory guides that are incorporated into CESSAR will also be incorporated into PVNGS by reference in this section.

REGULATORY GUIDE 1.1: Net Positive Suction Head for ECCS and Containment Heat Removal Systems Pumps (Revision 0, November 2, 1970)

RESPONSE

Refer to section 6.3, 6.2.2.3, 5.1.4, and 5.4.7.1.

REGULATORY GUIDE 1.2: Thermal Shock to Reactor Pressure Vessels (Revision 0, November 2, 1970)

RESPONSE

Refer to 5.2.3.3.1.1, 4.2.5, and 5.1.4.

REGULATORY GUIDE 1.3: Assumptions Used for Evaluating the Potential Consequences of a Loss-of-Coolant Accident for Boiling Water Reactors (Revision 1, June 1973)

RESPONSE

Not applicable.

REGULATORY GUIDE 1.4: Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Pressurized Water Reactors (Revision 2, June 1974)

RESPONSE

The position of Regulatory Guide 1.4 is accepted (refer to section 15.6). Additional references: 3.11, 5.1.4, 5.4.7.1, 6.4.4.3, 9.3.2.2.2, 9A.60, 12.2.3, 12.3.2.2.7, 15B.4, 18.II.B.2, and 18.II.B.3.

REGULATORY GUIDE 1.5: Assumptions Used for Evaluating the Potential Consequences of a Steam Line Break Accident for Boiling-Water Reactors (Revision 0, March 10, 1971)

RESPONSE

Not applicable.

REGULATORY GUIDE 1.6: Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems (Revision 0, March 10, 1971)

RESPONSE

The position of Regulatory Guide 1.6 is accepted (refer to section 8.3). Additional references: 7.1.2.13 and 8.1.4.3.

REGULATORY GUIDE 1.7: Control of Combustible Gas Concentrations in Containment Following a Loss-of-Coolant Accident (Revision 0, March 10, 1971)

RESPONSE

The position of Regulatory Guide 1.7 is accepted (refer to subsection 6.2.5). Additional references: 3.11, 6.2.5, 9.3.2.2.2, 12.2.3, and 18.II.B.3.

REGULATORY GUIDE 1.8: Personnel Selection and Training (Revision 1-R, May 1977).

RESPONSE

PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.8 (including any exemptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.9: Selection, Design, Qualification, and Testing of Emergency Diesel Generator Units used as Class 1E Onsite Electric Power Systems at Nuclear Power Stations, (Revision 3, July 1993)

RESPONSE

The position of Regulatory Guide 1.9 is accepted with the following clarifications and exceptions:

A. Clarification: The diesel generator power supplies were originally selected in accordance with R.G. 1.9, Rev. 0.

B. Regulatory Position C. Exception is taken to regulatory endorsement of IEEE Std 387 1984. Palo Verde retains commitments to earlier editions of IEEE Std 387. The original selection and qualification testing of the diesel generator power supplies were performed in accordance with IEEE Std 387-1972. The present design and testing of the diesel generators is performed in accordance with IEEE Std 387-1977. The following table identifies the applicable portions of IEEE Std 387-1977 that are equivalent to the general sections and specific paragraphs of IEEE Std 387-1984 referenced in Regulatory Guide 1.9, Revision 3.

IEEE Std 387-1984	IEEE Std 387-1977
Section 1, Scope	Section 1, Scope
Section 2, Purpose	Section 2, Purpose
Section 3, Definitions	Section 3, Definitions
Section 4, References	Section 4, References
Section 5, Principle Design Criteria	Section 5, Principle Design Criteria
Section 6, Testing	Section 6, Requirements for Testing and Analysis (excluding section 6.3)

Section 7, Qualification Requirements	Sections 5.4 and 6.3, Note 1
Appendix A, Load Profile	Note 2
Appendix B, Aging	Note 1, 2
Section 1.2, Inclusions	Section 1.2, Inclusions
Section 3.7.1, Continuous Rating	Section 3.7.1, Continuous Rating
Section 5.5.3.1, Surveillance Systems	Section 5.6.3.1, Surveillance Systems
Section 5.5.4, Protection	Note 3
Section 5.5.4(2), Other Protective Features	Note 3
Section 7.5.2, Records and Analysis	Note 4

Note 1. The emergency diesel generator supply units were originally qualified to IEEE Std 387-1972. Environmental qualification of the emergency diesel generators is not required per 10 CFR 50.49, Regulatory Guide 1.89, NUREG-0588 and IEEE Std 323 1974.

Note 2. As noted within the IEEE Std 387-1984, the appendixes of IEEE Std 387-1984 are not part of the standard.

Note 3. The guidance provided in Section 5.5.4 with regard to EDG protection is stated in UFSAR Section 8.3.1.1.4.3.

Note 4. The EDG performance records that are described in Section 7.5.2 of IEEE Std 387-1984 are addressed by the Maintenance Rule 10 CFR 50.65, Regulatory Guide 1.160, Rev. 3 and NUMARC 93-01.

C. Regulatory Position C.1.5. Exception to EDG fast start tests being performed from "normal standby conditions" as described in regulatory position C.1. Technical Specifications and its associated bases will define which EDG starts are performed from normal standby conditions (temperature of jacket water and lube oil systems within range of keep-warm system) and from hot conditions (immediately following an engine shutdown). The other EDG test starts may be performed from jacket water and lube oil system temperatures within Operability limits.

D. Regulatory Position C.2.1. Exception to the section describing EDG reliability. A new criterion is being

added to the list of EDG reliability failure "Exceptions" on page 1.9-6. This exception is stated as follows, "A failure that occurs during a post maintenance test, prior to declaring the EDGs Operable is not a valid failure, providing the failure is directly attributable preceding maintenance activity."

E. Regulatory Position C.2.2: Exception to the regulatory guidance that "jumpers and other nonstandard configurations or arrangements should not be used subsequent to initial equipment startup testing." Non-standard configurations and arrangements such as jumpers, lifted leads and connection of data recorder test connections will be utilized and administratively control during portions of the 18-month tests specified in R.G. 1.9, Rev. 3.

F. Regulatory Position C.2.2.6. Exception to regulatory guidance that the combined LOOP and SIAS testing is performed in whatever sequence they might occur. Combined LOOP and SIAS testing will be performed concurrently.

G. Exception to Regulatory Position C.2.2.7, C.2.2.8 and C.2.2.9. EDG tests of the single largest load reject, full load reject and, endurance tests will be performed in accordance with TS 3.8.1.

H. Exception to Regulatory Positions C.2.2 and C.2.3. Diesel Generator testing frequency is in accordance with the requirements of Technical Specification 5.5.18 (Surveillance Frequency Control Program).

Additional References: 8A.8 and 14.2.7.

REGULATORY GUIDE 1.10: Mechanical (Cadweld) Splices in Reinforcing Bars of Category 1 Concrete Structures (Revision 1, January 2, 1973)

RESPONSE

The position of Regulatory Guide 1.10 is accepted with the following clarifications to Sections 2 and 4.

Section 2:

Prior to casting, some, but not all, mechanical splices are inspected. An inspector covers the work of more than one crew and periodic preparation checks are made. Each completed splice is visually inspected.

Section 4:

A. The terms "horizontal, vertical, and diagonal bars" are interpreted to apply, respectively, to the following types of splice position:

1. Horizontal, including 10° to horizontal
2. Vertical, including 10° to vertical
3. Diagonal (45° angle), including 10° to 80°B.

B. The words "splicing crew" are interpreted to refer to all members on the project that are actively engaged in preparing and assembling cadweld mechanical splices at the final splice location.

C. A sister splice may be substituted for a production splice when:

1. Cadwelding to dowels which are too short to take a production splice

2. The responsible quality control engineer, in conjunction with engineering, determines that the area of reinforcing is too congested to take a production splice.

Reference 3.8.1.2, 3.8.1.6, and 3.8.3.2.

REGULATORY GUIDE 1.11: Instrument Lines Penetrating Primary Reactor Containment (Revision 0, March 10, 1971)

RESPONSE

The position of Regulatory Guide 1.11 is accepted (refer to subsection 6.2.4). Additional references: 3.1.47 and 7.1.2.14

REGULATORY GUIDE 1.12: Nuclear Power Plant Instrumentation for Earthquakes (Revision 2, March 1997)

RESPONSE

The position of Regulatory Guide 1.12 is accepted, except as noted below:

A. Force balance accelerometers are provided at select locations in lieu of triaxial time-history accelerographs. The force balance accelerometers are located at design critical points specifically selected to display significant strain under earthquake excitation. The force balance accelerometers, recorder, and trigger makes up the time-history accelerograph as defined in the "Definitions" of Regulatory Guide 2.12, Rev. 2. The recorder and seismic trigger are separately located (at the 140' level of the Control Building, Unit 1) from the force balance accelerometers.

B. Annunciation to more than one control room at a site, per Section 7 of Regulatory Guide 1.12, Revision 2, is not constructive at PVNGS, and an exception is taken to Section 7. Triggering of the free-field or any foundation level force balance accelerometer will be annunciated to the Unit 1 control room. The control rooms of Unit 2 and 3 will be administratively notified of the triggering by the Unit 1 control room.

Refer to subsection 3.7.4 and Table 3.2-1 for a description of the PVNGS instrumentation for earthquakes.

REGULATORY GUIDE 1.13: Fuel Storage Facility Design Bases (Revision 0, March 10, 1971)

RESPONSE

The position of Regulatory Guide 1.13 is accepted (refer to Sections 3.2.2 (Table 3.2-1), 3.5, 3.8, 4.2.5, 9.1 and 9.4, and 11.5.1.2 for descriptions).

REGULATORY GUIDE 1.14: Reactor Coolant Pump Flywheel Integrity (Revision 0, October 27, 1971)

RESPONSE

Refer to 5.1.4 and 5.4.1.

REGULATORY GUIDE 1.15: Testing of Reinforcing Bars for Category I Concrete Structures (Revision 1, December 28, 1972)

RESPONSE

The position of Regulatory Guide 1.15 is accepted (refer to section 3.8).

REGULATORY GUIDE 1.16: Reporting of Operating Information (Revision 1, October 1973)

RESPONSE

The guidance in Regulatory Guide 1.16, Revision 1, for reporting operating information has been superseded by changes to NRC regulations and PVNGS Technical Specifications and Technical Requirements Manual (TRM) (the TRM contains reporting requirements that were relocated from the Technical Specifications). Therefore, reporting of operating information

will be in accordance with current NRC regulations and PVNGS Technical Specifications and TRM.

REGULATORY GUIDE 1.17: Protection of Nuclear Power Plants Against Industrial Sabotage (Revision 1, June 1973)

RESPONSE

The position of Regulatory Guide 1.17 is accepted with the following exception to ANSI N18.17-1973 regarding employee screening.

Section 4.3 of ANSI N18.17-1973 addresses employee screening. Section 4.3 has become obsolete with the promulgation of 10CFR73.56, "Personnel Access Authorization Requirements for Nuclear Power Plants." APS complies with the requirements of 10CFR73.56 as described in the PVNGS Security Plan, rather than Section 4.3 of ANSI N18.17-1973. Reference 13.6.2.

REGULATORY GUIDE 1.18: Structural Acceptance Test for Concrete Primary Reactor Containments (Revision 1, December 28, 1972)

RESPONSE

Regulatory Guide 1.18 established a systematic approach to testing wherein quantitative information is obtained concerning structural response to pressurization. The following interpretations of Regulatory Guide 1.18 are provided:

A. Position C.2

The number and distribution of measuring points for monitoring radial deflection is selected so that the as-built condition can be considered in the assessment of roundup, buttress-shell interaction, and general shell response. Measurements are made at points similar to those shown in Chapter 9 of BC-TOP-5-A. However, to obtain the most significant data, the measuring point locations may be changed to those where the as-built containment is at the limit of tolerances if such points exist. Accordingly, an arbitrary selection of measurement points is not intended.

B. Position C.5

This containment structure is not a prototype. Therefore, this paragraph is not applicable.

C. Position C.9

Structural integrity testing is scheduled for periods when extremely inclement weather is not forecast. Should, despite the forecast, snow, heavy rain, or strong wind occur during the test, the test results will be considered valid unless there is evidence to indicate otherwise.

D. Position C.10

Any test will be continued, without a restart at atmospheric pressure, unless the structural response deviates significantly from that expected.

E. Position C.12

A description of structural tests will be submitted at a time to permit suitable review. Paragraph 3.8.1.7.1 provides a general description of the planned tests. Information on previous structural testing is contained in Chapter 9 of BC-TOP-5-A.

F. Appendix A

The containment has no prototypal features. Therefore, this appendix is not applicable.

Reference 3.8.1.7.1, 3.8.1.2.3, 14.2.7, and 14A.4.

REGULATORY GUIDE 1.19: Nondestructive Examination of Primary Containment Liner Welds (Revision 1, August 11, 1972)

RESPONSE

Nondestructive examination of primary containment liner welds is conducted in accordance with the procedures described in Regulatory Guide 1.19 except as noted herein.

A. Position C.1.b

Where radiography is not feasible, the full-length of the liner seam weld is examined by the magnetic particle or

liquid penetrant method in accordance with the methods and techniques of Section V of the ASME Boiler and Pressure Vessel Code. Since surface examination by the magnetic particle method is permitted by the Regulatory Guide 1.19, the liquid penetrant method is specified as an alternative since the two methods are considered comparable by ASME Section III, Division 1, 1974 Edition and Summer 1974 Addenda.

B. Position C.2.a

All welds in penetrations, airlocks, and access openings not backed by concrete are fully examined in accordance with NE 5200 of Section III, Division 1, 1974 Edition of the ASME Boiler and Pressure Vessel Code, Summer 1974 Addenda.

C. Position C.7

Acceptance standards for radiography, magnetic particle, and liquid penetrant examination are specified in NE 5300 of Section III, Division 1, 1974 Edition of the ASME Boiler and Pressure Vessel Code, Summer 1974 Addenda.

D. Positions C.8 and C.9

These procedures are complied with except as noted in the preceding paragraphs.

Reference 3.8.1.2.3 and 3.8.1.6.7.4.

REGULATORY GUIDE 1.20: Vibration Measurements on Reactor Internals (Revision 0, December 29, 1971)

RESPONSE

Refer to 3.9.2.4, 14.2.7, and 14A.3.

REGULATORY GUIDE 1.21: Measuring, Evaluating, and Reporting Radioactivity in Solid Wastes and Releases of Radioactive Materials in Liquid and Gaseous Effluents from Light-Water-Cooled Nuclear Power Plants (Revision 1, June 1974)

RESPONSE

The position of Regulatory Guide 1.21 is accepted (refer to section 11.5). Additional references: 4.2.5, 9.3.2.1, 12.3.4, and 12.5.1.3.

REGULATORY GUIDE 1.22: Periodic Testing of Protection System Actuation Functions (Revision 0, February 17, 1972)

RESPONSE

The position of Regulatory Guide 1.22 is accepted (refer to subsections 7.1.2 and 8.3.1). Also see 7.2.1.1.9, 7.2.2.3.3, 7.3.1, 7.3.2.3.3, and 7.3.5.1.17.

REGULATORY GUIDE 1.23: Onsite Meteorological Programs (Revision 0, February 17, 1972)

RESPONSE

The position of Regulatory Guide 1.23 is accepted (refer to section 2.3). Additional references: 18.III.A.1.1.

REGULATORY GUIDE 1.24: Assumptions Used for Evaluating the Potential Radiological Consequences of a Pressurized Water Reactor Radioactive Gas Storage Tank Failure (Revision 0, March 23, 1972)

RESPONSE

The position of Regulatory Guide 1.24 is accepted (refer to section 15.7 and 5.1.4).

REGULATORY GUIDE 1.25: Assumptions Used for Evaluating the Potential Radiological Consequences of a Fuel Handling Accident in the Fuel Handling and Storage Facility for Boiling and Pressurized Water Reactors (Revision 0, March 23, 1972)

RESPONSE

PVNGS deviates from Regulatory Guide 1.25 to allow use of 'peak assembly average fuel pin pressure is < 1200 psig' in place of 'maximum fuel rod pressurization is 1200 psig'. This approach allows a few fuel rods to exceed the 1200 psig maximum pressurization while still maintaining the conservative iodine DF value specified by Regulatory Guide 1.25. This deviation is

acceptable due to the overall conservatisms associated with analyzing the fuel handling accident. This deviation can not be used for fuel that incorporates zirconium diboride pellet coatings (i.e., integrated fuel burnable absorber (IFBA)).

Refer to section 15.7, 1.9.2.4.5, and 9.1.4.6.

REGULATORY GUIDE 1.26: Quality Group Classification and Standards for Water, Steam and Radioactive-Waste-Containing Components of Nuclear Power Plants (Revision 1, September 1974)

RESPONSE

For operational phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.26 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.27: Ultimate Heat Sink for Nuclear Power Plants (Revision 2, January 1976)

RESPONSE

The position of Regulatory Guide 1.27 is accepted (refer to subsections 9.2.5, 9.1.3, 9.2.1.1, and 3.1.40).

REGULATORY GUIDE 1.28: Quality Assurance Program Requirements (Design and Construction)

RESPONSE

For operational phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.28 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.29: Seismic Design Classification

RESPONSE

For operational phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.29 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.31: Control of Ferrite Content in Stainless Steel Weld Metal (Revision 3, April 1978)

RESPONSE

The recommendations of Regulatory Guide 1.31 are followed for non-NSSS ESF components except as noted below:

The delta-ferrite determination method specified in Part C is not met. Austenitic stainless steel welding filler materials used in the fabrication and installation of ASME Section III, Class 1, 2, and 3 components are controlled to deposit from 8 to 25% delta-ferrite except for 309 and 309L welding filler materials which are controlled to deposit from 5 to 15% delta-ferrite and are used when welding carbon or low alloy steel to austenitic stainless steel. Welding filler material 309L is

used further for the overlay deposit on the carbon or low alloy steel component nozzles or connecting pipe when postweld treatment is required. Meaningful control of delta-ferrite content is based on chemical analysis of the welding filler material to assure that there is an adequate margin above the minimum required to prevent fissuring. Delta-ferrite content of procedure qualification welds is determined by chemical analysis in accordance with ASME Code, Section III, Division 1, 1974 Edition, Paragraph NB-2433, instead of by magnetic measurement devices called for in Paragraph C.1. Since austenitic stainless steel welding materials are controlled to deposit 8 to 25% delta-ferrite based on chemistry, except for 309 and 309L welding materials, which are controlled to deposit 5 to 15% delta-ferrite based on chemistry, magnetic measurement of production welds required by Paragraph C.1 is not necessary to assure satisfactory delta-ferrite content. Reference 5.1.4, 5.1.5, 5.4.7, 5.2.3, 4.2.1, 4.2.5, 6.3.1, 6.1.1.1.4, 6.5.2.8, 9.1.4.6, 9.3.4, and 10.3.6.2.

REGULATORY GUIDE 1.32: Use of IEEE STD 308-1971, Criteria for Class 1E Electrical Systems for Nuclear Power Generating Stations (Revision 0, August 11, 1972)

RESPONSE

The position of Regulatory Guide 1.32 is accepted (refer to subsections 8.2.1.3 and 8.3.1). In addition, for a discussion of compliance with IEEE Standard 308-1974, refer to section 8.3.

REGULATORY GUIDE 1.33: Quality Assurance Program Requirements (Operation)

RESPONSE

For operational phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.33 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.34: Control of Electroslag Weld Properties (Revision 0, December 28, 1972)

RESPONSE

Refer to 5.2.3.3.2.2. Additional references: 4.2.5, 5.1.4, and 5.4.7.1.

REGULATORY GUIDE 1.35: Inservice Inspection of Ungrouted Tendons in Prestressed Concrete Containment Structures (Revision 1, June 1974)

RESPONSE

The inservice inspection requirements and positions described in Regulatory Guide 1.35 are now covered by ASME Code Section XI, Subsection IWL, 1992 Edition with the 1992 Addenda, as modified and supplemented by 10 CFR 50.55a. The design considerations discussed in this regulatory guide shall remain applicable.

The reportable conditions are detailed in 10 CFR 50.55a do not require prompt notification as described in Regulatory Guide 1.16, Regulatory Position c.2.a. In addition to the ISI Summary Report requirements described in 10 CFR 50.55a, any reportable condition detected during surveillance testing and inservice inspections shall be reported to the NRC as described in the PVNGS Technical Requirements Manual.

REGULATORY GUIDE 1.36: Nonmetallic Thermal Insulation for Austenitic Stainless Steel (Revision 0, February 23, 1973)

RESPONSE

The position of Regulatory Guide 1.36 is accepted (refer to section 6.1). Also see 5.2.3.2.3. Additional References: 6.3.1, 6.5.2, 4.2.5, 5.1.4, 5.1.5, 5.4.7, 5.2.3.4.1.2.2, and 9.3.4.

REGULATORY GUIDE 1.37: Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants

RESPONSE

For operational phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.37 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.40: Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants (Revision 0, March 16, 1973)

RESPONSE

Regulatory Guide 1.40 is not applicable to PVNGS as there are no safety-related, continuous-duty motors installed inside the containment. Reference 3.11.2, 7.1.2.18, 8.3.1.2.2.9, and 8.3.2.2.1.8.

REGULATORY GUIDE 1.41: Preoperational Testing of Redundant Onsite Electric Power Systems to Verify Proper Load Group Assignments (Revision 0, March 16, 1973)

RESPONSE

The position of Regulatory Guide 1.41 is accepted (refer to subsection 8.3.1 and section 14.2). Additional References: 8.3.2.2.1.9 and 14A.19.

REGULATORY GUIDE 1.42: Withdrawn.

REGULATORY GUIDE 1.43: Control of Stainless Steel Weld Cladding of Low-Alloy Steel Components (Revision 0, May 1973)

RESPONSE

For ASME Section III, Class 1, 2, and 3 components, the restrictions of Paragraph C.1.a of Regulatory Guide 1.43 are

observed. The remaining requirements of Regulatory Guide 1.43 are complied with when "high-heat-input" welding processes such as submerged-arc welding (SAW) and gas metal-arc welding (GMAW) are used by Bechtel suppliers to clad SA-508, Class 2 forgings or to plate material of equivalent composition. Regulatory Guide 1.43 is not complied with when "low-heat-input" welding processes such as shielded metal-arc welding (SMAW) and gas tungsten-arc welding (GTAW) are used in the field by Bechtel or Bechtel subcontractors to clad completed welds and adjacent SA-508, Class 2 material during installation. It is noted in Part B of Regulatory Guide 1.43 that underclad cracking has not been observed in SA-508, Class 2 material welded with the "low-heat-input" processes.

(Also see 5.2.3.3.2.1.) Additional references: 4.2.5 and 5.1.4.

REGULATORY GUIDE 1.44: Control of the Use of Sensitized Stainless Steel (Revision 0, May 1973)

RESPONSE

Refer to 5.2.3.4.1.1.1 for components within the C-E scope of supply. Additional references: 4.2.5, 5.1.4, 5.1.5, 5.4.7, 6.1.1.1.3.1, 6.3.1, 6.5.2, 9.1.4.6, 9.3.4, and 10.3.6.2.

For components within the Bechtel scope of supply, the position of Regulatory Guide 1.44 is accepted, except as indicated below:

Additional tests specified in Paragraph C.3 of Regulatory Guide 1.44 to verify the nonsensitization of the material will

not be performed for each different heat treatment practice and each material heat. All austenitic stainless steels are furnished in accordance with applicable ASME or ASTM material specifications. Testing to determine susceptibility to intergranular attack is performed when required by the ASME or ASTM material specification. Austenitic stainless steel exposed to temperatures in the range of 800 to 1500F during hot forming are solution heat-treated in accordance with the ASME or ASTM material specification after completion of hot forming. Certified materials test reports are checked upon receipt of the material to ensure that all requirements of the material specification have been met.

Intergranular corrosion testing specified in Paragraph C.6 of Regulatory Guide 1.44 is not performed on a routine basis.

Welding practices are controlled to avoid severe sensitization as follows:

A. Weld Heat Input

Weld heat input is controlled during field installation by using SMAW and GTAW processes only, and limiting the size of electrodes for each process to 5/32 inch and 1/8 inch diameter maximum, respectively.

In addition to the above two processes, suppliers and subcontractors are permitted to use automatic submerged-arc welding (ASAW) and GMAW. When ASAW or GMAW is used, or SMAW or GTAW is used with electrodes larger than those specified above, testing in

accordance with ASTM A262, Practice A or E, is required unless welding is followed by solution heat treatment.

B. Interpass Temperature

The interpass temperature is controlled to not exceed 350F.

C. Carbon Content

Susceptibility to sensitization is reduced significantly by selecting material with the lowest reported carbon content.

D. Solution Heat Treatment

Solution heat treatment in accordance with the material specification, although not required after welding, is permitted in order to avoid severe sensitization.

Severe sensitization is avoided by not permitting heat treatment in the temperature range of 800 to 1500F following welding. This requires a special technique when welding stainless safe ends (transition pieces) to carbon or low alloy steel component nozzles or piping. Specifically, a low carbon steel or Inconel weld overlay is deposited on the component and the component is postweld heat-treated. Following final postweld heat treatment of the component, the stainless steel safe end is welded to the weld overlay using welding materials to match the overlay.

Since severe sensitization is avoided, testing to determine susceptibility to intergranular attack is not performed.

REGULATORY GUIDE 1.45: Reactor Coolant Pressure Boundary Leakage Detection Systems (Revision 0, May 1973)

RESPONSE

The position of Regulatory Guide is accepted, except for the following:

A. Position C.5 states that each method of detection should have the capability of detecting leak rates of 1 gpm within 1 hour. The airborne particulate and airborne gaseous monitoring methods are capable of identifying leakage conditions, but are not used for quantifying that leakage. Procedures are available that instruct operators to perform a water inventory balance upon alarm or increasing trend of activity (refer to subsection 5.2.5). Additional references: 5.1.4, 5.1.5, 5A.3, 9A.34, 11.5.1.1.1, and 11.5.2.1.3.13.

B. Position C.4 states that the methods used to detect reactor coolant pressure boundary (RCPB) leakage to connecting systems "should include radioactivity monitoring and indicators to show abnormal water levels or flow in the affected area." As described in subsection 5.2.5.4, leakage past two shutdown cooling isolation valves in series would discharge through the Low Temperature Over-Pressure (LTOP) safety relief valves in the containment recirculation sumps. Given the capacity of the recirculation sump, this leakage would not be detected by level monitoring

instrumentation in the radwaste sumps. As an alternative to Position C.4, small leakage through this pathway would be detected by radiation monitoring and periodic RCS water inventory balance, not by level or flow indication. This is conservative because, unless such leakage could be quantified locally by containment entry, the leak rate would be applied to the unidentified leakage limit as opposed to the less restrictive identified leakage limit. In addition, a temperature indicator in the recirculation sump provides indication of large-scale leakage.

REGULATORY GUIDE 1.46: Protection Against Pipe Whip Inside Containment (Revision 0, May, 1973)

RESPONSE

Except as discussed below, protection against pipe whip inside the containment complies with Regulatory Guide 1.46. (For additional information refer to Section 3.6.2.1.1.2).

A. Position C.1.b

Intermediate break locations between terminal ends are postulated to occur at weld joints where the piping incorporates a fitting, valve, or welded attachment where the following are met (as specified in NRC Branch Technical Position MEB 3-1):

1. The stress range Sn exceeds 2.4 Sm, where Sm is the design stress intensity as defined in Section III of the ASME Code, or

2. The stress range S_n as calculated by Equation 10 of Paragraph NB-3653 exceeds 2.4 S_m and the stresses computed by Equations 12 and 13 of Paragraph NB-3653 are greater than 2.4 S_m, or

3. If fatigue analysis is performed, any intermediate location between terminal ends where the cumulative usage factor under loading associated with operational plant conditions and an operating basis earthquake (OBE) exceed 0.1 of the code allowable.

B. Position C.2.b

Intermediate break locations between terminal ends are selected where either the circumferential or longitudinal stress associated with specified seismic events and operational plant conditions exceeds 0.8 ($1.2S_h + S_A$) in accordance with NRC Branch Technical Position MEB 3-1. Also see 3.6.2.5.2.1.

C. Position C.3

1. Circumferential breaks are not postulated at locations where circumferential stress range is at least one and one-half times the axial stress range in accordance with NRC Branch Technical Position MEB 3-1.

2. Longitudinal breaks are not postulated at locations where axial stress range is at least one and one-half times the circumferential stress

range in accordance with NRC Branch Technical Position MEB 3-1.

Reference 3.8.1.2.3, 3.8.3.2.2, 4.2.5, 5.1.4, 5.4.7.1, and 6.3.1.3.

REGULATORY GUIDE 1.47: Bypassed and Inoperable Status Indication for Nuclear-Power Plant Safety Systems (Revision 0, May 1973)

RESPONSE

Refer to section 7.5 and 7.1.2.19. Additional references: 3.11.4, 5.1.4, 7.1.1.3, 7.1.2.19, 8.3.1.2.2.11, and 8.3.2.2.1.10.

REGULATORY GUIDE 1.48: Design Limits and Loading Combinations for Seismic Category I Fluid System Components (Revision 0, May 1973)

RESPONSE

The position of Regulatory Guide 1.48 is accepted with the following interpretations:

A. Load Combinations

Since neither the code (ASME Section III) nor Regulatory Guide 1.48 are explicit with regard to delineation of the actual loads to be combined under each plant operating condition, a position has been developed (refer to tables 3.9-5 and 3.9-6) which

reflects the intent of both the code and Regulatory Guide 1.48.

B. Stress Limits

ASME Section III, Code Cases 1606-1, 1607-1, 1635-1, and 1636-1, are utilized to establish stress limits for Class 2 and 3 components as an alternate to Regulatory Guide 1.48.

C. Operability

Regulatory Guide 1.48 requires that the operability of safety-related components be demonstrated without specifying how this shall be accomplished. This FSAR addresses in detail the methods used to ensure the operability of the safety-related components (refer to section 3.9). Also see CESSAR Section 1.8.

Additional references: 3.10.3, 4.2.5, 5.1.4, 5.4.7, 6.3.1.3, and 9.3.4.6.

REGULATORY GUIDE 1.49: Power Levels of Nuclear Power Plants (Revision 1, December 1973)

RESPONSE

Refer to section 1.1.4.

REGULATORY GUIDE 1.50: Control of Preheat Temperature for Welding of Low-Alloy Steel (Revision 0, May 1973)

RESPONSE

Refer to section 5.2.3.3.2.1. Additional references: 4.2.5, 5.1.4, 5.4.7.1, and 10.3.6.2.

In addition, for Bechtel and Bechtel suppliers the preheat for welding of low alloy steel is controlled in accordance with Regulatory Guide 1.50, except as described below:

A. Position C.1.a is complied with when impact testing, in accordance with ASME Boiler and Pressure Vessel Code, Section III, Subarticle 2300, is required.

   The maximum interpass temperature shall be 500F unless otherwise specified. When impact testing is not required, specification of a maximum interpass temperature in the welding procedure is not necessary in order to assure that the required mechanical properties are met. The minimum preheat temperatures of Appendix D of section III of the ASME Boiler and Pressure Vessel Code are required to be et regardless of whether impact testing is required or not.

B. Position C.1.b is not complied with since the welding procedure qualification of Section III and Section IX of the ASME Code are considered to be more than adequate.

C. Compliance with Position C.2 is not necessary for any Class 1, 2, or 3 component within the Bechtel scope of supply.

Current usage of low alloy steel in piping, pumps, and valves is minimal and is normally limited to Class 3 construction. When low alloy steel piping, pumps, and valves are used, preheat is maintained until welding is complete, but not until postweld heat treatment (PWHT) is performed, since the conditions which cause delayed cracking in the weld or heat affected zone (HAZ) are not present. Liquid penetrant or magnetic particle examination required by ASME Section III, Division 1, is capable of detecting cold cracking and this examination is required by ASME Section III, Division 1, to be performed after postweld heat treatment.

Experience has shown that delayed cracking due to hydrogen embrittlement is not a problem when the surface to be welded is dry. The preheat temperatures of Appendix D of ASME Section III, Division 1, are maintained during welding and low hydrogen electrodes are used which are packaged and stored so that the very low moisture contents are maintained until the electrodes are consumed.

D. Position C.4 is complied with when the positions stated in C above and section 5.2.3.3.2.1 are not met.

REGULATORY GUIDE 1.51: Withdrawn. Now covered by ASME Code Section XI. Refer to section 6.6.

REGULATORY GUIDE 1.52: Design, Testing, and Maintenance Criteria for Post Accident Engineered-Safety-Feature Atmosphere Cleanup System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants.
(Revision 2, March 1978)

RESPONSE

Regulatory Guide 1.52 applies to the control room essential ventilation system and the fuel building essential ventilation system.

Exceptions are taken to applicable portions of Regulatory Guide 1.52 in response to NRC Generic Letter 83-13, Clarification of Surveillance requirements for HEPA Filters and Charcoal Adsorber Units in Standard Technical Specifications of ESF Cleanup Systems, and NRC Generic Letter 99-02, Laboratory Testing of Nuclear-Grade Activated Charcoal (APS Letter #102-04373). Exception to applicable portions of Regulatory Guide 1.52 is taken in reference to using ANSI N509-1980 in place of ANSI N509-1976 and using ANSI N510 1980 in place of ANSI N510-1975.

Except as indicated below, including the general exception statements above, the design, testing and maintenance criteria for the above mentioned essential ventilation systems, commonly referred to as nuclear air treatment systems (NATS), comply with Regulatory Guide 1.52, Revision 2, March 1978.

A. Position C.1.b

For the control room essential ventilation system (CREVS), the postulated DBA is the design basis LOCA.

For the fuel building essential ventilation system operating in the fuel building essential ventilation actuation signal (FBEVAS) mode as the fuel building essential ventilation system (FBEVS), the postulated DBA is the design basis fuel handling accident.

For the fuel building essential ventilation system operating in the safety injection actuation signal (SIAS) mode as the pump room exhaust air cleanup system (PREACS), the postulated DBA is the design basis LOCA.

B. Position C.2.a

For the control building essential ventilation system, no mist eliminator nor electric heater is required upstream of the filters to limit relative humidity. Only approximately 4% of the total system capacity is drawn in from outside. The remaining fraction is recirculated air from the main control room, which is controlled to a relative humidity below 50% and thus the return air is below 70%.

For the fuel building essential ventilation system, demisters are not provided. Due to the low air velocity, water is not carried in the air stream.

C. Position C.2.c

The drain lines from the fuel building and auxiliary building essential air filtration units, and from the control building essential air handling units, are designated as Quality Class R and Seismic Category IX. An evaluation of these drain lines has identified that they are structurally equivalent to Seismic Category I and will maintain their structural integrity during and after a safe shutdown earthquake.

D. Position C.2.d

No significant pressure surges are foreseen for these systems during or following the postulated DBAs; thus, no special protective devices are needed.

E. Position C.2.f

The particulate filter banks of the control room nuclear air treatment system are arranged 5 wide by 6 high. A floor has been installed between the third and fourth level of the filters.

F. Position C.2.g

There are no Class 1E alarms associated with the control room and fuel building essential ventilation systems nor are there any recorders for pressure drops or flowrates.

Alarm status information is, however, logged in the plant computer. The annunciated and alarm status information is available in the main control room via the alarm display/computer log for pertinent pressure drops in these systems. The alarm is both visual and audible and no operator action is required to retrieve the alarm status from the computer.

Pertinent pressure drops are measured (ΔP indicators) across each section of the filter unit and across the entire filter unit itself. Both high- and low-pressure drop alarms are generated and provided in the main control room. A high-pressure drop alarm is indicative of high filter loading. A low-pressure drop alarm is indicative of a zero or low flow condition. Since the filter unit blower and blower motor are single speed devices, operation of the unit with no alarms present indicates delivery of rated flow to the filter unit. Pressure drop information is also indicated locally.

G. Position C.2.j

The filter unit Curie loading following a postulated DBA will consist mostly of short-lived isotopes. Credit will be taken for decay time to achieve permissible handling levels prior to workers removing components. Consequently, filter trains are not designed for intact removal. The charcoal adsorber section is designed to keep operator exposure as low as reasonably achievable during charcoal bed replacement.

The change out process involves only a few operator actions for hookup.

H. Position C.3.e

Upstream mounting of filters may be employed in some cases. Corrosion-resistant steel or carbon steel coated with inorganic nuclear grade paint will be used for construction of filter and adsorber mounting frames.

I. Position C.3.i

The activated carbon, when new, will be provided to meet the requirements of Regulatory Guide 1.52, Revision 2, March 1978, except using the physical property specifications of Table 5.1 of ANSI N509-1980 in place of Table 5.1 of ANSI N509-1976.

Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to NRC Generic Letter 99-02, APS Letter #102-04373).

J. Position C.3.k

There are no ESF filter units where the carbon bed temperature can exceed 200F following a postulated DBA as a result of loss of air flow.

K. Position C.3.o

Air straightening devices are installed only if tests indicate that uniform air flow distribution is not achieved.

L. Position C.4.a

Vacuum breakers would be of minimal assistance in opening doors to units during fan operation. The use of vacuum breakers creates potential leakage paths.

Units which operate at higher pressure than external pressures; i.e., push-through units, do not require vacuum breakers.

M. Position C.4.b

Accessibility for ease of maintenance is provided by removing opposing filters in opposite directions. The standard suggested distance of 3 feet plus length of component for removal of filters is met.

N. Position C.4.c

Piping associated with manifolding could result in plate-out of components of the sampled gas stream, leading to erroneous test results. The test probes are located in readily accessible locations with a minimum of piping, but are not manifolded.

O. Position C.4.d

Each atmosphere cleanup train will be operated per the required Surveillance Frequency listed in the Surveillance Frequency Control Program. There is not expected to be any moisture buildup on the absorbers and HEPA filters due to the low humidity at PVNGS.

P. Position C.5.a

Visual inspection of the ESF atmospheric cleanup system and all associated components will be done in accordance with Position C.5.a of Regulatory Guide 1.52, Revision 2, and using ANSI N510-1980 in place of ANSI N510-1975.

However, inspection criteria specific to each system will be developed to accommodate the uniqueness of each system.

Q. Position C.5.b

The air flow distribution test for the HEPA filter and iodine adsorbers will be tested in accordance with ANSI N510-1980 in place of ANSI Ns510-1975.

R. Position C.5.c

The in-place DOP test for HEPA filters will be done in accordance with Position C.5.c of Regulatory Guide 1.52, Revision 2, and using ANSI N510-1980 in place of ANSI N510-1975.

In-place filter testing will not be performed following painting, fire, or chemical release in a ventilation zone communicating with the system unless it has been evaluated that the event had the potential to adversely affect the integrity of the filters.

The in-place testing penetration acceptance criterion for penetration will be less than or equal to 1.0% in place of 0.05%. (Reference NRC Generic Letter 83-13).

If not removed during welding activities, the filters and adsorber section will be protected/isolated from the affects of the process.

Silicone sealant may be used to seal electrical and piping penetrations into filter housings. Use of silicone sealants will be within the manufacturer's recommended guidelines.

S. Position C.5.d

The activated carbon adsorber section will be leak-tested in accordance with Position C.5.d of Regulatory Guide 1.52, Revision 2, March 1978, and using ANSI N510-1980 in place of ANSI N510-1975.

The in-place testing penetration acceptance criterion for penetration will be less than or equal to 1.0% in place of 0.05%. (Reference NRC Generic Letter 83-13).

Airflow through the unit will not be maintained to remove the residual refrigerant gas.

In-place filter testing will not be performed following painting, fire, or chemical release in a ventilation zone communicating with the system or following the removal of adsorber carbon samples unless it has been evaluated that the event had the potential to adversely afect the integrity of the filters.

T. Position C.6.a

The laboratory testing criteria for testing a representative carbon absorber sample will be in

accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. Test acceptance criteria is derived by using the assigned activated carbon decontamination efficiency of 95% for organic iodide per Regulatory Guide 1.52, Revision 2, March 1978, Table 2, and imposing a safety factor of 2. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 2.5%. (In response to NRC Generic Letter 99-02, APS Letter #102-04373).

New activated carbon will meet the physical property specifications given in Table 5.1 of ANSI N509-1980, in place of Table 5.1 if ANSI N509-1976.

U. Position C.6.b

The number of samplers (sample stations) is not sufficient to last throughout the expected adsorbent life. Therefore, when depleted, they will be refilled from a composite sample taken from the absorber by means of a grain-thieving device.

The design of the samplers should be in accordance with the provisions of Appendix A of ANSI N509-1980 in place of ANSI N509-1976.

A representative carbon sample of the adsorber will be obtained in accordance with Regulatory Position C.6.b of Regulatory Guide 1.52, Revision 2, March 1978, using Appendix A of ANSI N509-1980 in place of Appendix A of ANSI N509-1976. However, a thieving device other than

a slotted tube sampler may be used when extracting carbon from the absorber section.

Laboratory tests of representative samples will be conducted in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity (In response to NRC Generic Letter 99-02, APS Letter #102-04373). As such, the representative sample media will not experience the test gas flow in the same direction as the flow during service conditions, as it will have been homogeneously mixed and fed into the test appratus. Therefore, it will be taken out of its orginal test canister (or, thieved directly from the absorber bed) and transferred into an airtight container until at which time it is prepared for the laboratory test.

The activated carbon adsorber section should be replaced with new unused activated carbon meeting the physical property specifications of Table 5.1 of ANSI N509-1980 in place of Table 5.1 of ANSI N509-1976 if (1) laboratory test results indicate a methyl iodide penetration greater than 2.5%, or (2) no representative sample is available for testing.

V. Table 2

The laboratory testing criteria for testing a representative carbon adsorber sample will be in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. Test acceptance

criteria is derived by using the assigned activated carbon decontamination efficiency of 95% for organic iodide, per Regulatory Guide 1.52, Revision 2, March 1978, Table 2, and imposing a safety factor of 2 on such effciency. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 2.5%. (In response to NRC Generic Letter 99-02, APS Letter #102-04373).

The activated carbon, when new, will be provided to meet the requirements of Regulatory Guide 1.52, Revision 2, March 1978, except using the physical property specifications of Table 5.1 of ANSI N509-1980 in place of Table 5.1 of ANSI N509-1976. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to NRC Generic Letter 99-02, APS Letter #102-04373).

Testing of adsorber samples should be performed (1) initially, (2) once every refueling cycle, (3) when certain events occur and have been evaluated that it could adversely affect the ability of the carbon to perform its intended function, and (4) following a defined period of continuous essential or ESF system operation. (In response to NRC Generic Letter 99-02, APS Letter #102-04373).

REGULATORY GUIDE 1.53: Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems (Revision 0, June 1973)

RESPONSE

The position of Regulatory Guide 1.53 is accepted (refer to section 7.1.2). Additional references: 7.3.5.1.18, 6.3.1.3, 8.3.1.2.2.12, and 8.3.2.2.1.11.

REGULATORY GUIDE 1.54: Quality Assurance Requirements for Protective Coatings Applied to Water-Cooled Nuclear Power Plants

RESPONSE

PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.54 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.55: Concrete Placement in Category I Structures (Revision 0, June 1973)

RESPONSE

Except as discussed below, concrete is placed in Category I structures in accordance with Regulatory Guide 1.55.

Creep tests are normally performed on prestressed structures only. Loss of prestress through creep is not applicable to

nonprestressed structures. Reference section 3.8.1.2.3, 3.8.1.6, and 3.8.3.2.2.

REGULATORY GUIDE 1.56: Maintenance of Water Purity in Boiling Water Reactors (Revision 0, June 1973)

RESPONSE

Not applicable.

REGULATORY GUIDE 1.57: Design Limits and Loading Combinations for Metal Primary Reactor Containment System Components (Revision 0, June 1973)

RESPONSE

Not applicable. Each PVNGS unit utilizes a prestressed concrete primary containment.

REGULATORY GUIDE 1.59: Design Basis Floods for Nuclear Power Plants (Revision 2, August 1977)

RESPONSE

The position of Regulatory Guide 1.59 is accepted (refer to subsection 2.4.2). Additional reference: 3.8.1.2.3.

REGULATORY GUIDE 1.60: Design Response Spectra for Seismic Design of Nuclear Power Plants (Revision 1, December 1973)

RESPONSE

The position of Regulatory Guide 1.60 is accepted (refer to subsection 3.7.1). Additional references: 2.5.2.6, 2A.5, 3.8.1.2.3, 3.8.3.2.2, 4.2.5, and 9.1.4.6.

REGULATORY GUIDE 1.61: Damping Values for Seismic Design of Nuclear Power Plants (Revision 0, October 1973)

RESPONSE

The position of Regulatory Guide 1.61 is accepted (refer to section 3.7) with the exception of the analysis and design of cable tray supports, and the evaluation of unrestrained piping uplift at support locations. The damping value for seismic design of cable tray supports is given in subsection 3.10.3. Increased damping values may be used, in some cases, for determining acceptability of unrestrained piping uplift at support locations (refer to paragraph 3.7.1.3). Additional references: 3.8.1.2.3, 3.8.3.2.2, 4.2.5, 5.1.4, 5.4.7.1, and 9.1.4.6.

REGULATORY GUIDE 1.62: Manual Initiation of Protective Actions (Revision 0, October 1973)

RESPONSE

The position of Regulatory Guide 1.62 is accepted (refer to subsection 7.1.2 and section 7.3). Also see section 7.1.2.21. Additional references: 7.2.1.1.1.11 and 8.3.1.2.2.13.

REGULATORY GUIDE 1.63: Electric Penetration Assemblies in Containment Structures for Light-Water-Cooled Nuclear Power Plants (Revision 2, July 1978)

RESPONSE

The position of Regulatory Guide 1.63 is accepted as interpreted below:

The electric penetration assemblies conform to IEEE Standard 317-1976.

Consistent with the recommendations of Regulatory Guide 1.63, the electrical penetration assemblies are designed to withstand, without loss of mechanical integrity, the maximum fault current vs. time conditions that could occur as a result of single random failures of circuit overload devices. The following system features are provided to be consistent with this recommendation of Regulatory Guide 1.63:

A. Medium Voltage System (13.8 kV system)

For medium voltage circuits feeding loads in the containment, the circuit breaker associated with the load is backed up by the main bus feeder breaker. These breakers are provided in the normal course of auxiliary system design and are non-Class 1E. The penetration withstands the available fault current and time duration for the main bus feeder breaker. Primary protection is provided by the individual load circuit breaker. The primary and backup circuit breakers are each provided

with independent dc control power from two different non-Class 1E batteries so that the failure of either battery will not violate the single failure criteria.

B. 480V Load Center Systems

For 480V load center power circuits feeding loads in the containment, redundant protection is provided by a combination of a breaker and a fuse or two breakers. The individual load circuit breaker provides primary protection. The load center bus feeder breaker is not used for backup because of its high, long time current rating. Breaker trip units are direct acting.

C. 480V Motor Control Center Systems

For 480V motor control center circuits feeding loads in the containment, a second breaker in series with the primary breaker of each load is used. Credit is not taken for the motor control center main bus feeder breaker because its large rating relative to the individual load breaker ratings may not provide adequate protection against individual faults.

As in the case of the load center feeds, separate battery sources are not provided. Molded case circuit breakers have direct-acting trips.

D. Low Voltage Control Systems

For low voltage protection circuits connected in the containment, redundant protection is provided by a combination of two fuses, a combination of a breaker and a fuse, or two breakers in series where the circuit resistance does not limit the fault current to a level that does not damage the penetration.

E. Instrument Systems

The energy levels in the instrument systems are sufficiently low so that no damage can occur to the containment penetration.

The circuit overload protection system for electric penetration assemblies meets the single failure criterion set forth in IEEE Standard 279-1971.

The overload protection systems do not conform to the online testability, bypassing, or manual initiation criteria of IEEE 279-1971, since these criteria do not apply to these systems.

Reference 3.8.1.2.3, 3.11.2, 7.1.2.22, 8.3.1.2.2.14, and 8A.11.

REGULATORY GUIDE 1.65: Materials and Inspections for Reactor Vessel Closure Studs (Revision 0, October 1973)

RESPONSE

Refer to Section 5.3.1.7. Additional references: 4.2.5, 5.1.4, 5.3.1.3, and 9.1.4.

REGULATORY GUIDE 1.66: Withdrawn.

REGULATORY GUIDE 1.67: Installation of Overpressure Protection Devices (Revision 0, October 1973)

RESPONSE

Except as discussed below and in section 5.2.2, the installation of overpressure protection devices complies with Regulatory Guide 1.67. Additional reference: 5.1.4.

A. The specifications are applicable to open discharge, simple configurations of stack, nonwater seal and nonslug flow, relief or safety valves.

B. Position C.1 of Regulatory Guide 1.67 requires that the magnitude of the reaction force, the anticipated transient behavior, and the basis for their determination should be included in the design specification for the valve. Since all of the above are characteristic to each valve manufacturer, it is not current practice to stipulate these data. Rather, the manufacturer supplies that information after selection of the valve, orifice size, inlet and outlet OD, etc., to accommodate the flowrates required by the design specification. This manufacturer supplied information is then used in the design of the relief/safety valve, as discussed in paragraph 3.9.3.3.

REGULATORY GUIDE 1.68: Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors (Revision 0, November 1973)

RESPONSE

The positions and guidelines of Regulatory Guide 1.68 are accepted with the following exceptions and clarifications:

A. Power ascension tests will be conducted using power plateaus of 20%, 50%, 80%, and 100% instead of 25%, 50%, 75%, and 100% as recommended in Paragraph D.4 of Appendix A to Regulatory Guide 1.68.

B. Procedures will be available either 60 days prior to fuel load or 60 days prior to their scheduled use as recommended in Appendix B of Regulatory Guide 1.68 (Revision 2, August 1978, which is used in lieu of the Revision 0, November 1973). See subsection 14.2.11 for a further clarification of procedure availability.

C. Implementation of Regulatory Guide 1.68 is discussed in section 14.2. See 14.2.7 for additional exceptions and clarifications to Regulatory Guide 1.68.

REGULATORY GUIDE 1.68.2: Initial Startup Test Program to Demonstrate Remote Shutdown Capability for Water-Cooled Nuclear Power Plants (Revision 1, July 1978)

RESPONSE

The position of Regulatory Guide 1.68.2 is accepted, except as follows:

Paragraph C indicates licensee should develop and conduct a test program for each unit. As the PVNGS units will be identical, testing on all units is unrealistic with the objectives of the test which are:

A. Verification that the plant can be shut down from outside the control room

B. Verification that the plant can be maintained in hot shutdown

C. Verification of cooldown capability.

Remote shutdown testing on the first unit will demonstrate the above objectives. Component and preoperational testing of following units and plant systems to be used in the remote shutdown panel will verify that they will function in the same manner as would be experienced on the first unit tested (see section 14.2).

REGULATORY GUIDE 1.68.3: Preoperational Testing of Instrument and Control Air Systems (Revision 0, April 1982)

RESPONSE

The position of Regulatory Guide 1.68.3 is accepted where applicable to the safety-related atmospheric dump valve nitrogen pressurization system. The PVNGS instrument air (IA)

system is not required for safe shutdown. There is no control air system. The design of the IA system is such that a malfunction cannot lead to failure of loads that are important to safety. The PVNGS design also precludes the inadvertent connection of poor quality air systems to loads that are important to safety since PVNGS has only one air system that supplies filtered, dry, oil-free compressed air for operation of pneumatic instruments and pneumatic actuators. The independent and separate service/breathing air system supplies oil-free compressed air to outlets throughout the plant for the operation of pneumatic tools and other service air requirements.* Reference 14.2.7.

(*) The IA system design has been modified per DMWO 3449152 to allow a cross-connection to the service air system, which contains poorer quality air. Local filters and an air dryer are provided for the cross-connection to ensure the necessary instrument air quality. The system no longer performs the function of providing breathing air.

REGULATORY GUIDE 1.69: Concrete Radiation Shields for Nuclear Power Plants (Revision 0, December 1973)

RESPONSE

The position of Regulatory Guide 1.69 is accepted (refer to section 12.3). Additional references: 3.8.1.2.3 and 3.8.3.2.2.

REGULATORY GUIDE 1.70: Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants – LWR Edition (Revision 3, November 1978)

RESPONSE

The original PVNGS FSAR content and format was specified by 10 CFR 50.34(b) and the position of Regulatory Guide 1.70 was accepted in that the required content was provided except as identified below. The recommended format also is followed, except when deviations were originally necessary to be consistent with CESSAR. These deviations followed the recommended format of Regulatory Guide 1.70, Revision 2.

Specific drawing revision numbers and dates were not identified in Tables 1.7-1 and 1.7-2, but were provided upon request. However, if the drawing is included in the UFSAR, they can be found on the drawing itself.

The requirement of Paragraph 13.1.1.3 of Regulatory Guide 1.70 to provide resumes of individuals already employed by the applicant to fulfill responsibilities identified in Item 3 of Section 13.1.1.1 was met by making these resumes available to the NRC by separate letter rather than including them in the FSAR.

The requirements of Sections 13.3 and 13.3.2 to consult Regulatory Guide 1.101, “Emergency Planning for Nuclear Power Plants,” were met by consulting NUREG-0654/FEMA-REP-1, Revision 1, “Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in

Support of Nuclear Power Plants.” This document superseded Regulatory Guide 1.101.

The requirements of Sections 3.10 and 3.11 of the Regulatory Guide to provide a list of equipment required to be environmentally and seismically qualified have been met by providing this information by separate letters to the NRC rather than including the information in the FSAR. The current list of equipment required to be environmentally and seismically qualified is controlled and maintained by the Equipment Qualification Program.

Regulatory Guide 1.181 is used to maintain the content of the UFSAR in accordance with 10 CFR 50.71(e). The references to RG 1.70 are being maintained for historical value.

References: 2.1.3.6, 2.2.2.2.4, 2.2.3.1.4, 2A.10, 4A.4, 12A.9, 12A.11, 12A.16, 14A.5, 15.0.1.1, and 17.1B.

<u>REGULATORY GUIDE 1.71</u>: Welder Qualification for Areas of Limited Accessibility (Revision 0, December 1973)

<u>RESPONSE</u>

The position of Regulatory Guide 1.71 is accepted with the following interpretations:

A. Position C.1.

For welds made under conditions of limited access as defined in Regulatory Position C.1 of Regulatory Guide 1.71, performance qualification to the applicable

requirements of ASME Sections III and IX are maintained with the additional requirement for selection and utilization of the more highly skilled welders for these applications as determined by responsible site supervisory personnel. Nondestructive examination requirements are determined by applicable codes, standards, specifications, and regulatory guides and any waiver or relaxation of either examination method or acceptance criteria for reasons of limited access is not permitted.

B. Position C.2.a

Requalification is required when any of the essential variables of ASME Section IX are changed or at any time the authorized inspector questions the ability of the welder to satisfactorily perform to the requirements of ASME Sections III or IX.

C. Position C.3

Production welding is monitored and welding qualifications are certified for the conditions described in the interpretations to Regulatory Positions C.1 and C.2.a.

Reference: 5.2.3.3.2.3. Additional references: 4.2.5, 5.1.4, and 10.3.6.2.

REGULATORY GUIDE 1.72: Spray Pond Plastic Piping (Revision 0, December 1973).

RESPONSE

Not applicable to PVNGS.

REGULATORY GUIDE 1.73: Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants (Revision 0, January 1974)

RESPONSE

The position of Regulatory Guide 1.73 is accepted (refer to section 3.11 and 7.1.2.22). Additional references: 5.1.4, 5.4.7.1, 6.2.4.2.2, 7.1.2.24, and 8.3.1.2.2.15.

REGULATORY GUIDE 1.75: Physical Independence of Electric Systems (Revision 1, January 1975

RESPONSE

The requirements of Regulatory Guide 1.75 are met, with the following clarifications and/or exceptions:

A. Isolation of non-Class 1E power circuits supplied by a Class 1E source is provided by a circuit interrupting device (circuit breaker) actuated by a safety injection actuation signal (SIAS), except for the circuits feeding the essential lighting system in the control room and remote shutdown panel, the backup supplies for the non-Class 1E instrument buses (E-NNN-D11, E-NNN-D12,

E-NNN-D15 and E-NNN-D16), and non-Class 1E valves XJ-CHN-UV501 and XJ-CHN-UV536. Class 1E regulating transformers with circuit limiting characteristics are provided as isolation devices to feed these non-Class 1E circuits of essential lighting. Two Class 1E interrupting devices connected in series with proper coordination are provided as isolation devices for the non-Class 1E valves. The two non-Class 1E instrument buses (E-NNN-D11 and E-NNN-D12) utilize Class 1E regulating transformers (E-NNA-V13 and E-NNB-V14) with current limiting characteristics to provide isolation of the devices. The non-Class 1E instrument buses (E-NNN-D15) and (2E-NNN-D16 and 3E-NNN-D16) utilize a non-Class 1E regulating transformer (E-NNN-V17, 2E-NNN-V18 and 3E-NNN-V18 respectively) with current limiting characteristics. These instrument buses however, are tripped on an SIAS signal and can be re-established manually after the sequential loading of the diesel generator. The non-Class 1E instrument bus (3E-NNN-D16) utilizes a non-Class 1E regulating transformer (3E-NNN-V18) with current limiting characteristics and two Class 1E interrupting devices connected in series with proper coordination to provide isolation of the instrument bus.

B. Isolation of control circuits is provided by photo isolators, relays, or operational amplifiers. The applied isolators provide isolation and separation between the Class 1E and nonsafety-related systems,

preventing degradation of the Class 1E system by any occurrence within the nonsafety system. Isolation of the diesel generators' nonsafety-related protective relay circuits from the Class 1E potential transformer circuits is provided with a single isolation fuse.

C. Associated power, control, and instrumentation cables which terminate on isolation devices are treated as Class1E through the isolation device to its outgoing terminals. Beyond this point, the cables lose their Class 1E preferential treatment. This precludes termination of associated circuits from redundant trains on a common device. Some associated circuit cables without isolation devices are uniquely identified as associated, per Regulatory Guide 1.75, and the identification scheme is in accordance with paragraph 7.1.3.16. In addition, some associated circuits are provided with two (redundant) isolation devices: i.e., fuses and/or circuit breakers. The identification of these cables is given in section 8.3.1.3.

The Safety Equipment Status System (SESS) described in section 7.5.2.6 provides by-passed and inoperable status indication of safety related equipment. The cables for this system are treated as described in section 8.3.1.3 and are color-coded as described in section 7.1.3.16. The channels of this system do not have isolation devices between them and the channels of the Class 1E equipment with which they are respectively

associated because, in accordance with IEEE 384-1974 as endorsed by Regulatory Guide 1.75, there exist within the SESS key subcomponents (which may include redundant fuses and/or circuit breakers) that prevent credible failures within the SESS from reducing the availability of the Class 1E equipment. These key subcomponents are maintained as Quality Class Q, although they are not safety-related and are not isolation devices as would be required by IEEE 384-1974.

D. Where the term "circuit" appears, it is construed to mean power, control, and instrumentation cables.

E. CEDM RSPT Type I and RSPT Type II circuits at the reactor head are run in flexible stainless steel conduits. Due to the configuration and proximity of control element assemblies, minimum separation requirement of 1 inch cannot be maintained.

F. A 1-inch separation exists between raceways and/or exposed cables of different separation groups prior to encircling a separation group raceway(s) and/or cable(s) with damage limiting barrier materials within areas deviating from standard Reg Guide 1.75 separation distances.

G. In instances where spatial constraints prevent non-Class 1E cables in totally enclosed raceways from maintaining a 1-inch minimum separation distance from Class 1E cables in totally enclosed raceways, analyses are performed demonstrating that failure of the non-

Class 1E cables will not prevent the proper functioning of the adjacent 1E circuits.

Further discussion pertaining to Regulatory Guide 1.75 is given in subsection 8.3.1.

For implementation of Regulatory Guide 1.75, refer to paragraphs 8.3.1.1.7 and 8.3.1.4. Additional references: 7.1.2, 7.1.4.19, 7.3.5.1.16, 8.1.4.2, 8.3.2.2.1.12, 8.3.6, 9A.84, and Table 9B.3-1.

REGULATORY GUIDE 1.76: Design Basis Tornado for Nuclear Power Plants (Revision 0, April 1974)

RESPONSE

The position of Regulatory Guide 1.76 is accepted (refer to paragraph 3.3.2.1) with the following exception:

A. Essential Spray Pond nozzles

Tornado missile protection is not provided for the essential spray pond nozzles because the loss of the unlimate heat sink safety function has been demonstrated by probabilistic risk assessment to be less than a median value of 10^-7 per reactor year or a mean value of 10^-6 per reactor year without missile protection (Ref. 5, Section 3.5.5).

Additional references: 2.3.1.2.2 and 3.8.1.2.3.

REGULATORY GUIDE 1.77: Assumptions Used for Evaluating a Control Rod Ejection Accident for Pressurized Water Reactors (Revision 0, May 1974)

RESPONSE

The position of Regulatory Guide 1.77 is accepted with the following exceptions:

A. Position C, Item 3

The offsite dose consequences for the CEA ejection event are limited to 100% of 10 CFR Part 100 exposure guideline values.

B. Appendix A, Item 14

The number of failed fuel rods equals the number of rods that experience Departure from Nucleate Boiling (DNB), as calculated with a statistical convolution technique. The statistical convolution technique involves the summation, over the reactor core, of the number of fuel rods with a specific Departure from Nucleate Boiling Ratio (DNBR) value, multiplied by the probability of DNB at that DNBR value.

Additional references: 15.3.4.3.2, 15.4.8, and 15.6.5.2.3.

REGULATORY GUIDE 1.78: Assumptions for Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release (Revision 0, June 1974)

RESPONSE

The position of Regulatory Guide 1.78 is accepted (refer to section 6.4). Additional references: 2.2.2.2.2 and 2.2.3.1.3.

REGULATORY GUIDE 1.79: Preoperational Testing of Emergency Core Cooling Systems for Pressurized Water Reactors (Revision 0, June 1974)

RESPONSE

The position of Regulatory Guide 1.79 is accepted with the exception that a hydraulic scale model test of the containment recirculation sump is performed in lieu of taking direct suction from this sump during recirculation tests (refer to subsection 6.2.2 and section 6.3). Also see Section 14.2.7. Additional references: 5.1.4, 5.4.7.1, and 6A.51.

REGULATORY GUIDE 1.80: Preoperational Testing of Instrument Air Systems (Revision 0, June 1974)

RESPONSE

Regulatory Guide 1.80 has been withdrawn and has been replaced by Regulatory Guide 1.68.3, "Preoperational Testing of Instrument and Control Air Systems (Revision 0, April 1982)."

REGULATORY GUIDE 1.81: Shared Emergency and Shutdown Electric Systems for Multi-Unit Nuclear Power Plants (Revision 1, January 1975)

RESPONSE

The position of Regulatory Guide 1.81 is accepted (refer to subsections 8.3.1 and 8.3.2.2.1.13).

REGULATORY GUIDE 1.82: Sumps for Emergency Core Cooling and Containment Spray Systems (Revision 0, June 1974)

RESPONSE

The position of Regulatory Guide 1.82 is accepted with exception to the guidance of approximate coolant velocity of 6 cm/sec (0.2 ft/sec), partial blockage of one-half of the inner screen surface area, and credit for horizontal surfaces in determining the available screen surface area (refer to subsection 6.2.2). Additional references: 6.3.1, 6.5.2, 6A.47, and 6A.58.

REGULATORY GUIDE 1.83: Inservice Inspection of Pressurized Water Reactor Steam Generator Tubes (Revision 0, June 1974)

RESPONSE

The position of Regulatory Guide 1.83 is accepted (refer to subsection 5.2.4) except that for compliance with Position c.3.a, the inspection shall be performed prior to the field hydrostatic test. Additional references: 5.1.4.

REGULATORY GUIDE 1.84: Design and Fabrication Code Case Acceptability ASME Section III Division 1

RESPONSE

The position of Regulatory Guide 1.84 is accepted (refer to table 5.2-3). Additional references: 5.2.1.2, 5.2.2, 3.7.1.3, 4.2.5, 5.1.4, and 5.4.7.1.

REGULATORY GUIDE 1.85: Materials Code Case Acceptability ASME Section III Division 1

RESPONSE

The position of Regulatory Guide 1.85 is accepted (refer to table 5.2-4). Additional references: 5.2.2, 5.2.1.2, 5.1.4, 5.4.7.1, 4.2.5, and 10.3.6.2.

REGULATORY GUIDE 1.86: Termination of Operating Licenses for Nuclear Reactors (Revision 0, June 1974)

RESPONSE

The position of Regulatory Guide 1.86 is accepted.

REGULATORY GUIDE 1.87: Construction Criteria for Class 1 Components in Elevated Temperature Reactors (Revision 0, June 1974)

RESPONSE

Not applicable.

REGULATORY GUIDE 1.89: Environmental Qualification of Certain Electronic Equipment Important to Safety for Nuclear Power Plants (Revision 1, June 1984)

RESPONSE

Class 1E equipment is qualified in accordance with IEEE 323-1974, IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations. However, clarifications to the guidelines presented in that document are necessary.

A. For equipment that has been seismically qualified by the testing procedures referenced in section 3.10, prior to qualification testing to IEEE 323-1974, the seismic qualification of IEEE 323-1974 of the aged equipment is by analysis using the testing outlined in section 3.10 and, if necessary, appropriate supplemental tests as a basis for the analysis. This combined qualification is in accordance with Sections 5.3 and 5.4 of IEEE 323-1974. Justification for qualification of equipment in this manner will be provided on an individual basis in qualification reports.

B. Objectives and methods described for aging are difficult to apply much of the equipment. The use of thermal and vibrational techniques to simulate aging may be valid for some components (cable or motor insulation), but is not valid or practical for many items. Any variation in aging methods or procedures

will be identified and justified on an individual basis in qualification reports.

C. Section 2.1 of Appendix D to this Regulatory Guide describes methods and assumptions used by the staff for calculating the radiation qualification dose in PWR dry containments. As part of this effort to eliminate the Iodine Removal (IR) System, the containment radiation qualification doses were calculated using the methodologies and guidance provided in Revision 2 of the Standard Review Plan. Some of these methodologies and assumptions differ from those presented in Revision 1 of Regulatory Guide 1.89. The differences, other than those plant specific characteristics such as containment volume, spray flow, etc., are summarized in the table below.

D. The following exception to Section 6.3.1.5.(7) of IEEE 323-1974 is taken:

For environmental qualification of equipment within the Palo Verde Equipment Qualification Program, the initial transient and the dwell at peak temperature need only be applied once during testing.

A description of the seismic qualification criteria of Class 1E equipment is provided in section 3.10. A description of the environmental qualification criteria of electrical equipment important to safety is provided in Section 3.11.

Additional references: 7.1.2.27, 8.3.1.2.2, 8.3.2.2.1.14, 18.II.F-1, and Table 18.II.F.2-3.

E. Regulatory Guide 1.89 Revision 1 does not specifically address qualification of equipment located outside the containment to beta radiation. PVNGS qualifies equipment located outside the containment to gamma radiation only.

Qualification Dose Analysis Characters/Parameter	Regulatory Guide 1.89, Revision 1	IR System Removal Analysis[3] (SRP, Rev. 2 Section 6.5.2)
% of core iodine activity instantly released to the containment atmosphere	50	50 (50)
% of iodine instantaneously plated out on cold surfaces	0	50 (50)
Hydrazine injection to spray	Yes	No (No)
pH of sump water during recirculation phase	8.5	7.0 (7.0)
Equilibrium iodine partition coefficent during injection phase	5000[1]	250[2] (250[2])
Spray removal constant for elemental iodine (hr^{-1})	27.2	19.6 (main spray region) 6.05 (auxiliary spray region) 0.0 (unsprayed region)
Overall plate out constant for elemental iodine (hr^{-1})	1.23	2.14 (main spray region) 14.4 (auxiliary spray region) 14.4 (unsprayed region)
Spray removal constant for particulate iodine (hr^{-1})	0.43	0.32 (main spray region) 0.09 (auxiliary spray region) 0.0 (unsprayed region)
Decontamination factor for elemental iodine	200	6.51 (main & aux. spray regions) 100 (time dependent plate out) Total=100[3]

1 Applicable to a sodium hydroxide system with pH > 8.0
2 Applicable for borated water with pH < 7.0
3 Combination of reduction in source term due to instantaneous plateout and time dependent plate out result in a total decontamination factor of 200.

REGULATORY GUIDE 1.90: Inservice Inspection of Prestressed Concrete Containment Structures with Grouted Tendons (Revision 0, November 1974)

RESPONSE

Not applicable. PVNGS tendons are ungrouted.

REGULATORY GUIDE 1.91: Evaluation of Explosions Postulated to Occur on Transportation Routes Near Nuclear Power Plant Sites (Revision 1, February 1978)

RESPONSE

There are no transportation routes or explosive quantities reflected in Regulatory Guide 1.91 which would impact PVNGS design (refer to section 2.2).

REGULATORY GUIDE 1.92: Combining Modal Responses and Spatial Components in Seismic Response Analysis (Revision 1, February 1976)

RESPONSE

Information contained in Regulatory Guide 1.92 is utilized as discussed in sections 3.7, 3.9, and 3A.9.

REGULATORY GUIDE 1.93: Availability of Electric Power Sources (Revision 0, December 1974)

RESPONSE

The position of Regulatory Guide 1.93 is accepted, as described in the Technical Specifications Bases.

Reference 8.3.1.2.2.19 and 8.3.2.2.1.15.

REGULATORY GUIDE 1.94: Quality Assurance Requirements for Installation, Inspection and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants

RESPONSE

For operations phase activities, PVNGS identifies conformance to the regulatory positions of Regulatory Guide 1.94 (including any exceptions or clarifications) in the PVNGS Operations Quality Assurance Program Description.

REGULATORY GUIDE 1.95: Protection of Nuclear Power Plant Control Room Operators Against an Accidental Chlorine Release (Revision 0, February 1975)

RESPONSE

Regulatory Guide 1.95 is not applicable to PVNGS as there is no gaseous chlorine stored onsite and the nearest railroad route for possible chlorine transportation is several miles away.

REGULATORY GUIDE 1.97: Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant Conditions During and Following an Accident

RESPONSE

PVNGS compliance with the recommendations of Revision 2 to Regulatory Guide 1.97 is addressed in table 1.8-1. Reference 2.3.3.1, 3.2.2 (Table 3.2-1), 6.2.5, 6A.14, 7.1.2.29, 7.5.2.5, 9.3.2.2, 9A.60, 11.5, 12.1.2, 12.3.2.1, and 18.

The NRC letter and Safety Evaluation for PVNGS license Amendment 136 dated September 28, 2001 states, in part: "The issuance of plant specific amendments to adopt this change, which would remove PASS and related administrative controls from TS, supersede the PASS specific requirements imposed by post-TMI confirmatory orders." Additionally, the operating license condition pertaining to Supplement No. 1 to NUREG-0737 was deleted from the operating licenses in NRC correspondence dated September 29, 2000.

REGULATORY GUIDE 1.99: Effects of Residual Elements on Predicted Radiation Damage to Reactor Vessel Materials (Revision 2, May 1988)

RESPONSE

This guide is not applicable to balance of plant design. For the CE supplied (NSSS) portion of the plant, the following response is applicable:

This Guide presents general procedures for predicting radiation-induced changes in the toughness properties of low alloy steels used in the fabrication of reactor pressure vessels. These procedures serve to meet certain requirements

of 10CFR50 Appendices G and H, which in turn implement 10CFR50 Appendix A, Criterion 31. The three principal positions of the Regulatory Guide are as follows:

C.1 Methods are presented to predict adjustment of the reference temperature and upper shelf impact energy based on neutron fluence and residual element content when credible surveillance data from the specific reactor vessel are not available.

C.2 Methods are presented to predict adjustment of the reference temperature and upper shelf impact energy by extrapolation or interpolation of credible surveillance data.

C.3 A 200°F limit is placed on the predicted adjusted reference temperature at the 1/4T position in the vessel wall at end-of-life for new plants.

POSITION:

Palo Verde reactor vessels, fabricated from SA 533 Grade B Class 1 material, are designed to maintain system integrity during their operating lifetime. Specifications for the toughness properties and residual chemistry of the vessel beltline materials are established to provide an ample margin against non-ductile failure during normal operation or under postulated accident conditions. The reactor vessel pressure-temperature operational limits are adjusted to account for the effects of neutron radiation on the toughness properties of the vessel beltline materials.

The methods used to predict adjustment of the reference temperature for Palo Verde reactor vessel beltline materials comply with the methods prescribed in Regulatory Guide 1.99, Revision 2. The Palo Verde surveillance program is designed to yield credible surveillance data for the verification or adjustment of plant operating parameters. Finally, the specifications for Palo Verde vessel beltline materials are designed to limit the adjusted reference temperature to 200°F at the inside surface of the reactor vessel wall at end-of-life.

Therefore, the prediction of neutron radiation effects in Palo Verde reactor pressure vessel materials is consistent with the procedures subsequently presented in Regulatory Guide 1.99, Revision 2.

REGULATORY GUIDE 1.100: Seismic Qualification of Electric Equipment for Nuclear Power Plants (Revision 0, March 1976)

RESPONSE

The position of Regulatory Guide 1.100 is accepted (refer to section 3.10). Additional references: Sections 7.1.2.30, 18.II.F.1, and Table 18.II.F.2-3.

REGULATORY GUIDE 1.101: Emergency Planning for Nuclear Power Plants (Revision 1, March 1977)

RESPONSE

Regulatory Guide 1.101 Revision 1 has been superseded by NUREG-0654/ FEMA-REP-1, Revision 1, "Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants." The guidance of NUREG-0654 was utilized in developing the PVNGS emergency plan.

Emergency action levels contained in the plan are based upon the guidance of NUMARC/NESP-007 and NEI-99-01 as endorsed by Regulatory Guide 1.101 Revisions 3 and 4 respectively.

Reference appendix 9B.3.1 (Table 9B.3-1).

REGULATORY GUIDE 1.102: Flood Protection for Nuclear Power Plants (Revision 1, September 1976)

RESPONSE

The position of Regulatory Guide 1.102 is accepted for a dry site (refer to subsection 2.4.10 and section 3.4).

REGULATORY GUIDE 1.105: Instrument Setpoints (Revision 1, November 1976)

RESPONSE

For instruments within the Bechtel scope of supply, the position of Regulatory Guide 1.105 is accepted, except that securing devices are not used since seismic and/or plant vibration tests have demonstrated that drift specifications are met without their use. Reference 7.1.2.31.

REGULATORY GUIDE 1.108: Periodic Testing of Diesel Generator Units Used as Onsite Electric Power Systems at Nuclear Power Plants **(Withdrawn 8/5/93)**

All references to Regulatory Guide 1.108 are historical. The commitment to Regulatory Guide 1.108 has been changed to Regulatory Guide 1.9.

REGULATORY GUIDE 1.109: Calculation of annual doses to man from routine releases of reactor effluents for the purpose of evaluating compliance with 10 CFR Part 50, Appendix I, (Revision 1, October 1977)

RESPONSE

The position of Regulatory Guide 1.109 is accepted

Reference 15.4.8.

REGULATORY GUIDE 1.111: Methods for Estimating Atmospheric Transport and Dispersion of Gaseous Effluents in Routine Releases from Light-Water-Cooled Reactors (Revision 1, July 1977)

RESPONSE

Information contained in Regulatory Guide 1.111 is utilized as discussed in section 2.3

REGULATORY GUIDE 1.112: Calculation of Releases of Radioactive Materials in Gaseous and Liquid Effluents from Light-Water-Cooled Power Reactors (Revision 0-R, May 1977)

PVNGS COMPLIANCE WITH REGULATORY GUIDE 1.97 (REVISION 2) REQUIREMENTS
(Sheet 10 of 37)

Plant Variable	Type - Categ.	Comply	Monitoring Instrumentation (a)	Instrument Range (a)	Env. Qual. (b)	Seismic Class (c)	Quality Class (d)	Sensing Location	Power Supply (e)	Display Location (RR)	Comments
34) Containment Area Radiation, High Range In-Cnmnt. Area Monitor, Ch A In-Cnmnt. Area Monitor, Ch B (see also row 76)	C-3	Fully	J-SQA-RU-0148 J-SQB-RU-0149	1.0×10^{0} to 1.0×10^{7} R/hr Sensitivity: 1 R/hr Accuracy: ± 20% @ 100KEV ± 35% @ 60KEV (p)	EQ (sensors) EM (micro)	I	Q	ion chambers, 'A' above refuel. area, 'B' east of access door	1E	CR, TSC, EOF. Displayed on qualified QSPDS. Also, displayed on non-qualified RMS terminal in CR and avail. on non-qualified ERFDADS. RU-148 & 149 are recorded on both RMS & ERFDADS for trending.	Redundant sensors and redundant displays. Micros are parallel-connected to QSPDS and RMS. (Also, ERFDADS values received from both QSPDS and RMS).
35) Effluent Radioactivity from Condenser Air Removal Exhaust (see also row 81)	C-3	N/A	NONE (not needed, effluent discharges through common plant vent, see row 38)								
36) RCS Pressure (see row 7)	C-1	Fully									
37) Containment H2 Concentration (see row 9)	C-1	See footnote (j)									
38) Containment Pressure (see row 4)	C-1	Fully									
39) Effluent Activity, Common Plant Vent (see note) Plant Vent Exhaust, Gas, Low Range Plant Vent Exhaust, Gas, High Range (see also row 83)	C-2	Fully	J-SQN-RU-0143, Ch 1 J-SQN-RU-0144	1.0×10^{-6} to 1.0×10^{-1} µCi/cc 3.0×10^{-2} to 1.0×10^{5} µCi/cc Accuracy: 25% (CC)	EM (sensors) EM (micro)	II	QAG	low range beta scintillator and mid and high range GM tubes in plant vent 176' Turb. Bldg., West	1E	CR, TSC, EOF Display on non-qualified RMS terminal in CR. Also avail. on non-qualified ERFDADS. RU-143 and RU-144 are recorded on both RMS and ERFDADS for trending.	Overlapping range sensors are not redundant, normal configuration with RU-144 in standby. Displays are not redundant since ERFDADS receives values from RMS via datalink. NOTE: includes Containment effluent and Condenser Air Removal exhaust.

Plant Variable	Type - Categ.	Comply	Monitoring Instrumentation (a)	Instrument Range (a)	Env. Qual. (b)	Seismic Class (c)	Quality Class (d)	Sensing Location	Power Supply (e)	Display Location	Comments
115) Containment Air Gamma Activity Grab Sample:	E-3	Fully See Footnote (PP)	(Sampling provided at RMS monitor RU-1 Grab Sampler). Multichannel Analyzer, and hand calculation.	Radionuclide isotopic identification from samples: 10 µCi/ml to 1.4 mCi/ml (with dilution capability to 10 Ci/ml) Sensitivity: 10 mCi/ml Accuracy: factor of 2	None (for Hot Lab equip)	None (for Hot Lab equip)	None (for Hot Lab equip)	Sample at RU-1 Skid at Cnmnt. 100' East Pene. Rm.	Non 1E (1E bkp)	Analysis results relayed to CR, TSC, EOF via fax.	Determination of radio-nuclides is performed on Multichannel Analyzer. I-131 Dose Equivalent is calculated from results. NOTE: Hot lab equip. backed-up by labs in unaffected units. NOTE: No heat tracing on sample lines. Plateout factor used for RU-1 cartridge samples. Samples are locally obtained in P&I grab sample chamber located at the RU-1 skid. Alternate sample collection may be access limited.

Footnotes:

(a) The identified instrumentation is usually the transmitter, although it is understood that the post-accident monitoring instrumentation loop extends from the sensing elements through to and including the control room display. In some cases the PVNGS instrumentation range is not literally that specified in RG 1.97. Some of these differences have been cited in letters to the NRC requesting an exception, other are cited in these footnotes; the differences cited in footnotes are not considered significant enough to render the "RG 1.97 compliance" of the instrumentation as questionable.

(b) Equipment Qualification Category Codes
- EQ = Component which is important to safety and qualified for harsh environment
- EM = Component performs safety-related function in a mild environment
- EP = Qualified as part of a larger component that has its own equip. ID tag.
- EX = Component which is important to safety but is exempt from qualification requirements based on an evaluation and/or NRC submittal.
- N = No equipment qualification requirements
- None = Item is not an Installed-Plant Component and has no assigned EQ Category.

Table 1.8-1
PVNGS COMPLIANCE WITH REGULATORY GUIDE 1.97 (REVISION 2) REQUIREMENTS
(Sheet 34 of 37)

(c) Seismic Category Codes
- I = Applies to components that must remain functional in the event of a Safe Shutdown Earthquake, including those items that perform a safety-related function
- II = Applies to components, not included in I or IX, which are essential to power generation or whose failure could cause a safety hazard to station personnel.
- III = Applies to components not included in I, II or IX categories.
- IX = Applies to components, not included in I, whose structural failure or collapse could reduce the functioning of any safety-related feature to an unacceptable level.
- None = Item is not an Installed-Plant Component and has no assigned Seismic Category.

(d) Quality Assurance Classification Codes
- Q = Applies to those components that perform a safety-related function
- QAG = Applies to those components that are not included in Q class, but on which PVNGS has made a regulatory or FSAR commitment to be included within the scope of the QA Program. QAG components have a quality class code conveying the basis for their classification; these codes are defined in an administratively controlled procedure.
- NQR = Applies to those components not included in Q or QAG classes. [NOTE: QAG is sub-divided by reference code conveying the basis for its classification]
- None = Item is not an Installed-Plant Component and has no assigned QA Classification.

[Note: The quality class code associated with the (bal of loop) notation represents the minimum classification level to meet RG 1.97 Type/Category requirements. Individual components within the loop may have a higher classification code for other reasons.]

(e) Power Supply Codes
- 1E = The sensing device up to and including any isolation device is powered from a Class 1E source which meets the “standby power with battery backup” requirement.
- 1E - DG bkp = The sensing device up to and including any isolation device is powered from a Class 1E source which receives backup from emergency diesel generators (but not batteries) [some tolerable interruption of indication occurs]
- Non-1E = The instrument loop is powered from a non-Class 1E source (no designed backup)
- Non 1E (1E bkp) = The instrument loop is normally powered from a non-Class 1E source; diesel-backed 1E power available through manual or automatic transfer [some tolerable interruption of indication may occur]
- Self = The instrument loop is powered from the same source it is monitoring
- N/A = Not applicable

(f) Type A variable per APS letter #ANPP-31334 (12/5/84)

(g) Note: Wide range level indication is provided for both steam generators. RG 1.97, Rev. 2, required range is from the tube sheet to separators, but due to the economizer design of the steam generators, measuring level down to the tubesheet is not practical. The indication range extends from approximately 167-inches above the tube sheet to approximately 57-inches above the separator deck for the steam generators. Plant operations procedures are based on the as-built tap locations.

(h) Note: Normal practice is for STA to calculate margin from lowest pressurizer pressure and highest T-hot; QSPDS value is used as backup.

Table 1.8-1
PVNGS COMPLIANCE WITH REGULATORY GUIDE 1.97 (REVISION 2) REQUIREMENTS
(Sheet 35 of 37)

(i) Note: CET readings are invalid above 25% reactor power.

(j) Note: Non-qualified heat trace on sample lines necessary for analyzer operability. Analyzer normally not in service; accurate readings after 30 minutes.

(k) Note: Footnote Deleted.

(l) Note: Zero point is top of vessel outlet plenum. RG 1.97, Rev. 2, required range is to the bottom of the core. This is accomplished indirectly by the use of the CETs.

(m) Note: Zero point is 4 inches above fuel alignment plate. Plenum level readings are unreliable when reactor coolant pumps are running.

(n) Note: Narrow Range overlaps the Wide Range by 0.5". Zero point on Wide Range is 6 inches above containment floor at approx. 40,000 gal. point. Upper limit is at approx. 960,000 gal. level equivalent.

(o) Note: Complies with R.G. 1.97 (Rev. 2) with the exception of the instrument range which does not meet the required range of ½ to 100 times Technical Specification limit in r/hr. The instruments cover the range from 10 to 100 times Technical Specification limit.

(p) Note: During extreme temperature ramps, radiation indication may exceed RG 1.97, Rev. 2 accuracy requirements for a short duration [less than 30 minutes].

(q) Note: Effectively top to bottom of vessel for operational use.

(r) Note: Lower range is 40°F instead of 32°F, exception approved in NRC letter Knighton to Van Brunt (6/18/85)

(s) Footnote deleted.

(t) Note: Upper range is equivalent to 105% design pressure, exception approved NRC letter Knighton to Van Brunt (6/18/85)

(u) Note: Upper range is 50 mph, exception approved NRC letter Knighton to Van Brunt (6/18/85)

(v) Note: Lower range is -6°F and upper range is +6°F (this has no effect on calculated Atmospheric Stability Class), see NRC letter Knighton to Van Brunt (6/18/85)

(w) Footnote deleted.

(x) Footnote deleted.

(y) Upper range is equivalent to approx. 20% above lowest safety valve setting.

(z) Upper range is equivalent to approx. 134% of vent design flow.

(aa) Upper range is equivalent to approx. 139% of vent design flow at rated pressure.

Table 1.8-1
PVNGS COMPLIANCE WITH REGULATORY GUIDE 1.97 (REVISION 2) REQUIREMENTS
(Sheet 36 of 37)

(bb) Upper range is equivalent to approx. 200% of maximum one-pump flow. Nominal one-pump flow is 4437 gpm while nominal two-pump flow is 7519 gpm, which is design flow in accordance with RG 1.97, Rev. 2, thus the upper range is equivalent to 133% of this flow.

(cc) Upper range is equivalent to approx. 184% of design flow at rated pressure.

(dd) Upper range is equivalent to approx. 116% of S/G design or rated flow at rated pressure.

(ee) Upper range is equivalent to approx. 136% of downcomer design flow or 17% of steam generator rated flow. Downcomer flow is the normal post trip flow path if main feedwater, main condensate or when the “N” auxiliary feedwater pump (AFN-P01) is being used.

(ff) Upper range is equivalent to approx. 198% of design flow at rated pressure.

(gg) Upper range is equivalent to approx. 128% of design flow at rated pressure.

(hh) Upper range is equivalent to approx. 148% of design flow at rated pressure.

(ii) Upper range is equivalent to approx. 126% of design flow at rated pressure.

(jj) Upper range is equivalent to approx. 102% of design tank capacity.

(kk) Lower range is equivalent to approx. 8×10^{-2} μCi/cc to 16 mCi/cc depending on time since reactor shutdown, and upper range is equivalent to approx. 8×10^{5} μCi/cc to 16×10^{7} μCi/cc depending on time since reactor shutdown.

(ll) deleted

(mm) Footnote deleted.

(oo) Footnote deleted.

(pp) Footnote deleted.

(qq) Footnote deleted.

(rr) Footnote deleted.

(ss) Footnote deleted.

(tt) Upper range is equivalent to approx. 113% of design flow.

(uu) Note: TLDs are part of normal environmental sampling program, specific dosimeters may be read during post-accident situations at the discretion of the emergency response team.

(vv) Footnote deleted.

(ww) Note: Coded “EX” on the basis that local conditions are “mild” although the EQ Zone for the transmitter is identified as “harsh”.

(xx) Note: Coded “EX’ on the basis of Not Needed for mitigation exclusion.

(yy) Note: footnote deleted.

(zz) Note: Coded “EX” on the basis of Not Needed for Mitigation exclusion.

(AA) Note: Coded “EX” on the basis of Limited Period of need exclusion.

(BB) Footnote deleted.

(CC) Note: Post-accident monitor correction factors are tabulated in a design calculation.

(DD) Note: Footnote deleted.

Table 1.8-1
PVNGS COMPLIANCE WITH REGULATORY GUIDE 1.97 (REVISION 2) REQUIREMENTS
(Sheet 37 of 37)

(EE) Note:	APS letter #102-02800-WFC/RAB/SAB (1/21/94) states PVNGS' acceptance of NRC relaxation of qualification requirements from Category 2 to Category 3
(FF) Note:	Containment Spray is primary post accident heat removal method; re-circulation fans used only when termination of containment spray criteria are met.
(GG) Note:	Calculation of flowrate currently done manually (no longer performed by CRACS) assuming full open position.
(HH) Note:	Redundant thermocouples at five separate locations; one set (TE-42A1 thru TE-42E1) is connected to ERFDADS, while the other set (TE-42A thru TE-42E) is connected to CR recorder (J-RMN-TJR1) and the plant computer. A single failure can eliminate five readings within a set, but not both sets. The calibration of set TE-42A1 thru TE-42E1 is quality-related although the equipment beyond the thermocouples is classed as NQR. Set TE-42A thru TE-42E is not environmentally qualified and is classified as NQR throughout. The maximum temperature displayable on recorder JRMNTJR1 and plant computer is 200 F.
(JJ) Note:	APS replaced direct measurement with indirect measurement using temperature and pressure of Containment and borated water storage tank, as recommended in CEN-415 and accepted by NRC in letter J.E. Richardson to CEOG, dated 4/12/93.
(KK) Note:	APS deleted sampling capability and relies on the passive pH control agent in the containment recirculation sump, as recommended in CEN-415 and accepted by NRC in letter J.E. Richardson to CEOG, dated 4/12/93.
(LL) Note:	APS deleted sampling capability and relies on the safety-grade hydrogen monitors, as recommended in CEN-415 and accepted by NRC in letter J.E. Richardson to CEOG, dated 4/12/93.
(MM) Note:	Coded "EX" on the basis of "not needed for mitigation exclusion."
(NN) Note:	Note: APS has eliminated all Containment Radwaste Sump Samples and Auxiliary Building Sump Grab Samples. The Containment Re circulation Sump Sample requirements are satisfied utilizing the Emergency Plan and RCS Sampling Procedures. The pH requirement is satisfied using passive pH control. All; of the above exceptions are recommended per CEN-415 and documented in Modification of Post Accident Sampling System commitments file: 94-009-545. (APS letter number 102-02938 dated April 29, 1994).
(OO) Note:	These instruments are required for manual balancing of HPSI flow during initiation of post LOCA Long Term Cooling, and are therefore defined as Regulatory Guide 1.97 Type A-1 variables. These components were not classified as Regulatory Guide 1.97 Type A-1 variables during the initial PAMI determination (see footnote f) since this balancing function was automatic at the time.
(PP) Note:	APS no longer must meet the licensing requirements for a dedicated Post Accident Sampling System (PASS) as described in NRC approved PVNGS License Amendment 136 dated September 28, 2001. Remaining post accident sampling requirements are met through the Emergency Plan and associated procedures. This change is supported by CE-NPSD-1157, as accepted by the NRC in Safety Evaluation Report, dated May 16, 2000, for CEOG Topical Report CE-1157 Revision 1 (WESTINGHOUSE CEOG-00-215).
(QQ) Note:	The two transmitters share a common sensing line; this is acceptable since no credible failure mechanism will affect this line.
(RR) Note:	EOF display of plant variable data is provided through modified ERFDADS data via a Wide Area Network (WAN). WAN provides data not directly connected to the plant ERFDADS System. Various plant variables would be available as needed. In addition, three screens have been configured to replicate the ERFDADS monitor displays.
(SS) Note:	In units where DMWO 2778159 has been implemented, applicable valve(s) have been removed.
(TT) Note:	In Units where DMWO 2529758 has been implemented, valve CHA-UV-715 is removed and valves HPA-UV-0023 & HPA-UV-0024 are de-terminated with upstream piping cut and capped as the new containment boundary.

RESPONSE

Information contained in Regulatory Guide 1.112 is utilized as discussed in section 11.3.

REGULATORY GUIDE 1.114: Guidance on Being Operator at the Controls of a Nuclear Power Plant (Revision 1, November 1976

RESPONSE

The position of Regulatory Guide 1.114 is accepted. Reference 13.1.3.1.

REGULATORY GUIDE 1.115: Protection Against Low-Trajectory Turbine Missiles (Revision 1, July 1977)

RESPONSE

The position of Regulatory Guide 1.115 is accepted as described in section 3.5.

REGULATORY GUIDE 1.117: Tornado Design Classification (Revision 1, April 1978)

RESPONSE

The position of Regulatory Guide 1.117 is accepted to the extent described in sections 3.3 and 3.5, and subsection 9.2.5.4. Also see Regulatory Guide 1.76.

REGULATORY GUIDE 1.118: Periodic Testing of Electric Power and Protection Systems (Revision 1, November 1977)

RESPONSE

The position of Regulatory Guide 1.118 is accepted as described in sections 7.1 and 8.3. Additional references 14.2.7 and Table 18.II.F.2-3.

REGULATORY GUIDE 1.121: Bases for Plugging Degraded PWR Steam Generator Tubes (Revision 0, August 1976)

RESPONSE

The position of Regulatory Guide 1.121 is accepted. Reference the Technical Specifications.

REGULATORY GUIDE 1.124: Service Limits and Loading Combinations for Class 1 Linear-Type Component Supports (Revision 1, January 1978)

RESPONSE

The position of Regulatory Guide 1.124 is accepted for the BOP Bechtel scope (see 3.9.3). The following response is applicable to the CE supplied (NSSS) scope:

The Regulatory Guide addresses service limits and loading combinations for Class I linear type component supports. The Regulatory Guide is more restrictive in terms of allowable

stresses than the previous revision and attempts to take into account the non-linear behavior encountered in bolted connections and shear stresses.

POSITION:

The RCS component supports as presently designed meet this latest revision of the regulatory guide.

The materials used in the design of the Reactor Coolant System components supports have been designed without using extremely high strength materials. This maintains an ultimate to yield strength ratio which is greater than 1.2 and as a result the allowable stresses used in the present design of the supports are the same as the allowable stresses in the latest revision of the regulatory guide. The regulatory guide addresses the fact that failure in shear may be a non-linear phenomenon. To compensate for this, the allowable stress in shear for Level "D" (faulted) is limited to 1.5 times the level of A & B allowable stresses in the latest revision of the regulatory guide. The RCS supports as presently designed meet this latest revision of the regulatory guide.

REGULATORY GUIDE 1.127: Inspection of Water-Control Structures Associated with Nuclear Power Plants (Revision 1, March 1978)

RESPONSE

The position of Regulatory Guide 1.127 does not apply to PVNGS.

REGULATORY GUIDE 1.129: Maintenance, Testing and Replacement of Large Lead Storage Batteries for Nuclear Power Plants (Revision 2, February 2007)

RESPONSE

The position of Regulatory Guide 1.129 Revision 2 is accepted with the following exceptions:

1. Battery temperature correction may be performed before or after conducting discharge tests.
2. RG 1.129 Regulatory Position 1 subsection 2, “References” is not applicable to the PVNGS Battery Monitoring and Maintenance program.
3. In lieu of RG 1.129, Regulatory Position 2, subsection 5.2, “Inspections” the following shall be used:

   “Where reference is made to the pilot cell, pilot cell selection shall be based on the lowest voltage cell in the battery.”

4. In Regulatory Guide 1.129, Regulatory Position 3, subsection 5.4.1,”State of Charge Indicator,” the following statements in paragraph (d) may be omitted:

   “When it has been recorded that the charging current has stabilized at the charging voltage for three consecutive hourly measurements, the battery is near full charge. These measurements shall be made after the initially high charging current decreases sharply and the battery voltage rises to approach the charger output voltage.”

5. In lieu of RG 1.129 Regulatory Position 7, Subsections 7.6, "Restoration" the following may be used.

   "Following the test, record the float voltage of each cell of the string."

   References 8.3.2.1.2.1 and 8.3.2.2.1.21.

REGULATORY GUIDE 1.130: Design Limits and Loading Combinations for Class 1 Plate-and-Shell Type Component Supports (Revision 0/1, July 1977/October 1978)

RESPONSE

There are no Class 1 plate-and-shell type component supports in the BOP Bechtel scope.

The following response is applicable to the CE supplied (NSSS) scope:

The Regulatory Guide addresses design limits and loading combinations for Class 1 plate and shell type component supports.

POSITION

Most Class 1 supports designed by C-E are of the linear type and, therefore, are not affected by this guide. The only exception is the steam generator sliding base support which is subjected to biaxial stress fields. The design for the steam generators conforms to revision 1 of Regulatory Guide 1.130.

REGULATORY GUIDE 1.133: Loose-Part Detection Program for the Primary System of Light-Water-Cooled Reactors (Revision 1, May 1981)

RESPONSE

The LPMS has been evaluated to determine conformance to the guidelines of Regulatory Guide 1.133, Revision 1. The evaluation is shown on table 1.8-2. Reference sections 4A.4, 7.7.1.1.8, and Table 3.2-1.

Table 1.8-2
LOOSE PARTS MONITORING SYSTEM CONFORMANCE EVALUATION
(Sheet 1 of 2)

Regulatory Guide 1.133, Rev. 1 Regulatory Positions	PVNGS Conformance to the Regulatory Positions
1. System characteristics	
a. Sensor locations	No exception
b. System sensitivity	No exception
c. Channel separation	No exception
d. Data acquisition system	A digital recording system is provided. Signals from all channels are continually sampled. Power is supplied from a 120 V-ac normal (non-seismically qualified) instrument bus, which has a Class 1E backup source. No exception
e. Alert level	No exception
f. Capability for sensor channel functionality test	
g. Functionality for seismic and environmental conditions	The LPMS components will be qualified to meet the normal environmental parameters of the areas in which they are installed.

Table 1.8-2
LOOSE PARTS MONITORING SYSTEM CONFORMANCE EVALUATION
(Sheet 2 of 2)

Regulatory Guide 1.133, Rev. 1 Regulatory Positions	PVNGS Conformance to the Regulatory Positions
h. Quality of system	No exception
i. System repair	No exception
2. Establishing the alert Level	No exception
3. Using the data acquisition Modes	APS takes exception to RG 1.133 regulatory position C.3.a(2)(e) to submit changes to the alert level and alert logic.
4. Content of safety analysis Reports	No exception to this section or section 7.7
5. Technical specification for the loose parts detection system	The guidance in Regulatory Position C.5, "Technical Specification for the Loose-Part Detection System," is implemented in the Technical Requirements Manual instead of the Technical Specifications.
6. Notification of a loose part	APS takes exception to RG 1.133 regulatory position C.6. This regulatory position has been superceded by 10 CFR 50.72 and 10 CFR 50.73.

REGULATORY GUIDE 1.134: Medical Evaluation of Licensed Personnel for Nuclear Power Plants (Revision 2, April 1987)

RESPONSE

The position of Regulatory Guide 1.134 is accepted.

REGULATORY GUIDE 1.137: Position C.2: Fuel Oil Systems for Standby Diesel Generators (Revision 1, October 1979)

RESPONSE

Position C.2 of Regulatory Guide 1.137 is accepted with the following exceptions to the Guide and the referenced standard (ANSI N195-1976):

A. ASTM D2276, Particulate Contaminant in Aviation Turbine Fuels, will replace ASTM D2274-70, Oxidation Stability of Distillate Fuel Oil (Accelerated Method), as outlined in Appendix B of ANSI N195-1976. The specification for particulate contamination will be 10 mg/l, maximum.

B. Fuel oil sampling will be in accordance with ASTM D4057-81, Manual Sampling of Petroleum and Petroleum Products. This replaces ASTM D270-1975, Standard Method of Sampling Petroleum and Petroleum Products, which has been deleted as an ASTM standard.

C. A high level alarm is not provided on the underground storage tanks. These tanks serve only the diesel

generators and are refilled only to replace fuel used during periodic testing. Safety grade level indication is provided in the main control room so that the refueling may be monitored.

D. Internal corrosion protection is not provided. Periodic (every 92 days) checks of fuel quality combined with low humidity and low rainfall at the site (see section 2.3) will preclude water accumulation and subsequent corrosion.

E. The fuel sampling connection is located within the vault above the tank. This connection can also be used as a stick gauge connection. The vault is approximately 6 feet high, which allows adequate access and use of a hinged stick gauge. This location precludes missile damage to a connection aboveground.

F. Analysis performed to determine if the "remaining applicable specifications" and "other properties" of new fuel and stored fuel, described in Position C.2.a and C.2.b, should be completed within 31 days of obtaining the sample.

G. Clarification: Fuel oil contained in the supply tank not meeting the "remaining applicable specifications" described in Position C.2.a (specifications other than viscosity or water and sediment) should, in a short period of time (about a week from identification), be replaced or returned to specification via processing.

H. Diesel fuel oil will meet the specifications of ASTM D975, Table 1, and analysis will be performed using the methods described in ASTM D975 per the ASTM standard revision referenced in the Technical Specification Bases 3.8.3 in lieu of ASTM D975-77 as described in Position C.2.a. For parameters not required by Technical Specifications, the analytical methods can be based on more current approved ASTM methods.

Reference 9.5.4.1.3, 9.5.4.2, 9A.9, and 9A.11.

REGULATORY GUIDE 1.140: Design, Testing and Maintenance Criteria for Normal Ventilation Exhaust System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants (Revision 1, October 1979)

RESPONSE

Exceptions are taken to applicable portions of Regulatory Guide 1.140 as referenced in NRC Generic Letter 83-13, Clarification of Surveillance requirements for HEPA Filters and Charcoal Adsorber Units in Standard Technical Specifications on ESF Cleanup Systems, and NRC Generic Letter 99-02, Laboratory Testing of Nuclear-Grade Activated Charcoal (APS Letter #102-04373). Exception to Regulatory Guide 1.140 is taken in reference to using ANSI N509-1980 in place of ANSI N509-1976 and using ANSI N510-1980 in place of ANSI N510-1975.

Information contained in Regulatory Guide 1.140 is utilized as discussed in sections 9.4 and 11.3, and in table 1.8-3.

Additional references: 9A.38 and 14.2.8.

REGULATORY GUIDE 1.141: Containment Isolation Provisions for Fluid Systems (Revision 0, April 1978)

RESPONSE

The position of Regulatory Guide 1.141 is accepted (refer to subsection 6.2.4) except for the following. An exception is taken to Regulatory Guide 1.141 for the CVCS charging line containment isolation valve CHA-HV-524. This valve does not meet the guidance of Section 4.2.2 of ANSI N271-1976 which requires all power-operated isolation valves to be capable of remote manual actuation from the control room. The power supply for this valve is removed by locking open its breaker at MCC PHA-M3520. The restoration of the power supply requires local operator action at the MCC. This exception to lock open valve CHA-HV-524 ensures that a flow path is available for charging or auxiliary spray flow by preventing inadvertent operation of the valve.

REGULATORY GUIDE 1.143: Design Guidance for Radioactive Waste Management Systems Structures, and Components Installed in Light-Water-Cooled Nuclear Power Plants (Revision 0, July 1978)

RESPONSE

PVNGS accepts the position of Regulatory Guide 1.143 including implementation of quality assurance requirements for the radwaste management systems (refer to sections 9.3, 11.2, 11.3, 11.4, and the PVNGS Operations Quality Assurance Program Description. Additional references: 3.2.2 (Table 3.2-1), 6.2.4.2.2, 11.5.4.2, and 11A.1) with the following exceptions:

A. Position B, (Discussion) - For the purpose of this guide the radwaste systems do not include instrumentation and sampling systems beyond the first root valve.

B. Position B - The instrument and controls of the gaseous radioactive waste processing system satisfy the requirements of Section 7.2 of ANSI/ANS-55.4-1979 referenced by Regulatory Guide 1.143, Rev. 1, with the following exception:

   The system gas analyzer, as specified in Table 6, will not record the H_2% by volume. It is assumed that the gaseous radwaste system will contain > 4% H_2 by volume whenever the system is in service. Monitoring the potentially explosive mixture will be based upon this assumption and the measured O_2 concentration by the gas analyzers.

C. Position C, Paragraph 1.1.3

   The turbine building, which houses most of the steam generator blowdown system, is a Seismic Category II braced steel and concrete structure with a design that

has been shown not to collapse under SSE loads. The turbine building has no means of containing the maximum liquid inventory contained in the potentially radioactive portions of the steam generator blowdown system. This potential for liquid/gaseous release is less than that resulting from failure of the refueling water tank analyzed in subsection 15.7.3 where the radiological consequences have been determined to be less than 1% of the 10CFR100 limits.

D. Position C, Paragraph 1.2.1

High level alarms on tanks in the radwaste building alarm in the radwaste control room instead of the main control room. A common radwaste alarm sounds in the main control room for any alarm that exists in the radwaste control room. No tank has a local alarm as the tank overflows are hardpiped to sumps avoiding local uncontrolled spillage.

E. Position C, Paragraph 1.2.3

The blowdown flashtank, (SCN-X01) in the turbine building, does not have an elevated threshold to catch potential leakage. However, because this tank operates at an elevated temperature and pressure, any leakage would be initially visible as steam. Liquid leaks would be collected by the turbine building drain system, which can be routed to the liquid radwaste system.

F. Position C, Paragraph 4.3

Pressure testing (hydrostatic or equivalent pneumatic) is conducted using the applicable ASME or ANSI code, but in no case less than one and one-half times the line design pressure for hydrostatic testing and no less than 1.2 times design pressure for pneumatic testing of the GRS for a minimum of 10 minutes as required by the above codes.

G. Position C, Paragraphs 5.1.2 and 5.2.4

The reinforced concrete design of these structures is in accordance with American Concrete Standard ACI 318 in lieu of ACI 349-76. Structures containing radwaste systems are analytically verified to withstand SSE loads without collapse.

H. Position C, Paragraph 1.1.2

"Materials for pressure retaining components" will be met for Chemical Waste (CM) system, except that ferritic ductile cast iron that meets the requirement of ASTM A-395 may be substituted for low carbon steel components where the maximum service temperature is 200°F and the maximum service pressure is 200 psig. Welding shall not be permitted on any ductile iron component.

(Sheet 5 of 9)

Radioactivity Removal Normal Ventilation Systems	Containment Power Access Purge	Auxiliary Building	Radwaste Building	Turbine Building Vacuum Pump Exhaust	Containment Preaccess (Air Cleanup Recirculation)
C.6.a	The activated carbon, when new, will be provided to meet the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02). The laboratory testing criteria for testing a representative carbon adsorber sample will be in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. Test acceptance criteria is derived by using the assigned activated carbon decontamination efficiency of 70% for organic iodide per Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02).	The activated carbon, when new, will be provided to meet the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02). The laboratory testing criteria for testing a representative carbon adsorber sample will be in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. Test acceptance criteria is derived by using the assigned activated carbon decontamination efficiency of 70% for organic iodide per Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02).	Position does not apply. No charcoal adsorber has been included into the design of this system. It is designed to remove particulates only.	The activated carbon, when new, will be provided to meet the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02). The laboratory testing criteria for testing a representative carbon adsorber sample will be in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. Test acceptance criteria is derived by using the assigned activated carbon decontamination efficiency of 70% for organic iodide per Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02).	The activated carbon, when new, will be provided to meet the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02) The laboratory testing criteria for testing a representative carbon adsorber sample will be in accordance with ASTM D3803-1989, using a temperature of 30°C and 70% relative humidity. (In response to Generic Letter 99-02). These units are recirculating systems (not exhaust systems) and are used for general atmosphere cleanup purposes. Additionally, ASTM D3803-1989 is a more stringent test than that described in Section 4.5.4 of RDT M16-1T (reference Regulatory Guide 1.140, Revision 1, October 1979, Table 2). Therefore, exception is taken to Table 2 criteria and an acceptance criteria of a methyl iodide penetration of less than or equal to 15% will be established.

Radioactivity Removal Normal Ventilation Systems Regulatory Guide 1.140 Positions	Containment Power Access Purge	Auxiliary Building	Radwaste Building	Turbine Building Vacuum Pump Exhaust	Containment Preaccess (Air Cleanup Recirculation)
	Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2 on such efficiency. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02). The activated carbon, when new, will be provided using the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02).	Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2 on such efficiency. This results in the test acceptance criteria of a methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02). The activated carbon, when new, will be provided using the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02).		Regulatory Guide 1.140, Revision 1, October 1979, Table 2, and imposing a safety factor of 2 on such efficiency. This results in the test acceptance criteria of methyl iodide penetration of less than or equal to 15%. (In response to Generic Letter 99-02). The activated carbon, when new, will be provided using the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02).	general atmosphere cleanup purposes. Additionally, ASTM D3803-1989 is a more stringent test than that described in Section 4.5.4 of RDT M16-1T (reference Regulatory Guide 1.140, Revision 1, October 1979, Table 2). Therefore, exception is taken to Table 2 criteria and an acceptance criteria of a methyl iodide penetration of less than or equal to 15% will be established. The activated carbon, when new, will be provided using the physical property specifications of Table 5.1 of ANSI N509-1980. Additionally, for optimum service life, the new carbon should exhibit a penetration less than 1.0% when tested in accordance with ASTM D3803-1989. (In response to Generic Letter 99-02).

REGULATORY GUIDE 1.145: Atmospheric Dispersion Models for Potential Accident Consequence Assessment at Nuclear Power Plants (November 1982)

RESPONSE

Information contained in Regulatory Guide 1.145 is utilized as discussed in section 2.3.

REGULATORY GUIDE 1.147: Inservice Inspection Code Case Acceptability ASME Section XI Division 1

RESPONSE

The position of Regulatory Guide 1.147 is accepted. Code Cases that are actually used will be identified in the applicable Inservice Inspection Programs. Reference 5.2.1.2.

REGULATORY GUIDE 1.155: Station Blackout Revision 0, August 1988

The position of Regulatory Guide 1.155 is accepted as described in Table 1.8-4. The compliance of PVNGS to Regulatory Guide 1.155 is based on the following significant issues:

a. A minimum emergency diesel generator (EDG) reliability target of 0.95 per demand for each EDG has been selected and a reliability program is in place to monitor and maintain this reliability level.

1. Regulatory Guide 1.155 section 1.1.1 (NUMARC 87-00 sections 3.2.3, 3.2.4) - Exception is taken to monitoring failures based on 20, 50, and 100 demands. Since the Maintenance Rule has been accepted and utilized for system reliability monitoring, Maintenance Rule EDG Performance Criteria (PC) for Reliability has been set to meet the overall goal of EDG targeted reliability of 0.95.

2. Section 1.1.2 – Exception is taken to averaging a nuclear unit’s failures based on 20, 50, and 100 demands. Per the Maintenance Rule, monitoring and tracking of failures is performed per train to avoid masking a poor performing EDG. Also 20, 50, and 100 demands are not used per the Maintenance Rule PC.

3. Section 1.1.3 – Comparison on average nuclear unit EDG reliability is not performed per 20, 50, and 100 demands, but per the Maintenance Rule PC.

4. Section 1.2 (various NUMARC 87-00 App. D sections) – Exceptions are taken to:

   a. NUMARC various App. D sections – General exception is taken to counting 20, 50, and 100 demands. Per Maintenance Rule PC, overall target meets Regulatory Guide 1.155 and NUMARC 87-00 target of 0.95.

   b. NUMARC 87-00 section D 2.2 – Exception is taken to counting start demands and load-run demands separately. All engine starts are counted as

demands (no separating start demands and load-run demands).

c. NUMARC 87-00 sections D 2.2.2, 2.2.3, 2.3.4, 2.3.5, 2.4.2, 2.4.3 – Exception is taken to monitoring failures to 50 and 100 demands per the Maintenance Rule PC. In addition, the Corrective Action Program performs monitoring of failures and maintenance performance under these NUMARC sections.

d. NUMARC D 2.4.4 – Exception is taken to requirements for a problem diesel and accelerated testing based on the Maintenance Rule and Corrective Action Program providing monitoring of failures and maintenance performance.

e. NUMARC D 2.4.5 – Exception is taken to requirements from exceeding failure trigger values. The Maintenance Rule and Corrective Action Program provide monitoring of failures and maintenance performance.

f. NUMARC D 2.4.6 – Exception is taken to requirements to retain demands and failures, corrective actions etc. for 50 and 100 demands. Since the Maintenance Rule PC and Corrective Action Program is used to track and monitor EDG performance, 50 and 100 demands are not specifically tracked.

g. NUMARC D 2.4.7 – Exception is taken to reporting to the NRC all failures/demands per 20, 50, and 100 demands. Exception is taken to the 20, 50, and 100 demand trigger values.

b. The minimum acceptable station blackout (SBO) coping duration was determined to be 16 hours. Studies and analyses have been performed to demonstrate the capability of withstanding and recovering from a station blackout event of 16 hour duration.

c. An onsite Alternate AC (AAC) power system has been installed to provide power to plant loads that have been determined to be important to the mitigation of a station blackout event. This system is manually started and can be connected to the affected nuclear unit within one hour of the onset of a SBO. The AAC power system is inspected and tested periodically to demonstrate its availability and reliability. Further discussion of the AAC power system is provided in Section 8.3.1.1.10.

d. A minimum reliability target of 0.95 per demand for the AAC power system has been selected and a reliability program is in place to monitor and maintain this reliability level.

e. Procedures and training have been established for operator actions necessary to cope with a station blackout event.

f. Quality assurance activities have been implemented as applicable for the non-safety related systems and

equipment installed and dedicated for the operation of the AAC power source. Further discussion of the quality assurance program for SBO is provided in the PVNGS Operations Quality Assurance Program Description.

Table 1.8-4
PVNGS Position to Regulatory Guide 1.155 – Station Blackout Revision 0, August 1988
(Sheet 1 of 4)

Regulatory Position	RG 1.155 Applicable Sections	PVNGS Position
ONSITE EMERGENCY AC POWER SOURCES	1.0	
Emergency Diesel Generator Target Reliability Levels	1.1	No exception taken
Reliability Program	1.2	No exception taken
Procedures for restoring Emergency AC Power	1.3	No exception taken
OFFSITE POWER	2.0	No exception taken
ABILITY TO COPE WITH A SBO	3.0	
Minimum Acceptable SBO Duration Capability.	3.1	Exception taken, 16 hour coping time is based on a voluntary license condition rather than an evaluation of the factors discussed in section 3.1.
Evaluation of Plant-Specific SBO Capability	3.2	
The evaluation should be performed assuming that the SBO event occurs while the reactor is operating at 100% rated thermal power and has been at this power level for at least 100 days.	3.2.1	Exception taken, The NSSS, secondary performance, and condensate volume are calculated using the decay heat used for the 16 hour analyses based on the ANSI/ANS-5.1 1979 decay heat curve, plus a 2 sigma uncertainty at equilibrium.
The capability of all systems and components necessary to provide core cooling and decay heat removal following a SBO should be determined, including station battery capacity, condensate storage tank capacity, compressed air capacity, and instrumentation and control requirements.	3.2.2	No exception taken
The ability to maintain adequate reactor coolant system inventory to ensure that the core is cooled should be evaluated, taking into consideration shrinkage, leakage from pump seals, and inventory loss from letdown or other normally open lines dependent on ac power for isolation.	3.2.3	No exception taken – Methodology used is different than NUMARC 87-00.
The design adequacy and capability of equipment needed to cope with a SBO for the required duration and recovery period should be addressed and evaluated as appropriate for the associated environmental conditions.	3.2.4	No exception taken – Methodology used is different than NUMARC 87-00.

Table 1.8-4
PVNGS Position to Regulatory Guide 1.155 – Station Blackout Revision 0, August 1988
(Sheet 2 of 4)

Regulatory Position	RG 1.155 Applicable Sections	PVNGS Position
Consideration should be given to using available non-safety-related equipment, as well as safety-related equipment to cope with a SBO provided such equipment meets the recommendations of Regulatory Positions 3.3.3 and 3.3.4. Onsite or nearby AAC power sources that are independent and diverse from the normal Class 1E emergency ac power sources (e.g., gas turbine, separate diesel engine, steam supplies) will constitute an acceptable SBO copying capability provided an analysis is performed that demonstrates the plant has this capability from the onset of SBO until the AAC power source or sources are started and lined up to operate all equipment necessary to cope with SBO for the required duration.	3.2.5	No exception taken – It has been demonstrated that in onset of SBO event, the station can cope for duration of 1 hour without any AC sources until the AAC power sources are started and lined up to operate all equipment necessary to cope with SBO for the 16 hour required duration. Based on regulatory guidelines, it is assumed that only one of three units at the Palo Verde site would experience SBO.
Consideration should be given to timely operator actions inside or outside the control room that would increase the length of time that the plant can cope with a SBO provided it can be demonstrated that these actions can be carried out in a timely fashion.	3.2.6	No exception taken
The ability to maintain appropriate containment integrity should be addressed. “Appropriate containment integrity” for SBO means that adequate containment integrity is ensured by providing the capability, independent of the preferred and blackout unit’s onsite emergency ac power supplies, for valve position indication and closure for containment isolation valves that may be in the open position at the onset of a SBO.	3.2.7	No exception taken
Modifications To Cope with SBO.	3.3	
If, after considering load shedding to extend the time until battery depletion, battery capacity must be extended further to meet the SBO duration recommended in Regulatory Position 3.1, it is considered acceptable either to add batteries or to add a charging system for the existing batteries that is independent of both the offsite and the blacked-out unit’s onsite emergency ac power systems, such as a dedicated diesel generator.	3.3.1	No exception taken. Batteries have the capacity to serve the required loads for one hour, without additional equipment or load shedding, until charging is restored from the AAC source.

Table 1.8-4
PVNGS Position to Regulatory Guide 1.155 - Station Blackout Revision 0, August 1988
(Sheet 3 of 4)

Regulatory Position	RG 1.155 Applicable Sections	PVNGS Position
If the capacity of the condensate storage tank is not sufficient to remove decay heat for the SBO duration recommended in Regulatory Position 3.1, a system meeting the requirements of Regulatory Position 3.5 to resupply the tank from an alternative water source is an acceptable means to increase its capacity provided any power source necessary to provide additional water is independent of both the offsite and the blacked-out unit's onsite emergency ac power systems.	3.3.2	No exception taken. Plant CST has sufficient volume.
If the compressed air capacity is not sufficient to remove decay heat and to maintain appropriate containment integrity for the SBO duration recommended in Regulatory Position 3.1, a system to provide sufficient capacity from an alternative source that meets Regulatory Position 3.5 is an acceptable means to increase the air capacity provided any power source necessary to provide additional air is independent of both the offsite and the blacked-out unit's onsite emergency ac power systems.	3.3.3	No exception taken. The longer duration event was originally supported by addition of a supplementary nitrogen system. This supplementary nitrogen system is no longer necessary and is now functionally retired because the ADV accumulator tanks capacity have been increased. Currently the long duration event is supported via design capacity of the ADV accumulator tanks.
A system is required for primary coolant charging and makeup, reactor coolant pump seal cooling or injection, decay heat removal, or maintaining appropriate containment integrity specifically to meet the SBO duration recommended in Regulatory Position 3.1, the following criteria should be met: 1. The system should be capable of being actuated and controlled from the control room, or if other means of control are required, it should be demonstrated that these steps can be carried out in a timely fashion, and 2. If the system must operate at 10 minutes of a loss of all ac power, it should be capable of being actuated from the control room.	3.3.4	No exception taken.

Table 1.8-4
PVNGS Position to Regulatory Guide 1.155 – Station Blackout Revision 0, August 1988
(Sheet 4 of 4)

Regulatory Position	RG 1.155 Applicable Sections	PVNGS Position
If an AAC power source is selected specifically for satisfying the requirements for SBO, the design should meet the following criteria: 1. The AAC power source should not normally be directly connected to the preferred or the blacked-out unit's onsite emergency ac power system. 2. There should be a minimum potential for common –cause failure with the preferred or the blacked-out unit's onsite emergency ac power sources. No single-point vulnerability should exist whereby a weather-related event or single active failure could disable any portion of the blacked-out unit's onsite emergency ac power sources or the preferred power sources and simultaneously fail the AAC power. 3. The AAC power source should be available in a timely manner after the onset of SBO and have provisions to be manually connected to one or all of the redundant safety buses as required. The time required for making this equipment available should not be more than 1 hour as demonstrated by test. If the AAC power source can be demonstrated by test to be available to power the shutdown buses at 10 minutes of the onset of SBO, no coping analysis is required. 4. The AAC power source should have sufficient capacity to operate the systems necessary for coping with a SBO for the time required to bring and maintain the plant in safe shutdown. 5. The AAC power system should be inspected, maintained, and tested periodically to demonstrate operability and reliability. The reliability of the AAC power system should meet or exceed 95 percent as determined in accordance with NSAC-108 or equivalent methodology.	3.3.5	No exception taken.
If a system or component is added specifically to meet the recommendations on SBO duration in Regulatory Position 3.1 system walkdowns and initial tests of new or modified systems or critical components should be performed to verify that the modifications were performed properly. Failures of added components that may be vulnerable to internal or external hazards within the design basis (e.g., seismic events) should not affect the operation of systems required for the design basis accident.	3.3.6	No exception taken
A system or component added specifically to meet the recommendations on SBO duration in Regulatory Position 3.1 should be inspected, maintained, and tested periodically to demonstrate equipment operability and reliability.	3.3.7	No exception taken
Procedures and Training to Cope with SBO. Procedures and training should include all operator actions necessary to cope with a SBO for at least the duration determined according to Regulatory Position 3.1.	3.4	No exception taken – Methodology used different than NUMARC 87-00.
Quality Assurance and Specification Guidance for SBO Equipment That is Not Safety-Related.	3.5	No exception taken

REGULATORY GUIDE 1.160: Monitoring the Effectiveness of Maintenance at Nuclear Power Plants (Revision 3, May 2012)

RESPONSE

APS accepts the position of Regulatory Guide 1.160.

REGULATORY GUIDE 1.163 Performance – Based Containment Leak-Test Program (Revision 0, September, 1995)

RESPONSE

The positions of Regulatory Guide 1.163 are accepted except as provided below.

In Regulatory Guide 1.163, Regulatory Position C.3 specifies containment visual examination requirements. However, visual examinations of containment concrete surfaces and the steel liner plate are performed in accordance with the ASME Boiler and Pressure Vessel Code, Section XI, Subsections IWL and IWE respectively, as described by Technical Specification 5.5.16.

REGULATORY GUIDE 1.181: Content of the Updated Final Safety Analysis Report in accordance with 10 CFR 50.71(e). (Revision 0, September 1999)

RESPONSE

The positions of Regulatory Guide 1.181 are accepted except as provided below.

With respect to NEI 98-03, Revision 1, Section A5, any NRC commitments incorporated into the UFSAR become part of the UFSAR, and are no longer part of the commitment management program. Therefore, implementing and reporting any changes to commitments incorporated in the UFSAR (including removals) are done under the appropriate change process (e.g., 10 CFR 50.59, 10 CFR 50.54, and 10 CFR 50.71(e), etc.), and are outside of the scope of the commitment management or corrective action programs.

With respect to NEI 98-03, Revision 1, Section A6, the reporting requirements of 10 CFR 50.71(e) and 10 CFR 50.59 provide adequate and complete information to the NRC regarding relevant deletions of information from the UFSAR. The additional reporting identified in Section A6 is not required.

REGULATORY GUIDE 1.187 Guidance for Implementation of 10 CFR 50.59, Changes, Tests, and Experiments (Revision 0, November 2000)

RESPONSE

The position of Regulatory Guide 1.187 is accepted, except as provided below.

NEI 96-07, Revision 1, “Guidelines for 10 CFR 50.59 Implementation”, Section 5.0, Documentation and Reporting, restates the requirements of 10 CFR 50.59(d). In addition, this section states that “A summary of 10 CFR 50.59 evaluations for activities *implemented* under 10 CFR 50.59 must be provided to NRC… The 10 CFR 50.59 reporting requirement (every 24 months) is identical to that for UFSAR updates such that licensees may provide these reports to NRC on the same schedule.” (emphasis added).

10 CFR 50.59 evaluation summary reports will include a summary of all 10 CFR 50.59 evaluations that were performed for the stated time period, regardless of the implementation status for the change, test, or experiment that was evaluated.

REGULATORY GUIDE 1.190 Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence (March 2001)

RESPONSE

The position of Regulatory Guide 1.190 is accepted for Generic Letter (GL) 96-03 implementation as provided below.

NRC GL 96-03, "Relocation of Pressure-Temperature Limit Curves and Low Temperature Overpressure Protection System Limits", January 1996, specifies that licensees use acceptable methods for reactor vessel neutron calculations (PTLR Criterion 1). PVNGS provided the fluence methodology details and provisions used to develop its Pressure-Temperature Limits Report (PTLR) in Westinghouse Electric Company, LLC, "Palo Verde Nuclear Generating Stations Units 1, 2, and 3: Basis for RCS Pressure and Temperature Limits Report", WCAP-16835-NP, Revision 0. In the Safety Evaluation for Operating License Amendment No. 178 for PVNGS Unit 1, 2, and 3, the NRC staff evaluated that information to establish that it adheres to the guidance contained in RG 1.190 and is thereby acceptable for GL 96-03 implementation.

REGULATORY GUIDE 3.72 Guidance for Implementation of 10 CFR 72.48, Changes, Tests, and Experiments (Revision 0, March 2001)

RESPONSE

The position of Regulatory Guide 3.72 is accepted, except as provided below.

NEI 96-07, Appendix B, "Guidelines for 10 CFR 72.48 Implementation", Section B5, Documentation and Reporting, restates the requirements of 10 CFR 72.48(d). In addition, this

section states that “A summary of 10 CFR 72.48 evaluations for activities *implemented* under 10 CFR 72.48 must be provided to NRC… The 10 CFR 72.48 reporting requirement (every 24 months) is identical to that for UFSAR updates such that licensees and CoC holders may provide these reports to NRC on the same schedule.” (emphasis added).

10 CFR 72.48 evaluation summary reports will include a summary of all 10 CFR 72.48 evaluations that were performed for the stated time period, regardless of the implementation status for the change, test, or experiment that was evaluated.

REGULATORY GUIDE 4.1: Programs for Monitoring Radioactivity in the Environs of Nuclear Power Plants (Revision 1, April 1975)

RESPONSE

The position of Regulatory Guide 4.1 is accepted.

REGULATORY GUIDE 8.2: Guide for Administrative Practices in Radiation Monitoring (Revision 0, February 2, 1973)

RESPONSE

The position of Regulatory Guide 8.2 is accepted (refer to subsections 12.1.1, 12.3.4, 11.5.1.1.3, and sections 12.5 and 13.2).

REGULATORY GUIDE 8.4: Personnel Monitoring Device – Direct-Reading Pocket Dosimeters (Revision 1, June 2011)

RESPONSE

The position of Regulatory Guide 8.4 is accepted; although PVNGS no longer uses direct-reading pocket dosimeters, PVNGS would conform to Regulatory Guide 8.4 if direct-reading dosimeters were to be used in the future.

REGULATORY GUIDE 8.7: Occupational Radiation Exposure Records Systems (Revision 0, May 1973)

RESPONSE

The position of Regulatory Guide 8.7 is accepted (refer to section 12.5.2.2.7).

REGULATORY GUIDE 8.8: Information Relevant to Ensuring that Occupational Radiation Exposures at Nuclear Power Stations Will Be As Low As Is Reasonably Achievable (Revision 3, June 1978)

RESPONSE

The position of Regulatory Guide 8.8 is accepted (refer to subsections 5.4.7 and 12.3.4 and sections 11.3, 12.1, 12.5, and 13.1.2.2.1.5). Additional references: 11.4.1, 11.5.1, 12.2.1, and 12.3.

REGULATORY GUIDE 8.9: Acceptable Concepts, Models, Equations, and Assumptions for a Bioassay Program (Revision 1, July 1993)

RESPONSE

The position of Regulatory Guide 8.9 is accepted (refer to section 12.5).

REGULATORY GUIDE 8.10: Operating Philosophy for Maintaining Occupational Radiation Exposures As Low As Is Reasonably Achievable (Revision 1-R, May 1977)

RESPONSE

The position of Regulatory Guide 8.10 is accepted (refer to subsection 12.1.3 and sections 12.5 and 13.2).

REGULATORY GUIDE 8.12: Criticality Accident Alarm Systems (Revision 0, December 1974)

RESPONSE

The position of Regulatory Guide 8.12 is accepted as clarified in section 11.5, and 12.3.4.

REGULATORY GUIDE 8.13: Instruction Concerning Prenatal Radiation Exposure

RESPONSE

The guidance of Regulatory Guide 8.13 is utilized in developing lesson plans. Reference section 12.5.3.8.

REGULATORY GUIDE 8.14: Personnel Neutron Dosimeters (Revision 1, August 1977)

RESPONSE

Regulatory Guide 8.14 has been withdrawn by the NRC, as described in the February 26, 2001. Federal Register (66 FR 11611). RG 8.14 guidance was superseded by 10 CFR 20.1501 (Refer to paragraph 12.5.3.6).

REGULATORY GUIDE 8.19: Occupational Radiation Dose Assessment in Light-Water Reactor Power Plants Design Stage Man-Rem Estimates (Revision 1, June 1979)

RESPONSE

The dose assessments noted in section 12.4 have been provided to demonstrate that occupational exposures will be ALARA by design and by operation. The assessments have considered operational experience and plant specific shielding, access control, and maintainability. The specific data requested by Regulatory Guide 8.19 was not provided as the Regulatory Guide 8.19 was issued subsequent to the construction permit.

To satisfy the intent and concerns of Regulatory Guide 8.19, as well as Regulatory Guide 8.8, PVNGS conducted extensive ALARA reviews as described in paragraph 12.1.1.1 and appendix 12B.

These reviews, in conjunction with the radiation zones in the plant, the shielding design criteria, and the operating policies for ALARA will ensure that occupational man-rem will be ALARA.

REGULATORY GUIDE 8.26: Applications of Bioassay for Fission and Activation Products (Revision 0, September 1980)

RESPONSE

The position of Regulatory Guide 8.26 is accepted. (Refer to paragraph 12.5.3.6.)

1.9 STANDARD DESIGNS

The CESSAR design scope has been incorporated in each PVNGS unit and described in the UFSAR to the maximum extent practical. Subsection 1.9.1 describes the specific procedures that are used to incorporate CESSAR in the PVNGS FSAR. Subsection 1.9.2 describes the exceptions and/or deviations from the CESSAR design. Both Subsection 1.9.1 and 1.9.2 describe the methods used, at the time the operating licenses were issued. If a CESSAR subsection is referenced by the applicable UFSAR Section, then the methods described in UFSAR subsections 1.9.1 and 1.9.2 remain applicable.

1.9.1 REFERENCES TO CESSAR

Refer to the CESSAR introductory statement for the format and content used in CESSAR. Where applicable, the PVNGS NSSS design information required by Regulatory Guide 1.70, Revision 3, is incorporated in the PVNGS FSAR by reference to the appropriate CESSAR chapter, section, table, or figure. For example, the phrase "refer to CESSAR Section 9.3.5" is used to incorporate the identified CESSAR section into the PVNGS FSAR. Any other chapter, section, table, or figure referenced in the FSAR refers to a chapter, section, table, or figure of this FSAR.

Each reference to a CESSAR section also incorporates all figures, tables, and appendices referred to in such incorporated CESSAR section. All topical reports referred to in such CESSAR section and listed in CESSAR Section 1.6 are also incorporated in the PVNGS FSAR. Where the CESSAR section incorporated in this FSAR refers to another CESSAR section, the

latter section is not incorporated herein unless it is also incorporated by specific reference in the corresponding section of this FSAR. However, reference to CESSAR Section 1.8 incorporates those positions of CESSAR sections referenced in CESSAR Section 1.8 which respond to the Regulatory Guides.

Where the PVNGS FSAR refers to CESSAR sections relating to systems not in the C-E scope of responsibility (table 1.9-1), the reference means that the CESSAR section is applicable to and descriptive of the non-C-E system.

1.9.1.1 PVNGS Scope of Supply

Table 1.9-1 sets forth the PVNGS scope of responsibility for the NSSS, safety-related components, and other auxiliary systems. CESSAR systems comprising the C-E System 80 are delineated in UFSAR Table 1.2-1.

1.9.1.2 Interfaces with CESSAR Systems

The method of addressing CESSAR interface information in the PVNGS FSAR is described in CESSAR Section 1.1.3.

Interface sections in CESSAR have been identified in CESSAR Table 1.2-2. The CESSAR sections containing interface requirements that are addressed herein and sections of the PVNGS FSAR that evaluate how the applicable CESSAR interface requirements are satisfied are itemized in table 1.9-2.

Each applicable balance of plant interface requirement is repeated in the appropriate section of the PVNGS FSAR under the heading "CESSAR Interface Requirements". Information in sections titled “CESSAR Interface Requirements” has been

reproduced verbatim from the CESSAR for incorporation into the UFSAR and, therefore, should not be altered or revised. If information in any of these sections is different from actual plant design, that should be addressed in the “CESSAR Interface Evaluation” section. A discussion regarding compliance of the PVNGS system design with the applicable interface requirements is provided under the heading "CESSAR Interface Evaluation".

STANDARD DESIGNS

1.9.2 EXCEPTIONS TO CESSAR

Any CESSAR exception that meets the definition of a system deviation given in paragraph 1.9.2.4 is discussed in that paragraph. Differences which are within the definitions of either envelope deviations, terminology deviations, or analysis deviations set forth in paragraphs 1.9.2.1, 1.9.2.2, and 1.9.2.3, respectively, are not interpreted to be CESSAR exceptions. Changes to the CESSAR design that do not modify interface requirements are indicated in the applicable FSAR sections.

1.9.2.1 Envelope Deviations

Site-related characteristics, such as meteorology, hydrology, site boundaries, and cooling water sources are within CESSAR envelopes. There are no envelope deviations.

1.9.2.2 Terminology Deviations

Differences in PVNGS system nomenclature from nomenclature used in CESSAR are defined as terminology deviations.

Table 1.9-3 provides a cross-reference of terminology used. Valve and instrument numbers contained in those CESSAR sections incorporated by reference are illustrative only and do not represent the PVNGS system component nomenclature.

1.9.2.3 Analysis Deviations

Differences in methods of analysis, calculational techniques, and models used by C-E and Bechtel are defined as analysis deviations. These differences achieve similar results by alternative means and are not, therefore, considered analysis deviations.

1.9.2.4 System Deviations

Each of the systems that are within the C-E scope of responsibility, as defined in table 1.9-1, have interface sections. System interfaces which do not conform to those described in CESSAR are categorized as system deviations.

In this situation, an alternative method of providing the functional requirement specified by the CESSAR interface has been adopted for PVNGS. A description of each of these system interface deviations is given in the following sections.

1.9.2.4.1 Containment Spray System (CESSAR Appendix 6A, Section 7.14/FSAR paragraph 6.5.2.8 (RA) 7.1.4)

Containment spray system (CSS) actuation and flow delivery occurs on a preestablished schedule given in Section 6.3 of CESSAR Appendix 6A. This schedule determines flow conditions in various analyses that take credit for a train of the CSS functioning to mitigate the consequences of postulated transients. The maximum time to establish rated flow given in CESSAR Appendix 6A, Section 7.1.4, is 58 seconds after receipt of CSAS. For PVNGS, CSS rated flow will be delivered in greater than 58 seconds (table 6.2.1-7). The exception to the

Table 1.9-3
PVNGS SYSTEM TERMINOLOGY COMPARISON

PVNGS System or Component	CESSAR System or Component
Essential cooling water system (ECWS)	Component cooling water system (CCWS)
Nuclear cooling water system (NCWS)	Component cooling water system (CCWS)
Essential spray pond system (ESPS)	Station service water system
Fuel pool cooling and cleanup system	Pool cooling and purification system
Liquid radwaste system (LRS)	Liquid waste management system
Gaseous radwaste system (GRS)	Gaseous waste management system
Solid radwaste system (SRS)	Solid waste management system
Demineralized water system	Demineralized water makeup system
Auxiliary feedwater system	Emergency feedwater system/auxiliary feedwater system
Auxiliary feedwater actuation signal (AFAS)	Emergency feedwater actuation signal (EFAS)
Load Group 1	Train A
Load Group 2	Train B
Diesel generator	Emergency generator

CESSAR interface requirement for the CSS flow delivery time is only significant in the determination of the in-containment equipment qualification temperature parameters. However, under the worst case temperature conditions (i.e., main steam line 7.16 square feet slot break at 102% power, loss of one containment spray train, and no loss of offsite power), the calculated temperature transient of paragraph 6.2.1.8 is bounded by the equipment qualification environment of Appendix A of the Equipment Qualification Program Manual. Combustion Engineering has also committed to qualify safety-related equipment within their scope to the same environment. By this analysis, the delay in delivery of rated flow to the CSS has been shown to have no adverse consequences under postulated transients.

1.9.2.4.2 Containment Spray System (CESSAR Appendix 6A, Section 7.13.14/FSAR paragraph 6.5.2.8 (RA) 7.13.14)

The head loss requirements of CESSAR Appendix 6A are not applicable to the PVNGS design due to the addition of the auxiliary spray headers. The analyses of both train A and train B of the containment spray system have shown that either train of the system will operate satisfactorily and meet the design flow requirements independent of the other train during all modes of operation. The design flow includes the additional flow for auxiliary spray headers.

1.9.2.4.3 DELETED

1.9.2.4.4 Engineered Safety Features Monitoring (CESSAR Section 7.5.1.1.3/FSAR paragraph 7.5.1.1.3)

The PVNGS design has two Class 1E wide range refueling water tank (RWT) level indicator channels with Class 1E indicators on the remote shutdown panel and one Class 1E indicator channel in the control room. The second channel in the control room is Class 1E with the exception of the isolated non Class 1E indicator and indicator power supply. This arrangement is acceptable in that both Class 1E channels are displayed on the remote shutdown panel and there are four narrow range Class 1E level indicator channels in the control room which are redundant for the volume of the RWT required to mitigate the consequences of a LOCA.

1.9.2.4.5 Spent Fuel Pool (CESSAR Section 9.1.4.6/FSAR paragraph 9.1.4.7)

CESSAR Section 9.1.4.6 requires 23 feet of water cover for a fuel rod assembly lying horizontally on top of the fuel racks.

In the evaluation of a fuel handling accident, Regulatory Guide 1.25 permits an overall iodine decontamination factor of 100 for pool depths of 23 feet or greater above the broken fuel pins. At PVNGS, there is a minimum of 22 feet 6 inches of water over the damaged fuel pins at the pool low level alarm point. As iodine decontamination by 22 feet 6 inches of covering water is considered virtually the same as the decontamination provided by 23 feet 0 inch of covering water, this 6-inch difference has a negligible impact on the radiological effects of a fuel handling accident.

1.9.2.4.6 Refueling Water Tank (CESSAR Section 9.3.4.6/FSAR paragraph 9.3.4.2)

CESSAR Section 9.3.4.6 requires that the vent piping of the refueling water tank be maintained at a minimum temperature of 40F. As noted in response to related NRC concerns (see Question 6A.55), the water within the RWT will be kept above 60F at all times. The vent is located in the uppermost portion of the tank. The vent pipes are routed without piping pockets that could cause the accumulation of moisture. As the design winter ambient temperature at PVNGS is 25F for 24 hours, plugging of the RWT vent line is considered very improbable.

CESSAR Section 9.3.4.6 requires that redundant CVCS equipment loads shall be supplied by separate buses or motor control centers to minimize the effect of power outages. The two RWT heaters are powered through separate circuit breakers in a single motor control center fed from a single 480V load center. The tank contents are normally above 60F and redundant low temperature annunciation in the main control room is provided. The thick concrete wall tank construction, relatively mild Palo Verde climate, and large tank inventory combine to allow only very slow tank content temperature changes. Adequate time is available to restore heater power following distribution equipment malfunction without concern for precipitation of tank contents.

1.9.2.4.7 Safety Injection System (CESSAR Section 6.3.1.3.M.8/ FSAR paragraph 6.3.1.4, listing M.8)

Section 6.3.1.3.M.8.b requires that the volume in each safety injection (SI) line between the RCS and the first SI valve to

be less than 30 cubic feet. This requirement ensures that the time taken to inject borated water from the SI system into the RCS is minimized. The PVNGS design satisfies this requirement for each of the four, 12-inch diameter, cold leg injection SI lines. These four cold leg injection paths are used for boration of the RCS.

The ‘A’ train SI long term recirculation line conforms to, but, the ‘B’ train line exceeds the maximum water volume requirement of Section 6.3.1.3.M.8.b. The PVNGS design for the ‘A’ train lines has less than 16 cubic feet of unborated water volume between the RCS and the first SI valve. The PVNGS design for the ‘B’ train lines has less than 44 cubic feet of unborated water volume between the RCS and the first SI valve. The excess 14 cubic feet of unborated water volume is acceptable since these lines are not required for boration of the RCS. The long term recirculation lines are used to prevent boron precipitation in the core following a LOCA.

1.9.2.4.8 Containment Spray System (CESSAR Appendix 6A, Section 7.13.7.B/FSAR paragraph 6.5.2.8, listing A (RA)7.13.7.B)

CESSAR Appendix 6A, Section 7.13.7.B, discusses delay time for spray of borated water. This interface requirement uses the term "borated water" because the containment spray pump suction is from the RWT which is borated. The total volume of water in both spray headers inside containment when filled to the 113-foot indicated elevation (110-foot actual) is less than 700 gallons, and filling this volume with fresh instead of borated water will have no impact on the performance of the

containment spray system in removing containment heat or iodine, and negligible potential for boron dilution following sump recirculation after a loss-of-coolant accident. The intent of the CESSAR interface requirement is met as described in paragraph 6.5.2.8, listing A (RA)7.13.7.B by filling the spray headers inside containment to the 113-foot indicated elevation (110-foot actual) with fresh water.

1.9.2.4.9 Preoperational Test Descriptions for HPSI, LPSI, and SIT Subsystem Tests (CESSAR Sections 14.2.12.1.22, 14.2.12.1.23, and 14.2.12.1.24)

CESSAR Sections 14.2.12.1.22 (HPSI), 14.2.12.1.23 (LPSI), and 14.2.12.1.24 (SIT) each include as a prerequisite:

> "2.4 The reactor vessel head and internals have been removed."

These tests will be accomplished, in part, on PVNGS Unit 1, with the reactor vessel head and internals in place.

For CESSAR Sections 14.2.12.1.22 (HPSI), and 14.2.12.1.23 (LPSI), for PVNGS Unit 1 only, replace the existing Item 2.4 with:

> 2.4 Four pressurizer safety valves removed to provide a pressure vent path.

For CESSAR Section 14.2.12.1.23 (LPSI), for PVNGS Unit 1 only, replace the first two lines of existing Item 3.4 with:

> 3.4 Start each LPSI pump using an SIAS signal and collect initial pump operating data. For this

portion of the test, the pump under test will....................

For CESSAR Section 14.2.12.1.24 (SIT), for PVNGS Unit 1 only, replace the existing Item 2.4 with:

2.4 Test method Item 3.6 (discharge of safety injection tanks into RCS) will be accomplished with the reactor vessel head and internals removed. Test method Items 3.1 through 3.5 may be accomplished with the reactor vessel head and internals installed or removed.

The CESSAR prerequisite 2.4 that the reactor vessel head and internals be removed ensures an adequate pressure vent path to allow operation of tested components at near runout conditions to confirm system design in case of RCS rupture, and to prevent flow-induced movement of unrestrained reactor vessel internals. By draining the RCS to the mid-point of the cold legs prior to the test and by providing a pressure vent path through the removed pressurizer safety valves, and additionally, in the case of the LPSI test, aligning the LPSI pump not under test to take a suction from the RCS and discharge to the RWT, sufficient room exists in the RCS to obtain the required test data. By ensuring a test backpressure less than or equal to the head of water at a level equal to the reactor vessel flange, as indicated by the refueling level indicator, the intent of the original test prerequisite is maintained. If insufficient test data can be obtained because of some unforeseen reason with the reactor vessel head and internals installed, portions of the test will be repeated with the

reactor vessel head and internals removed, as needed to meet the acceptance criteria of the CESSAR test descriptions.

1.9.2.4.10 Main and Auxiliary Feedwater System (CESSAR Sections 5.1.4.G.6.a, 5.1.4.G.7, 5.1.4.I.9.a, 8.3.1.3.d/FSAR subsection 5.1.5, listing G.6, G.7, and I.9.a, and paragraph 8.3.1.1.4.6)

The PVNGS design takes exception to four CESSAR interface requirements with respect to the main and auxiliary feedwater systems. These exceptions are:

A. An increase in the feedwater isolation valve closure time (in both the downcomer and economizer lines) from 4.6 to 9.6 seconds (CESSAR Section 5.1.4.I.9.a),

B. A reduction in the auxiliary feedwater flowrate from 875 to 650 gal/min per pump (CESSAR Section 5.1.4.G.7),

C. An increase in the auxiliary feedwater pump start times when normal ac is available from 10 seconds to 22 and 45 seconds for the motor and turbine-driven pumps, respectively (CESSAR Section 5.1.4.G.6.a), and

D. An increase in the time delay from 15 to 23 seconds in which interrupted auxiliary feedwater flow must be fully reestablished to the steam generators (CESSAR Section 8.3.1.3.d).

Table 1.9-4 provides a matrix which describes how these exceptions impact the chapter 15 safety and chapter 6 containment analyses. This table demonstrates that the consequences of all of these analyses remain acceptable.

Table 1.9-4

IMPACT OF MAIN AND AUXILIARY FEEDWATER DEVIATIONS FROM THE CESSAR INTERFACE REQUIREMENTS AND REDUCTION OF LPSI AND HPSI FLOW (Sheet 4 of 6)

a. This column identifies the PVNGS FSAR sections that reference the CESSAR safety analyses.

b. For the inadvertent opening of an ADV transient, an increase in the feedwater isolation valve closure time from 4.6 to 9.6 seconds does not alter the minimum DNBR or the maximum RCS pressure of the event. Therefore, with respect to the Standard Review Plan (SRP) criteria, there is no impact on the consequences of the event.

c. The interface requirement for auxiliary feedwater delivery when ac power is not available is 45 seconds following the generation of an AFAS signal, and when ac power is available, 22 seconds for the motor driven pump. Therefore, if flow reestablishment following the loss of ac occurs in less than the difference between these two times. i.e., 23 seconds, then it is assured that the total delay is less than the 45 seconds assumed in the chapter 15 safety analysis.

d. For the loss of condenser vacuum transient, the maximum reactor coolant system (RCS) pressure occurs before the delivery of auxiliary feedwater or safety injection. Therefore, with respect to SRP criteria, there will be no impact on the consequences of the event.

e. The maximum RCS pressure of the feedwater line break transient is unaffected by the reduction in auxiliary feedwater flow because the pressure occurs before auxiliary feedwater delivery. However, this transient was reanalyzed in subsection 15.2.8 in order to demonstrate that 650 gal/min is adequate for long term RCS heat removal.

f. For the locked rotor and sheared shaft transients, the minimum departure from nucleate boiling ratio (DNBR) occurs before auxiliary feedwater delivery, and is not changed. In addition, the integrated atmospheric steam releases and therefore the radiological consequences of the event remain unchanged by the reduction in auxiliary feedwater flow. Therefore, with respect to the SRP criteria, there is no impact on the consequences of the event.

g. The steam generator tube rupture (SGTR) transient presented in CESSAR Section 15.6.3 is not impacted by the reduction in auxiliary feedwater because the integrated atmospheric steam releases, and therefore the radiological consequences of the event, remain unchanged. However, the SGTR transient with a fully stuck open atmospheric dump valve (ADV) is sensitive to this reduction in auxiliary feedwater flow. This transient was reanalyzed using the PVNGS specific auxiliary feedwater system in response to NRC questions (see note j).

h. For the steam generator tube rupture with ac available, the auxiliary feedwater system is not actuated. Therefore, these changes do not impact the transient's results and the tube rupture discussion is limited to the case with the loss of ac power.

i. The minimum auxiliary feedwater flowrate of 650 gal/min does not alter the reported results of the emergency core cooling system (ECCS) performance analysis referenced in subsection 15.6.5. Therefore, conformance to the 10CFR50.46 ECCS acceptance criteria is preserved.

   The large break loss-of-coolant accident (LOCA) and long-term cooling evaluations in the CESSAR Sections 6.3.3.2 and 6.3.3.4 are unaffected by the reduced minimum auxiliary feed flowrate. The energy removal capability of large breaks overwhelms steam generator heat transfer and auxiliary feed flowrate considerations. Post-LOCA RCS heat removal in the long term cooling mode (after 1 hour) requires a much lower auxiliary feedwater flowrate to remove the diminished decay heat values which occur at this later time.

   The small break LOCA evaluation in CESSAR Section 6.3.3.3 is sensitive to steam generator heat removal and hence auxiliary feedwater flowrate. However, an evaluation of the auxiliary feedwater flowrate of 650 gal/min shows that this flowrate is sufficient to preserve the RCS depressurization, core liquid inventory and hence, the peak cladding temperature results presented in CESSAR.

   With respect to the feedwater isolation valve closure time change, the LOCA analyses conservatively assumed that main feedwater flow is terminated in less than 1 second after the reactor trip.

Table 1.9-4
IMPACT OF MAIN AND AUXILIARY FEEDWATER DEVIATIONS FROM THE CESSAR
INTERFACE REQUIREMENTS AND REDUCTION OF LPSI AND HPSI FLOW (Sheet 5 of 6)

j. This reanalysis was provided in response to NRC questions on the steam generator tube rupture transient via letter ANPP-30572 from E. E. Van Brunt, Jr. to G. W. Knighton dated September 19, 1984. The questions and responses are presented in appendix 15A as Questions 15A.56 through 15A.62.

k. The peak containment pressure of a steam line break transient will be increased (4.5 psi) as a result of an increase in the feedwater isolation valve closure time from 4.6 to 9.6 seconds. The peak containment pressure of a steam line break will still be bounded by the loss of coolant accident, which is unaffected by the change.

l. These changes to the interface requirements tend to reduce the quantity of auxiliary feed flow to the generators. As a result, the containment response to the transient will improve as the mass and energy releases will be reduced.

m. In no case does the SI flow effect the offsite dose. Therefore, the SLB consequences with respect to SRP criteria are not affected by the reduced SI flow.

n. Maximum RCS pressure and minimum DNBR occur before SI flow delivery. Calculated radiological dose is not dependent on SI flow. Therefore, with respect to SRP criteria, there is no impact on the event. LOCA considerations are bounded by subsection 15.6.5.

o. Reduced SI flow reduces the severity of this event.

p. For the SGTR with loss of offsite power event, the reduced HPSI flow curve will result in a slightly lower primary pressure at 30 minutes, which is the time at which the CESEC analysis was terminated. However, this difference will have no significance on the radiological consequences of the event during the subsequent cooldown. The cooldown for this case was performed by a hand calculation which did not include the feedback effects of the primary and secondary responses.

   For the SGTR with loss of offsite power with a stuck open ADV event, changes in HPSI now will have minimal impact. A decrease in HPSI flow will result in a slight decrease in offsite dose which is confirmed by an analysis which assumed maximum (higher) HPSI flow which resulted in a slightly higher dose (1% increase). For this event the feedback effects of the primary and secondary system responses are dynamically modeled for the 8 hour transient. Operator actions are simulated as per the CE emergency procedure guidelines in bringing the plant to hot shutdown. As a result, the operator is assumed to throttle the HPSI as necessary to maintain the safety functions as specified by the guidelines.

q. Since the reduced auxiliary feedwater and HPSI flows do not significantly impact the integrated atmospheric steam releases, no overall impact in the radiological consequences of the event would occur.

Table 1.9-4

IMPACT OF MAIN AND AUXILIARY FEEDWATER DEVIATIONS FROM THE CESSAR INTERFACE REQUIREMENTS AND REDUCTION OF LPSI AND HPSI FLOW (Sheet 6 of 6)

r. The reduction in SI flow was evaluated for its impact on both large and small break LOCA. The evaluation also considered the additional effects, if any, caused by the AFW flow reduction. The evaluation confirmed that the large break LOCA results in CESSAR Section 6.3.3.2 are unaffected, but the small break LOCA results were affected. Consequently, the worst case small break LOCA was reanalyzed to consider the HPSI, LPSI, and AFW pump flowrate reductions. Section 6.3.3.3 was revised accordingly.

The large break LOCA spectrum is unaffected by the combined effects of the HPSI, LPSI, and AFW flowrate reductions because:

(1) The energy release through the break overwhelms the amount of SG heat transfer.

(2) There is no credit taken for SI pump flow until the SIT is empty, at which time the reflood has already begun and the downcomer is full of water.

(3) Once credit is taken for the SI flow, the total flow reduction of concern is much less than the amount of calculated spillage to the containment. Therefore, the amount of injection water flowing into the reactor vessel and core remains unchanged.

The small break LOCA spectrum is affected by the SI pump flow reduction. Although the smallest sizes (0.05 square foot and less) are sensitive to SG heat removal, the AFW flow reduction of concern was found insufficient to change their response. To assess the combined influence of the HPSI, LPSI, and AFW pump flow reduction, the worst small break (0.05 square foot cold leg break) was reanalyzed. The combined effect caused a peak cladding temperature increase from 1557F to 1630F. The increased temperature remains more than 500F lower than the limiting large break LOCA. Other small break sizes are influenced to a lesser amount. Breaks greater than 0.05 square foot are not sensitive to AFW flow and inventory recovery is provided by the SITs. Breaks smaller than 0.05 square foot lead to little or no uncovering of the core and, hence, significantly lower peak cladding temperatures. The 0.05 square foot, therefore, remains the worst case small LOCA and yields a peak cladding temperature more than 500F higher than other small break sizes.

s. The combined influence of reduced AFW flow and SI flow results in lower mass/energy releases to the containment for the LOCA. The LOCA event results in the calculated peak pressure.

t. Safety injection flow has no impact on secondary mass/energy releases during an SLB.

u. For RCS pressure consideration only. For cooldown consideration, the MSLB is limiting (see subsection 15.1.5).

1.9.2.4.11 DELETED

1.9.2.4.12 Containment Sump Isolation Valves Actuation Time Acceptance Criteria (CESSAR Section 6.2.4/ FSAR subsection 6.2.4)

CESSAR Table 6.2.4-1 indicates a closure time of 20 seconds for the following valves which are actuated by a recirculation actuation signal (RAS): SIA-UV673, SIA-UV674, SIB-UV675, and SIB-UV676. Though the CESSAR Table specifies a closure time for these valves, the recirculation sump suction is an essential system penetrating containment and is not functionally isolated by a CIAS. These valves are normally closed and the automatic actuation stroke position for these valves is open. The recirculation sump suction is critical to ensure the capability to mitigate consequences of accidents, and the valves are designed to open at a RAS. An increased actuation (open) time of 35 seconds was reviewed against the safety analysis requirements for these valves and found to be acceptable. These valves are required to open upon receipt of a RAS, which is generated by a low RWT level signal. These valves are required to open before the RWT level reaches the level of the SI pump suction line to ensure an uninterrupted source of water for the SI pumps. Sufficient margin is available in the low RWT setpoint to allow for a 15-second increase in the valve open time. The increased actuation time limit will not affect these valves' operability or durability. This deviation from these valves' original specification is acceptable. Any mechanical failure of a valve or its operator

which would not cause the valves' actuation time to exceed 35 seconds would not jeopardize the function of the valve.

1.9.2.4.13 Chemical and Volume Control System (CVCS) (CESSAR Section 9.3.4.4/FSAR subsection 9.3.4)

CESSAR Section 9.3.4.4, Testing and Inspection Requirements, states in part: "All sections of the CVCS will be operated and tested initially with respect to flow paths, flow capacity, and mechanical operability. Pumps will be tested to demonstrate head and capacity."

The gas stripper pumps were supplied as an integral part of the gas stripper which is comprised of a stripper column, heat exchange equipment, piping subassemblies, pumps, valves, structural hardware, and instrumentation; as such, the pumps were not provided with provisions for measuring suction and discharge pressures. This lack of test connections precludes the ability to satisfy the aforementioned requirement.

Combustion Engineering has determined that the requirement to prove head and capacity does not apply to the gas stripper pumps and may be exempted for the following reasons:

A. Operation of the gas stripper is not required during or after an accident. Therefore, pump performance and operability is not a criteria for plant safety.

B. The gas stripper was tested and qualified by the vendor. As long as the proper interface requirements (i.e., inlet pressure, backpressures, flows, temperatures) to the gas stripper are maintained, the

stripper will operate as required during normal plant operation.

1.9.2.4.15 Historical information moved to Appendix 1A

1.9.2.4.16 Historical information moved to Appendix 1A

1.9.2.4.17 Historical information moved to Appendix 1A

1.9.2.4.18 Historical information moved to Appendix 1A

1.9.2.4.19 Fuel Handling System (CESSAR Section 9.1.4.2.2.11/ FSAR subsection 9.1.4) Refueling Equipment Test (CESSAR Section 14.2.12.1.36)

CESSAR Section 9.1.4.2.2.11 describes a dry sipping system to be utilized in the detection of fuel cladding failures during refueling operations. This system is currently not utilized at PVNGS; instead, as a minimum, a visual surveillance program for discharged fuel assemblies will be instituted as stated in the response to NRC Question 490.3 (FSAR Question 4A.3).

Since the dry sipping system is currently not being utilized at PVNGS, exception is being taken to Paragraph 3.3 of the refueling equipment test description, CESSAR Section 14.2.12.1.36, of the preoperational test program.

NOTE

Equipment for the purpose of detecting fuel cladding failure will be preoperationally tested prior to its use.

1.9.2.4.20 Historical information moved to Appendix 1A

1.9.2.4.21 Historical information moved to Appendix 1A

1.9.2.4.22 Historical information moved to Appendix 1A

1.9.2.4.23 Demineralized Water System (CESSAR Table 9.2-1, FSAR paragraph 9.2.3.1.2, listing D)

CESSAR Table 9.2-1 imposes certain water quality requirements on the demineralized water system at PVNGS. As discussed in paragraph 9.2.3.1.2, listing D, PVNGS does not fully meet these CESSAR requirements. However, this condition is acceptable since the water quality specifications for the ultimate uses of demineralized water (such as the reactor coolant system, the feedwater system, and the steam generators) are in accordance with the CESSAR.

1.9.2.4.24 Use of Inhibited (with Hydrazine) Water for Cleaning, Flushing, and Pressure Testing (CESSAR Sections 4.5.1.5 and 5.2.3.4.1.2)

To prevent halide-induced intergranular corrosion in the RCS, CESSAR Sections 4.5.1.5 and 5.2.3.4.1.2 require the water for cleaning, flushing, and pressure testing to be inhibited with hydrazine. Welding electrodes are coated with fluorine-containing material and small amounts of the coatings can be left behind from the field welds of the piping, etc. Hydrazine will prevent SCC scavenging any oxygen that may be dissolved in the water. Because of the numerous personnel precautions needed for hydrazine, a closer look was taken at the use of

inhibited water. It was found that the use of inhibited water is not needed for cleaning, flushing, or pressure testing as long as water does not remain in the RCS for a long (weeks) period of time. A review of the literature showed that it takes about a week to produce fluorine-induced stress corrosion cracking (SCC) in sensitizing weldments. Hence, if the length of time a component is wet is limited to a day or two and weldments are not sensitized, the possibility of SCC is precluded. Therefore, Sections 4.5.1.5 and 5.2.3.4.1.2 have been changed to make the use of inhibited water mandatory only if the water will remain in the component or RCS for a long period of time; i.e., wet layup.

1.9.2.4.25 Historical information moved to Appendix 1A

1.9.2.4.26 Inadvertent Loading of a Fuel Assembly Into the Improper Position (CESSAR Section 15.4.7.2)

CESSAR 15.4.7.2 indicates that a licensed operator will be present in the area where fuel assemblies are being handled to ensure that the assemblies are moved to their correct location. PVNGS takes exception to this in that all core alterations shall be observed and directly supervised by either a licensed senior reactor operator or a senior reactor operator limited to fuel handling who has no other concurrent responsibilities during this operation.

In addition, PVNGS takes exception to CESSAR 15.4.7.2 with respect to "periodic" independent inventories of components in the reactor core, spent fuel, and new fuel storage areas to ensure that the tag board is correct. PVNGS does perform

annual inventories of the spent fuel and new fuel storage areas in addition to post refueling reactor core mapping. These inventories are then used as the basis for setting up the tag board for use during fuel movement.

1.9.2.4.27 Increase in Feedwater Flow (CESSAR Section 15.1.2)

CESSAR 15.1.2 assumes a maximum increase to feedwater flow at full power to be 110% of the nominal feedwater flow. After testing, the feedwater system has been found to be capable of supplying 125% of the nominal flow at full power. To assure conservatism, a re-evaluation of the increase in feedwater flow event was made. The results of this re-evaluation showed that the most limiting event in UFSAR Section 15.1 is the increase in main steam flow event due to the quick opening of 8 steam bypass valves (Section 15.1.3). Therefore, the assumed feedwater flow value should be 125% of the nominal flow instead of 110%.

1.9.2.4.28 Reactor Vessel Closure Head Handling/Containment Polar Crane (CESSAR Sections 9.1.4.3.5 and 9.1.4.6.I.1/FSAR sections 9.1.4.1.3., 9.1.4.2.2.18, 9.1.4.3.3, and 9.1.4.7.I.1)

CESSAR Section 9.1.4.6.I.1 states that the reactor vessel closure head assembly shall not be raised to a height greater than 17 feet while above the reactor vessel flange. This maximum drop limit will be exceeded due to the height of the reactor closure head alignment pins being at 16'-8" and the polar crane limit switch tolerance of $\pm$ 6".

CESSAR Section 9.1.4.3.5 made the analysis and conclusion that the reactor core is maintained in a coolable configuration, and the reactor vessel support system, the fuel assembly, and the shutdown cooling supply flow paths will remain functional in the unlikely event of a free fall of the reactor head assembly from 18 feet above the reactor vessel flange.

References to the reactor vessel closure head assembly raised height of 18 feet in CESSAR Interface Evaluation section 9.1.4.7 are no longer applicable to PVNGS. Refer to section 9.1.4.3.5 for closure head lift height evaluation.

1.9.2.4.29 Initial Test Program (CESSAR Section 14.2.12.2.14)

Based upon the satisfactory results of the feedwater water hammer tests in Unit 1 and Unit 3, the visual inspection of the feedwater sparger in Unit 2 will not be performed.

1.9.2.4.30 Safety Injection System (CESSAR Section 6.3.2.2.5.b)

See Section 6.3.2.2.5.b.

1.9.2.4.31 Section 5.4.7.2.P.2, Cooling Water System Requirements, describes the interface deviations of the PVNGS Essential Cooling Water (EW) system from the CESSAR interface requirement for the Shutdown Cooling Heat Exchangers described in Section 5.4.7.1.P.2. These deviations are acceptable as noted in Section 5.4.7.2.P.2.b.

1.9.2.4.32 Containment Spray System (CESSAR 6A)

The containment spray system (CSS) was originally intended to interface with the iodine removal system (IRS). The IRS would inject hydrazine into the CSS to remove iodine from the containment atmosphere. PVNGS will no longer use the IRS and will not inject hydrazine into the CSS for the purpose of removing iodine from the containment atmosphere. For a discussion on the methodology for removing iodine from the containment atmosphere, see subsection 6.5.2.

1.9.2.4.33 Power Sources for Containment Spray (CESSAR Appendix 6A Section 7.1.1/FSAR Section 6.5.2.8.A.7.1.1)

CESSAR Appendix 6A section 7.1.1 states that the plant turbine generator, plant startup power source, and the emergency generators are available to power the containment spray pumps, valves, and associated instrumentation. PVNGS is not designed to power any class equipment via the onsite turbine generator.

Aligning the onsite turbine generator would place both (redundant) trains of safety related equipment tied to a single power source (the main generator) and would not comply with 10 CFR 50 GDC 17 requirements relating to single failure criteria. The trip of the generator would cause a loss of power to both safety trains. Therefore, no in-plant interconnection to/from the plant main generator to the Class 1E power system has ever existed at PVNGS. This is consistent with the as licensed configuration documented in UFSAR Chapter 8 and related design drawings.

This page intentionally left blank

1.10 EXEMPTIONS TO 10 CFR PART 50 REQUIREMENTS

Table 1.10-1, 10 CFR Part 50 Approved Exemptions, lists PVNGS exemptions which have been approved by the NRC in accordance with 10 CFR 50.12 and are currently effective. 10 CFR 50.12, Specific Exemptions, provides a means by which the "Commission may, upon application by any interested person or upon its own initiative, grant exemptions from the requirements of the regulations of this part [10 CFR 50], which are authorized by law, will not present an undue risk to the public health and safety, and are consistent with the common defense and security."

Table 1.10-1

10 CFR PART 50 APPROVED EXEMPTIONS (Sheet 1 of 2)

Unit	**Expiration Date**	**Description of Exemption**	**Date Granted**	**Reference**
1, 2, & 3	none	Exemption from certain requirements of 10 CFR 50.71(e)(4) to allow submittal of UFSAR revisions; changes to the QA program (10 CFR 50.54(a)(3)); and reports of changes, test, and experiments made in accordance with 10 CFR 50.59 (10 CFR 50.59(b)(2)) on a 24-month periodicity not tied to a particular unit's refueling outage schedule. (Note: The revised 10 CFR 50.59(d)(2), effective March 13, 2001, changed the reporting interval such that these reports are to be submitted at intervals not to exceed 24 months.)	July 8, 1999	NRC Letter dated July 8, 1999, "Palo Verde Nuclear Generating Station, Unit Nos. 1, 2, and 3 – Issuance of Exemption from Certain Requirements of 10 CFR 50.71(e)(4)"
1, 2, & 3	none	Exemption from 10 CFR Part 50, Appendix J, Paragraph III.D.2(b)(ii) "Air locks opened during periods when containment integrity is not required by the plant's Technical Specifications shall be tested at the end of such periods at not less than Pa." This exemption allows the substitution of the seal leakage test of Paragraph III.D.2(b)(iii) when no maintenance has been performed on an air lock.	Dec. 1984	SSER Supplement 7, Section 6.2.6 Operating Licenses, Section 2.D.
1	End of Cycle 17	Exemption from specific requirements of 10 CFR 50.46 and 10 CFR 50 Appendix K to allow use of up to eight lead fuel assemblies manufactured by AREVA NP consisting of fuel rods with M5 cladding material.	Oct. 14, 2008	NRC letter dated, October 14, 2008 "Palo Verde Nuclear Generating Station, Unit 1 – Temporary Exemption from the Requirements of 10 CFR Part 50, Section 50.46 and Appendix K for Lead Fuel Assemblies (TAC NO. MD8330)"
3	End of Cycle 18	Exemption from certain requirements of 10 CFR 50 Section 50.46, and Appendix K to allow use of eight lead fuel assemblies that contain Optimized Zirlo cladding material.	August 26, 2010	NRC Letter dated, August 26, 2010, "Palo Verde Nuclear Generating Station, Unit 3- Temporary Exemption from the Requirements of 10 CFR Part 50, Section 50.46 and Appendix K (TAC NO. ME2590)"

Unit	**Expiration Date**	**Description of Exemption**	**Date Granted**	**Reference**
1, 2, & 3	None	Exemption from specific requirements of 10 CFR 50 Appendix G, “Fracture Toughness Requirements,” to allow the application of the methodology in Combustion Engineering Topical Report NPSD-683-A, Revision 6, “Development of a RCS Pressure and Temperature Limits Report for the Removal of P-T Limits and LTOP requirements from the Technical Specifications,” for the calculation of stress intensity factors due to internal pressure loadings.	February 24, 2010	NRC Letter dated February 24, 2010 “Palo Verde Nuclear Generating Station, Units 1, 2, and 3 - Exemption from the Requirements of Appendix G to 10 CFR Part 50”

1.11 BEYOND DESIGN BASIS EXTERNAL EVENTS – DIVERSE AND FLEXIBLE COPING STRATEGIES (FLEX)

As a result of the NRC's evaluation of the lessons learned from the accident at Fukushima Dai-ichi in March 2011, the NRC required additional defense-in-depth measures to address uncertainties associated with protection from beyond-design-basis external events. The NRC issued Orders EA-12-049 (Mitigating Strategies) and EA-12-051 (Reliable Spent Fuel Pool Instrumentation) to direct nuclear power plant licensees and construction permit holders to take certain actions. To support the industry's completion of these actions, the Nuclear Energy Institute (NEI) prepared NEI 12-06 (Diverse and Flexible Coping Strategies (FLEX) Implementation Guide) which was subsequently endorsed by the NRC.

Modified plant systems include, but are not limited to: Chemical and Volume Control System, Emergency Core Cooling(Safety Injection), Main Steam, Auxiliary Feedwater, Condensate Storage, and Emergency Diesel Fuel Oil and Transfer. Electrical systems have been modified to support alternate power source connections.

The Spent Fuel Pool (SFP) Cooling system has been modified to address the following: SFP level monitoring, make-up, sloshing barriers, and gate seal gas backup.

APPENDIX 1A
HISTORICAL INFORMATION
FROM CHAPTER 1

CONTENTS

HISTORICAL

1.9.2.4.14 Preoperational Test Description for the Boric Acid Batching Tank Subsystem Test (CESSAR Section 14.2.12.1.12/FSAR subsection 14.2.12)

CESSAR Section 14.2.12.1.12 has the following required test method:

3.3 Refill the boric acid batching tank, dissolve boric acid crystals, and start the batch tank mixer. Take samples as the tank is drained to the equipment drain tank and determine the boric acid concentration.

The requirement to drain the tank to the equipment drain tank cannot be achieved at PVNGS since the as-built configuration does not include a drain path to the equipment drain tank. Drainage from this tank is routed to the non-ESF sump.

To satisfy the requirement to obtain boric acid concentration data the samples will be taken while transferring the contents of the boric acid batching tank to the refueling water tank or when draining the contents to the non-ESF sump.

HISTORICAL

1.9.2.4.15 Power Ascension Testing for Incore Detectors, Variable T_{avg}, Control Systems Checkout Test, and Turbine Test (CESSAR Sections 14.2.12.5.2, 14.2.12.5.20, and Table 14.2-2/FSAR subsection 14.2.12)

For Units 2 and 3, the variable T_{avg} test method (item 3.0) and data required (item 4.0) is modified as shown below (CESSAR

Section 14.2.12.5.2). This CESSAR exception modifies the test method, but the purpose and results of the test remain the same.

3.0 Test Method

3.1 The ITC is measured as follows:

3.1.1 Changes are made to core average temperature and power is maintained essentially constant using CEA movement or adjustment to the RCS boron concentration.

3.2 The power coefficient is measured using one of the following methods:

3.2.1 Changes are made to core power using CEA motion and core average temperature is maintained essentially constant.

3.2.2 Changes are made to core power and balanced by allowing core average temperature to change to a new value.

4.0 Data Required

4.1 Conditions of the measurement

4.1.1 Power

4.1.2 CEA configuration

4.1.3 Core burnup

4.2 Time dependent data

4.2.1 Power

4.2.2 RCS temperatures

4.2.3 CEA positions

4.2.4 Boron concentration

For Units 2 and 3, the incore detector test deviates from CESSAR Section 14.2.12.5.20. Items 1.2, 3.2, and 5.2 in CESSAR Section 14.2.12.5.20 are deleted for Units 2 and 3. In deleting these steps, only the movable incore data will be affected. Since the units are identical, this part of the testing is redundant. This portion of incore detector testing is not required by Regulatory Guide 1.68. The movable incore detectors are not required for the operation of the plant.

Replace CESSAR Table 14.2-2 with FSAR table 1.9-5. The modified power ascension percent loads for the following tests are acceptable as described below:

A. The control systems checkout testing is not being reduced in scope; it is only being changed from 80% to 100%. The main reason for the change is that reactor regulating system testing requires rod insertion resulting in axial perturbations. There are no other tests at 80% on Units 2 and 3 which will require rod insertion. Therefore, it is actually safer to do the testing at 100% and eliminate the possibility of axial perturbations.

STANDARD DESIGNS

HISTORICAL

Table 1.9-5

POWER ASCENSION TEST (Sheet 1 of 2)

Test Title	Unit 1	Units 2 and 3[(a)]
Natural Circulation Test	≥ 80%[(b)]	N/A
Variable T_{avg} (Isothermal Temperature Coefficient and Power Coefficient) Test	20, 50, 80, 100%[(c)]	50[(d)] and 100%[(c)]
Unit Load Transient Test	50, 100%	50, 100%
Control Systems Checkout Test	20, 50, 80, 100%	50, 100%
RCS and Secondary Chemistry and Radio chemistry Test	20, 50, 80, 100%	20, 50, 80, 100%
Turbine Trip Test	100%	N/A
Unit Load Rejection Test	100%	100%

a. Reduced testing is contingent upon the demonstration that Units 2 and 3 behave in an identical manner as Unit 1 through conformance with the acceptance criteria given in Table 14.2-7 of CESSAR.

b. Initial power level.

c. The temperature and power coefficient measurements are done as close as possible to 100% power at a level where CEA motion is practical accounting for margin considerations.

d. Unit 3 will perform a reduced scope test at the 50% power plateau.

e. This test will not be performed on Unit 3.

f. This test will not be performed at either 20% or 80% power on Unit 3.

HISTORICAL

Table 1.9-5

POWER ASCENSION TEST (Sheet 2 of 2)

Test Title	Unit 1	Units 2 and 3[(a)]
Shutdown from Outside the Control Room Test	≥ 10%	≥ 10%
Loss of Offsite Power Test	≥ 10%	≥ 10%[(e)]
Biological Shield Survey Test	20, 50, 80, 100%	20, 50, 80, 100%
Xenon Oscillation Control Test	≥ 50%	N/A
Dropped CEA Test	Post 80%	N/A
"Ejected" CEA Test	Post 80%	N/A
Steady-State Core Performance Test	20, 50, 80, 100%	20, 50, 80, 100%
Intercomparison of PPS, CPC and Process Computer Inputs	20, 50, 80, 100%	20, 50, 80, 100%
Verification of CPC Power Distribution Related Constants	20, 50%	20,50%
Main and Emergency Feedwater	≥ 10%[(b)]	≥ 10%[(b)]
CPC Verification	20, 50, 80, 100%	20, 50, 80, 100%[(f)]
Steam Dump and Bypass Valve Capacity Test	≥ 15%	≥ 15%
Incore Detector Test	20, 50, 80, 100%	20, 50, 80, 100%
COLSS Verification	20, 50, 80, 100%	20, 50, 80, 100%[(f)]

B. Since the units are identical and the turbine will be tripped during unit load rejection testing, there is no need to perform the turbine trip test for Units 2 and 3 as was done on Unit 1.

HISTORICAL

1.9.2.4.16 Post-Core Hot Functional Testing of CEDM Performance (CESSAR Section 14.2.12.3.4/FSAR subsection 14.2.12)

The objective of the post-core hot functional testing of CEDM performance for PVNGS is to demonstrate the proper operation of the CEDMs and CEAs. This demonstration will be performed under hot shutdown (Unit 1 only) and hot, zero power conditions (Units 1, 2, and 3). The withdrawal and insertion of each CEA to verify proper operation of the CEDM under hot shutdown conditions will be performed for Unit 1 only.

Testing at hot shutdown conditions for Units 2 and 3 is eliminated because criticality will not be reached until hot, zero power conditions. All Units 2 and 3 CEDM performance testing can be done at hot, zero power conditions, and as required at cold shutdown conditions.

HISTORICAL

1.9.2.4.17 Low Power Physics Testing of Shutdown CEA Group Worth (CESSAR Section 14.2.12.4.4 and CESSAR Table 14.2-1/FSAR subsection 14.2.12)

For Units 2 and 3 only, FSAR paragraph 1.9.2.4.17.1 and table 1.9-6 replace CESSAR Section 14.2.12.4.4 and CESSAR

Table 14.2-1. Due to these changes, the shutdown margin will not be explicitly measured; however, it is verified by analysis.

Since the core design for PVNGS Units 1, 2, and 3 is essentially identical, the nuclear characteristics and performance of all three units are expected to be equivalent. Unit 1 underwent extensive testing. The test program for Unit 2 will be a subset of the testing performed on Unit 1, but more stringent acceptance criteria will be applied. The test program for Unit 3 will include the same type of measurements as the Unit 2 program; however, the CEA exchange method, in accordance with Technical Specifications, may be used in place of the boration/dilution technique to measure control rod worths. If the CEA exchange method is used, all regulating and shutdown CEA group worths will be measured and the CEA symmetry test will be deleted as shown in table 1.9-6. If similarity of Units 2 and 3 to Unit 1 cannot be adequately demonstrated, additional testing will be performed.

HISTORICAL

1.9.2.4.17.1 Shutdown and Regulating CEA Group Worth Test for Units 2 and 3.

1.0 Objective

To determine regulating and shutdown CEA group worths necessary to demonstrate shutdown margin (i.e., worth of all CEAs less the highest worth CEA), see item 3.1.2 below for the requirements to measure shutdown group worths and net shutdown

margin. (For Unit 3, section 3.2 below, in accordance with Technical Specifications, may be performed in place of section 3.1.)

2.0 Prerequisites

2.1 The reactor is critical.

2.2 The reactivity computer is operating.

3.0 Test Method

3.1 Boration/Dilution Technique

STANDARD DESIGNS

HISTORICAL

Table 1.9-6

LOW POWER PHYSICS TESTS

Test Title	Unit 1	Unit 2 and 3[a][c]	CEA Exch. Method
Low Power Biological Shield Survey Test	320F/565F	565F	565F
CEA Symmetry Test	565F	565F	N/A
Isothermal Temperature Coefficient Test	320F-565F	565F	565F
Regulating CEA Group Worth Test	320F and 565F	565F	565F
Shutdown CEA Group Worth Test	320F	N/A[b]	565F
Differential Boron Worth Test	320F and 565F	565F	565F
Critical Boron Concentration Test	320F-565F	565F	565F
Pseudo Dropped and Ejected CEA Worth Test	565F	N/A	N/A

a. Reduced testing is contingent upon the demonstration that Units 2 and 3 behave in an identical manner as Unit 1 through conformance with the acceptance criteria given in CESSAR Table 14.2-7.

b. Deletion of this measurement on Units 2 and 3 is contingent upon the regulating CEA worths satisfying acceptance criteria of CESSAR Table 14.2-7. If this is not the case and the measurement is required, it will be performed at an RCS temperature of 565F.

c. Unit 3, in accordance with Technical Specifications, may utilize the CEA exchange method. The acceptance criteria for CEA group worth is as specified in CEN-319, "Control Rod Group Exchange Technique", November 1985.

3.1.1 The CEA group worths will be measured by dilution/boration of the RCS at hot zero power.

3.1.2 Shutdown group worths and net shutdown margin will be measured at hot zero power if the total regulating CEA worth does not fall within a ±10% tolerance of the predicted worth.

3.1.3 Where dilution/boration is not feasible, worths may be determined by CEA drop and/or by use of alternate CEA configurations.

3.2 CEA Exchange Technique

3.2.1 The referenced CEA group worth(s) will be measured by dilution/boration of the RCS at hot zero power.

3.2.2 CEA groups are individually fully inserted while the reference CEA group is withdrawn. Final CEA group positions are recorded.

3.2.3 The individual CEA group worths are determined from the final positions of the reference CEA group.

4.0 Data Required

4.1 Conditions of the Measurement

4.1.1 RCS temperature

4.1.2 Pressurizer pressure

4.1.3 CEA configuration

4.1.4 Boron concentration

4.2 Time dependant information

4.2.1 Reactivity variation (strip chart)

4.2.2 CEA positions

5.0 Acceptance Criteria

5.1 The measured CEA group worths agree with predictions within the acceptance criteria specified in table 1.9-6.

HISTORICAL

1.9.2.4.18 Initial Criticality (CESSAR Section 14.2.10.2/FSAR paragraph 14.2.10.2)

For Units 2 and 3, the final approach to initial criticality may be made by either withdrawal of the last regulating group or by RCS boric acid concentration reduction. In either case, the last regulating group will be used to control the chain reaction after achieving criticality.

HISTORICAL

1.9.2.4.20 Chemical and Volume Control System (CESSAR Section 9.3.4.4/FSAR subsection 9.3.4)

CESSAR Section 9.3.4.4, Testing and Inspection Requirements, states in part: "All sections of the CVCS will be operated and tested initially with respect to flowpaths, flow capacity, and mechanical operability. Pumps will be tested to demonstrate head and capacity."

The testing requirements regarding the head and capacity of the boric acid concentrator (BAC) pumps may be deleted without impacting plant safety. The BAC package is a nonsafety-related system which is not required for accident mitigation or safe shutdown of the reactor.

The performance of the BAC pumps has been demonstrated as follows:

- The pump head and capacity were tested on a component basis by the manufacturer.
- The BAC package unit was tested and qualified by C-E.
- The proper function of the BAC pumps is assured by demonstrating, during preoperational testing, the BAC's processing of the holdup tank contents at a rate of 20 gallons per minute (refer to CESSAR Section 14.2.12.1.16).

HISTORICAL

1.9.2.4.21 Unit Load Rejection Test (CESSAR Section 14.2.12.5.7)

CESSAR Section 14.2.12.5.7, Test Method, states that "a breaker(s) is tripped so as to subject the turbine to the maximum credible overspeed condition." For Units 2 and 3, PVNGS takes exception to that part of the test method. Instead of the method described in 3.1 of that test description, the method used will be to trip the breaker(s) in order to initiate the load rejection. Maximum overspeed condition will not be achieved.

The alternate test method still meets the objective of the test and the acceptance criteria still applies. This alternate method allows PVNGS to test the fast bus transfer during the unit load rejection test.

Since all three units have the same circuitry to arrest turbine acceleration and Units 2 and 3 have circuitry that has been functionally tested, performing the unit load rejection test with the same method for all three units is not necessary. PVNGS will gather more useful information by taking this exception to CESSAR for Units 2 and 3.

HISTORICAL

1.9.2.4.22 Precore Reactor Coolant System Heat Loss (CESSAR Section 14.2.12.2.9)

CESSAR Section 14.2.12.2.9 requires that a precore hot functional test be performed to measure RCS heat loss and pressurizer heat loss under hot, zero power conditions. The

RCS heat loss is measured to determine a value for use in the RCS thermal performance program COLSS, and pressurizer heat loss is measured to satisfy the requirements of Regulatory Guide 1.68.

A more accurate determination of the RCS heat loss value for the COLSS program in Unit 3 is to be achieved utilizing test data obtained from the Unit 3 containment HVAC systems. The objective of CESSAR Section 14.2.12.2.9 is still met if the containment HVAC test method replaces the steam-down test method that is specified within Section 14.2.12.2.9 to measure RCS heat loss.

HISTORICAL

1.9.2.4.25 Preoperational Test Description for the Holdup Subsystem Test (CESSAR Section 14.2.12.1.15)

CESSAR Section 14.2.12.1.15 specifies the following as a test method for the holdup subsystem preoperational test:

3.1 Fill the holdup tank and observe level indications and alarms.

3.2 Simulate holdup tank temperature and observe indications and alarms.

3.3 Using each holdup pump, drain the holdup tank to the boric acid concentrator. Observe holdup tank level indications, alarms, and interlocks and holdup pump discharge pressure.

3.4 Refill and isolate the holdup tank. Open the holdup tank recirculation valves and start each holdup pump. Observe tank level. Line up the holdup pumps to the reactor drain tank filter and observe holdup tank level.

This CESSAR-specified test method precludes the capability to adjust for plant conditions at the time of testing, and also does not address the site-specific need to conserve treated water at PVNGS. Therefore, the following modification to the CESSAR test description is utilized:

2.5 There is a sufficient inventory of water contained in the holdup tank to conduct testing in accordance with section 3.0.

3.0 Test Method

3.1 Observe level indication, alarms, and interlocks in response to actual or simulated holdup tank levels.

3.2 Simulate holdup tank temperature and observe indications and alarms.

3.3 Using each holdup pump, transfer holdup tank contents to the boric acid concentrator. Observe holdup tank level indication, alarms, and interlocks and holdup pump discharge pressure.

3.4 Refill and isolate the holdup tank. Open the holdup tank recirculation valves and start each holdup pump. Observe tank level. Line up the holdup pumps to the reactor drain tank filter and observe holdup tank level.

APPENDIX 1B

HISTORICAL REGULATORY GUIDE INFORMATION

FROM CHAPTER 1

APPENDIX 1B

HISTORICAL

REGULATORY GUIDE 1.28: Quality Assurance Program Requirements (Design and Construction) (Revision 0, June 7, 1972)

RESPONSE

For construction phase activities and prerequisite and phase I startup testing, the position of Regulatory Guide 1.28 is accepted. Also see 17.1 and 17.2. For operations phase activities including phase II through phase IV startup testing, the regulatory position found in Regulatory Guide 1.28 will be replaced by the regulatory position found in Regulatory Guide 1.33 as modified and interpreted by APS in Section 1.8. Additional References: 4.2.5, 5.4.7.1, 6.3.1.3, 9.1.4.6, and 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.30: Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electronic Equipment (Revision 0, August 11, 1972)

RESPONSE

The requirements of the referenced standard (ANSI N45.2.4-1972) will be applied to the Bechtel quality program for construction of safety-related items as interpreted in the regulatory position as modified and interpreted below:

A. Section 2.1, Planning. The required planning is frequently performed on a generic basis for application to many installations on one or more projects. This results

in standard procedures or plans for installation and inspection and testing which meet the requirements of the standard. Individual plans for each item or system are not normally prepared unless the work operations are unique; however, standard procedures or plans are reviewed for applicability in each case. Installation plans or procedures are also limited in scope to those actions or activities which are essential to maintain or achieve required quality.

B. Section 3, Preconstruction Verification. The requirements of this section are applied to items which are received and stored prior to installation. They are combined with receiving inspection activities in accordance with ANSI N45.2.2 requirements for items which are installed immediately after receiving inspection.

For operations phase activities that are comparable to activities occurring during the construction phase, the following interpretations apply to the position of Regulatory Guide 1.30:

A. Section 5.2:

The various tests are performed “as appropriate” as determined by PVNGS Engineering Department based upon the significance of the change or modification.

B. Section 6.2.1:

PVNGS utilizes a computer information management system to maintain plant equipment calibration status including the date of calibration and identity of the person that

performed the calibration. The computer information management system provides a more reliable and accessible method of documenting plant equipment calibration status than the use of tags or labels affixed to equipment.

C. Section 6.2.2:

The requirement that systems tests be made to verify that all parts of a system properly coordinate with each other is interpreted as not requiring that an entire system be retested after modification of only a portion of that system. The testing requirements of the Technical Specifications are met for inoperable equipment.

Reference 3.11.2, 7.1.2.6, 7.1.2.17, 8.3.1.2.2.7, 8.3.2.2.1.6, 14.2.7, 17.1, 17.2, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.33: Quality Assurance Program Requirements (Operation) (Revision 2, February 1978)

RESPONSE

The position of Regulatory Guide 1.33 is accepted with the following exceptions to Regulatory Positions C.2 and C.4:

For Regulatory Position C.2, the APS commitment refers to regulatory guides, and revisions thereof, specifically identified in this FSAR.

For Regulatory Position C.4, the specific audits at C.4.a, C.4.b, and C.4.c shall be performed at a frequency of at least once per 24 months. In addition, a grace period of 90 days

beyond the specified frequency shall be permitted for completion of internal audits. When the grace period is utilized, subsequent scheduling for the audit shall be based upon the original due date. This grace period shall not be applied to those audits that have a frequency specifically defined by regulation.

In addition, the following clarification is made in APS' position regarding Regulatory Guide 1.33:

> Compliance to ANSI standards referenced throughout ANSI N18.7-1976/ANS-3.2 are addressed separately in APS' response to conformance with the regulatory guides listed in section C.2 of Regulatory Guide 1.33.

The following exceptions are taken to ANSI N18.7:

A. Section 3.4.2

> The APS commitment on the qualification of personnel who are performing preoperational and startup test functions is found in paragraph 14.2.2.12.

B. Section 5.2.13.1

> When purchasing commercial-grade calibration services from certain accredited calibration laboratories, the procurement documents are not required to impose a quality assurance program consistent with ANSI N45.2-1971. Alternative requirements described in UFSAR Section 1.8 for Regulatory Guide 1.123 may be implemented in lieu of imposing a quality assurance program consistent with ANSI N45.2-1971.

In addition, the following interpretations of ANSI N18.7 are made:

A. Section 5.2.2

The requirements of this section are accepted with the following interpretations:

Temporary changes to procedures may be made provided the change is approved by two members of the plant management staff, at least one of whom holds a senior reactor operator license on the unit affected.

Procedural steps traditionally identified as immediate actions are incorporated into standard post-trip actions. Following a manual or automatic reactor trip, standard post-trip actions will be performed. The reactor operators are expected to know the standard post-trip actions and begin to take action.

The control room supervisor shall perform the standard post-trip actions in the order written and go over each step with the control room staff.

B. Section 5.2.13.1

The requirement that changes made to procurement documents be subject to the same degree of control as was used in the preparation of the original documents is applied consistent with the requirements of ANSI N45.2.11, Paragraph 7.2. Minor changes to documents, such as inconsequential editorial corrections or changes to commercial terms and conditions, may not require that the

revised document receive the same review and approval as the original documents.

C. Section 5.2.17

The requirements of this section are accepted with the following interpretation:

The requirement that deviations, their cause, and any corrective action completed or planned shall be documented shall apply to significant deviations. Other identified deviations will be documented and corrected. This interpretation is consistent with Appendix B to 10CFR50, Criterion XVI, Corrective Action.

D. Section 5.2.19.1

Preoperational testing (phase I startup testing) addressed in ANSI N18.7, Paragraph 5.2.19.1, will be conducted in accordance with Regulatory Guide 1.68, Revision 0.

E. Section 5.3.9.1

The requirements of this section are accepted with the following interpretation:

Actions identified as immediate operator actions have been standardized in the form of safety function status checks. Safety functions are maintained for all transients when the emergency procedure is implemented. This ensures proper operator response independent of event diagnosis. This approach is consistent with CEN-152, CE Emergency Procedure Guidelines.

Actions identified as subsequent operator action are addressed as a recovery procedure, implemented after event

diagnosis. This approach is consistent with CEN-152, CE Emergency Procedure Guidelines.

The specific procedure format and content have been identified in the Emergency Procedure Generation Package and submitted to the NRC for review. This is consistent with NUREG-0899.

F. Section 5.2.15

The requirements of this section are accepted with the following interpretation(s):

The requirement for periodic review of routine plant procedures no less frequently than every two years may be exceeded for routine plant procedures which are used infrequently, when alternative means are provided to ensure review of these procedures prior to use.

Periodic review of plant procedures no less frequently than every two years is not required for routine, frequently-used plant procedures. Periodic audits to satisfy regulatory requirements and commitments include an assessment of a representative sample of related procedures to validate that the procedures are acceptable for use and that the procedure review and revision process is being effectively implemented.

The exceptions to periodic review requirements stated above do not apply to non-routine procedures (such as abnormal operating procedures, emergency operating procedures, alarm response procedures, procedures which implement the Emergency Plan, or procedures which implement the Security Plan). The periodic review

requirement for these procedures may be satisfied by the use or review of the procedure during plant operation, training exercise, drill, or by other such review activity which validates acceptability of the procedure, provided the procedure use or review activity is documented.

G. Section 5.2.7

The requirements of this section are accepted with the following interpretations:

Activities occurring during the operational phase that are comparable in nature and extent to related activities occurring during initial plant design and construction shall be interpreted to mean those activities of such a scale and type that the following conditions are met:

A. The work is to be performed by an outside contractor or owner’s service organization not part of the plant organization.

B. The system or area of the plant affected by the work is released to the contractor or service organization during the activity, and, except for radiological protection purposes, effectively ceases to be part of an operating nuclear power plant.

C. The contractor or service organization has been directed in advance of the work that conformance to Regulatory Guide 1.33, ANSI N18.7, and Applicable standards referenced in ANSI N18.7 will be required, consistent with the PVNGS UFSAR position on these standards.

The implementation of the positions of Regulatory Guide 1.33 are described in chapters 13 and 17 and the Technical Specifications.

HISTORICAL

REGULATORY GUIDE 1.37: Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants (Revision 0, March 16, 1973)

RESPONSE

The requirements of the referenced standard (ANSI N45.2.1-1973) as modified in the regulatory position are applied to cleaning activities specified or applied by Bechtel to safety-related items as modified and interpreted below:

A. Section 2.1, Planning. The required planning is frequently performed on a generic basis for application to many installations on one or more projects. This results in standard procedures or plans for installation and inspection and testing which meet the requirements of the standard. Individual plans for each item or system are not normally prepared unless the work operations are unique; however, standard procedures or plans are reviewed for applicability in each case. Installation plans or procedures are also limited in scope to those actions or activities which are essential to maintain or achieve required quality. This is consistent with Section II, Paragraphs 2 and 3, of ANSI N45.2-1971 which provide for examination, measurement, or testing to assure quality or

indirect control by monitoring of processing methods. However, final cleaning or flushing activities are performed in accordance with procedures specific to the system.

Also see 5.2.3.4.1.2.1. Additional References: 4.2.5, 4.5.1.5, 5.1.5, 5.2.3, 5.4.2.4, 5.3.3.5, 5.4.7, 6.1.1.1.3.2, 6.3.1.4, 6.5.2.8, (RA) 7.12.5, 9.3.4, 10.3.6.2, 14.2.7, 17.1, and 17.2.

For operations phase activities that are comparable to activities occurring during the construction phase, the referenced standard (ANSI N45.2.1-1973) as modified by Regulatory Guide 1.37 is accepted as modified below.

A. Section 2.1, Planning. The required planning is frequently performed on a generic basis for application to many systems and component installations. This results in standard procedures for cleaning, inspection, and testing which meet the requirements of the standard.

B. Individual plans for each item or system are not normally prepared unless the work operations are unique; however, standard procedures are reviewed for applicability in each case. Cleaning procedures are limited in scope to those actions or activities which are essential to maintain or achieve required quality. This is consistent with Section 5.2.17, Paragraph 5, of ANSI N18.7-1976 which provides for examination, measurement, or testing to assure quality or indirect control by monitoring of processing methods.

HISTORICAL

REGULATORY GUIDE 1.38: Quality Assurance Requirements for Packaging, Shipping, Receiving, Storage, and Handling of Items for Water-Cooled Nuclear Power Plants (Revision 0, March 16, 1973)

RESPONSE

The requirements of the referenced standard (ANSI N45.2.2-1972) as modified and interpreted in the regulatory position are applied to the Bechtel quality program for construction of safety-related items, except as modified and interpreted below:

A. Section 2.4, Personnel Qualification. Personnel performing offsite audits shall be qualified to ANSI N45.2.23. Personnel performing offsite material inspection shall be qualified to ANSI N45.2.6. Personnel performing offsite monitoring activities shall be qualified to ANSI N45.2.23 or ANSI N45.2.6.

B. Section 2.7, Classification of Items. The four-level classification system may not be used explicitly. However, the specific requirements for each classification as specified in the standard are applied to the items suggested in each classification and for similar items.

C. Section 3.9, Marking. Identification of items after the outside of the container has been removed, is accomplished in accordance with ANSI N18.7, Section 5.2.13.3.

D. Section 6.2, Storage Areas. Paragraph 6.2.1 requires control and limited access to storage areas. In lieu of and to amplify this paragraph, the following is applied:

"Access to storage areas for levels A, B, and C is controlled by the individual(s) responsible for material storage." Level D items are stored in a site area which has access control consistent with zone IV of ANSI N45.2.3-1973. While the areas may be posted to limit access, other positive controls (other than that for the overall site area) or guards may not be provided.

E. Sections 3.9 and 5.6, and Section A3.9 of Appendix A, Marking. These ANSI N45.2.2 sections control direct marking of austenitic stainless steel and nickel based alloys. Marking is in compliance with the requirements of these sections except that markings may be directly applied using inks controlled so as not to contain more than 200 ppm of inorganic halogens.

Reference 4.2.5, 5.1.4, 5.2.3.4.1.2.2, 6.3.1.3, 9.1.4.6, 17.1A.2, 17.1B, 17.2B, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.39: Housekeeping Requirements for Water-Cooled Nuclear Power Plants (Revision 2, September 1977) [Historical]

RESPONSE

The requirements of the referenced standard (ANSI N45.2.3-1973) are applied to the Bechtel quality program for construction of safety-related items except as modified and interpreted below:

A. Section 2.1, Planning. The required planning is frequently performed on a generic basis for application to many installations on one or more projects. This results in standard procedures or plans for installation and inspection and testing which meet the requirements of the standard. Individual plans for each item or system are not normally prepared unless the work operations are unique; however, standard procedures or plans are reviewed for applicability in each case. Installation plans or procedures are also limited in scope to those actions or activities which are essential to maintain or achieve required quality.

B. Alternative equivalent zone designations and requirements may be utilized to cover those situations not included in the subject standard. For example, situations in which shoe covers and/or coveralls are required but material accountability is not.

   For operations phase activities that are comparable to activities occurring during the construction phase, the position of Regulatory Guide 1.39 is accepted with the following exception:

   Alternative equivalent zone designations and requirements may be utilized to cover those situations not included in the subject standard. For example, situations in which

shoe covers and/or coveralls are required but material accountability is not.

Reference 5.3.3.5, 9A.33, 12.5.3.4, 17.1B, 17.1A.2, and 17.2B.

HISTORICAL

REGULATORY GUIDE 1.58: Qualification of Nuclear Power Plant Inspection, Examination and Testing Personnel (Revision 1, September 1980) [Historical]

RESPONSE

The position of Regulatory Guide 1.58 is accepted with the following exceptions:

A. Position C.1

The qualification of personnel who approve preoperational and startup test procedures and test results, and those who direct or supervise the conduct of individual preoperational and startup tests is discussed in paragraph 14.2.2.12. The qualification of other personnel discussed in Position C.1 follows the guidelines of Regulatory Guide 1.8 as discussed in sections 13.1 and 13.2.

B. Position C.6

The specified education and experience recommendation of ANSI N45.2.6-1978 for various levels of inspectors shall not be treated as absolute when other factors provide reasonable assurance that a person can competently perform

a particular task. These factors will be documented, with justification by management (on an individual basis), demonstrating that the individual does have equivalent competence to that which would be gained from having the required education and experience.

In addition, the following exceptions are taken to the referenced standard ANSI N45.2.6-1978 are made:

A. The first sentence of Paragraph 3.4 states that a Level III qualified person shall have all the capabilities of a Level II qualified person for the inspection, examination or test category or class in question. APS will qualify Level III persons without the actual hands on experience and capability to perform specific inspections, examinations or tests required of a Level I or II qualified person, and utilize these persons for administrative and supervisory functions including certifying persons at the same or lower level.

B. Paragraph 3.3 states that a Level II qualified person shall have demonstrated experience in certifying lower level qualified persons. APS does not use Level II qualified persons to certify lower level qualified persons, and does not require Level II qualified persons to demonstrate this capability.

The following interpretation is also made to Regulatory Guide 1.58:

A. Position C.1

For qualification of personnel, (1) who perform or approve operational test procedures and test results, and (2) who

direct or supervise the conduct of individual operational tests, the guidelines contained in Regulatory Guide 1.8, Revision 1-R, "Personnel Selection and Training" with the criteria for selection and training contained in ANSI/ANS 3.1-1978, substituted for ANSI N18.1-1971, will be followed.

See also conformance to Regulatory Guide 1.8:

Personnel Selection and Training (Revision 1-R, May 1977)

Reference sections 17.1A.2, 17.1B, 17.2B, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.64: Quality Assurance Requirements for the Design of Nuclear Power Plants (Revision 0, October 1973) [Historical]

RESPONSE

Regulatory Guide 1.64 endorses a superseded draft issue of ANSI N45.2.11. For C-E's program, refer to Section 17.1C. The Bechtel program complies with ANSI N45.2.11-1974 as interpreted herein.

A. Section 3.1

This section implies that all necessary design input (as listed in section 3.2) should be available prior to the start of a design activity. In practice, certain design activities are initiated before the firm input requirements are available. (For example, foundation

designs prepared based on preliminary information or equipment sizes and mounting and embedded conduit run based on preliminary estimates of circuit requirements.) The design phase QA program is structured to assure that all necessary design input is available before completion of final design of the work affected by the input and that final design input is available for use in verification of the final design.

B. Section 4.1, Design Process General

Paragraph 3 implies traceability back from final design to the source of design input. In practice, a literal interpretation of this is not always possible. For example, final design drawings do not identify the related calculations. This paragraph is interpreted to mean that it shall be possible to relate the criteria used and analyses performed to the final design documents and that record files will permit location of analyses supporting specific design output documents.

Additional References: 3.8.1.2.3, 4.2.5, 5.1.4, 5.4.7.1, 6.3.1.3, 9.1.4.6, 9.3.4.6, 17, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.64: Quality Assurance Requirements for the Design of Nuclear Power Plants (Revision 2, June 1976)

RESPONSE

For operations phase activities that are comparable to activities occurring during the construction phase, the

position of Regulatory Guide 1.64 is accepted with the following exception to Position C.2:

Supervisory personnel may perform design verification under exceptional circumstances as documented and approved by the next level of supervision, if:

1. The justification (for design verification by a designer's immediate supervisor) is individually documented and approved in advance, and

2. Quality assurance audits cover frequency and effectiveness of use of supervisors as design verifiers to guard against abuse.

APS interprets ANSI N45.2.11-1974, Sections 3.1 and 4.1, as follows:

A. Section 3.1

   This section implies that all necessary design input (as listed in section 3.2) should be available prior to the start of a design activity. In practice, certain design activities are initiated before the firm input requirements are available. (For example, foundation designs prepared based on preliminary information or equipment sizes and mounting and embedded conduit run based on preliminary estimates of circuit requirements).

   The design phase QA program is structured to assure that all necessary design input is available before completion of final design of the work affected by the input and that final design input is available for use in verification of the final design.

B. Section 4.1, Design Process General

Paragraph 3 implies traceability back from final design to the source of design input. In practice, a literal interpretation of this is not always possible. For example, final design drawings do not identify the related calculations. This paragraph is interpreted to mean that it shall be possible to relate the criteria used and analyses performed to the final design documents and that record files will permit location of analyses supporting specific design output documents.

References: 3.8.1.2.3, 4.2.5, 5.1.4, 5.4.7.1, 6.3.1.3, 9.1.4.6, 9.3.4.6, 17, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.74: Quality Assurance Terms and Definitions (Revision 0, February 1974)

RESPONSE

The position of Regulatory Guide 1.74 is accepted (refer to section 17.2 and 17.16). Additional references: 4.2.5, 5.1.4, 5.4.7.1, 9.1.4.6, 17.1A, 17.1B, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.88: Collection, Storage and Maintenance of Nuclear Power Plant Quality Assurance Records (Revision 2, October 1976) [Historical]

RESPONSE

The position of Regulatory Guide 1.88 is accepted with the following exceptions to Section 5.6 of ANSI N45.2.9-1974:

A. Doors, structures and frames, and hardware shall be designed to comply with the requirements of a minimum 2-hour fire rating. (Section 4.4.1 (c) of Supplement 17S-1 of NQA-1 requires 2-hour rated doors and dampers, and the latest version of Regulatory Guide 1.28 provides no additional guidance in this area.)

B. Vinyl tile is used on the floor in lieu of a surface sealant.

C. A roof drainage line penetrating the structure has been plugged to avoid any potential flooding due to rain. There is a floor drain with a vent line located in the center of the room. The vent line to the roof is exclusively for the drain and it does not carry liquids, therefore it does not present any potential flooding problems to the storage room.

D. PVNGS also provides the following clarification with regard to application of ANSI N45.2.9-1974: PVNGS adheres to the guidance of the Standard for classification and retention periods of quality assurance records, unless other more stringent requirements apply or a graded approach as defined in Section 17.2 has been applied to determine the relative value of the record or group of records. When the graded approach is utilized, the extent to which the record maintenance and storage requirements of the Standard apply may be modified.

For quality assurance records to which the graded approach is not applied, the records shall be maintained and stored consistent with applicable regulatory requirements and the pertinent requirements of R.G. 1.88 and ANSI N45.2.9-1974, with exceptions as noted in A through C above.

Reference: 17.1, 17.2, and Table 18.II.F.2-3.

HISTORICAL

REGULATORY GUIDE 1.116: Quality Assurance Requirements for Installation, Inspection, and Testing of Mechanical Equipment and Systems (Revision 0-R, May 1977) [Historical]

RESPONSE

For operations phase activities, the position of Regulatory Guide 1.116 is accepted with the following interpretations of ANSI N45.2.8:

A. Section 2.3

Test reports attached to or referenced in data sheets may meet the evaluation requirements of the last paragraph.

B. Sections 2.2 and 2.3; 5.2 and 5.4

For application of the provisions of these sections to preoperational and startup testing, the APS position on the applicable revision of Regulatory Guide 1.68, “Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors,” shall take precedence where there is a conflict or difference.

C. Item 2.9e (6)

This item shall be interpreted to mean that any work performed without an approved design change shall not be considered complete and acceptable for its intended use until the change is approved, and that the intent of this item will be satisfied provided that such work is performed only with approved procedures and that the activities and the results are documented. Evidence of design change approval shall be required prior to placing the affected item in service.

D. Section 5

For purposes of functional tests addressed by this standard, APS defines completed systems as any system, or portion or component thereof, on which construction is sufficiently complete to allow the required testing, and on which further or adjacent construction will not render the results of such testing invalid or indeterminate.

E. Item 5.1.g

Traceability as used in this item is considered to be the same as discussed in Section 5.2.13.3 of ANSI N18.7.

Reference sections 14.2.7, 17.1A.2, 17.1B, and 17.2B.

HISTORICAL

REGULATORY GUIDE 1.123: Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants (Revision 1, July 1977) [Historical]

RESPONSE

For operations phase activities, the position of Regulatory Guide 1.123 is accepted with the following modifications to ANSI N45.2.13-1976:

A. Section 7.5, Personnel Qualifications

Personnel performing offsite audits shall be qualified to ANSI N45.2.23. Personnel performing offsite material inspection shall be qualified to ANSI N45.2.6. Personnel performing offsite monitoring activities shall be qualified to ANSI N45.2.23 or ANSI N45.2.6.

B. Section 3.2.3

The requirements of this section are accepted with the following exception:

When purchasing commercial grade calibration services from calibration laboratories accredited by a nationally recognized accrediting body, the procurement documents are not required to impose a quality assurance program consistent with ANSI N45.2-1971. Nationally-recognized accrediting bodies include the National Voluntary Laboratory Accreditation Program (NVLAP) administered by the National Institute of Standards and Technology (NIST) and other accrediting bodies recognized by NVLAP via a Mutual Recognition Agreement (MRA). In such cases, accreditation may be accepted in lieu of the Purchaser imposing a QA program consistent with ANSI N45.2-1971, provided all the following are met:

1. The accreditation is to ANSI/ISO/IEC 17025.

2. The accrediting body is either NVLAP or the American Association for Laboratory Accreditation (A2LA) based upon A2LA continued NVLAP recognition through the International Laboratory Accreditation Corporation (ILAC) Mutual Recognition Agreement.

3. The published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.

4. The purchase documents impose additional technical and administrative requirements, as necessary, to satisfy APS QA Program and technical requirements. The purchase documents shall specifically require that the calibration certificate or report will include identification of the equipment and/or standards used.

5. The purchase documents require reporting as-found calibration data when calibrated items are found to be out-of-tolerance.

HISTORICAL

REGULATORY GUIDE 1.144: Auditing of Quality Assurance Program for Nuclear Power Plants (Revision 1, September 1980) [Historical]

RESPONSE

The requirements of the referenced standard (ANSI N45.2.12-1977) as modified and interpreted in the position of Regulatory Guide 1.144 are applied to the APS

quality assurance program for operations phase activities, with the following exceptions:

A. Section 4.3.1 requires that a brief preaudit conference may be conducted with cognizant organization management. A formal preaudit conference may not be required for some routine internal audits where informal preaudit communication is determined to be adequate. The manager of the auditing organization will monitor the performance of audits, through review of audit reports, to ensure that informal preaudit communication is utilized only in cases where such informal communication is adequate.

B. Section 4.5.1 states that any “adverse findings” shall be reviewed and investigated to determine and schedule appropriate corrective action including action to prevent recurrence. Consistent with the PVNGS position established in Section 1.8 for Regulatory Guide 1.33, PVNGS requires determination of root cause and actions to prevent recurrence for significant conditions adverse to quality that are identified during audits. This interpretation is consistent with Appendix B to 10CFR50, Criterion XVI, Corrective Action.

C. A grace period of 90 days beyond the specified frequency shall be permitted for completion of supplier annual evaluations and supplier audits. When the grace period is utilized, subsequent scheduling for the evaluation or audit shall be based upon the original due date. This grace period shall not be applied to evaluations or audits that have a frequency specifically defined by regulation.

Reference: 17.1, 17.2, and Table 18.II.F.2-3.

D. Regulatory Guide 1.144, Section C.3.b (2)

The requirements of this section are accepted with the following interpretation:

When purchasing commercial grade calibration services from calibration laboratories accredited by a nationally-recognized accrediting body, the accreditation process and accrediting body may be credited with carrying out a portion of the Purchaser's duties of verifying acceptability and effective implementation of the calibration service supplier's quality assurance program. Nationally-recognized accrediting bodies include the National Voluntary Laboratory Accreditation Program (NVLAP) administered by the National Institute of Standards and Technology (NIST) and other accrediting bodies recognized by NVLAP via a Mutual Recognition Arrangement (MRA).

In lieu of performing an audit, accepting an audit by another licensee, or performing a commercial-grade supplier survey, a documented review of the supplier's accreditation shall be performed by the Purchaser. This review shall include, at a minimum, all of the following:

1. The accreditation is to ANSI/ISO/IEC 17025.
2. The accrediting body is either NVLAP or the American Association for Laboratory Accreditation (A2LA) based upon A2LA continued NVLAP recognition through the International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement.

3. The published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.

HISTORICAL

REGULATORY GUIDE 1.146: Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants (Revision 0, August 1980) [Historical]

RESPONSE

The requirements of the referenced standard (ANSI N45.2.23-1978) as modified and interpreted in the position of Regulatory Guide 1.146 are applied to the quality assurance program with the following modifications:

A. At paragraph 2.2.1 of ANSI N45.2.23: Orientation of auditors is provided to produce a working knowledge and understanding of ANSI N18.7, ANSI N45.2.12, this standard, and the auditing organization’s procedures for implementing audits and reporting results.

B. At paragraph 2.3.4 of ANSI N45.2.23: Prospective lead auditors shall demonstrate their ability to effectively implement the audit process and lead an audit team. They shall have participated in at least one audit within the year preceding the individual’s effective date of qualification. Upon successful demonstration of the ability to effectively lead audits, licensee management may designate a prospective lead auditor as a “lead auditor”.

2. SITE CHARACTERISTICS

2.1 GEOGRAPHY AND DEMOGRAPHY

2.1.1 SITE LOCATION AND DESCRIPTION

2.1.1.1 Specification of Location

The PVNGS site is located in Maricopa County in southwestern Arizona, 16 miles west of the city of Buckeye and 34 miles west of the nearest boundary of the city of Phoenix. Figure 2.1-1 identifies the general location of the plant site with respect to roads and highways, communities, and cities in the vicinity. The site area is flat with small, scattered hills.

To the west and northwest of the site are the Palo Verde Hills, sharply rising to 2172 feet above mean sea level.[1] To the south is Centennial Wash, an intermittent stream backed by gently rising uplands with scattered, isolated, steeply sloped hills and buttes. Buckeye Valley, bisected by the Gila River, lies to the east and southeast. To the north and northeast, the terrain is a relatively flat desert traversed by numerous intermittent streams that are typical of the region (refer to engineering drawings 13-C-ZVA-005, 13-P-OOB-001, and UFSAR figures 2.1-2 and 2.1-3).

The location of the centerline of each containment building is given in table 2.1-1.

2.1.1.2 Site Area Maps

Engineering drawings 13-C-ZVA-005 and 13-P-OOB-001 illustrate the plant site, including topographical features and the location and orientation of principal plant structures.

The total area of the plant property is approximately 4250 acres. The plant property line coincides with the plant site boundary. Units 1, 2, and 3 and their supporting facilities are located in the northern half of the site. The site

Table 2.1-1

CONTAINMENT BUILDING CENTERLINES[2]

PVNGS Unit	Geodetic Coordinates	Universal Transverse Mercator Zone 12S
1	Latitude 33°23'23.269"	N 3,695,857.885
	Longitude 112°51'43.375"	E 326,808.124
2	Latitude 33°23'14.152"	N 3,695,581.206
	Longitude 112°51'52.327"	E 326,571.769
3	Latitude 33°23'3.016"	N 3,695,240.368
	Longitude 112°51'57.022"	E 326,444.304

is bounded on the south by Ward Road (Elliot Road) and on the west by Wintersburg Road. No public roads or railroads cross the site. Site elevations range from 890 feet above mean sea level at the southern boundary to 1030 feet above mean sea level at the northern boundary.

Figure 2.1-4 defines the boundaries of the plant exclusion area. The exclusion area boundary coincides with the plant site boundary, except in the southern portion of the property. Minimum distances from each unit to the site boundary and exclusion boundary are provided in tables 2.1-2 and 2.1-3, respectively.

2.1.1.3 Boundaries for Establishing Effluent Release Limits

The boundary for establishing effluent release limits coincides with the plant site boundary (refer to figure 2.1-4). For purposes of radiation protection and general safety, the area Table 2.1-2 within the site boundary will be under the control of the applicant. The areas around the main buildings of the plant site are fenced and patrolled. One guard house is provided. Distances from plant effluent release points to the site boundary are given in table 2.1-2.

MINIMUM DISTANCES TO SITE BOUNDARY FROM CONTAINMENT EDGE[a]

Exposure Direction	Site Boundary Distance (Meters)		
	Unit 1	Unit 2	Unit 3

NNW	1,037	1,318	1,288

a. Based on 45° sectors.

2.1.2 EXCLUSION AREA AUTHORITY AND CONTROL

2.1.2.1 Authority

The applicant owns all land within the site boundary; therefore, the applicant also owns all land within the exclusion area. The applicant has complete authority to regulate any and all access and activity within the exclusion area. There will be no unauthorized public access or activity allowed within the exclusion area. The site boundary will be posted and fenced with light gauge wire such as that used to contain cattle. This will prevent inadvertent public access.

The applicant has examined the titles of each parcel of land owned within the PVNGS exclusion area and site boundary. Based on such title examination, it is clear that the applicant owns or controls all minerals, including oil and gas, within the PVNGS exclusion area and site boundary.

In respect to the following described parcels:

Parcel B

The Southeast quarter (SE-1/4) of Section Twenty-Eight (28), Township One North (TSlN), Range Six West (R6W) of the Gila and Salt River Base and Meridian.

Parcel C

The West quarter (W-1/4) of Section Two (2), Township One South (TSlS), Range Six West (R6W) of the Gila and Salt River Base and Meridian.

There are outstanding reservations for a 50% interest in respect to parcel B and a 1/16% interest in respect to parcel C in any oil, gas, or other minerals therein. In neither case,

however, does the owner of the reservation have the right of ingress or egress to or from property for any purpose, including the prospecting for or removal of any oil or gas therein.

2.1.2.2 Control of Activities Unrelated to Plant Operation

Activities unrelated to operation of the reactor may be permitted within the plant site exclusion area under appropriate limitations, provided that no significant hazards to public health and safety will result and senior management has concurred with the unrelated activity.

2.1.2.3 Arrangements for Traffic Control

No public roads, railways, or waterways traverse the plant site exclusion area.

2.1.2.4 Abandonment or Relocation of Roads

No public roads presently traverse the plant site exclusion area; hence, none will have to be abandoned or relocated.

2.1.3 POPULATION DISTRIBUTION

Population centers within a 50-mile radius of the plant are shown in figure 2.1-3. Of these population centers, those that are larger than 500 persons as of July 1, 1978 are listed in table 2.1-4 by distance and direction from the plant and actual size. The remaining population centers, i.e., those smaller than 500 persons and for which no statistics are available, are listed in table 2.1-5 by distance and direction

from the plant. Figure 2.1-2 shows the location of population centers within a 10-mile radius of the plant.

2.1.3.1 Population Within 10 Miles

Figure 2.1-5 illustrates the 1978 estimated residential population located within a 10-mile radius of the plant site. Data are displayed at 1-, 2-, 3-, 4-, 5-, and 10-mile distances from the centerline of the Unit 2 containment building for 16 compass sectors. Population data for the 0- to 5- and 5- to 10-mile areas were tabulated from primary and secondary data sources, respectively. An aerial house count backed by ground verification was performed in October 1978 for the first 5-mile radii. Population figures were obtained by multiplying the number of dwelling units times a factor of 3.44; i.e., the 1970 Buckeye Census Enumeration District statistic on dwelling unit occupancy.[5] The 1978 population distributions for the 5- to 10-mile radii were based on 1970 U.S. Bureau of the Census data. Population centroids, that is, the locations of population within 1970 census enumeration districts, were assigned by the Census Bureau. Population totals per segment were calculated based on the location of the centroids relative to PVNGS.

Table 2.1-4

JULY 1, 1978, POPULATION ESTIMATE FOR CITIES WITH 500 OR MORE PERSONS WITHIN A 50-MILE RADIUS OF PVNGS[3]

Heaton	48.0 ESE
Horn	48.5 SW
Wenden	50.0 NW
Freeman	50.0 SE

Figures 2.1-6 through 2.1-14 illustrate the estimated residential population located within a 10-mile radius of the plant site for the years 1980, 1982, 1984, 1986, 1990, 2000, 2010, 2020, and 2030. Data are displayed at 1-, 2-, 3-, 4-, 5- and 10-mile distances from the centerline of the Unit 2 containment building for 16 compass sectors. Maricopa County population estimates provided by the Arizona State Department of Economic Security(6) for the years 1980, 1982, 1984, 1986, 1990, and 2000 were used for all six radii calculations. Maricopa County population projections for the years 2010, 2020, and 2030 were derived from the assumption that decennial growth rates from 2000 to 2030 would be held constant to the same rate of growth as experienced between 1990 and 2000. Population projections were calculated according to the methodology described above for the 1978 estimated 5- to 10-mile radii population.

2.1.3.2 Population Between 10 and 50 Miles

Figure 2.1-5 illustrates the 1978 estimated residential population located between 10 and 50 miles of the plant site. Figures 2.1-6 through 2.1-14 show the estimated residential population located between 10 and 50 miles of the plant site for the years 1980, 1982, 1984, 1986, 1990, 2000, 2010, 2020, and 2030. Data are displayed at 10-, 20-, 30-, 40-, and 50-mile distances from the centerline of the Unit 2 containment building for 16 compass sectors. Population input data for Maricopa, Pinal, Yavapai, and Yuma Counties were supplied by the Arizona State Department of Economic Security(6) and calculated according to the methodology described in paragraph 2.1.3.1.

2.1.3.3 Transient Population

Transient population within a 10-mile radius of the centerline of the Unit 2 containment building for 1978 is estimated to be approximately 150 persons.[(7),(8),(9),(10),(11)] This is a conservative estimate based upon the consideration that 100 people included in the total represent migrant farm workers -- a figure that can be considered excessively high.[(7)] The remaining 50 persons are employed at the Hassayampa Cotton Gin, the Ruth Fisher and Arlington School Districts, and the Gila Compressor Station. Table 2.1-6 lists employment centers within a 10-mile radius of the PVNGS according to distance and direction from the plant site, number of employees, seasonality of employment, and combined residential and transient population totals per sector.

Table 2.1-6

1978 TRANSIENT POPULATION WITHIN A 10-MILE RADIUS OF PVNGS[(7),(8),(9),(10),(11)]

Employment Center	Distance and Direction From PVNGS[(a)]	Number of Employees	Seasonality of Employment	Combined 1978 Residential and Transient Population Total, Per Sector
Farms	3 to 10 miles N, NNE, ENE, E, ESE, SE, SSE, S, SSW, SW, WSW, WNW, NW, NNW	100 (Migrant)	High in spring and fall; low in summer and winter	3,032
Hassaympa Cotton Gin	6.0 miles SE	10	November to March	10
Ruth Fisher School District	7.5 miles N	6	September to June	6
Arlington School District	8.0 miles SE	10	September to June	10
Gila Compressor Station	10.0 miles SSE	25	Year-round	25

a. Measurements taken from centerline of Unit 2 containment building.

2.1.3.4 Low Population Zone

The PVNGS low population zone (LPZ) has been defined as a 6400-meter (4-mile) radius area, based on the centerline of the Unit 2 containment building. The LPZ has been conservatively selected on the basis of providing effective emergency planning for the residents in the LPZ, as well as limiting radiation doses to below 10CFR100 limits to those residents outside the LPZ under the most conservative assumptions for a design basis accident.

As indicated in figures 2.1-6 through 2.1-14, the population density of the LPZ is low and is expected to remain as such throughout the plant life, thereby enabling effective emergency planning. Figure 2.1-15 illustrates the LPZ in terms of topographic features and transportation for evacuation purposes. There are no hospitals, prisons, or parks located within either the LPZ or a 5-mile radius.

There is one school located within the LPZ, Arlington Elementary at 3.3 miles to the south east. Winters Well Elementary school is located north of the plant site at approximately 4.4 miles.

2.1.3.5 Population Center

Currently, the nearest population center as defined in 10CFR100 is Sun City, which had a 1977 estimated residential population of 43,500 persons.(1) Its nearest city limit boundary, as represented on a 1979 Maricopa Country road map,(12) in relation to the plant site and the LPZ is approximately 36 miles and 32 miles, respectively, east-northeast. Sun City transient population has not been included in the 1977 population estimate. In assuming for Sun City a growth rate identical to

Maricopa County, by the year 2030 Sun City is expected to sustain a residential population of 170,988 persons. By that same time, the sector in which Sun City is located is expected to sustain 283,107 persons, for a population density of 2060 persons per square mile.

It is projected that by 1995, the cities of Avondale and Goodyear will have qualified as the nearest population centers as defined in 10CFR100 with estimated residential populations of 28,600 and 26,800 persons, respectively.(13) Their nearest city limit boundaries, as represented on a 1979 Maricopa County road map,(12) in relation to the plant site and the LPZ are 29 miles and 25 miles east for both adjacent cities. Avondale and Goodyear transient population has not been included in the 1995 population estimate. In assuming for Avondale and Goodyear growth rates identical to Maricopa County, by the year 2030 Avondale and Goodyear are expected to sustain residential populations of 76,127 persons and 75,288 persons, respectively. By that same time, the sector in which Avondale and Goodyear are located is expected to sustain 145,581 persons, for a population density of 1059 persons per square mile.

2.1.3.6 Population Density

Figures 2.1-7 through 2.1-9 show the estimated residential population located within a 50-mile radius of the site for the years of initial unit operation; i.e., 1982, 1984, and 1986. Within a 30-mile radius of the site, the following residential population projections are estimated:

1982 32,187 persons

1984 33,701 persons

1986 35,415 persons

Table 2.1-7 lists the cumulative residential population density within a 30-mile radius of the site by annulus for the three unit startup dates. As can be seen from table 2.1-7, the PVNGS site falls well below the uniform population density standard of 500 persons per square mile as expressed in Regulatory Guide 1.70, Revision 3.

Table 2.1-7

CUMULATIVE RESIDENTIAL POPULATION DENSITY WITHIN A 30-MILE RADIUS OF THE PVNGS PLANT SITE DURING YEARS OF INITIAL PLANT STARTUP (PERSONS PER SQUARE MILE)

Miles From Plant	1982	1984	1986
0-1	0	0	0
0-2	1	1	1
0-3	20	21	22

0-5	16	17	18
0-10	12	13	14
0-20	13	13	14
0-30	11	12	13

Figure 2.1-14 shows the estimated residential population located within a 50-mile radius of the site for the end of the decade of plant life end; i.e., 2030. Within a 30-mile radius

of the site, the 2030 residential population projection is estimated to be 106,914 persons.

Table 2.1-8 lists the cumulative residential population density within a 30-mile radius of the site by annulus for the end of the decade of plant life end.

As can be seen from table 2.1-8, the PVNGS site falls well below the uniform population density standard of 1000 persons per square mile as expressed in Regulatory Guide 1.70, Revision 3

Table 2.1-8

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

2.2.1 LOCATIONS AND ROUTES

This section contains initial licensing information and is not expected to be routinely updated. Significant changes that could potentially affect the content of this section should be evaluated for inclusion as discussed in NEI 98-03, Guidelines for updating Final Safety Analysis Reports, Section A3.

2.2.1.1 Industrial Facilities

Figure 2.2-1 shows the location of the nearest industrial facilities. The closest industrial facility to PVNGS is the Mesquite natural gas fired combined cycle power generation station owned and operated by SEMPRA. The station is located approximately 2.6 miles south of unit 3. Two other electric generating stations in the immediate area are the Redhawk station owned and operated by Pinnacle West Capital Corporation and the Arlington Valley station owned and operated by Duke Energy Company.

There are no chemical plants, refineries, oil storage facilities, oil drilling operations and wells, underground gas storage facilities, or mining and quarrying operations located within a 10-mile radius of the PVNGS plant site.

2.2.1.2 Transportation Facilities

2.2.1.2.1 Roads

Figure 2.2-1 shows the location of two major roads (i.e., Interstate 10 and Buckeye-Salome Road) and a number of lesser

used roads within a 10-mile radius of the plant site. At its closest point to the PVNGS site, Interstate 10 (I-10) is located approximately 6.5 miles northeast of the centerline of the Unit 2 containment building. Buckeye-Salome Road is closest to the PVNGS site at a point 2 miles north-northeast of the centerline of the Unit 2 containment building.

2.2.1.2.2 Railroads

Figure 2.2-1 shows the location of the only railroad within a 10-mile radius of the plant site. It is owned by the Union Pacific Railroad. At its closest point to the PVNGS site, the railroad is located approximately 4.5 miles south-southeast of the centerline of the Unit 2 containment building. A railroad spur extends from this line to the site.

2.2.1.2.3 Airways

Figure 2.2-2 shows the location of both high- and low-level altitude airways within the jurisdiction of the U.S. Federal Aviation Administration (FAA) Air Route Traffic Control Centers in Albuquerque, New Mexico and Los Angeles, California. In the airspace west of the Phoenix Sky Harbor International Airport, Victor Airways 16 (V-16) and 461 (V-461) and Jet Routes 4 (J-4) and 65 (J-65) are routed within a 10-mile radius of the plant site.

2.2.1.2.3.1 <u>Victor 16 Airway</u>. Victor 16 is a low-altitude airway that extends from Los Angeles through Ontario, Palm Springs, and Blythe, California, and Phoenix and Tucson,

Arizona, to points as far east as Lynchburg, Virginia. The centerline of V-16 passes directly over the Buckeye VORTAC[a], and at its closest point is located approximately 4 nautical miles north of the centerline of the Unit 2 containment building. The total width of the band over which the airway extends is 8 nautical miles, that is, 4 nautical miles on either side of the centerline. Hence, aircraft using V-16 could pass directly over PVNGS.

Along this airway, aircraft flying by visual flight rules (VFRs) and instrument flight rules (IFRs) may not exceed a maximum altitude of 17,000 and 30,000 feet above mean sea level, respectively.[1] Minimal enroute altitude for IFR aircraft is 5600 feet above mean sea level.

2.2.1.2.3.2 Victor 461 Airway. Victor 461 is a low-altitude airway that extends from the Buckeye VORTAC to the Gila Bend VORTAC. At its closest point, the centerline of V-461 is located approximately 3 nautical miles east of the centerline of the Unit 2 containment building. The total width of the band over which the airway extends is 8 nautical miles, that is, 4 nautical miles on either side of the centerline. Hence, aircraft using V-461 could pass directly over PVNGS. Minimal enroute altitude for aircraft flying by IFR is 4000 feet above mean sea level.

a. VORTAC refers to a very high frequency omnidirectional range station (VOR) and ultrahigh frequency tactical air navigation aid (TACAN).

2.2.1.2.3.3 Jet Route 4. Jet Route 4 is a high-altitude airway that extends from Twenty-Nine Palms, California, through Casa Grande and San Simon, Arizona, to points as far east as Wilmington, Delaware. At its closest point, the centerline of J-4 is located approximately 3 nautical miles southwest of the centerline of the Unit 2 containment building. The total width of the band over which the airway extends is 8 nautical miles. Hence, aircraft using J-4 could pass directly over PVNGS. As a high-altitude airway, aircraft operating along J-4 may not pass below a minimum altitude of 18,000 feet above mean sea level.

2.2.1.2.3.4 Jet Route 65. Jet Route 65 is a high-altitude airway that extends from Red Bluff, California, through Sacramento, Fresno, Bakersfield, Palmdale, and Blythe, California; Phoenix, Arizona, and Truth or Consequences, New Mexico, to points as far east as Abilene, Texas. Jet Route 65 passes directly over the Buckeye VORTAC and parallels the V-16 airway from there to the Phoenix Sky Harbor International Airport. At its closest point, J-65 is located approximately 4 nautical miles north-northeast of the centerline of the Unit 2 containment building. The total width of the band over which the airway extends is 8 nautical miles. Hence, aircraft using J-65 could pass directly over PVNGS. As a high-altitude airway, aircraft operating along J-65 may not pass below a minimum altitude of 18,000 feet above mean sea level.

2.2.1.2.4 Airports

Figure 2.2-1 shows two airports located in the PVNGS environs: the Buckeye Municipal and Pierce Airports. Buckeye Municipal and Pierce Airports are located outside a 10-mile radius of the plant site at approximately 11 miles east-northeast and 15.5 miles east of the centerline of the Unit 2 containment building, respectively. Not shown on figure 2.2-1 is the Arizona Public Service (APS) company private helipad. The helipad is located on the PVNGS plant site as shown in figure 2.2-4.

2.2.1.2.5 Natural Gas and Petroleum Pipelines

Figure 2.2-1 shows two operating pipelines to be within a 10-mile radius of the plant site. One is owned by Southern Pacific Pipelines, Inc. (SPPL); the other is owned by El Paso Natural Gas Company (EPNG). At its closest point to the PVNGS site, the SPPL pipeline is approximately 4.5 miles south-southeast of the centerline of the Unit 2 containment building. The EPNG pipeline is approximately 6 miles southwest of the Unit 2 containment building at its closest point to the PVNGS site. In addition there are three smaller pipelines connecting the gas fired electric plants discussed in section 2.2.1.1 to the EPNG pipeline.

2.2.1.3 Military Facilities

2.2.1.3.1 Luke Air Force Base

Figure 2.2-2 shows Luke Air Force Base (LAFB) to be approximately 33 miles east-northeast of the plant site. Alert area A-231 and restricted areas R-2301, R-2304, and R-2305 used by the base in its training missions are located well outside a 10-mile radius of the plant site. The closest Air Force training area, A-231, is located approximately 10 miles north-northeast of the Unit 2 containment building. It should be noted that the LAFB corridor used to traverse V-16 enroute to and from LAFB restricted areas is located approximately 15 miles east of the PVNGS site.

2.2.2 DESCRIPTIONS

2.2.2.1 Industrial Facilities

The closest industrial facility to PVNGS is the Mesquite natural gas fired combined cycle power generation station owned and operated by SEMPRA. The station is located approximately 2.6 miles south of unit 3. Two other electric generating stations in the area are the Redhawk station owned and operated by Pinnacle West Capital Corporation and the Arlington Valley station owned and operated by Duke Energy Company.

NEARBY INDUSTRIAL, TRANSPORTATION,

AND MILITARY FACILITIES

Table 2.2-1

AVERAGE DAILY TRAFFIC (ADT) IN THE VICINITY OF THE

PALO VERDE NUCLEAR GENERATING STATION JUNE 1978[4]

Traffic Count Location	ADT (Actual)
Buckeye-Salome Road between Wintersburg Road and 339th Avenue	4,859
Buckeye-Salome Road between 339th Avenue and Baseline Road	4,375
Buckeye-Salome Road between Wintersburg Road and 411th Avenue	794
Wintersburg Road between Buckeye-Salome Road and plant site entrance	3,814
Wintersburg Road between Buckeye-Salome Road and Buckeye Road	296

2.2.2.2 Transportation Facilities

2.2.2.2.1 Roads

The road system in the vicinity of the plant site is essentially a rectangular grid oriented on north-south and east-west axes, following township and sectional lines. The plant site is bounded on two sides by Wintersburg Road and Ward (Elliot) Road. A June 1978 traffic count of the area has revealed average daily traffic (ADT) listed in table 2.2-1.[3] June 1978 ADT counts are well below design levels.[4] As of early 1979, Wintersburg Road and Buckeye-Salome Road are the major asphalt roads in the area. Given the amount of traffic

in the area, several projects are either planned or underway to improve roadway conditions.[4] If hazardous materials were shipped in the area, the most probable route taken is expected to be I-10, rather than over the county road system.[5]

2.2.2.2.2 Railroads

The Union Pacific Railroad operates over the Arlington-Wellton line, which is the segment that runs past PVNGS at an approximate distance of 4.5 miles from the south-southeast of the centerline of the Unit 2 containment building.

Short term exposure limits for hazardous materials like those carried over the Arlington-Wellton line can be found in OSHA 29 CFR part 1910-1000 Subpart Z, or in Reg. Guide 1.78. Ammonia, sulfur dioxide and chlorine are classified as poison gases, class 2.3. The DOT hazard classes are as follows:

Hazard Class	Description
2.1	Flammable Compressed Gas
2.2	Non-Flammable Compressed Gas
2.3	Poison Gas
3	Flammable Liquids
4	Flammable Solids
5.1	Oxidizers
6.1	Poison Liquids
8	Corrosive Liquids
9	Hazardous Substances
	Combustible Liquids
	Etiologic Agents
	Hazardous Waste

2.2.2.2.3 Airways

2.2.2.2.3.1 Victor 16 Airway. The V-16 airway is used by commercial, general aviation, and military aircraft that range in size from single-engine, propeller-driven airplanes to four-engine, wide-body jets. Typical peak-day IFR air traffic statistics are given in table 2.2-2. For the same reporting period, a total of 250 aircraft are estimated to be flying by VFR in both directions. No estimates are available on the level of future growth.[(1)]

2.2.2.2.3.2 Victor 461 Airway. The V-461 airway can be used by commercial, general aviation, and military aircraft that range in size from single-engine, propeller-driven airplanes to four-engine, wide-body jets. It is estimated that current aircraft operations flying by VFR and IFR number approximately 100 movements annually.[(9)]

2.2.2.2.3.3 Jet Routes 4 and 65. Jet Routes 4 and 65 are used by commercial, general aviation, and military aircraft capable of performing at high altitudes. Typical peak-day IFR air traffic using routes J-4 and J-65, or flying parallel to them above 24,000 feet above mean sea level within range of the Buckeye VORTAC, is estimated to be 204 flights in 1979. This is a 13% increase in Phoenix area air traffic over 1978 estimates. It is expected that this growth rate will apply in future years.[(9)]

b. Not available.

2.2.2.2.4 Airports

2.2.2.2.4.1 Buckeye Municipal Airport. Buckeye Municipal Airport, once called Luke Air Force Base Auxiliary Field No. 5, is located 6 miles northwest of the city of Buckeye. It is classified as a Class 2 Fixed-Base Operator. The elevation of the airport is 1024 feet above mean sea level. The airport is open during daylight hours. Services offered there include fuel sales, storage, and major airframe and power plant repairs. The Slurry Bomber Company is based there. The airport consists of three runways oriented north-south, northeast-southwest, and southeast-northwest, forming a triangle. Each leg is 3820 feet long. One runway is paved, the other two are turf. The traffic pattern altitude above ground level is 800 feet or 1800 feet above mean sea level.(10)

Buckeye Municipal Airport is used primarily as a base for local general aviation activities and student training. It has been estimated that approximately 90% of the planes using Buckeye Municipal Airport are single-engine aircraft; the rest are twin-engine airplanes. The largest type of aircraft served is a four-engine, propeller-driven DC-7.(11) The local estimate of the number of annual aircraft operations for 1978 is 6000 movements.(12) In accordance with Regulatory Guide 1.70 criteria, given the low number of annual movements, it is not necessary to report aircraft accident statistics.

The Maricopa Association of Governments Regional Aviation System Plan calls for the expansion of the Buckeye Municipal Airport. Construction of a runway parallel to the most

frequently used one and the dismantling of the other two cross-wind runways is planned.[13]

2.2.2.2.4.2 Pierce Airport. Pierce Airport is a privately-owned facility of Pierce Aviation, which is considered by the FAA not to be a Fixed-Base Operator because, even though fuel is sold, business is not actively solicited. Pierce Airport is located 2 miles west of the city of Buckeye, east of U.S. Highway 85, and 0.75 miles north of Hozen Road. The elevation of the airport is 860 feet above mean sea level. The airport is open during daylight hours, Monday through Saturday. Services offered include storage and minor airframe and power-plant repairs. The airport consists of one turf runway 2990 feet long with an east-west orientation. The traffic pattern altitude above ground is 800 feet or 1700 feet above mean sea level.[10]

Pierce Airport is used primarily as a base for crop dusting activities, although some farmers within a 40-mile area use it to station their planes. Pierce Aviation conducts roughly 15 to 21% of its crop dusting business from Pierce Airport. The remainder takes place at satellite duster strips located throughout Western Maricopa County.[14]

Approximately 30 airplanes are hangered at Pierce Airport, 10 of which are owned by Pierce Aviation. Of these 30 air-planes, two are privately-owned, twin-engine aircraft. The rest are single-engine aircraft.[14]

Peak aircraft operations occur during the months of July through September when there is a lot of crop dusting. It has been estimated that the daily peak traffic during this season is approximately 108, based on 72 takeoffs and landings in the mornings and half that number in the afternoons.[14]

It is estimated that during the period from October through June, there are 25 airplanes, each making one takeoff and landing daily, that use the facility. Based on this information, the annual number of operations are set at approximately 24,000 movements.[14] According to Regulatory Guide 1.70 criteria, given the number of annual movements at Pierce Airport, it is not necessary to report aircraft accident statistics.

Pierce Aviation aircraft direct their flights to either the north or the south of the PVNGS plant site; hence, no over-flights are conducted.[14]

Future plans for expansion of Pierce Airport include the possibility of increasing its facilities to accommodate a maximum of 50 aircraft.[14]

2.2.2.2.4.3 Arizona Public Service Company PVNGS Helipad. The Arizona Public Service (APS) Company has built a private helipad located on the PVNGS plant site as shown in figure 2.2-4. APS will operate a helicopter to and from the site for approximately 1000 helicopter operations annually. The approach and departure path(s) are kept away from the plant safety-related structures to the maximum extent possible.

Since there are no planned instrument approaches,[17] the helicopter operations will only be conducted under VFR conditions.

2.2.2.2.5 Pipelines

2.2.2.2.5.1 Southern Pacific Pipelines. Southern Pacific Pipelines owns and operates a 12-inch, high-pressure refined petroleum-products pipeline located within a Southern Pacific Transportation Company operating right-of-way. The pipeline was constructed in 1955 and buried approximately 5 feet deep. Pipeline gate valves are installed generally at 20-mile intervals. The unmanned Palo Verde Booster Station is located approximately 11 miles east-southeast of the centerline of the Unit 2 containment building at the intersection of Palo Verde Road and the pipeline right-of-way. Maximum operating pressure in the line is at the booster station, where the discharge pressure is calculated at 1160 psig.[18]

Southern Pacific Pipe Lines is currently studying the feasibility of installing a second pipeline parallel to the existing line for transport of refined petroleum products.[18]

2.2.2.2.5.2 El Paso Natural Gas Company. El Paso Natural Gas Company (EPNG) owns and operates one 26-inch (line number 1100) and three 30-inch (line numbers 1103, 1110, and 1600), high-pressure, natural-gas pipelines within its right-of-way. Line 1100 was constructed in 1948 and buried 3 feet deep. Plug valves, manually operated at an American National Standards Institute (ANSI) 400 rating, are located at the Gila Compressor

Station, which is approximately 10 miles south-southeast of the centerline of the Unit 2 containment building. The line is maintained at a maximum operating pressure of 837 psig. Line 1103 was constructed in 1951 and buried 3 feet deep. Plug valves, manually operated at an ANSI 400 rating, are located at the Gila Compressor Station and at approximately 8 and 17 miles west of it. The line is maintained at a maximum operating pressure of 837 psig. Line 1110 was constructed in 1957 and buried 3 feet deep. Plug valves, manually operated at an ANSI 400 rating, are located at the Gila Compressor Station and at approximately 8 and 17 miles west of it. The line is maintained at a maximum operating pressure of 837 psig. Pipeline 1600 was constructed in 1970 and buried 3 feet deep. Ball valves, manually operated at an ANSI 600 rating, are located at the Gila Compressor Station; and gate valves, manually operated at an ANSI 600 rating, are located approximately 17 miles west of the Gila Compressor Station. Pipeline 1600 is maintained at a maximum operating pressure of 1080 psig. The Gila Compressor Station employs approximately 25 persons. A company-owned airstrip is located at the facility. It is used seldom, if at all.[19]

El Paso Natural Gas Company has no plans to use any of the four pipelines for gas storage at higher than normal pressure.[19]

2.2.2.3 Military Facilities

2.2.2.3.1 Luke Air Force Base

The primary mission of Luke Air Force Base (LAFB) is F-4, F-5, F-15, and F-104 combat-fighter, air-crew training. Other significant functions include the following:

- F-104 Starfighter training
- The provision of air defense coverage for the south-western United States by the 26th North American Air Defense region air division
- Support for the 2.7-million acre LAFB Gunnery Range complex and the Gila Bend Auxiliary Air Field located 65 miles south of Phoenix.[20]

Other aircraft stationed at LAFB include T-33s, used for targets or in providing cross-country proficiency training; CH-3s, used in special operations such as search and rescue missions by the 302nd Special Operations Squadron; and UH-1 helicopters used in mission support.[20]

Luke Air Force Base maintains two parallel 11,000-foot runways, oriented to 030-210 magnetic. Landing facilities include an instrument landing system (ILS), precision approach radar, ultrahigh frequency tactical air navigation aid (TACAN), and other nonprecision approach equipment for both runways. All approaches are conventional except those that use ILS and TACAN from the north in accordance with a published deviation used to avoid Sun City overflights.[20]

Runways are capable of withstanding aircraft landings and take-offs for planes up to 200,000 pounds gross weight. Luke Air Force Base facilities can provide service to transient aircraft of all services, including military air cargo airplanes and normal transient transport aircraft such as C-141s and C-9s. Emergency support can be provided to all types of aircraft; however, because LAFB is in a high-density traffic area, prior clearance is required before landing except in emergency situations.[20]

Luke Air Force Base operates approximately 180 to 210 sorties daily, usually five days per week. For each of the four major aircraft types operating out of LAFB, the average is 40 to 50 daily sorties. The number of annual LAFB aircraft operations is estimated to be approximately 100,000 movements. In accordance with Regulatory Guide 1.70 criteria, given the low number of annual movements, it is not necessary to report aircraft accident statistics.

Luke Air Force Base aviation routes for normal cross-country flights follow conventional airways established by the FAA.

Low-level training flights follow two military training routes. All routes are published in government and privately-printed aeronautical charts.[20]

Luke Air Force Base flight operations to restricted areas R-2301, R-2304, and R-2305 follow an outbound route which, at its closest point, comes to within 11 nautical miles of the centerline of the Unit 2 containment building. Inbound flights returning from the restricted areas to LAFB follow a route

which, at its closest point, comes to within 17 nautical miles of the centerline of the Unit 2 containment building. Luke Air Force Base flight operations to areas northwest of the base follow a route which, at its closest point, comes to within 13 nautical miles of the centerline of the Unit 2 containment building.

There are no VFR low-altitude training or other flight routes below 3000 feet above ground level (AGL) over the PVNGS site nor are any planned for the future. The closest to the planned PVNGS site that some of these routes are located is in the restricted area R-2305 complex underlying the SELLS airspace.[20]

There are no plans to establish any training routes or flight paths below 3000 feet AGL within 5 nautical miles of PVNGS.[20]

2.2.2.3.2 Other Low-Altitude Military Training Routes

The El Toro Marine Corps Air Station, California, conducts some of its low-altitude pilot training in the vicinity of the PVNGS plant site. At its closest point, the centerline of military training route IR-218 is located approximately 11 nautical miles west of the centerline of the Unit 2 containment building. The total width of the band over which the training route extends is 10 nautical miles, that is, 5 nautical miles on either side of the centerline. Hence, the closest to PVNGS that an aircraft using IR-218 could pass is 6 nautical miles. Nevertheless, most operations are expected to be routed close

to the centerline of IR-218. Training operations generally take place between 3500 and 4000 feet above mean sea level.

The route is flown by fighter and attack bomber types of aircraft. There are approximately 180 operations annually scheduled over this route.[23]

2.2.2.4 Projections of Industrial Growth

Future development in the vicinity of the PVNGS site is expected to be limited and scattered.[24]

2.2.3 EVALUATION OF POTENTIAL ACCIDENTS

As indicated in the previous sections, there are no significant industrial or military facilities near PVNGS. The industrial facilities south of unit 3 and the nearby transportation routes were evaluated for the determination of potential design basis events.

2.2.3.1 Determination of Design Basis Events

2.2.3.1.1 Industrial Facilities

The closest industrial facility to PVNGS is the Mesquite natural gas fired combined cycle power generation station owned and operated by SEMPRA. The station is located approximately 2.6 miles south of unit 3. Two other electric generating stations in the area are the Redhawk station owned and operated by Pinnacle West Capital Corporation and the Arlington Valley station owned and operated by Duke Energy Company.

The chemicals used at the plants have been evaluated per Reg. Guide 1.78 “Assumptions for Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release.”

2.2.3.1.2 Highway Transportation

Since Interstate 10 is over 5 miles from the plant, no credible accident could have any effect on safety-related structures. Flammable or toxic vapor clouds from maximum truck load quantities of materials or credible missiles cannot reach PVNGS. Hazardous materials that are carried by other transportation routes near PVNGS to the closest industrial facilities have been evaluated per Reg. Guide 1.78 “Assumptions for Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release.”

2.2.3.1.3 Rail Transportation

As indicated, the Union Pacific Railroad Arlington-Wellton line passes approximately 4.5 miles south-southeast of the plant. At this distance, only compressed liquified gases could be a potential hazard. Materials that are liquids at normal temperatures and pressure will not vaporize fast enough to present either a flammable cloud or toxic cloud hazard. For compressed liquified gases, a gross tank car failure could lead to a large "puff" type release which, under adverse weather conditions, could travel significant distances.

The flammable compressed gas category includes mostly liquefied hydrocarbons such as LPG, propane, butane and a few other materials such as methyl chloride and vinyl chloride. Flammable liquids, corrosive liquids and other hazardous substances are not hazards at this distance because only compressed gases could cause an uninhabitable condition in the control room. The non-flammable compressed gas class contains mostly chloro fluorocarbons and inert gasses which would not create a toxic hazard due to either a very high toxicity limit, or being non-toxic. The chemicals in each hazard class can be found in reference 47.

From the above discussion, studies of hazardous material storage and transport (25), (26), (27), (28) and from a review of 1973 to 1977 records of spills reported to the Office of Hazardous Materials, Department of Transportation, the chemicals listed in table 2.2-3 were identified as potentially shipped past PVNGS and a potential toxic chemical hazard for further investigation. This list includes materials shipped as compressed liquified gases and involved in two or more rail accidents that led to a spill during the 5 year period 1973 to 1977. It should be noted that of these materials, only LPG (propane or butane) and anhydrous ammonia were involved in spills in the five-state region: Arizona, New Mexico, Utah, Nevada, and California. Most of the cars of flammable compressed gasses shipped past the plant were LPG since this is by far the largest commodity in this category. From a review of the U.S. DOT Hazardous Material Information System for 1991-1995 (48), there were no spills along the line past PVNGS. The

Regulatory Guide 1.78 allowable weight of the commodities in table 2.2-3 was determined conservatively for a type C control room but with an air exchange rate of 0.45 h^{-1}, type G dispersion and a 4.2-mile distance to the nearest safety-related structure. The hazardous chemicals were analyzed utilizing the basic puff dispersion model assumptions of Reg. Guide 1.78 and the following control room model:

$$V_{cr}\frac{dC_{cr}}{dt} = x(t)F\,Q_{in} - C_{cr}Q_{out}$$

where:

C_{cr} = concentration in the control room
V_{cr} = volume of control room = 161,000 cubic feet
$x(t)$ = concentration outside the building
F = nonfiltered coefficient = 1.0
Q_{in} = flow coming into the control room = 1200 cfm
Q_{out} = flow going out of the control room = Q_{in}

Dispersion parameters utilized were from site data analyzed to obtain a direction dependent 0.5 percentile χ/Q. Values for σ_y were determined from the standard Pasquill-Gifford (P-G) curves with no credit allowed due to meander. Vertical dispersion parameters, σ_z, are based on curves developed for use in dispersion modelling in desert regimes and reflect the decreased vertical dispersion encountered in a desert climate.(29) The cloud and control room concentration time-histories are provided in figures 2.2-3a and 2.2-3b respectively. While the maximum concentration is greater than the toxic limit, there is more than 2 minutes between the odor

threshold of 17 ppm [30] and the toxic limit. This meets the Regulatory Guide 1.78 criteria for donning self-contained breathing apparatus.

Analysis of the potential effect of an LPG spill has been made by considering a vapor cloud made up of an instantaneous puff of the isenthalpic flash fraction. The cloud undergoes gravity-induced spreading analyzed by the Van Ulden Model[31] followed by normal Gaussian dispersion utilizing the same dispersion coefficients discussed above. With this model, the resulting vapor cloud would be a potential hazard at the plant only for the G stability class. For class F stability, the gas concentration decreased below the flammable limit prior to reaching the point where an explosion could damage the plant. Statistics[28],[32],[33] show that 48% of spills of flammable vapor are ignited at the accident site and are no hazard at 4.2 miles. The remaining 52% would form vapor clouds which could be blown toward the plant. Section 2.3 provides the probability of winds blowing toward the plant with G stability. Utilizing a 20% energy equivalent TNT yield, overpressure data from TM-5-1300[34] a nationwide loss of lading accident rate of 0.152×10^{-6} per mile[28] results in a probability of a peak incident overpressure in excess of 1 psi at the plant of 1.3×10^{-7}. This result is conservative since it assumes all 185 shipments of the flammable compressible gas to be LPG, a very limited vertical dispersion, no ignition until the cloud reaches its closest approach to the plant, the cloud ignites at this point with all ignitions leading to a 20% energy equivalent TNT detonation involving all vapor in the cloud. A

Table 2.2-3

TOXICITY LIMITS

Chemical	Toxic Limit[a] ppm	Remarks
Anhydrous ammonia	300[b]	
Propane	Simple asphyxiant[c]	No toxicity hazard
Butane	Simple asphyxiant[c]	No toxicity hazard
Butadiene	2000[b]	
Carbon dioxide	40,000[b]	
Hydrogen sulfide	100[b]	
Vinyl chloride	1000	
Chlorine	10[b]	
Sulfur Dioxide	100[b]	

a. From Regulatory Guide 1.78 unless otherwise indicated.

b. NUREG/CR-6624, Recommendations for Revision of Regulatory Guide 1.78.

c. TLV-STEL from "Threshold Limit Valves for Chemical Substances in Work Room Air Adopted by ACGIH for 1978."

realistic evaluation would lead to a significantly lower probability.

The frequency of a release that leads to a hazardous condition must be less than 10^{-6} times per reactor year to be probabilistically insignificant. This is consistent with NUREG-0800 and Reg Guide 1.91. The allowable number of shipments by rail for the probability to remain below 1.0 x 10^{-6} is significantly above the number of actual shipments.

2.2.3.1.4 Air Traffic

2.2.3.1.4.1 Airports. Airports in the vicinity of PVNGS are described in paragraph 2.2.1.2.4 and 2.2.2.2.4. As indicated, there are no major airports near the plant. Two small facilities occur at 11 and 16-mile distances from the plant. In addition, the APS private helipad is located on the plant site. The number of operations from these facilities and those from LAFB are compared with the Regulatory Guide 1.70 airport criteria in table 2.2-4. Annual operations at each facility are seen to be much less than the Regulatory Guide 1.70 criteria.

As indicated in paragraph 2.2.2.2.4.2, long-range regional government plans include expansion of operations at Buckeye Airport. This is a new plan and actual implementation is not certain. Buckeye Airport is not included in the Federal Aviation Administrations satellite airport development program.[35] Most growth is expected in local operations

NEARBY INDUSTRIAL, TRANSPORTATION,

AND MILITARY FACILITIES

Table 2.2-4

ANNUAL OPERATIONS AT NEARBY AIRPORTS

Airport	Closest Distance and Orientation between the Airport and PVNGS (mi)	1978 Estimated No. of Annual Operations	Regulatory Guide 1.70 Allowable Number of Operations[a]
Buckeye Municipal Airport	10.8	6,000	116,640
Pierce Airport	15.5 E	23,586	240,250
LAFB	32.8 ENE	100,000	1,075,840
APS Helipad	Onsite	1,000[b]	na

a. 500 d^2 for airports located between 5 and 10 miles.
1000 d^2 for airports located more than 10 miles.
d is distance from plant in miles

b. Estimated annual activity after PVNGS becomes operational.

(flights within 5 miles of the airport) which will not affect PVNGS.

2.2.3.1.4.2 Airways. The federal civil airways which pass within 2 miles of PVNGS and the closest military routes from LAFB are given in table 2.2-5. A study of the probability of potentially unacceptable impact from operations on these airways on the PVNGS units has been performed. This study is an update of the study[36] referenced in the PVNGS PSAR. The basic methodology has been retained with various parameters updated to reflect current conditions.

In general, the probability of impact is given by:[37]

$$P = \sum_{i=I}^{I} \sum_{j=I}^{J} N_{ij} C_i A_i f_{ij}(x)$$

where:

P = Annual probability of unacceptable impact per year

N_{ij} = Annual operation of aircraft of type i along airway or from airport j per year

C_i = Crash rate for aircraft of type i per mile

A_i = Effective impact area for each unit for aircraft of type i, square mile

$f_{ij}(x)$ = Aircraft lateral crash density at plant site for aircraft of type i operating along airway or from airport j per mile

The values of various parameters used in the analysis are included in table 2.2-5 and the basis of their determination are discussed in the following paragraphs. As indicated above, the methodology is as described in reference 36.

The annual number of operations is taken from information in paragraph 2.2.2.2.3.

The crash rates used are based on National Transportation Safety Board (NTSB) crash data and FAA flight data. Accident rates which might cause significant damage are based on historical records of crashes which resulted in fatalities. Non-fatal accidents are not considered severe enough to cause significant damage to the plant structures. In-flight or enroute fatal crash rates are used since the plant is more than 5 miles from the nearest airport.

For all general aviation operations, the NTSB[(38)] reported a fatal crash rate of 1.82×10^{-5} per hour. Of these, approximately 67% were enroute. Using an average speed estimated from FAA data,[(39)] the resulting fatal in-flight crash rate is 9.8×10^{-8} crashes/flight mile.

For U.S. certified route and supplemental air carriers, there were eight fatal in-flight crashes in the years 1972-1977.[(40),(41)] During this time, 15.28×10^{9} miles were flown by these air carriers.[(41)] The resultant crash rate is 5.9×10^{-10} crashes/flight mile. Crash statistics on military aircraft are difficult to obtain, and they would not be directly useful since total domestic miles flown do not even appear to be tabulated. It is expected that military experience should fall

Table 2.2-5

AIRCRAFT IMPACT EVALUATION

Airway	Distance to Nearest Safety Related Structure (mi)	Type of Operation	Number of Flights per year	Crash Rate (mi^{-1})	Effective Impact Area (mi^2)	Lateral Crash Density (mi^{-1})	Impact Probability (10^{-7}/yr)
V-16	4.5	AC[a]	27,740	5.9 X 10^{-10}	0.05	6 x 10^{-4}	0.005
		Mil[b]	5,110	1.2 x 10^{-8}	0.04	5.6 x 10^{-3}	0.14
		GA[c]	107,300	9.8 x 10^{-8}	0.01	1.2 x 10^{-4}	0.13
V-461	3.2	GA	100	9.8 x 10^{-8}	0.01	1.7 x 10^{-3}	0.002
J-65	4.5	AC	37,230	5.9 x 10^{-10}	0.05	6.0 x 10^{-4}	0.007
J-4	2.9	AC	37,230	5.9 x 10^{-10}	0.05	7.7 x 10^{-3}	0.085
Luke Departure	12.5	Mil	54,800	1.2 x 10^{-8}	0.04	1.9 x 10^{-6}	<0.001
IR218	12.6	Mil	180	1.2 x 10^{-8}	0.04	1.7 x 10^{-6}	<0.001
IR272	12.4	Mil	500	1.2 x 10^{-8}	0.04	2.1 x 10^{-6}	<0.001
PVNGS Approach/ Departure	0.13[f]	Privately owned heli-copter	1,000	4.9 x 10^{-7} [d]	----	7.5 x 10^{-5} [e]	0.37[f]
TOTAL							0.74

a. AC is air carrier

b. Mil is military

c. GA is general aviation

d. Crash rate per takeoff or landing operation.

e. Conditional probability of impacting any safety-related structure

f. The helipad was relocated in 2013 (see Figure 2.2-4 for new location). These values correspond to the original location of the helipad – southwest of the switchyard. The distance to the nearest safety related structure now exceeds 0.13 miles.

somewhere between the commercial crash rate and the 200 times higher general aviation total crash rate. Most general aviation crashes are caused by pilot error. Military pilots and commercial pilots have similar training which suggests a military crash rate close to the commercial experience. On the other hand, military crashes occur mainly in training, acrobatics, or low-level photographic missions. None of these activities occur on the departure route from LAFB. While they may be training flights, actual training operations occur in restricted air space or the military operations areas. Flights departing from LAFB are under IFR and their movements controlled by FAA air route traffic control center. Flights along V-16 are also IFR and mainly involve itinerant aircraft and not local-based training. For purposes of this analysis, we have, therefore, chosen the military crash rate to be 20 times the commercial crash rate or 1.2×10^{-8} crashes per flight mile.

Flights on low-level training routes IR-218 and IR-272 are quite infrequent and are not a significant contributor to overall impact probability.

The effective impact area is defined as that horizontal area which, if impacted by an aircraft, could lead to consequences in excess of the guidelines of 10CFR100. The area consists of the actual plan area of the target, a shadow area considering target height, and a skid area considering potential sliding into the target. For the updated study, the effective impact area is based on a single unit and considers self shielding by

other plant structures and by local site features such as railroad embankments. For air carrier and military operations, all plant safety-related structures were included. For general aviation operations, the containment was excluded since it would withstand the impact of the relatively light and slow general aviation aircraft.

The lateral crash density was calculated as in reference 36.

The parameters used to calculate impact probability are summarized in table 2.2-5, along with resultant probabilities. The total probability of potentially unacceptable impact is 7.4×10^{-8}.

2.2.3.1.5 Pipeline Transportation

Southern Pacific Pipeline operates a 12-inch pipeline that passes through the vicinity of PVNGS. The closest point lies 4.2 miles SSE from the nearest safety-related structure (see figure 2.2-1). The pipeline is at a lower elevation than the plant.

Based on the data supplied from the Office of General Superintendent of Operations of Southern Pacific Pipe, the products shipped via this pipeline are exclusively refined petroleum products such as gasoline, diesel fuel, and jet fuel. No flammable liquified compressed gases such as LNG or LPG are carried in this line section. Considering the distance involved, there is no credible explosive, flammable cloud, toxic gas, fire, or liquid spill hazards that would originate from this pipeline.

The El Paso Natural Gas Company pipelines are over 6 miles from the plant. At this distance, there is no flammable cloud hazard to the plant.

2.2.3.2 Effects of Design Basis Events

As discussed in the previous section, the nearby industrial, military, and transportation facilities present no hazard to the operation of PVNGS, and there are no site-related design basis events due to accidents at these facilities.

2.3 METEOROLOGY

This section provides a description of the meteorology and climatology of the Palo Verde Nuclear Generating Station (PVNGS) and surrounding area. The PVNGS site is located in southwestern Arizona, approximately 50 miles WSW of Phoenix (Sky Harbor International Airport). This section contains initial licensing information and is not expected to be routinely updated. Significant changes that could potentially affect the content of this section should be evaluated for inclusion as discussed in NEI 98-03, Guidelines for updating Final Safety Analysis Reports, Section A3.

2.3.1 REGIONAL CLIMATOLOGY

2.3.1.1 General Climate

PVNGS is located in southwest Arizona, a region characterized by a desert-type climate. This area, which is in the Inter-mountain Plateau Climatic zone, is in the driest region of the United States.(1) Typical characteristics of this large, arid region include abundant sunshine, infrequent precipitation, low relative humidities, large diurnal temperature ranges, moderate wind speeds, and an occasional intense summer thunderstorm.(2) The summers are hot and the winters are mild.

Table 2.3-1 presents the normals, means, and extremes of climatological data for the National Weather Service (NWS) station at Phoenix, Arizona - Sky Harbor International Airport, the most consistent record of offsite meteorological data representative of the PVNGS region.

Table 2.3-1

∅ Peak Gust observed during Airway observational program from January 1938 through October 1953; from recorder charts thereafter.
† Combined record from Post Office, August 1895 through October 1953, and from Sky Harbor Airport, November 1953 to date.
$ Broken record: 1940, 1941, and 1948 to date.
Means and extremes above are from existing and comparable exposures. Annual extremes have been exceeded at other sites in the locality as follows:
Highest temperature 118 in July 1958+; lowest temperature 16 in January 1913; maximum monthly precipitation 6.47 in July 1911; maximum precipitation in 24 hours 4.98 in July 1911; maximum monthly snowfall 1.0 in January 1937 and earlier; maximum snowfall in 24 hours 1.0 in January 1937 and earlier.

(a) Length of record, years, based on January data. Other months may be for more or fewer years if there have been breaks in the record.
(b) Climatological normals (1941-1970).
* Less than one half.
\+ Also on earlier dates, months, or years.
T Trace, an amount too small to measure.
\- Below zero temperatures are preceded by a minus sign.
‡ ≥ 70° at Alaskan stations.

The prevailing direction for wind in the Normals, Means, and Extremes table is from records through 1963.

Unless otherwise indicated, dimensional units used in this bulletin are: temperature in degrees F.; precipitation, including snowfall, in inches; wind movement in miles per hour; and relative humidity in percent. Heating degree day totals are the sums of negative departures of average daily temperatures from 65° F. Cooling degree day totals are the sums of positive departures of average daily temperatures from 65° F. Sleet was included in snowfall totals beginning with July 1948. The term "ice pellets" includes solid grains of ice (sleet) and particles consisting of snow pellets encased in a thin layer of ice. Heavy fog reduces visibility to 1/4 mile or less.

Sky cover is expressed in a range of 0 for no clouds or obscuring phenomena to 10 for complete sky cover. The number of clear days is based on average cloudiness 0-3, partly cloudy days 4-7, and cloudy days 8-10 tenths.

Solar radiation data are the averages of direct and diffuse radiation on a horizontal surface. The langley denotes one gram calorie per square centimeter.

& Figures instead of letters in a direction column indicate direction in tens of degrees from true North; i.e., 09 - East, 18 - South, 27 - West, 36 - North, and 00 - Calm. Resultant wind is the vector sum of wind directions and speeds divided by the number of observations. If figures appear in the direction column under "Fastest mile" the corresponding speeds are fastest observed 1-minute values.

** The National Weather Service considers the accuracy of solar radiation data questionable; therefore, publication is suspended pending determination of corrected values.

2.3.1.1.1 Types of Air Masses

The air masses that dominate the Arizona region are mostly continental in nature. Although the Rocky Mountains to the north normally prevent cold Canadian air masses from penetrating into Arizona in the winter, occasionally these air masses can influence the weather in the entire state. However, the cold air is somewhat modified if it reaches the central-southwest Arizona area. Air masses approaching from the Pacific Ocean are moist and mild initially on the west coast, but are substantially drier when they reach Arizona because of orographic effects when encountering the Sierra Nevada mountain ranges west of Arizona.[3] Moist, tropical air can penetrate into Arizona from the Gulf of Mexico southeast of the state, and more rarely from the southwest off the west coast of Mexico, providing the moisture sources for summer thundershowers and the heaviest precipitation episodes.[4]

2.3.1.1.2 Regional Synoptic Features

The primary synoptic features that influence the region are associated with the seasonal position and intensity of a semi-permanent ridge of high-pressure off the Pacific West Coast and a semi-permanent high-pressure cell protruding into the central part of the United States from the Atlantic Ocean in the summer season. Large-scale synoptic storms typically follow a path around the north side of the Pacific high-pressure ridge, entering the continent in northern Oregon and Washington and producing only partly cloudy and increased wind conditions in Arizona. Displacement of the ridge of Pacific high-pressure can cause the storm systems to move southward along the west

coast, often as far south as San Francisco before turning inland, rather than passing eastward through Oregon and Washington and bring precipitation to the Arizona region. Certain low-pressure systems have a tendency to stagnate and intensify off the California coast for several days before moving inland. These storms are fully developed by the time they reach Arizona and can bring intense precipitation.(3) On occasion, tropical air associated with dying tropical storms and hurricanes that originated off the west coast of Mexico penetrate the state from the Gulf of California and the Pacific Ocean. Once every 4 or 5 years, a tropical storm may cross into Arizona, accompanied by gale-force winds and flood-producing rains.(3)

2.3.1.1.3 General Airflow Patterns

Prevailing winds in the state are strongly influenced by the orientation of the mountain ranges and the local topography. Ordinarily, if no large-scale weather disturbances are present and the winds in the free atmosphere are light, local and mesoscale wind circulation patterns will dominate. In this situation, the surface wind will blow upslope or upvalley during the daytime, when the air overlying the slope is heated more rapidly than that at the same elevation over the valley. At night, rapid radiational cooling of the air overlying the mountain slopes compared to the slow cooling of the free atmosphere air over the valleys induces downslope or downvalley winds.

The primary station for data comparison with the PVNGS site, Phoenix, is located near the center of the Salt River Valley, a

broad, relatively flat plain. The valley, in general, is characterized by light winds. Annually, predominant winds are from the east; however, during the spring months, prevailing winds are from the southwest and west associated with the passage of low-pressure systems. Throughout the year, there are periods, often several days in length, in which winds remain under 10 miles per hour. The annual mean wind speed at Phoenix-Sky Harbor International Airport is 6 mi/h. The prevailing direction is from the east.(2)

2.3.1.1.4 Temperature and Humidity

Average temperatures throughout the state are dependent on the elevation and latitude. Great extremes occur between day and night temperatures throughout Arizona. The daily range between maximum and minimum temperatures sometimes runs as high as 50F to 60F during drier portions of the year.(4) The warmest weather in Arizona usually occurs during the last week of June and the first 2 weeks in July.(3) The site area normally experiences temperatures above 100F in the mid-afternoon in the summer and experiences relatively mild winter temperatures. Harsher winter temperatures characterize the northern, more mountainous, portion of the state.

Based on the period 1941 to 1970, the normal maximum and minimum temperatures at Phoenix are 64.8F and 37.6F in January (the coldest month) and 104.8F and 77.5F in July (the warmest month). The annual mean temperature is 70.3F. The mean number of days per year with maximum temperatures of 90F and above is 165. The mean annual number of days with a minimum temperature

of 32F and below is 12. There has never been a below zero reading recorded in Phoenix.[2]

Seasonally, the highest relative humidity values in Arizona are observed in winter and the lowest values in summer, but when unusually moist tropical air enters the state from the Gulf of Mexico, high relative humidities can occur during July and August.[3] During the period late spring to fall, relative humidities of 10% or lower are recorded in the mid-afternoon in the southwestern desert regions.

At Phoenix, the lowest relative humidities are found in the afternoon hours, corresponding to the maximum daily temperature readings during that time. The highest relative humidities at Phoenix occur shortly before sunrise, corresponding with minimum temperature readings. The mean annual average humidity value at Phoenix is 36%, based on four observations per day.[2]

2.3.1.1.5 Precipitation

The state of Arizona normally experiences two "wet" seasons. The summer wet season occurs during July and August, which are the wettest months in all parts of Arizona. The winter wet season extends from November or December through the middle of March. The severity of a drought is difficult to assess in southwest Arizona because of already existing extreme dry conditions. May and June are the driest months, especially in the desert-type climate of the site region. The heavier summer precipitation is associated with thundershower activity induced primarily by a flow of moist tropical air from the Gulf of Mexico. Record precipitation amounts in the state have

occurred in August and September from tropical flows of moist air from the Gulf of California and Pacific Ocean associated with tropical depressions and hurricanes off the west coast of Mexico. Winter precipitation is generally widespread over the state and is normally of light or moderate intensity. Greater amounts occur in the higher latitudes, on exposed southwest slopes, and at higher elevations. Winter precipitation is heaviest when the middle latitude storm track is unusually far south, so that storms enter Arizona directly from the west or southwest after picking up considerable moisture from the Pacific Ocean. The mean number of days of precipitation of 0.01 inch or more at Phoenix is 34, based on 38 years of data. The normal annual rainfall at Phoenix is 7.05 inches.(2) Snow rarely falls on the desert floor in the site region, but when it does, the snow usually melts almost as soon as it contacts the ground. At Phoenix, trace amounts have been recorded in December to April, with 0.6 inch of snow the maximum monthly recorded amount.(2)

2.3.1.1.6 Relationships Between Synoptic and Local Meteorological Conditions

The topography of the region strongly influences the meteorological conditions and climate at specific locations within the state of Arizona. The general orientation of topographic features such as mountains with respect to the site of interest and the elevation and exposure of the site itself can result in local wind flows, precipitation amounts, and temperature patterns differing substantially from large synoptic-scale conditions. The effects of topography on

climatological conditions have been discussed in the preceding sections.

2.3.1.2 Regional Meteorological Conditions for Design and Operating Bases

2.3.1.2.1 Hurricanes

Most of the record summer rains in the past century in Arizona have been associated with tropical storms moving into the state from the Gulf of California or the Pacific Ocean.

These storms, which occur most frequently in late August and September, usually originate as hurricanes off the west coast of Mexico. As they move northward, they weaken considerably, sometimes to the point of dissipating completely; however, once every 4 or 5 years, a tropical storm may affect Arizona with gale-force winds and flood-producing rains.[3]

2.3.1.2.2 Tornadoes

In the period January 1950 through December 1977, a total of 23 tornadoes was reported and characterized by the National Severe Storms Forecast Center within a 50-nautical-mile radius of the PVNGS site. This is an average of 0.82 tornadoes per year within this radius.[5]

To derive an average tornado path area for tornadoes within a 50-nautical-mile radius of the site, all reported tornado path lengths and path widths were respectively ranked and the median path length and median path width were selected from the two groupings. Because of the sparsity of data, this approach was followed to include unpaired tornado path lengths and path

widths in the analysis. Multiplying the median path length (13 data points) and width (12 data points) results in a median tornado path area of 0.014 square nautical mile.

Based on methods outlined by Thom,[6] the probability of a tornado hitting a particular point within 50 nautical miles of the PVNGS site is 1.46×10^{-6} per year, or a recurrence interval of 6.85×10^{5} years. Analyses of tornado occurrences in the PVNGS site region indicate that the average individual path area of a tornado provided by Thom, 2.82 square miles, is not representative and is overly conservative for the site area. Therefore, the site-specific tornado path length and width data were used for the calculation of tornado occurrence probabilities.

Table 2.3-2

DESIGN BASIS TORNADO CHARACTERISTICS FOR THE PVNGS SITE

Region II Characteristics	Value
Maximum windspeed (mi/h)	300
Rotational speed (mi/h)	240
Maximum translational speed (mi/h)	60
Minimum translational speed (mi/h)	5
Radius of maximum rotational speed (feet)	150
Pressure drop (psi)	2.25
Rate of pressure drop (psi/s)	1.2

Of the total of 23 tornadoes reported within 50 nautical miles of the site, 18 occurred to the east (in the Phoenix area), while the remaining five occurred to the south and south-southwest of the site. No tornadoes were reported within 50 nautical miles northwest of the site region from 1950 to 1977. The spatial differences in the frequency of tornado sightings may possibly be attributed to the higher population density east of the site and sparsity of population elsewhere. The closest tornado touched down on October 18, 1971, 1340 MST, 12 nautical miles south-southwest of the PVNGS site. The tornado had a path length of 0.5 mile and a path width of 150 feet. No deaths or injuries were reported, and the tornado had a damage class designation of 4 ($5000 to $50,000). The tornado had a Fujita-Pearson scale estimate of 1, which indicates winds of 73-112 mi/h. The average Fujita-Pearson scale estimate of force for the tornado was also 1. The design basis tornado (DBT) for PVNGS is as provided in USNRC Regulatory Guide 1.76, Design Basis Tornadoes for Nuclear Power Plants, for Region II. The DBT characteristics are provided in table 2.3-2.

2.3.1.2.3 Extreme Winds

The extreme mile wind speed is defined as the 1-mile passage of wind with the highest speed for the day and includes all meteorological phenomena (extra tropical cyclones, thunderstorms, and tropical cyclones including hurricanes) except tornadoes. The highest such extreme wind speed predicted to occur at the PVNGS site once in 100 years has been calculated based on the statistical methodology of Brooks and Carruthers.[7] In this procedure, the reported annual fastest

mile wind speeds for Phoenix for the period January 1949 to December 1977 are corrected to a standard design level of 30 feet with the assumption that the vertical distribution of velocity is defined by the 1/7 power law.[8] The following relationship was then applied to the wind speed data:

$$u_n = \bar{u} + \frac{(u_k - \bar{u})\log_{10} n}{\log_{10} k} \qquad (1)$$

where:

u_n = extreme fastest mile wind speed, miles per hour

$\bar{u}$ = mean annual fastest mile wind speed, miles per hour

u_k = absolute maximum wind speed, miles per hour

n = recurrence interval of interest, year

k = data record length, year

The operating basis wind speed (100-year recurrence fastest mile wind) for the site region is calculated to be 105 miles per hour. Based on a gustiness factor of 1.3,[9],[10] the highest instantaneous gust expected once in 100 years is 138 miles per hour.

The fastest mile wind speed recorded at Phoenix during the 29-year period of record from January 1949 through December 1977 was 86 miles per hour (unadjusted for height) which occurred during a thunderstorm in July 1976.

2.3.1.2.4 Thunderstorms and Lightning

Widespread thundershower occurrence in Arizona is most frequent in the months of July to September. These thundershowers are most common and most intense over the mountainous sections of the state, where the combined effects of thermal heating and orographic uplift, as well as convergence of air on the windward side of mountain ranges, favor the formation of strong vertical air currents.(4) The mean annual number of days with thunderstorms is 23 for Phoenix, based on a 38-year period of record. The seasonal distribution of the mean number of thunderstorm days at Phoenix is shown in table 2.3-3.

Table 2.3-3 also provides estimates of seasonal and annual frequencies of cloud-to-ground lightning calculated based on the mean number of thunderstorm days at Phoenix.(2),(11) The site area averages three predicted strikes per square kilometer per year. A structure with the approximate dimensions of a PVNGS containment building will average approximately one strike every 6 years.

2.3.1.2.5 Hail, Freezing Rain, and Ice Pellets

Hail occurs in the site region primarily during the warmer half of the year, although its occurrence in winter is not unusual, particularly in southern Arizona.(3) One estimate of the annual mean number of days with hail in the region ranges between 2 and 4.(1) The most destructive hailstorm ever reported in Arizona hit the Phoenix area in the early afternoon of September 18, 1950. Within a period of less than 25 minutes, this storm, accompanied by heavy rain and winds,

caused almost 1.75 million dollars worth of damage ($680,000 by hail, $554,000 by wind, and $510,000 by rain). From the period of 1950 to 1972, property and crop losses due to hail have amounted to more than 4 million dollars.(3) During the period of January 1973 to September 1978, one instance of golf ball size hail was reported during a severe thunderstorm about 15 miles south of Sky Harbor International Airport on July 26, 1978. This storm was also responsible for the record highest wind speed (86 mi/h) at the airport. An additional storm, occurring near Stanton (25 miles north of the PVNGS site) on September 2, 1965, had hailstones with diameters up to 1-1/2 inches.(12)

Table 2.3-3

SEASONAL AND ANNUAL FREQUENCIES OF THUNDERSTORM DAYS
AND PREDICTED CLOUD-TO-GROUND LIGHTNING FLASHES
IN THE VICINITY OF THE PVNGS SITE

Season	Thunderstorm Days	Predicted Number of Cloud-to-Ground Lightning Flashes Per Square Kilometer
Winter (December to February)	2	<1
Spring (March to May)	3	<1
Summer (June to August)	14	2
Fall (September to November)	4	<1
Annual	23	3

The mean annual number of days with glaze (freezing rain) and ice pellets in the region is less than one.[1]

2.3.1.2.6 Dust and Sand Storms

Historical dust storm data for the PVNGS site area were determined from long-term records at Phoenix (1956 to 1978).[13] Characteristic of these storms are high winds, reduced visibilities, and increased particulate loading. Dust storms are generally associated with the decaying stages of thunderstorms. The blowing dust is due primarily to wind direction shifts and high wind speeds generated by cold air downdrafts from the thunderstorms. The NWS differentiates between a dust storm, associated with poor visibility (generally less than 1/2 mile) arising from a high concentration of airborne dust, and blowing dust, which has less severe visibility reductions. Phoenix averaged nearly four dust storms and over three blowing dust events per year during the 1956 to 1978 period. The storms occurred primarily in the summer months, with 79% occurring during July and August -- the peak months of the thunderstorm season in the Phoenix area. The average duration of dust storms was 48 minutes with a maximum duration of 4 hours.[13]

In order to more explicitly characterize dust storms in the immediate PVNGS site area, a monitoring program was conducted at the site. The program was designed to measure total suspended particulate concentration and its size distribution during dust storms. Measurements were made at 10, 40, and 75

feet above ground level. The major conclusions of the study were:

A. Dust storms are short duration events characterized by extremely high particulate concentrations. Short term particulate concentrations in excess of 100 milligrams per cubic meter can occur. No apparent variation of mass loading with height was observed.

B. The size distribution of dust storm particulates is greatly biased towards the 20- to 100-micron range. Approximately 60% of the total particulate concentration was in the 20- to 53-micron range and approximately 22% in the 53- to 106-micron range.

C. The mass loading during nondust storm conditions was very low in comparison to dust storm events. A geometric mean of 61.3 micrograms per cubic meter was observed during the season of study (June 9 to September 8, 1978). Because higher particulate concentrations are normally measured during summer conditions, a lower annual geometric mean would be expected. A decrease in small-sized particulates concentration with height was also observed for nondust storm days.

A more detailed discussion of the program, its results, and general dust storm characteristics based on long-term data from Phoenix is provided in reference 13. A more recent study was conducted to update dust concentration for Palo Verde. This study, 13-MS-A44, titled "Dust Concentration Evaluation for Palo Verde Nuclear Generating Station Units 1, 2, and 3," is

based on a comprehensive data base comprised of 41 years of dust storm weather data, and complements the earlier study in reference 13. For Palo Verde, an average design loading of 1.78 mg/m^3 is used, which is based on an average maximum dust concentration for a 30 day period. This value is derived from the aforementioned data base and is described in detail in reference 29. Refer to sections 6.4 and 9.4 for a discussion of dust loading on HVAC filter systems.

2.3.1.2.7 Snowload

Because of the lack of measurable snowfall in this section of the state, the extreme winter precipitation load (snowload) considered in the design of safety-related plant structures is only 10 pounds per square foot. The normal winter precipitation load used for design (100 year return snowpack) is 5 pounds per square foot.[(10),(14)]

2.3.1.2.8 High Air Pollution Potential

The frequency of low-level inversions is an important consideration in determining the dispersion capability of the atmosphere. The occurrence of low-level inversions or isothermal layers based at or below a 500-foot elevation in the site region is approximately 45% of the total hours on an annual basis. Seasonally, the greatest frequency of inversions, based on percent of total hours, occur during the winter and is approximately 57%. The summer has the lowest inversion frequency, occurring approximately 35% of the time. The majority of these inversions are nocturnal in nature.[(15)]

The mixing height, defined as "the height above the surface through which relatively vigorous vertical mixing occurs,"[16] is also a consideration in determining the potential for the atmosphere to disperse pollutants. The average seasonal and annual mixing heights (based on morning and afternoon measurements) for the site region are as follows:

Mean Annual and Seasonal Mixing Heights for the PVNGS Site Area[16]

	Mixing Height (ft)
Winter	2625
Spring	4760
Summer	5740
Fall	3855
Annual	4245

2.3.1.2.9 Ultimate Heat Sink

The meteorological discussion concerning the ultimate heat sink performance evaluation is provided in subsection 9.2.5.

2.3.2 LOCAL METEOROLOGY

2.3.2.1 Normal and Extreme Values of Meteorological Parameters

Local meteorological data are based on offsite data from Phoenix, Luke Air Force Base, Gila Bend, Buckeye, and Litchfield Park, Arizona and data collected from the onsite meteorological measurements program (see subsection 2.3.3). Onsite data are available for the 5-year period August 13, 1973

through August 13, 1978. All references to onsite meteorological data are for this data period unless indicated otherwise. Offsite data are provided for a long-term period (5 years or greater) and, where appropriate, concurrent with onsite data. Analysis of the data summaries in this section provides a determination of the representativeness of the onsite meteorological data for the 5-year period with respect to long-term conditions and local meteorological conditions (including atmospheric diffusion) expected at and in the vicinity of the PVNGS site.

Figure 2.3-1 indicates the location of the PVNGS site and the meteorological data collection stations used to assess the local meteorology. Table 2.3-4 more specifically provides the locations and a brief topographical description of the offsite meteorological stations.

2.3.2.1.1 Wind Direction and Speed

Onsite monthly and annual wind roses for the 35-foot and 200-foot levels are presented in figures 2.3-2 through 2.3-6 for the 5-year period August 13, 1973 to August 13, 1978. Wind roses are provided monthly for the 5 years combined, as well as annually for each individual year and the 5-year summary. Wind direction distributions are similar for both levels on the tower and for all 5 years of data collection. Prevailing winds are from the southwesterly sectors on an annual basis and during the spring and summer months. During the fall and winter months, however, prevailing winds are from the east and northeast sectors.

Table 2.3-4

OFFSITE METEOROLOGICAL DATA COLLECTION STATIONS

USED TO ASSESS THE LOCAL METEOROLOGY

Station	Distance From Site (Miles)	Direction	Local Topography
Phoenix (Sky Harbor International Airport)	50	ENE	Flat; east-west valley
Luke Air Force Base	33	ENE	Flat; mountains immediately to the west
Gila Bend Airport	34	SSE	Flat; scattered hills in the area
Buckeye	18	E	Flat
Litchfield Park	32	ENE	Flat

Shown in figures 2.3-7 through 2.3-9 are monthly and annual wind roses for Phoenix for the same 5-year period as the onsite data. For comparison to the 5-year period of site data, annual 5-year wind roses for Phoenix (1960 to 1964), Gila Bend (1948 to 1953), and Luke AFB (1960 to 1964) are presented in figure 2.3-10.

Comparison of the wind roses for the various time periods and locations shows the topographic influences on predominant wind flows and the inherent differences in wind distributions between the recording stations. Prevailing winds at Phoenix are east and west along the axis of the valley in which the airport and city are situated. The effect of the north-south oriented White Tank Mountains, immediately to the west of Luke AFB, are evident with the north-south prevailing winds at that site. Gila Bend shows less topographic influences than the other offsite locations with prevailing southwest winds due to the predominant synoptic wind flows in the area. A secondary maximum at Gila Bend of winds from the southeast may be due to the mountain ranges to the south.

The 5 years of onsite wind data appear to provide representative wind direction data for long-term considerations for the site area. There are small deviations in predominant directional frequencies from year to year at both PVNGS and Phoenix for the 5-year period. Comparisons of the two 5-year periods at Phoenix (1960 to 1964 and August 1973 to August 1978) show little difference in the distributions.

Comparisons of onsite and Phoenix monthly and annual average wind speeds are presented in table 2.3-5. The average wind

speed at the 35-foot level for PVNGS was 6.4 miles per hour for the 5 years. The 200-foot level average wind speed was higher, as expected, 8.7 mi/h. The Phoenix concurrent 5-year average wind speeds are consistently higher than both the onsite 35-foot level wind speeds and the 29-year climatological average see table 2.3-1). Average wind speeds for Gila Bend, Phoenix, and Luke AFB for the 5-year periods presented in figure 2.3-10 are 7.7, 6.8, and 6.8 miles per hour, respectively. Data from all locations show the relatively low average windspeeds indicative of wind conditions in the Salt River Valley.

The frequency of calm winds is reported in the wind rose figures 2.3-2 through 2.3-10. The 5-year composite for PVNGS indicates 0.16% and 0.07% calms at 35 feet and 200 feet, respectively. All offsite data collection station summaries indicate a higher frequency of calms than the onsite data.

Luke AFB has an unrealistically high frequency of calms when compared with all the other meteorological stations. The difference in frequency of calms between PVNGS and the offsite stations is attributed primarily to differences in wind speed sensor thresholds and exposure (see subsection 2.3.3 regarding instrumentation specifications).

Wind direction persistence is defined as the number of consecutive hours of air flow within a 22-1/2 degree sector. Wind direction persistence summaries for the 5 years of onsite data are presented in table 2.3-6 for the 35-foot level and in table 2.3-7 for the 200-foot level. Concurrent data for Phoenix are not provided since persistence summaries are not

a. Number of observations = 41,978.

b. Equal to or greater than hours indicated.

meaningful unless consecutive, hourly data are used. Since 1965, only three-hourly (eight observations per day) observations from NWS data collection stations are achieved on magnetic tape. Because of the 5-year data period, the onsite summaries should be representative of expected long-term conditions at the site. Probability distributions of persistence periods for offsite data from Phoenix, Luke AFB, and Gila Bend for data periods prior to 1965 are provided in figure 2.3-11.

Wind direction persistence occurrences at the site of greater than 5 hours are mostly associated with winds from the east and southwest. The maximum wind direction persistence event at the 35-foot level for PVNGS during the period of record was 19 hours for a wind from the north-northwest. The maximum 200-foot wind persistence event was 18 hours for a wind from the west-northwest direction. The maximum event for offsite data was 16 hours from the east at Phoenix (1960 to 1964 data period).

The majority of persistence occurrences of calms at the 35-foot level at PVNGS has been limited to 3 hours or less in duration during the 5-year period.

2.3.2.1.2 Ambient and Dewpoint Temperature

Monthly means of temperature and dewpoint for PVNGS and Phoenix for each year of the August 13, 1973 through August 13, 1978 period are presented in table 2.3-8. Measurements made at Phoenix tend to average higher than the site for both dewpoint and ambient temperature, indicative of the effects of urbanization. Each of the 5 years at Phoenix had higher

average ambient temperatures than the climatological normal, 70F (30-year period, 1941 to 1970). Table 2.3-9 shows the monthly and annual means and extremes of temperature for the entire 5-year period at both PVNGS and Phoenix. Table 2.3-9 indicates a fairly good comparison between the two locations with some large differences in absolute minimum temperatures, which are expected due to differences in instrument exposure. The highest monthly mean temperature at PVNGS occurred in July (91F). The lowest monthly mean temperature at PVNGS occurred in January (52F). Tables 2.3-1 and 2.3-10 through 2.3-12[(2),(17),(18),(19)] present normals, means, and extremes of ambient temperature and other meteorological parameters at the offsite locations of Phoenix, Gila Bend, Buckeye, and Litchfield Park, Arizona. There is consistent agreement between the long-term data provided in these tables and the 5-year period of site and Phoenix data provided in table 2.3-9.

Monthly and annual summaries of dewpoint temperatures for the PVNGS site and Phoenix are provided in table 2.3-13 for the 5-year period of onsite data. The table shows that relatively low dewpoint temperatures occur at both sites which, when combined with the relatively high ambient temperatures shown in the preceding tables, is indicative of the low relative humidities associated with the general climate of the site area.

The annual diurnal pattern of ambient and dewpoint temperature at PVNGS for the 5 years is provided in table 2.3-14. It indicates that the warmest part of the day usually occurs between 3 p.m. and 6 p.m. MST; the coolest, just before sunrise, at about 6 a.m. to 7 a.m. MST.

2.3.2.1.3 Atmospheric Water Vapor

Monthly and annual means of relative humidity for PVNGS and Phoenix are presented in table 2.3-15 for each of the 5 years of onsite data. The PVNGS data are similar to the Phoenix summaries. Minimum relative humidities occur consistently in the summer months with maximums occurring in the winter.

The annual average diurnal variation of relative and absolute humidity at PVNGS is presented in table 2.3-16 for the 5 years. It indicates that the highest relative humidities occurred between 5 a.m. and 8 a.m. MST during the cool part of the day, and that the lowest relative humidities occurred generally during the warm part of the day.

Tables 2.3-1 and 2.3-10 through 2.3-12 provide long-term monthly means and diurnal variations of relative humidity for Phoenix, Gila Bend, Buckeye, and Litchfield Park, Arizona. These long-term means are similar to the 5-year values.

2.3.2.1.4 Precipitation

Monthly and annual extreme precipitation by time interval are presented in table 2.3-17 for PVNGS for the 5 years of onsite data. It indicates that, for the 5 years, the extreme 1-hour precipitation was 0.89 inch and occurred in August 1978. The extreme 24-hour precipitation was 1.95 inches and occurred in September 1974. During the 5-year period, there was only one hourly occurrence of precipitation when the ambient temperature was less than or equal to 32F. Additional information on rainfall rate distributions for PVNGS is presented on an annual basis in table 2.3-18.

In table 2.3-19, the extreme 24-hour precipitation for PVNGS is compared to Phoenix for the 5 years of onsite data collection. In table 2.3-20, the monthly and annual average total precipitation for the 5 years for PVNGS and Phoenix are compared. The PVNGS monthly precipitation patterns are generally consistent with Phoenix with the largest differences occurring during the summer months.

The long-term total precipitation values for offsite locations are presented in tables 2.3-1 and 2.3-10 through 2.3-12. Comparison with these tables shows that the first 4 years of site data were at or below normal for total precipitation while the 1977 to 1978 period was well above normal.

Monthly and annual precipitation wind roses for PVNGS (35-foot winds) are presented in figures 2.3-12 through 2.3-14 for the 5 years combined. These show the average speed by direction of winds during precipitation events and the percentage of total hours that precipitation occurs with each wind direction. Seasonal variations are apparent. On an annual basis, precipitation frequencies are greatest for winds from the easterly and southwesterly sectors and are least frequent for winds out of the west and northwesterly sectors. Concurrent precipitation wind roses from Phoenix are not provided since these data summaries, based on every third hour, would not be meaningful, especially in a desert climate where precipitation is very infrequent. The 5 years of onsite data should provide a representative data set.

2.3.2.1.5 Natural Fog

On the average, there is a low frequency of natural fog in the PVNGS site region. Phoenix averages only 2 days per year with heavy fog.[(2)] Because of the low number of occurrences, expected frequencies and durations are not discussed.

2.3.2.1.6 Atmospheric Stability

Site atmospheric stability is classified by the vertical temperature gradient, ΔT (200 feet - 35 feet), in accordance with the position in Regulatory Guide 1.23. The onsite monthly and annual distributions of atmospheric stability classes for PVNGS are presented in table 2.3-21 for the combined 5 years. Table 2.3-22 presents the annual distributions for each of the 5 years.

The data show that extremely stable conditions are generally the most frequent at PVNGS. There were 29.18% occurrences of the "G" category during the first year, 24.45% during the second year, 28.12% during the third year, 24.12% during the fourth data year, and 25.27% during the fifth data year. The average frequency for the 5 years combined is 26.29%. This unusually high frequency of "G" atmospheric stability is most prevalent in the fall and winter months and consistently occurs in each of the 5 years. Examination of hourly and summarized wind and ΔT data show that these conditions occur primarily with winds from the NNW clockwise through NE (the directions toward the higher terrain) with wind speeds at the 35-foot level less than 5 miles per hour.

a. Climatological normal precipitation (in inches) for Phoenix is 7.05.

Table 2.3-23 presents the diurnal distribution of atmospheric stability classes for PVNGS. The stable classes (E, F, and G) occur primarily during the nighttime hours, and the unstable classes (A, B, and C) occur during the daytime hours.
Table 2.3-24 presents, for each stability class, the number of occurrences of persistence for a specific hourly persistence period. The longest persistence period for extremely stable conditions (Class G) was 18 hours. The longest persistence period for stable (inversion) conditions (Classes E, F, and G) was 40 hours.

Seasonal frequencies of stability indices for Phoenix are given in table 2.3-25 for the 5-year periods August 13, 1973 to August 13, 1978 and January 1960 to December 1964. These stability data were classified according to the Pasquill-Turner[20] method. This method is an empirical approach and involves utilization of factors such as cloud cover, insolation, time of day, and wind speed to determine stability from data that are generally available at NWS observation stations.

Appendices 2B and 2C provide annual joint frequency distributions of wind speed and wind direction by atmospheric stability class for the 35-foot and 200-foot winds, respectively. Monthly joint frequency distributions are not provided since hourly data on magnetic tape are being provided.

2.3.2.2 Potential Influence of the Plant and Its Facilities on Local Meteorology

2.3.2.2.1 Cooling Tower Operation

The impacts on the local meteorology, which can result from the operation of the round mechanical draft cooling towers, include the formation of ground level fog, increased ground level temperature, increased ground level relative humidity, and elevated visible plumes. A computer analysis was performed to determine these expected atmospheric effects due to the operation of the cooling towers.[21]

The effect of an evaporative heat dissipation system on the formation of fogging conditions is determined by the quantity and location of added moisture, and on the existing ambient air conditions. The major factors of significance in determining the enhancement of fogging occurrences are the characteristics and quantity of effluent air, the height of the effluent plume rise, and the downwind dispersion of the effluent plume.

The fogging results were calculated based on a visibility criterion that a liquid water content of 1.2×10^{-5} pounds of liquid water per pound of dry air (0.015 gm H_2O/m^3 of dry air) would produce a visibility of 5/8 mile or less[22]. The predicted results show that the occurrence of reduced ground level visibility to less than 5/8 mile within 0.25 mile of the tower would occur for not more than 3 hours per year for any given direction. These predictions of insignificant fogging occurrences may be attributed to the arid climate of the site. Additionally, these predictions are consistent with the

experience of APS with operating cooling towers in the Phoenix area.

Potential horizontal and vertical icing conditions were not considered for the cooling towers at the PVNGS site. A day or more of subfreezing temperatures is necessary for any ice to accumulate to significant thicknesses. Therefore, since the maximum daily temperature in the site vicinity has never been reported below 32F[(2),(17),(18),(19)], no quantitative estimates were made of potential icing conditions.

The round mechanical draft towers for PVNGS are predicted to have a negligible effect on increased ground level temperature and relative humidity. The predicted maximum increased ground level temperature and relative humidity were less than 0.2F and 1%, respectively.

The maximum occurrence of elevated visible plumes within one-half mile of the towers is approximately 530 h/yr. Generally, visible plumes will dissipate rapidly as they are emitted from the towers due to the arid climate.

The initial momentum and buoyancy of the effluent from the cooling towers are expected to raise the vapor plume to a height of approximately 920 feet during the average winter morning. Neutral buoyancy height is about 630 feet. No major difference in plume rise was predicted between winter mornings and winter evenings. For all wind directions, a saturated plume extending through the maximum height of penetration was predicted.

During the average summer morning, a plume can penetrate through a height of approximately 1900 feet. Plume buoyancy

becomes neutral at a height of 1210 feet. No saturated plume was predicted for the average summertime condition.

The visible plume length is estimated to be 870 feet during the average winter morning and 784 feet during the average winter evening.

Under typical wind speeds, the plume height from the cooling tower system can be expected to exceed 410 feet for all seasons. The lowest plume rise is predicted under strong ground based inversion conditions during summer mornings.

The effect of wind speed on plume rise is pronounced. Very strong wind (on the order of 30 to 40 miles per hour at tower height) could limit the plume rise to less than 310 feet from the tower top.

In general, the effects on local meteorology due to the operation of the evaporative cooling systems at the PVNGS site are expected to be minimal.

2.3.2.2.2 Topographic Effects

The terrain in the region of the site is generally flat with an approximate elevation of 950 feet above mean sea level (msl). The Palo Verde Hills, a range of hills with a maximum elevation of 2172 feet above msl, are located approximately 5 miles to the west and north of the site. Scattered hills are in the area (approximately 2 miles from the site) with peak elevations of 1100 feet above msl. One effect on site meteorology results from the mountains to the north and the north-to-south downward sloping terrain. At night, when stable atmospheric conditions are prevalent at the site, drainage wind flows from the north

can occur. Figure 2.3-15 is a topographic map of the site area within a 5-mile radius and figure 2.3-1 is a topographic map of the site area within a 50-mile radius. Figures 2.3-16 through 2.3-23 are the topographic cross-sections of the site area, to distances of 10 miles. A more detailed site area map with buildings, site boundary, and meteorological tower location is provided in engineering drawings 13-C-ZVA-005 and 13-P-OOB-001.

2.3.2.3 Local Meteorological Conditions for Design and Operating Bases

Design bases meteorological parameters are discussed in chapter 3.

2.3.3 ONSITE METEOROLOGICAL MEASUREMENTS PROGRAMS

2.3.3.1 Meteorological Facility Operations

The onsite meteorological measurements program at PVNGS began on August 13, 1973. The system consists of the existing 200 foot tower with two trains of sensors, designated as Primary and Redundant. Additionally, housed in a climate controlled shelter adjacent to the base of the tower, are the related signal conditioning, digital processing, power, and communication systems. The meteorological measuring sensors and support hardware are located on the northwest portion of the site (Engineering drawings 13-C-ZVA-005 and 13-P-OOB-001).

Wind and temperature data are collected at the 35 foot and 200 foot levels of the tower. Precipitation data are obtained from a rain gauge near the base of the tower. Dewpoint data are collected at the 35 foot level.

Offsite PVNGS data summaries were obtained from the NWS station at Phoenix. All measurements reported for Phoenix were made at Sky Harbor International Airport. Temperature and humidity measurements at Phoenix were made at 5 feet above ground level (AGL). Precipitation measurements were at 3 feed AGL. Wind measurements were at 41 feet AGL until December 12, 1960, then 18 feed AGL until September 19, 1975, and at 36 feet (10 meters) through the present. The wind instrumentation consists of anemometers with starting threshold speed of approximately 1.1 miles per hour, higher than the instrumentation at the PVNGS site. The instrumentation at the NWS station at Phoenix is the standard instrumentation in use at most NWS stations throughout the United States. Similar wind instrumentation was in use at Luke AFB and Gila Bend.

Real time validation of digital meteorological data will identify suspect data so that backup data will be used based on data reasonability. This validation is carried out initially by computer software designed to extract and compare data and final validation is determined by the site meteorologist. Data Acquisition of the two independent meteorological system signals (primary and redundant) may be accomplished for projected dose calculations, visual displays, and remote data can achieve a high degree of reliability.

As of December, 1995, the primary data collection method makes use of four digital data processors. These devices store 15 minute averages of preconditioned meteorological data obtained from sensors mounted on the tower. In its original configurations, the digital system, which consisted of a single computer, was backed up with analog strip chart recorders.

With the quadruple digital processors and the ability to display data in chart format, the electromechanical chart recorders have been made obsolete and are no longer included in the design. The first year of data collection was reduced from the electromechanical strip chart recorders.

The environmental parameters monitored by the tower system permit highly accurate and reliable meteorological data necessary to cover all data for the Pasquill stability classes and transport projections needed for the PVNGS site. Analog sensor information for the tower system is converted to digital data and transmitted by two separate serial links to the Meteorological Data Transmission Station (MDTS) translator/server (DataLink). It is converted here to a form recognizable to the Emergency Response Facility Data Acquisition Display System (ERFDADS) server and is reduced to 15 minute and hourly averaged meteorological parameters. This data is in turn displayed on all ERFDADS terminals and made available for time-history displays in the control room, emergency response facilities, and at external locations.

Wind and temperature data are collected at the 35 foot and 200 foot levels of the tower. Precipitation data are obtained from a rain gauge near the base of the tower. Dewpoint data are collected at the 35 foot level.

The design includes four separate reliable digital processor systems, two that process and provide data directly to the Emergency Radiological Facility Data Acquisition System (ERFDADS) and two that are accessed by telephone. Each of the four digital processing systems receives the stores conditioned

data from a common bus and this data can be extracted manually at any time, providing multiple backup in the case of a single mode failure. Accumulated data is displayed and organized by means of personal computer supplied with commonly available data display software. This data is accessed either by telephone link, by ERFDADS display, or manually by control panel at the shelter.

The specifications of the equipment for the meteorological system, which complies with the intent of the position in Regulatory Guide 1.23 (Proposed) and Safety Guide 23, are provided in the technical manuals supplied with the sensing and data processing hardware. The PVNGS meteorological system satisfies requirements set forth in Regulatory Guide 1.97, Revision 2, and NUREGs-0654, 0696, 0737, and SECY-82-111.

Using the data supplied by the equipment manufacturers, the overall system accuracy from the sensors through the signal conditioners and digital processors may be calculated. Accuracy for instantaneous recorded values is calculated using the root sum squares of the accuracy of each component. Time averaged accuracy is computed by dividing the instantaneous accuracy by the square root of the number of samples taken per hour. Sampling rates for the digital system are one per 5 seconds for wind direction, wind speed, temperature, and dewpoint. These calculations indicate that the accuracy for time averaged values exceed the recommendations in Regulatory Guide 1.23.

The primary data collection method makes use of a digital data processor subsystem. This subsystem consists of four data

loggers, all ties to a common data bus where processed analog data is supplied by the tower signal processors. Two of these data loggers are configured to be accessed remotely via dialup modem, and the remaining two are directly connected via shorthaul modem to ERFDADS. In addition to data collection, the digital processing subsystem is designed to reduce the basic data.

Table 2.3-26

OVERALL SYSTEM ACCURACY

Parameter	Full Scale Accuracy (Instantaneous)	Full Scale Accuracy (Time Averaged)
Wind Direction, degrees (Full scale 0-540 degrees)	± 3.24	±.12
Windspeed, miles per hour (35 feet) (Full scale .70-50 MPH)	±.53	±.02
Windspeed, miles per hour (nominal 195 feet) (Full scale .70-100 MPH)	±.015 or ± 1%, whichever is greater	±.04
Temperature, degrees Fahrenheit (Full scale 0-120 Degrees F.)	±.24	±.01
Temperature, difference (first Delta T range only) degrees Fahrenheit	±.24	±.01
Dewpoint, degrees Fahrenheit (Full Scale −22 -+122 degrees F.)	±1.38	±.05

Datalogger-resident software to direct data acquisition and processing events is virtually the same in all four dataloggers. All four dataloggers may also be accessed by direct connection to a laptop or similar personal computer or

by use of a manual keypad. The system is configured in such a way that any one of either the dialup or ERFDADS may be off line for maintenance and the remaining dataloggers will be available to provide quasi-real-time or averaged data on demand.

The ERFDADS dedicated dataloggers supply data to a personal computer based translator/server located in the Technical Support Center computer room. This server makes simple decisions to provide the most reliable and seemingly accurate data prior to sending it to ERFDADS. For protection, the computer is housed in a standard nineteen inch equipment cabined located in the Technical Support Center computer room.

The dose projection models used for providing the estimates of offsite exposure are described in the PVNGS Emergency Plan.

2.3.3.2 Meteorological Data Reduction

The meteorological data acquisition system consists of a computerized data processing system which collects and reduces data on a real-time basis. The average wind direction, wind speed, temperature differential, ambient temperature and dewpoint are determined for four fifteen minute samples each hour by ERFDADS. The sampling rate for each parameter for each level is once per five seconds. These data and total precipitation are available for direct access and display from the digital processing sub-system via dialup link as fifteen minute averages, as well as quasi real-time in engineering units or a graphical display.

2.3.3.3 Quality Assurance Procedures

The meteorological data collection program at PVNGS is subject to detailed APS quality assurance and quality control procedures.

The procedures involve daily examinations by a meteorologist of the digitally reduced data, redundant data storage to mitigate data losses, detailed records keeping (data corrections, calculations, etc.), site specific work plans, and internal audits.

Calibrations of the meteorological system are subject to the APS quality assurance program.

2.3.3.4 Meteorological Data Recovery

The meteorological data recovery rates for the PVNGS meteorological program (August 13, 1973 to August 13, 1978) are listed in table 2.3-27.

The data recovery for wind data at the 10 meter level and 60 meter level was 97% and 94%, respectively, for the report period.

Data recovery of the Dewpoint temperature was 94%. The data recovery for Delta temperatures was 94%. Since the initial fuel load in Unit one, data recovery rates have exceeded 90%. In contrast, since the replacement of the digital data processing subsystem in December, 1995, the data recovery rate for all parameters has been 100%.

Most of the data losses on the system are due to sensor malfunctions and calibrations. Other than sensor problems,

periods of data loss on the digital system were due primarily to data transmission and computer malfunctions. Losses due to recorder malfunctions were rare with the analog system, but became significant as the system aged. The analog strip chart recorders are no longer part of the design, having been replaced with a redundant digital system.

Calibration and maintenance of the PVNGS meteorological system are conducted at scheduled intervals according to written procedures. Maintenance trips are made as required. Equipment surveillance and routine maintenance are being performed according to established checklist and procedures by PVNGS technical personnel in order to maintain maximum data recovery.

2.3.4 SHORT-TERM (ACCIDENT) DIFFUSION ESTIMATES

2.3.4.1 Objective

Onsite data for the period 1986 through 1991 have been used to evaluate the accident meteorology for the site. Accidents are postulated to characterize upper limit concentrations and dosages that might occur in the event of plant releases. Among the basic inputs to the accident analysis are the meteorological conditions, which determine the atmospheric transport and dispersion of radioactive plumes.

2.3.4.2 Calculations

Dilution factors (χ/Q) were determined using the methodology presented in Regulatory Guide 1.145[23] using dispersion coefficients for desert regime[24] and computer code AZAP[28].

Table 2.3-27

METEOROLOGICAL DATA RECOVERY AT PVNGS (PERCENT)

(AUGUST 13, 1973, TO AUGUST 13, 1978)

Annual	94	97	94	93	94	94

χ/Q values were calculated at the exclusion area boundary (EAB) and at the outer boundary of the low population zone (LPZ). Table 2.3-30 presents the minimum distances to the EAB and LPZ for each sector (conservatively measured as the shortest distance between the outer edge of the reactor containment building and the boundary within a 45° direction sector centered on the direction of interest[23]. The χ/Q values applicable for release duration less than or equal to 2 hours were calculated at the EAB distances using the joint frequency distributions of wind speed and wind direction by atmospheric stability class. Winds were determined at the 35-foot level and the stability class was based on the vertical temperature gradient between the 35- and 200-foot levels, Delta-T (200 – 35 feet), based on the position in Regulatory Guide 1.23.

The short term χ/Q is defined as the site boundary χ/Q that will not be exceeded more than 5% of the time. The following equations are utilized to develop the probability distribution for each sector:

$$\frac{\overline{\chi}}{Q}(x, i, j) = \left\{u_i\left[\pi\sigma_{yj}(x)\sigma_{zj}(x) + CA\right]\right\}^{-1} \tag{1}$$

and

$$\frac{\overline{\chi}}{Q}(x, i, j) = \left\{3u_i\pi\sigma_{yj}(x)\sigma_{zj}(x)\right\}^{-1} \tag{2}$$

Table 2.3-30

a. Distances used for X/Q calculation are minimum distances from the surface of the three containment buildings within 45° sectors centered on each compass direction.

where:

$\chi/Q\ (x,i,j)$ = average effluent concentration normalized by source strength at distance x for i-th wind-speed category and j-th stability category (second/cubic meter).

X = shortest distance to the site boundary in a 45° sector (meters)

u_1 = the upper limit of the i-th wind-speed class (meters/second)

σ_{yj} = the lateral plume spread for stability class j at distance x (meters).

σ_{zj} = the Vertical plume spread for stability class j at distance x (meters).

A = minimum cross-sectional area of the building used to describe dilution due to the building wake (square meters).

C = mixing volume coefficient (shape factor) in the building-wake term.

The larger of the two values is selected for each combination of wind speed and stability class. Regulatory Guide 1.145 has a third equation incorporating a meander factor to account for the movement of the plume within the sector. Because desert χ/Q's are based on long term measurements, meander is already accounted for and, therefore, only the two equations above are used.

The χ/Q at the EAB, which is used to determine accident consequences during the first two hours of an accident, is the five percentile χ/Q, i.e., the χ/Q that will not be exceeded more than 5% of the time. To determine the 5% χ/Q, each direction sector is investigated separately. The χ/Q for each combination of stability and wind speed class is calculated, and arranged in descending order. A cumulative probability distribution for each sector is created by summing the frequencies of ordered χ/Q. The 5% χ/Q is identified by drawing a curve through the probability distribution. In addition, as discussed in Regulatory Guide 1.145, an overall 5th percentile χ/Q value was calculated at the EAB. The computation consists of determining the χ/Q values for each of the sectors and distance of interest and ordering these values without regard to the sector. The 5th percentile value (based on total observations) was then selected and was shown not to exceed the highest sector χ/Q value. The two hour χ/Q is the largest sector 5% χ/Q.

The χ/Q for time periods longer than two hours are based on values at the outer boundary of the LPZ. First, the two-hour value for each sector is determined as described above. Then the annual average χ/Q is determined for the sector using the methodology in Reg Guide 1.111. The χ/Q for any time is then determined by logarithmic interpolation between the two hour and one year (8760 hour) χ/Q. The sector with the largest value is selected to represent the site.

The calculation of χ/Q involves the determination of horizontal and vertical dispersion parameters (σ_y and σ_z). PVNGS is

committed to using the desert sigmas that characterizes arid regimes as developed in Reference 24 and 25.

Table 2.3-31 presents χ/Q values at the EAB and LPZ distances for the periods of interest for the period 1986 through 1991.

2.3.5 LONG-TERM DIFFUSION ESTIMATES

2.3.5.1 Objective

Onsite emteorological data for the period 1986 to 1991 were used to determine the long-term diffusion estimates for the area. The atmospheric dilution factors (χ/Q) were determined for the site boundary and for distances out to 50 miles from the containment structures. A set of distances by sector direction from the containment was developed for the analysis by determining the shortest distance to the site boundary from the closest edge of the containment in each sector. These distances are presented in table 2.3-32.

2.3.5.2 Calculations

Long term atmospheric dispersion factors or annual dispersion factors are used in determation of offsite dose design calculation due to long-term annual releases of radionuclides in gaseous effluents. PVNGS's annual average χ/Q values are determined following guidance given in SRP 2.3.5 to NUREG-75/087 and Regulatory Guide 1.111. Regulatory Guide 1.111 indicates that the χ/Q values must be related to measured meteorological parameters and extend from the site boundary to a radius of 50 miles from the plant for the 16 radial direction sectors. Site topography or unusual meteorological conditions

a. Based on 22-1/2° sectors.

b. Distance is based on Exclusion Area Boundary (EAB).

which could influence the effluent trajectories are to be accounted for. Site topography influences are addressed in the analysis via the use of terrain correction factors (Reference 27). Terrain correction factors are presented in Table 2.3-33 Influences on long-term meteorology around the PVNGS site due to the desert regime are addressed with the use of desert sigmas for lateral and vertical dispersion coefficients in the equations used to calculate χ/Q.

Site Boundary Distances for Long Term χ/Q Determination

The site boundary distances used in long-term χ/Q determination within each of the 16 direction sectors are the minimum distances between the nearest point on the outer surface of the containment building under consideration and the closest point on the site boundary within a 22.5° sector, centered on the compass direction of interest. Direction sectors are defined using the center point of the containment under consideration as the origin. Overall minimum site boundary sector dependent distances are the smallest of the minimum sector distances determined for the 3 PVNGS units.

Equation Used for Long Term χ/Q Determination

The Regulatory Guide 1.111 equations are used to determine long-term χ/Q values (the constant mean wind direction model). χ/Q values are determined for a continuous ground level release assumed to be distributed over a 22.5°sector. Following equations are used:

$$\frac{\overline{\chi}}{Q}(x, k) = \frac{2.032}{x} RF(x, k) \sum_{i,j}^{N,7} \frac{DEPL_{ij}(x, k) \times DEC_i(x) \times f_{ij}(k)}{\overline{U}_i \sqrt{\left(\sigma_{zj}^2(x) + cD_z^2 / \pi\right)}} \qquad (3)$$

$$\frac{\overline{\chi}}{Q}(x, k) = \frac{2.032}{x} RF(x, k) \sum_{i,j}^{N,7} \frac{DEPL_{ij}(x, k) \times DEC_i(x) \times f_{ij}(k)}{\sqrt{3}\,\overline{U}_i \sigma_{zj}(x)} \qquad (4)$$

where:

χ/Q (x, k) = average effluent concentration (sec/m3) normalized by source strength at distance x in wind directional sector k.

x = downwind distance (meters)

i = The i(th) wind speed class

j = The j(th) atmospheric stability class, grouped into seven classes according to Regulatory Guide 1.23

k = k(th) wind direction sector

U_i = mid point value of the i(th) wind-speed class (meter/second)

σ_{zj} = the vertical plume spread for stability class j at distance x (meter)

$DEPL_{ij}$ (x, K) = plume depletion reduction factor at distance x for the i(th) wind speed class, the j(th) stability class, and k(th) wind direction sector.

DEC_i(x) = radiodecay reduction factor at distance x for the i(th) wind speed class. Radiodecay is based on a half-life of 2.26 days per Regulatory Guide 1.111.

RF (x, k) = Terrain Adjustment Factor at downwind distance x and k(th) wind direction sector.

F_{ij} (k) = joint probability of occurrence of the i(th) wind speed class, j(th) stability class, and K(th) wind direction sector.

c = mixing volume coefficient (shape factor) in the building-wake term

D_z = building height (meters) used to compute additional atmospheric dispersion due to the building wake. For the PVNGS analysis

Dz = 58 meters (the containment building height).

Equation (4) represents the maximum additional atmospheric dispersion due to the building wake. The results of both equations are compared and the largest (most conservative) value is used. In this analysis credit is not taken for depletion, gravitational settling or dry deposition.

2.4 HYDROLOGIC ENGINEERING

This section contains initial licensing information and is not expected to be routinely updated. Significant changes that could potentially affect the content of this section should be evaluated for inclusion as discussed in NEI 98-03, Guidelines for updating Final Safety Analysis Report, Section A3.

2.4.1 HYDROLOGIC DESCRIPTION

2.4.1.1 Site and Facilities

The site is located west of Phoenix in a dry, desert region adjacent to the Palo Verde Hills. The terrain has very little topographic relief and slopes gently southward. Hydrologic features of significance to the site are indicated in figure 2.4-1. Proposed changes to natural drainage features and site facilities of hydrologic significance are indicated in figure 2.4-2.

Permanent access to the site is from the existing Buckeye-Salome Road which passes within 2 miles of the northern site boundary. Access among the units is by means of onsite roads and railroad spurs. Access into Seismic Category I structures is located above grade so that safety-related facilities are protected from any possibility of flooding.

Major structures and site facilities are protected from off-site floods by their locations, as shown in figure 2.4-2. A minor existing drainage course (East Wash) has been realigned to a new drainage ditch along the east side of the site. Flood calculations performed in this study for the East Wash are based upon the realigned channel.

2.4.1.2 Hydrosphere

The site is on a desert valley plain near a ridge separating the drainage basins of the Hassayampa River and Centennial Wash. Both are ephemeral desert streams which flow only with rainfall runoff. These streams are tributaries of the Gila River, which drains most of the southern half of Arizona. Other local water courses include Winters Wash and a wash draining a narrow strip extending a few miles north of the plant site, which is named East Wash for convenience. These water courses are also ephemeral. Figure 2.4-1 shows the locations of rivers and washes relative to the site.

There are no dams on East Wash, Winters Wash, or the Hassayampa River. There are several small detention dams on Centennial Wash, the largest being a low earthfill dam about 45 miles upstream from the site, which has a capacity of about 100 acre-feet. There are several large water-storage dams on the Gila River system upstream from the site. The locations of these dams are shown in figure 2.4-3. Data on these dams are presented in table 2.4-1 and paragraph 2.4.4.1.

Other dams on the Gila River system are the following:[(1),(2),(3)]

A. Sonoita Creek Dam on Sonoita Creek, a tributary of the Santa Cruz River, stores less than 10,000 acre-feet of water and is more than 200 miles upstream from the plant site.

B. Granite Reef Dam on the Salt River at the eastern end of the Salt River Valley is approximately 63 miles from the site and is a diversion dam with no storage capacity.

C. Ashurst-Hayden Dam on the Gila River, at the eastern end of the Gila River Valley, is a diversion dam with no storage capacity.

D. Sacaton Dam on the Gila River, near the town of Sacaton on the Gila River Indian Reservation, is a diversion dam no longer useful because the river has been mostly dry for many years

E. Gillespie Dam on the Gila River is about 4.5 miles downstream from the point on the river nearest the site, and is a diversion dam now filled with stream sediment.

F. Painted Rock Dam is a flood control dam on the Gila River about 40 miles downstream from Gillespie Dam. When the Painted Rock Reservoir is full, the tail water would not reach the foot of the Gillespie Dam.

   The Painted Rock Dam is earth filled to a height of 181 feet and crest length of 4780 feet, forming a reservoir with a capacity of 2,493,000 acre-feet, including 200,000 acre-feet for sedimentation.

Surface water diversion downstream from the site occurs at Gillespie Dam, where water from irrigation is diverted into the Enterprise Canal and Gila Bend Canal. Because of the poor quality of water in the canals, there is little direct diversion of canal water for irrigation.

A review of the files of the Arizona State Land Department, Water Rights Division, indicates that there are four diverters of surface water from the Gila River located south of the confluence with Centennial Wash.

This page has been redacted.

These rights are located on the Gila River between Gillespie Dam (sec. 28, T.2 S, R.5 W.) and Painted Rock Dam (sec. 18 and 19, T.4 S, R.7 W.).

Application No. A-1920, Permit 1227, Certificate 1824, was issued to A. E. Pettit for 5 million gallons per year for stock watering and for 2400 acre-feet per year for irrigation (on the basis of 3.75 acre-feet per year for 640 acres). The place of use is E1/2 sec. 23, NE1/4 and E1/2NW1/4 sec. 26, and W1/2NW1/4 sec. 25, all in T.4 S., R.8 W. The priority date is June 17, 1938.

Application No. A-2608, Permit 1866, was issued to S. L. and Alice Narramore and W. 0. and Eliza Narramore for 3729 acre-feet/per year for irrigation (on the basis of 6 acre-feet per year for 620 acres). The place of use is N1/2NW NE and NW and S1/2NW sec. 3; W1/2NW sec. 4; N1/2 sec. 5; and S1/2NE sec. 12, all in T.5 S., R.6 W. The priority date is March 16, 1943.

Application No. A-4940 was made by Floyd R., Roy D., and Russell L. Pierpont for 618,950 gallons per year for domestic use; for 2,519,500 gallons per year for stock watering; and for 18,700 acre-feet per year for irrigation (on the basis of 10 acre-feet per year for 1870 acres). Place of use is in numerous locations in T.4 S., R.4 W., and T.5 S., R.4 W. This application is presently under protest by S. L. Narramore and others.

Application No. A-5008, Permit 3288, was issued to Minnesota Title Co., as trustee for Litchfield Park Development Co., for 6300 acre-feet per year for irrigation (on the basis of 5 acre-feet per year for 1260 acres). The place of use is in various

locations in secs. 1, 2, 11, 12, and 18, T.3 S., R.5 W. The priority date of this permit is December 18, 1972.

The list includes those surface water users who have applied for permits since June 12, 1919. Prior to this date, no permit was required for withdrawal of surface water from rivers in Arizona. On August 9, 1974, the State of Arizona passed legislation requiring all diverters of surface water in Arizona to apply for a permit within 3 years of passage of the law. There are no other recorded users of surface water from the Gila River, from the confluence of Centennial Wash south to Painted Rock Dam.

Although these water users have been listed, PVNGS will not affect any of them adversely. There will be no routine liquid releases to contaminate the surface water and the analysis discussed in paragraph 2.4.13.3 shows that there will be no contamination of the groundwater offsite due to an accidental release (refer to paragraph 2.4.13.2 for information on groundwater users in the vicinity of the site).

2.4.2 FLOODS

2.4.2.1 Flood History

The U.S. Geological Survey (USGS) operates a water-stage recorder on Centennial Wash that gauges the runoff from 1810 square miles, and a flood hydrographic recorder on Winters Wash that gauges the runoff from 47.8 square miles. The Centennial Wash gauge is located at latitude 33°16'12", longitude 112°47'50", in sec. 7, T.2 S., R.5 W., Maricopa County, on the upstream side of the ford on former U.S. Highway 80, 3 miles upstream from Gillespie Dam and 4.4 miles

southwest of Arlington. The gauge datum is 773.22 feet above msl (Arizona Highway Department bench mark), obtained by use of a water-stage recorder. The base discharge is 1000 cubic feet per second, with the flow regulated by several small detention dams.

The Winters Wash gauge is located at latitude 33°29'22", longitude 112°55'05", in SW1/4NW1/4 sec. 3.0, T.2 N., R.6 W, Maricopa County, on the right bank 0.3 mile downstream from Airline Road and 1 mile east of Tonopah. The altitude of the gauge, a flood-hydrograph recorder, is 1080 feet. The base discharge is 100 cubic feet per second, with neither storage nor diversion above the station.

For the period of record (water years 1961 to 1977), maximum recorded discharge in Centennial Wash was 14,500 cubic feet per second on July 23, 1961. Maximum recorded discharge in Winters Wash for the period of record (water years 1962 to 1977) was 3640 cubic feet per second on September 25, 1976. Tables 2.4-2 and 2.4-3 give the peak discharges recorded for Centennial Wash and Winters Wash, respectively.(1),(2)

Maximum recorded discharge of the Hassayampa River, as recorded by a crest-stage recorder located near Morristown, Arizona (which gauges the runoff from 774 square miles), was 47,500 cubic feet per second on September 5, 1970. The period of record for the gauge near Morristown includes the water years 1939 to 1947, 1954, 1956, and 1964 to 1977. Table 2.4-4 gives the peak discharges recorded for the Hassayampa River at Morristown.(1),(2)

The crest-stage recorder for the Hassayampa River is located at latitude 33°53'06", longitude 112°39'41", in SW1/4SE1/4 sec. 3, T. 6N, R. 4W.; Maricopa County, on left bank 600 feet downstream from San Domingo Wash, 3 miles northwest of Morristown, and 7 miles southeast of Wickenburg. The datum of the gauge is 1831.16 feet above msl. From October 1938 to June 1947, data is from the water-stage recorder; from June 1947 to November 1963, there is miscellaneous data only. The base discharge is 1100 cubic feet per second. There are annual peaks for 1947 and 1964 through 1965 only.

Maximum observed discharge of the Gila River, at the USGS gauging station below Gillespie Dam (which gauges the runoff from 49,650 square miles), was 85,000 cubic feet per second on December 28, 1923. The period of record for the Gillespie Dam gauge includes the water years 1921 to 1977. (A maximum discharge of 250,000 cubic feet per second was estimated to have occurred in February 1891 at the Gillespie damsite.) A provisional value of 12,000 cubic feet per second has been established for the maximum discharge observed on December 20, 1978.(4) Table 2.4-5 shows the peak discharges recorded for the Gila River below Gillespie Dam.(1),(2) The gauge, a water-stage recorder since July 28, 1924, is located at latitude 33°13'45", longitude 112°46'00", in SE1/2NE1/4 sec. 28, T.2 S., R.5 W., Maricopa County, Hydrologic Unit 15070101, at the left end of the Gillespie Dam, 8 miles (13 km) downstream from the Hassayampa River. The datum of the gauge is 9.95 feet below the average elevation of the crest of the dam, which is 753.46 feet above msl. Prior to November 11, 1924, the depth of water was read on the crest at the left end of the

dam. From November 11, 1924, to July 22, 1932, the datum of gauge was at the average elevation of the dam crest. From July 23, 1932 to April 27, 1955, the datum of the gauge was 5 feet below the average elevation of the crest of the dam. Since April 2, 1974, the supplementary water-stage recorder and concrete control 70 feet downstream from the crest of the dam at datum 5.64 feet lower than datum of base gauge. The base discharge was 2000 cubic feet per second from 1925 to 1938; 1000 cubic feet per second from 1939 to the current year. The flood record shown is that for uncontrolled areas below the major dams. The records include flow over the crest and through the sluice gates of the Gillespie Dam, but do not include flow in the Gila Bend and Enterprise Canals, which divert from the river immediately above the dam. There are other large diversions above the station for irrigation, municipal, and industrial use. The flow of the Gila River and its tributaries above this station is regulated by the San Carlos Reservoir on the Gila River (capacity 1,206,000 acre-feet); by a series of reservoirs on Salt River (capacity 1,755,000 acre-feet); by the Bartlett and Horseshoe Reservoirs on Verde River (capacity 317,700 acre-feet); and by Lake Pleasant on Agua Fria River (capacity 157,600 acre-feet).

Table 2.4-5 shows only the annual peaks prior to 1925. Prior to 1939, published as "at Gillespie Dam."

1976	Sept. 27, 1976	10.51	1,920
1977	Apr. 5, 1977	10.04	100

As stated above, the maximum observed discharge was 85,000 cubic feet per second on December 28, 1923 (gauge height, 16 feet, present datum; maximum gauge height, 16.1 feet on January 2, 1966; probably no flow at times; period of no flow unknown due to not publishing leakage of less than 5 cubic feet per second (0.14 cubic meter per second).

Figure 2.4-3 shows the locations of the gauging stations. No historical flood data are available for East Wash.

2.4.2.2 Flood Design Considerations

Flood design considerations for safety-related components and structures of the plant include the following:

A. Flood effects resulting from the probable maximum flood, along with a coincident wind-wave activity

B. Flood effects resulting from seismically induced upstream dam failures, along with a coincident standard project flood

Regulatory Guide 1.59, Design Basis Floods for Nuclear Power Plants, Revision 2, August 1977, has been used as the general basis for flood determination and evaluation.

The occurrence of surge, seiche, tsunami, or ice flooding is not considered to be a probable event.

2.4.2.2.1 Offsite Flood Design Considerations

The plant site is not susceptible to flooding by the Gila River, the Hassayampa River, or the Centennial Wash. The nearest approach of the Gila River to the site is 6 miles to the southeast; the probable maximum flood stage of elevation

776 is 175 feet below the lowest plant grade of 951 at Unit 3. The Hassayampa River is 5 miles to the east, with a high-water level of elevation 942. A topographic ridge between the plant site and the Hassayampa River (minimum elevation 975) provides a natural barrier against site flooding from the Hassayampa River. Centennial Wash is approximately 5 miles south of Unit 3, with a probable maximum flood level of elevation 888. The only drainage affecting plant design is from nearby offsite sources and from onsite sources.

Potential offsite flooding sources are East Wash and Winters Wash (figure 2.4-1). Since these washes have no reservoirs upstream from the plant site, flooding could occur only from precipitation. The probable maximum water levels at selected cross sections on East Wash and Winters Wash are presented in paragraph 2.4.3.5. Protection of safety-related facilities from inundation by offsite flood sources is achieved by the location of the facilities beyond the extent of flooding. East Wash has been realigned to flow past plant facilities along the east boundary of the site. Grade elevations and drainage features important to external flooding protection are shown in figure 2.4-4.

2.4.2.2.2 Onsite Flood Design Considerations

Safety-related structures and equipment are protected from the effects of onsite flood due to probable maximum thunderstorm precipitation (PMP), wind-driven water, yard pondage, and uncontrolled release of water from onsite water impoundments. The onsite drainage system is designed to minimize water pondage in the yard adjacent to plant facilities. Surface

runoff from the power block area will be collected in drainage ditches and discharged into the realigned East Wash in a lower portion of the site. The drainage system and grading plan is designed with sufficient capacity to prevent flooding of Seismic Category I structures and loss of access to these facilities due to PMP.

There are no onsite water impoundments susceptible to uncontrolled releases which could endanger Seismic Category I structures. The maximum water surface elevation in the reservoirs will be 952.5 feet. The lowest unit (Unit 3) will not be flooded even though the maximum water surface in the storage reservoirs can temporarily be at elevation 952.5 due to a 6-hour PMP, since 6 inches of additional water will be dispersed and follow the ground slopes in a southerly direction.

Plant grades for Units 1, 2, and 3 are all 951 feet or above.

The reservoirs will be protected with berms to divert surface runoff and to provide freeboard to protect against waves and runup. The essential spray ponds are designed to prevent loss of function as described in subsection 2.4.8.

2.4.2.3 Effects of Local Intense Precipitation

The onsite drainage system is designed so that runoff due to PMP will not inundate the safety-related structures, equipment, and access to these facilities. The point value PMP intensity for critically arranged time increments as presented in table 2.4-6 is based on reference 5.

Areas adjacent to the power block are sloped away at 0.5 to 1%. This results in a minimum drop of 5 to 7 feet at the peripheral drainage system, as compared to the grade elevation at each unit. The power block areas are divided into smaller tributary areas for purposes of drainage calculations. Runoff from each tributary area is collected in drainage ditches and conveyed to the peripheral drainage system. The peripheral drainage system consists of drainage ditches and culverts along the peripheral access road as shown in figure 2.4-4. The collector ditches and culverts are designed for the 50-year storm and checked for pondage effects due to a probable maximum flood. The volume of water in the vicinity of the power block area consequent to a 6-hour PMP is based on zero infiltration losses and a complete blockage of the drainage culverts for the storm duration. These assumptions are conservative for calculation of pondage around the power block area. The volume of ponded storm water around the power block area is calculated by using the formula:

$$V = \frac{i}{12} \times A \qquad (1)$$

where:

V = volume of ponded storm water in acre-feet

i = PMP-6 hour rainfall in inches = 15.53 inches

A = drainage area in acres

Table 2.4-6

LOCAL INTENSE PROBABLE MAXIMUM THUNDERSTORM PRECIPITATION[5]

Time (h)	PMP Total (in.)	PMP Incremental (in.)	Critically Arranged Thunderstorm (in.)
0.25	8.0	8.0	0.03
0.50	10.0	2.0	0.05
0.75	11.0	1.0	0.05
1.00	11.8	0.8	0.05

2.25	14.0	0.3	0.4
2.50	14.2	0.2	0.4
2.75	14.4	0.2	0.5
3.00	14.6	0.2	0.6
3.25	14.8	0.2	8.0
3.50	15.0	0.2	2.0
3.75	15.1	0.1	1.0
4.00	15.15	0.05	0.8
4.25	15.2	0.05	0.3
4.50	15.25	0.05	0.2
4.75	15.3	0.05	0.2
5.00	15.35	0.05	0.2
5.25	15.4	0.05	0.05
5.50	15.45	0.05	0.05
5.75	15.5	0.05	0.05
6.00	15.53	0.03	0.05

For each tributary area around the power block area, an elevation-volume curve is developed. The maximum water surface elevation within each tributary area is determined from the elevation-volume curve assuming no overflow across roads surrounding the tributary area. The calculated maximum water surface elevations due to local PMP storm are 955.5, 952.5, and 949.5 at Units 1, 2, and 3, respectively. These maximum flood elevations are 2.0 feet below the floor elevations at the respective units. Downslope road elevations surrounding each tributary area are conservatively established at least 0.5 feet below the maximum water elevation to ensure drainage away from the area such that the maximum water levels cannot be exceeded. To the western side of each power block area, some of the PMP runoff overflows the peripheral access road. This does not endanger the power block area because the peripheral road elevations are 2 feet below the power block grade elevations. The area surrounding the cooling towers is graded away from the power block area at 0.5 to 1% to the ditch, so the PMP runoff over the peripheral road will flow toward the ditch system. Although PMP runoff over roads located between units may cause failure from erosion, this conservative situation in no way endangers the safety-related structures because the power block grade elevations are 2 feet above the downslope road elevations.

The roofs of safety-related structures are designed for a live load of 30 pounds per square foot which approximates 6 inches of water accumulation. The roof drainage structures (roof drains and scuppers) are designed for a 50-year storm with a minimum time of concentration of 5 minutes. In addition, the

roof drainage structures are designed to limit ponding due to a 6-hour thunderstorm PMP to 6 inches. Runoff from the plant roof drains will be conveyed away from the critical areas either through ditches or buried pipes.

The occurrence of snow and ice accumulation coincident with PMP is not considered to be a probable event.

2.4.3 PROBABLE MAXIMUM FLOOD ON STREAMS AND RIVERS

The probable maximum flood (PMF) peak discharge was calculated for each of the streams in the site vicinity. The maximum water surface elevation of peak discharge was then computed for each of the streams. Figure 2.4-1 shows the locations of the cross-sections at which the PMF was calculated.

The PMF of the Gila River, as computed by the U.S. Army Corps of Engineers at Gillespie Dam, is 730,000 cubic feet per second.[3] Gillespie Dam is approximately 4.5 miles downstream from the closest point of approach of the Gila River to the plant site. To be conservative, the PMF computed at Gillespie Dam was used to compute water surface elevations of the point in the Gila River closest to the plant site. The PMF water surface elevation was computed to be 776, which is 175 feet below the lowest plant elevation of 951 for Unit 3. The PMF on the Gila River will not flood the plant site.

The PMF on Centennial Wash was computed to be 291,500 cubic feet per second. The water surface elevation of this peak discharge is 888, which is 63 feet below the lowest plant grade of 951 feet at Unit 3. The capacity of Centennial Wash to

accommodate this discharge without flooding the plant site is further discussed in paragraph 2.4.3.5.

The computed PMF on the Hassayampa River is 228,000 cubic feet per second. The water surface elevation of this peak discharge is 942 which is well below the crest of a ridge (elevation 975) located between the river and the plant site. The site is safe from inundation by the PMF on the Hassayampa River.

The unit hydrograph method of drainage basins greater than 10 square miles in area(6) was used to compute the PMF on Winters Wash. The computed PMF using this method is 172,400 cubic feet per second measured at cross-section D. This peak discharge was applied at the cross sections shown in figure 2.4-2. Water level determination at these cross-sections indicates that the water surface elevation of the PMF ranges from 929.5 feet at cross-section D to 956.4 feet at cross-section AA. The site facilities will not be inundated by the PMF in Winters Wash.

The unit hydrograph method for drainage basins less than 10 square miles was used to compute the PMF on the realigned East Wash.(6) To be conservative, the PMF was determined for cross-section E (see figure 2.4-2) to be 17,640 cubic feet per second and was used to determine the maximum water levels. With the realigned East Wash as shown in figure 2.4-2, the computed water surface elevation is from 926.6 feet at cross-section F to 978.8 feet at cross-section G_2. All Category I facilities are safe from inundation by the PMF on East Wash.

The PMF analysis for the Hassayampa River and Centennial Wash was based upon a computed ratio between the 100-year flood and

the computed PMF for area drainage basins. For the Gila River at McDowell Damsite and Painted Rock Damsite, the U.S. Army Corps of Engineers (COE) computed the following 100-year flood and PMF:[3]

	McDowell Damsite	Painted Rock Damsite
100-year flood peak, cubic feet per second	240,000	261,000
PMF, cubic feet per second	600,000	690,000
Ratio PMF to 100-year	2.50	2.64

The 100-year flood flows for Winters Wash and East Wash were computed using the method presented in reference 7. Table 2.4-7 presents the input data used to compute the 100-year flood and PMF for Winters Wash and East Wash.

	Winters Wash	East Wash
100-year flood peak, cubic feet per second	29,200	2,200
PMF, cubic feet per second	172,400	16,600
Ratio PMF to 100-year flood	5.90	7.55

To determine the PMF to 100-year flood ratio for the Hassayampa River and Centennial Wash, a log-log plot of cubic feet per second per square mile versus drainage area was plotted for the 100-year floods and PMF for McDowell Damsite, Painted Rock Damsite, Winters Wash, and East Wash. From figure 2.4-5 it is shown that using a 5 to 1 ratio of PMF to 100-year flood for the Hassayampa River and Centennial Wash results in a conservative estimate of the PMF for those water courses. Table 2.4-8 lists the data used to develop figure 2.4-5.

2.4.3.1 Probable Maximum Precipitation

To calculate the PMF, an estimate of the probable maximum precipitation (PMP) must first be made. A design PMP was selected for the Winters Wash drainage basin and East Wash drainage basin such that the resulting PMF would represent the most severe case. To accomplish this, a comparison was made between the PMF obtained from a 24-hour PMP and that obtained from a 6-hour thunderstorm PMP. The comparison showed that the 24-hour PMP produced the most severe PMF for Winters Wash, while the 6-hour thunderstorm PMP produced the most severe PMF for East Wash. The procedure used to develop the PMP for the respective drainage basins is given below.

2.4.3.1.1 Probable Maximum Precipitation for Winters Wash

The method used to estimate PMP for Winters Wash was developed by Hershfield(8) and is based on the statistics of extreme events. However, the method is not a probability approach to frequency analysis such as a Gumbel or Log-Pearson extreme value curve. Hershfield's method for estimating PMP develops the necessary statistics from envelope curves which encompass all the maximum measured precipitation data. It shows that no systematic geographic pattern for this statistic exists. Regionalization of PMP is accomplished by incorporating mean and standard deviation statistics of local precipitation records. This method provides a conservative upper limit for the PMP that does not rely on a combination of theoretical and empirical methods. The data are obtained from worldwide official observations of maximum rainfall. Since the method is based upon curves which are greater than maximum observed

values, there is no confidence interval associated with the PMP estimates. This is considerably more conservative than an upper 95% confidence interval which may be used with other statistical methods.

The method is not a frequency model and, therefore, there is no probability associated with the PMP estimates. The method yields a PMP value which is greater than any maximum observed value. The PMP estimate using this method can, therefore, be construed to be analogous to the PMP values developed by other methods.

Table 2.4-9 compares the values obtained from various methods. The table indicates that the Hershfield method results in greater precipitation values than other methods compared, except those obtained from Technical Paper 38 which is presently being revised for the southwest. Previous revisions of Technical Paper 38[9] for other areas in the west have shown that the PMP estimates from this reference are unrealistically over-estimated in some cases. The U.S. Soil Conservation Service (SCS), in the evaluation of design criteria for Queen Creek Flood Dam and Reservoir,[10] a 255-square-mile watershed located southeast of Phoenix, Arizona, obtained PMP estimates in table 2.4-9 directly from the National Oceanic and Atmospheric Association (NOAA).

The Hershfield method for estimating PMP results in a PMP value which exceeds the estimates obtained from thunderstorm precipitation and the estimates obtained by the SCS for Queen Creek.

Table 2.4-8

FLOOD DATA USED TO COMPUTE PMF TO 100-YEAR FLOOD RATIO

	McDowell[a] Damsite	Paitned Rock[a] Damsite	Winters[b] Wash	East[c] Wash	Centennial[d] Wash	Hassayampa[d] River
Drainage Area (square miles)	12,900	50,910	250	6.8	1,421	912
PMF (ft^3/s)[e]	600,000	690,000	172,400	16,600	291,500	228,000
$ft^3/(s\text{-}mi^2)$ for PMF	46.5	13.6	689.6	2,441	205	250

Table 2.4-9

COMPARISON OF PMP ESTIMATES FOR WINTERS WASH (INCHES)

	Storm Duration	
	(6 h)	(24 h)
Hershfield[8] - precipitation, in.	9.1	14.6
Technical Paper 38[9] - precipitation, in.	15.1	19.6
Queen Creek PMP[10] - precipitation, in.	7.0	10.9
Thunderstorm PMP[5] - precipitation, in.	7.6	--

The computed PMP for the Winters Wash drainage basin after reduction for basin size is 14.6 inches. This value was computed using the 6- and 24-hour precipitation amounts[7] as input to Hershfield's method for estimating PMP. The resulting 6- and 24-hour PMP values were reduced by areal reduction percentages.[9]

The areal reduction percentages for a drainage basin of 250 square miles are shown below:

	Duration (h)	
	6	24
Areal reduction percentage	84	89
Precipitation, in.	9.1	14.6

A depth-duration relationship was then developed from a log-log plot of the reduced 6- and 24-hour PMP values. Figure 2.4-6 shows the resulting depth-duration relationship.

Rainfall increments were then read from the depth-duration relationship using ΔD time intervals:[6]

$$\Delta D = 0.133\ T_c \qquad (2)$$

where:

ΔD = Duration of unit excess rainfall in hours

T_c = Time of concentration in hours

The sequence of the rainfall increments is then arranged according to the unit hydrograph so that the maximum peak discharge of the flood hydrograph is obtained. That is, the largest increment is paired with the maximum discharge of the unit hydrograph, the second largest increment is paired with the second highest discharge of the unit hydrograph, and so forth. The resulting maximized time distribution of the 24-hour precipitation for the Winters Wash drainage basin is listed in table 2.4-10.

2.4.3.1.2 PMP for East Wash

The design PMP for the East Wash drainage basin was obtained using extreme summer thunderstorm rainfall for the southwest.[5] This rainfall represents PMP over an area of 1 square mile. An analysis of 6:1 hour ratio was used to extend the 1-hour PMP to the 6-hour PMP.

The 1-hour, 1-square mile PMP for the East Wash drainage basin is 11.5 inches. The 6:1 ratio for the site vicinity is given as 135% of the 1-hour PMP, or 15.53 inches.[5] To break down the 6-hour PMP into smaller time intervals, the 1-hour

precipitation amount is multiplied by percentages applicable to an area with a 6:1-hour ratio of 1.35.

Duration (h)	1/4	1/2	1	2	3	4	5	6
6:1-hour ratio	68.5	86	100	116	123.5	128.5	132.5	135

The values obtained are multiplied by areal reduction percentages which reduce the precipitation amounts in relation to basin size. The areal reduction percentages for East Wash are as follows:

Duration (h)	1/4	1/2	1	2	3	4	5	6
Areal reduction percentages	79	82	87	88	90	91	92	93

Figure 2.4-7 shows the graph from which these percentages are taken.

The incremental values of the hourly PMP values are found by subtracting each hourly value from the following hourly value. These hourly increments are then arranged according to a critical time sequence.[5]

Increment	Sequence Position
Largest hourly amount	Third
2nd largest	Fourth
3rd largest	Second
4th largest	Fifth
5th largest	First
Least	Last

Figure 2.4-8 shows the resulting PMP depth-duration curve for the East Wash drainage basin.

Table 2.4-10

MAXIMIZED STORM PRECIPITATION DISTRIBUTION
WINTERS WASH

Time (h)	Precipitation Increments (in.)
0	0
1.15	0.40
2.30	0.40
3.45	0.60
4.60	1.35
5.75	5.20
6.90	0.95
8.05	0.80
9.20	0.60
10.35	0.50
11.50	0.40
12.65	0.40
13.80	0.40
14.95	0.40
16.10	0.35
17.25	0.30
18.40	0.30
19.55	0.25
20.70	0.25
21.85	0.25
23.00	0.25
24.15	0.25

Rainfall increments were then read from the depth-duration curve using ΔD increments and then maximized according to the unit hydrograph for East Wash. The resulting maximized time distribution of the 6-hour precipitation for the East Wash drainage basin is listed in table 2.4-11.

2.4.3.2 Precipitation Losses

The method to determine precipitation losses was developed by the U.S. Soil Conservation Service[6] from studies of many small watersheds. This method was used to calculate the precipitation losses in the Winters Wash and East Wash drainage basins. The method involves the determination of a hydrologic soil cover complex number from the following parameters: hydrologic cover types, hydrologic cover density, and hydrologic soil groups.

Hydrologic soil cover complexes most commonly encountered in Arizona are shown in figure 2.4-9, together with the associated curve number (CN). These curve numbers are used to determine the volume of direct runoff (Q) from the design rainfall.[7]

2.4.3.2.1 Hydrologic Cover Types

Vegetative types that basically affect the runoff process in the southwest desert areas can be divided into five groups:

A. Desert brush includes such plants as mesquite, creosote bush, black bush, catclaw, cactus; desert brush is typical of lower elevations and low annual rainfall.

Table 2.4-11

MAXIMIZED STORM PRECIPITATION DISTRIBUTION
EAST WASH

Time (h)	Precipitation Increments (in.)
0	0
0.32	0.04
0.64	0.19
0.96	0.30
1.28	0.35
1.60	0.63
1.92	2.12
2.23	6.65
2.55	1.18
2.87	0.62
3.19	0.45
3.51	0.33
3.83	0.31
4.15	0.23
4.47	0.22
4.79	0.21
5.11	0.18
5.43	0.18
5.75	0.15
6.06	0.10

B. Herbaceous includes short desert grasses with some brush; herbaceous is typical of intermediate elevations and higher annual rainfall than desert areas.

C. Mountain brush includes mixtures of oak, aspen, mountain mahogany, manzanita, bitter brush, maple; mountain brush is typical of intermediate elevations and generally higher annual rainfall than herbaceous areas.

D. Juniper-grass includes juniper areas mixed with varying grass cover that is generally heavier than desert grasses, due to higher annual precipitation -- typical of higher elevations.

E. Ponderosa pine forests typical of high elevations and high annual precipitation are found along the Mogollon Rim, the Kaibab Plateau, and the White Mountains.

The Winters Wash basin is divided into two hydrologic sub-areas with the upper area having a hydrologic cover type of desert brush and the lower having herbaceous as the cover type. The hydrologic cover type for the East Wash drainage basin is desert brush. These cover types were determined from field inspection of the respective drainage basins.

2.4.3.2.2 Hydrologic Cover Density

Hydrologic cover density is defined as the percentage of the ground surface covered by the crown canopy of live plants and litter. Three broad ranges of vegetative cover density have been established by the SCS:

Poor 0 - 20% vegetative cover

Fair	20 - 40% vegetative cover
Good	40% + vegetative cover

From aerial photographs, topographic maps, and field inspection of the study area, the hydrologic cover density for the two sub-areas of the Winters Wash basin was determined to be 10%.

The hydrologic cover density for East Wash was considered to be 10%. Both basins fall into the range of poor vegetative cover.

2.4.3.2.3 Hydrologic Soil Groups

Surface soils which materially affect the rate of runoff have been classified into four major groups according to the infiltration rate of each soil. The distribution of these soils in Arizona is shown in figure 2.4-10. These soil groups are defined as follows:[7]

A. Low runoff potential soils having high infiltration rates even when thoroughly soaked and consisting chiefly of deep, well to excessively well-drained sands or gravels. These soils have a high rate of water transmission.

B. Soils having moderate infiltration rates when thoroughly soaked, consisting chiefly of moderately deep to deep, moderately well to well-drained soils with moderately fine to moderately coarse textures. These soils have a moderate rate of water transmission.

C. Soils having slow infiltration rates when thoroughly soaked, consisting chiefly of soils with a layer that impedes the downward movement of water, or soils with

moderately fine to fine texture and a slow infiltration rate. These soils have a slow rate of water transmission.

D. High runoff potential soils having very slow infiltration rates when thoroughly soaked, consisting chiefly of clay soils with a high swelling potential; soils with claypan or clay layer at or near the surface; and shallow soils over nearly impervious materials. These soils have a very slow rate of water transmission.

The upper sub-area of the Winters Wash basin falls within soil Group C, while the lower sub-area falls within soil Group D. The whole of the East Wash drainage basin contains soil Group C. This determination was made from field inspection and from the hydrologic soil map, figure 2.4-10.

2.4.3.2.4 Curve Numbers

The curve number associated with the upper sub-area of Winters Wash is 89, while the lower sub-area curve number is 92, and the East Wash basin curve number is 89. These curve numbers were determined from figure 2.4-9, using the appropriate hydrologic soil group, vegetative type, and vegetative cover density for the respective drainage basins.(7)

2.4.3.3 Runoff and Stream Course Models

The methods employed in computing the runoff properties of the Winters Wash drainage basin and the East Wash drainage basin were developed by the U.S. Soil Conservation Service(6) and

Arizona Highway Department.[7] These methods are applicable to small watersheds with limited hydrologic data and are the result of extensive studies on small watersheds throughout the United States.

Flood hydrographs for each hydrologic area were developed by applying the maximized runoff sequence (paragraph 2.4.3.1) to unit hydrographs for each drainage area. These unit hydrographs are based on the dimensionless unit hydrograph.[6] The procedures developed by the U.S. Soil Conservation Service apply both to small drainage areas (less than 10 square miles) and, with some modification, to drainage areas larger than 10 square miles.

The drainage area of Winters Wash is 250 square miles. The peak discharge (Q_p) and time to peak (T_p) used for developing the unit hydrograph for Winters Wash are calculated by the following equations.[6]

$$Q_p = \frac{484A}{\frac{\Delta D}{2} + 0.6T_c} \tag{3}$$

$$T_p = \frac{T_c + \Delta D}{1.7} \tag{4}$$

where:

$$T_c = \frac{L^{1.15}}{7700H^{0.38}}$$

A = drainage area in square miles

Q_p = peak discharge in cubic feet per second

T_c = time of concentration in hours

L = length of drainage area in feet

H = difference in elevation in feet

ΔD = duration of unit excess rainfall in hours

T_p = time to peak in hours

The duration of unit excess rainfall, ΔD, for the unit hydrograph is determined by equation 2.

The peak discharge (Q_p) and time to peak (T_p) used for developing the unit hydrograph for East Wash are calculated by the following equations:[7]

$$Q_p = \frac{484A}{T_p} \qquad (5)$$

$$T_p = (T_c) \times (\text{Width Factor}) \qquad (6)$$

where

Q_p = peak rate of discharge in cubic feet per second

A = contributing drainage area in square miles

T_p = time to peak in hours

T_c = time of concentration in hours

For drainage basins less than 10 square miles, T_c is determined from a graph of drainage area in square miles versus water-course slope in percent, developed by the Arizona Highway Department Bridge Division.[7] The resulting unit hydrographs of the Winters Wash drainage basin and the East Wash drainage

basin are shown in figures 2.4-11 and 2.4-12. Table 2.4-7 presents the parameters used in the above equations and the solutions for the respective drainage basins.

2.4.3.3.1 Verification of the Unit Hydrograph Model

To choose a model for calculating storm runoff, a method was purposely chosen that is in common use in Arizona. The SCS method as modified (not significantly) by the Arizona Highway Department (1968) is a good choice of models because it is in current use for a variety of design problems. The model was tested by simulating measured runoff events from the Walnut Gulch Experimental Watersheds(11) near Tombstone, Arizona. These watersheds were chosen because the soils and land use are similar to the area above the proposed plant, but more importantly, these experimental watersheds have a dense network of continuously recording instruments. The 53-square-mile area has 78 rain gauges. Accurate definition of the rainfall input becomes very important when verifying a model. This is especially important in the Southwest where small area thunderstorm rainfall dominates the runoff producing events.

Verification was accomplished by calculating a synthetic unit hydrograph for the 57.66- and 5.98-square-mile research watersheds. The measured storm rainfall of September 4, 1965, was used as input to the model, and the calculated hydrograph compared to the measured hydrograph. The results for the two areas are summarized in the table below:

Area (mi^2)	Average Precipitation (in.)	Measured Peak Flow (ft^3/s)	Calculated Peak Flow (ft^3/s)
57.66	0.92	744	2780
5.98	1.28	838	1050

The results illustrate that the model chosen for analysis is very conservative and overestimates the flow for both the large and small watersheds.

These areas were chosen as representative of the two areas in question: Winters Wash and East Wash. The test area (57.66 square miles) is smaller than Winters Wash (250 square miles) but this should in no way negate the conclusions of the verification. Both areas are complex watersheds. A good definition of rainfall input far outweighs any advantages that a test of a larger watershed might offer.

2.4.3.3.2 Nonlinearity

Unit hydrograph theory depends on two basic assumptions: time invariance and linearity. Time invariance refers to an assumption that the watershed has not changed (either in morphology or in seasonal influences) with time. This assumption may be questionable in certain areas where derived hydrographs may become invalid through urban development in the watershed. However, this should not pose a problem when using synthetic unit hydrographs for evaluating a PMF in an ungauged area. On the other hand, the assumption of linearity may be seriously violated when using unit hydrographs to predict a PMF from extraordinarily large rainfall amounts and intensities.

Unit hydrographs have been a successful tool for hydrologists for many years. Their success is, to a certain degree, due to the highly damped response (the hydrograph) of watersheds to their input (rainfall). This high degree of damping enables the hydrologist to successfully use a linear model for a highly nonlinear system. For many cases, the results are acceptable. This is at least in part due to the fact that the concept is used for generally the same conditions (rainfall rates) as those for which it was derived and not for events greatly larger. Thus, it is only when the unit hydrograph is used for conditions far different than those from which it was derived that the assumption of linearity becomes inadequate.

Unit hydrograph linearity has been the subject of several recent technical articles and studies.[(12),(13)] These studies have diagnosed the problem but have offered little in the way of solutions. A study by Givler[(13)] based on mathematical model results proposes relationships for adjusting the peak flow and time to peak according to rainfall intensity as follows:

$$q_p \propto (i)^{1.40}$$

$$t_p \propto (i)^{-0.38}$$

where:

q_p = peak flow, cubic feet per second

t_p = time to peak, hour

i = rainfall intensity, inches per hour

When considering the use of such relationships in applied hydrology, the conditions for which they were derived should be

taken into account. Givler's mathematical model consisted of a uniform flow plane and a wide channel. To the extent that this geometry represents a natural watershed, the results could be considered reasonable. However, Givler warns that hydraulically narrow channels would reduce the effect on non-linearity predicted by these relationships. Natural watersheds seldom resemble a series of uniform flow planes connected by hydraulically wide channels. Overland flow generally concentrates in narrow rills or hydraulically narrow channels. Natural channels would act as narrow channels, especially as a PMF event flows onto the flood plain, which, by nature of its increased roughness, acts as a narrow channel. What this means is that in natural watersheds with well-defined channel systems, the effects of nonlinearity between very high rainfall rates and runoff will be less dominant than in small watersheds dominated by an overland runoff regime.

In analyzing the PMF for the PVNGS site, a very conservative runoff model was used to calculate the peak discharge. Because the model is very conservative, it was felt that further adjustment for non-linearity would not be necessary. The conservative nature of the procedure used here is probably analogous to how hydrologists have historically adjusted a unit hydrograph to reflect the magnitude of the storm. Linsley, et al[14] state that hydrologists frequently increase peak flows from 5 to 15% when making estimates of very extreme floods. The Corps of Engineers[15] recommends increasing the peaks of unit hydrographs by 25 to 50% when making estimates of extreme floods. Using a very conservative synthetic unit hydrograph

procedure is equivalent to historical procedures used by hydrologists for estimating extreme floods.

2.4.3.4 Probable Maximum Flood Flow

The peak discharge of the PMF on the Gila River has been determined by the U.S. Army Corps of Engineers at Gillespie Damsite, located approximately 4.5 miles downstream from the closest point of approach of the Gila River to the plant site.[3] The figure of 730,000 cubic feet per second was applied at the nearest approach of the river to the plant site as a conservative estimate to the PMF.

The peak discharge of the PMF on Centennial Wash was estimated by computing the 100-year flood for a drainage area of 1421 square miles based on the U.S. Geological Survey method,[16] and then multiplying this flood flow by a factor of 5 as discussed in subsection 2.4.3.

Centennial Wash carries infrequent runoff. The drainage basin is divisible into three distinct parts. The uppermost part is McMullen Valley, which ends at the bedrock narrows south of Salome. Most of the runoff generated in McMullen Valley sinks into the coarse valleyfill sediments along the axis of the valley. The central part is the largest and is called Harquahala Valley. The valleyfill sediments along the axis of this valley also are extremely coarse. Runoff sinks readily into the ground. The lowest part of Centennial Wash meanders eastward and southeastward through low hills, from Harquahala Valley to the Gila River near Gillespie Dam.

The map of Arizona showing hydrologic areas from Water-Supply Paper 1683(16) shows cross-hatching in the Centennial Wash area, identified in the map legend with the words "Flood-frequency relations not defined." The nearest hydrologic area for which flood-frequency relations were defined was used to determine flood conditions of Centennial Wash.

The USGS gives the mean annual flood in the hydrologic area nearest the site for which flood frequencies are defined as about 11,000 cubic feet per second for an area of 1421 square miles. The 100-year flood for the region in which the drainage basin is located is 5.3 times greater than the mean annual flood. Therefore, using this method, the 100-year flood on Centennial Wash near the site was approximated to be 58,300 cubic feet per second. Using the conservative ratio of 5:1 for the relationship of the PMF to the 100-year flood, as discussed in subsection 2.4.3, the PMF on Centennial Wash was estimated at 291,500 cubic feet per second. The point on Centennial Wash for which the contributing drainage area of 1421 square miles was measured is at the cross-section shown in figure 2.4-1. The center of the Wash on this cross-section is approximately 6 miles southwest of the site.

The peak discharge of the PMF on the Hassayampa River is based upon the USGS method used to calculate the PMF on Centennial Wash.(16) The mean annual flood for an area of 912 square miles as determined by the USGS was found to be approximately 8600 cubic feet per second. The 100-year flood for the region in which the drainage basin lies was again 5.3 times greater than the mean annual flood. Therefore, using this method, the 100-year flood on the Hassayampa River at the selected point

was approximated at 45,600 cubic feet per second. Using the multiplying factor of 5, the PMF on the Hassayampa River was estimated at 228,000 cubic feet per second. The point on the Hassayampa River for which the contributing drainage area of 912 square miles was measured is at the cross-section shown in figure 2.4-1.

The PMF for Winters Wash and East Wash was calculated using the SCS method.[6] Runoff increments were computed from the sequence of rainfall increments shown in tables 2.4-10 and 2.4-11 for Winters Wash and East Wash, respectively, using the equation:

$$Q = \frac{(P-0.2S)^2}{(P+0.8S)} \tag{7}$$

where:

Q = runoff in inches

P = precipitation amount in inches

$$S = \frac{1000}{CN} - 10$$

CN = curve number.

The sequence of runoff increments was then combined with the respective unit hydrographs to determine the probable inflow flood hydrographs. Figures 2.4-13 and 2.4-14 represent the hydrographs of the probable maximum flow near the site of Winters Wash and East Wash, respectively.

The peak discharge of Winters Wash PMF is 172,400 cubic feet per second which was used to estimate the water level along the wash. The point on Winters Wash for which the contributing

drainage area of 250 square miles was measured is at cross section D as shown in figure 2.4-1.

The peak discharge of East Wash PMF is 16,600 cubic feet per second. The point on East Wash for which the contributing drainage area of 6.8 square miles was measured is at the north line of Sec. 34 (Arlington Quadrangle) extended eastward.

Since both Winters Wash and East Wash are ephemeral desert streams with infrequent flow near the plant site, no consideration was given to increasing the flood hydrographs with the addition of base flow.

2.4.3.5 Water Level Determinations

Water levels for PMF peak discharges were computed for each of the streams in the site vicinity. The location of each cross-section used to determine the extent of flooding is shown in figure 2.4-1. The detailed profile of each cross-section is shown in figure 2.4-15. The calculations showing the channel capacities at the selected cross-sections for each stream in the site vicinity and the associated water surface levels are shown in the tables and figures referring to each stream. Cross-section elevations for the Gila River, Centennial Wash, and the Hassayampa River were taken from the 15-minute USGA Arlington Quadrangle with 20-foot contours. The Winters Wash cross-sections at A, B, C, and D were specially prepared from the same topographic control as the contours shown in figures 2.4-2. Cross-sections AA, A_1, A_2, B_1, B_2, and C_1 were linearly interpolated from the detailed elevations prepared for cross-sections A, B, C, and D. All East Wash cross-sections

were taken directly from a 2-foot contour map prepared specifically for the site area.

Table 2.4-12 gives the cross-sectional data for the Gila River and channel capacities at elevations 775 and 776, respectively. From these computations it was found that the capacity of the Gila River channel at flow elevation 775 is 690,000 cubic feet per second and at flow elevation 776 of 785,000 cubic feet per second. A PMF at a peak discharge of 730,000 cubic feet per second would reach a peak water surface level of elevation 776, which is 175 feet below the plant grade for Unit 3. The slope area calculated for high water level during PMF was made by drawing on the Arlington 15-minute quadrangle from a point at the peak of the Buckeye Hills in sec. 10, T.2 S., R.5 W., extending northwestward to the center of sec. 34, T.1 N., R.6 W. (southwest corner of plant site).

The capacity of Centennial Wash to carry floodwaters at high water level of elevation 888 was computed and found to be 307,000 cubic feet per second which is greater than the computed PMF of 291,500 cubic feet per second. Calculations to determine the high water surface during the PMF peak discharge are shown in table 2.4-13. The PMF water surface elevation is at least 63 feet below the plant grade of Unit 3. To perform the slope area calculation for the high water level during PMF, a line was drawn on the Arlington 15-minute quadrangle extending northeastward across Centennial Wash. The southwest end of the line was SW cor. sec. 35, T.1 S., R.7 W. The northeast end of the line was SW cor. NE sec. 34, T.1 N., R.6 W (plant site). Zero distance was taken at the point where the 960-foot contour line crosses the line of the section and

increasing distances were along the line of the section in a northwestward direction.

The capacity of the Hassayampa River to carry floodwaters at a high water level of elevation 942 was computed and found to be 230,000 cubic feet per second which is greater than the computed PMF of 228,000 cubic feet per second. The difference in elevation between the high water level and the crest of the ridge located between the plant site and the Hassayampa River is 33 feet (ridge elevation is 975). Calculations to determine the high water surface during the PMF peak discharge are shown in table 2.4-14. The slope area calculation for the high water level during PMF was made by drawing a line on topographic maps extending across the Hassayampa River through the point above which a calculation was made for peak discharge during a mean annual flood. The eastern end of the line was the 960-foot contour line on the Buckeye NW sheet in SW sec. 23, T.1 N., R.5 W. The line extended westward and ended about 500 feet south of NW cor. sec. 34, T.1 N., R.6 W., about 1/2 mile west of the west boundary of NE sec. 34 (plant site).

Streambed profiles for realigned East Wash and Winters Wash are provided in figures 2.4-16 and 2.4-17. The Manning's "n" value of 0.045, which is considered applicable to Winters Wash and East Wash, was determined from references which recommended values ranging from 0.035 to 0.050.[(17),(18),(19)] This value (0.045) is considered conservative for calculating flood flows in ephemeral desert streams in the site area.

= 231,125 ft^3/s
Use 230,000 ft^3/s

In Winters Wash, the standard step method[20] was used to calculate a backwater profile from section D, a potential constriction of the channel. Data of the cross-sections used to determine the high water surface during the PMF peak discharge are shown in table 2.4-15. The computed water elevations due to the PMF flood of 172,400 cubic feet per second are shown in table 2.4-16. It can be seen that the high water elevation near Unit 3 is 944.7 feet, which is 6.3 feet lower than the grade level of Unit 3.

Since the drainage basin of East Wash at the north line of section 34 extended eastward is only 6.8 square miles and the area from the point to cross-section F is 1.2 square miles, the added area contributes a significant amount of additional drainage to East Wash at cross-section F. A PMF was, therefore, computed at cross-section F and found to be 18,700 cubic feet per second. Due to the constricted East Wash channel at cross-section E, a PMF of 17,640 cubic feet per second was calculated at cross-section E by interpolating between the PMF at the north line of section 34 (Arlington Quadrangle) extended eastward (16,600 cubic feet per second) and the PMF at cross-section F (18,700 cubic feet per second). The drainage basin of East Wash measured at cross-section E is 7.4 square miles. The assumption was made that the 3:1 slope of the riprapped embankment shown in figure 2.4-18 was in place and of sufficient height to prevent overtopping. Data of the cross-sections used to determine the high water surface during the PMF peak discharge are shown in tables 2.4-17 and 2.4-18. The standard step method[20] was used to calculate the backwater profile from cross-section F to determine the water surface

elevation at various cross-sections. A PMF of 17,640 cubic feet per second was applied at cross-section F by assuming the normal depth at this cross-section. The computed results are summarized in table 2.4-16. It is shown that the proposed embankment on the site is not inundated by the PMF in East Wash. A construction access road crosses realigned East Wash between sections G and H of figure 2.4-2. The road crossing was not originally designed to pass the PMF for East Wash; however, the East Wash embankment was raised, from the road crossing to the hill near section G of figure 2.4-2, and the road profile was modified to maintain an adequate cross-sectional flow area to pass the PMF with 2 feet of freeboard on the East Wash embankment.

2.4.3.6 Coincident Wind Wave Activity

As discussed in paragraph 2.4.3.5, the plant site is protected by high ground from the PMF on the Gila River, Hassayampa River, and Centennial Wash. Determination of wind waves and runup were made for Winters and East Wash since the PMF on these streams presents a potential flood hazard to the plant site.

In order to examine the effect of severe wind waves and associated runup occurring coincidentally with the maximum water level during a PMF, a severe wind condition was assumed at the site. A westerly wind with a sustained overland speed of 40 miles per hour was applied to the Winters Wash PMF and both an easterly wind and northerly wind with a sustained overland speed of 40 miles per hour was applied to the East Wash PMF. Tables 2.4-19, 2.4-20, and 2.4-21 present the data

and results of the wind wave and runup calculations for Winters Wash and East Wash.[(21),(22)] Streambed profiles for East Wash and Winters Wash are shown on figures 2.4-15 and 2.4-16. These calculations are based on the assumption that the embankment shown in figure 2.4-2 has 1 on 3 (rise on run) slope with stone riprap facing East Wash. Fetch diagrams for East Wash and Winters Wash are shown on figures 2.4-19 and 2.4-20, respectively.

The maximum water surface elevation was obtained at each cross-section by summing the PMF elevation, the maximum wave height, and runup on the embankment and are tabulated in table 2.4-16.

2.4.4 POTENTIAL DAM FAILURES (SEISMICALLY INDUCED)

As discussed in paragraph 2.4.1.2, there are currently eight water storage reservoirs on the Gila River system upstream from the plant site. The primary functions of these dams are:

- Generation of hydroelectric power
- Regulation of river flows for flood control
- Storage of irrigation
- Storage for industrial and municipal water supplies
- Control of water levels of natural lakes for recreation and fish and wildlife conservation.

There are also several diversion dams with no water storage capacity. Figure 2.4-3 shows the locations of the dams. Seismically induced failure of these dams was assumed. The effect of the worst permutation of dam failures on the site was evaluated. This worst case was assumed when sequential, total

failure of major dams on the Gila River and its tributaries would occur with simultaneous arrival of the peak discharge at the point in the Gila River nearest the plant site. In this manner a maximum discharge into the Gila River and its flood plain would result.

The assumption was made that Roosevelt Dam on the Salt River, Horseshoe Dam on the Verde River, Coolidge Dam on the Gila River, and Waddell Dam on the Agua Fria River fail instantaneously and completely from seismic shock. The resulting flood waves would demolish Horse Mesa, Mormon Flat, and Stewart Mountain Dams on the Salt River and Bartlett Dam on the Verde River. The flood waves generated by the dam failures on the four rivers would flow down the canyons of the respective rivers to the valleys downstream, would flow through and spread into these valleys, and would reach the point in the Gila River nearest the plant site at the same time. Reservoirs were assumed full at the time of failure.

In addition, a standard project flood (SPF) was assumed to be in progress at the time of the dam failures, with the peak discharge arriving at the point in the Gila River nearest the plant site at the same instant as the maximum peak caused by the dam failures. For this extremely conservative approach, the results indicate the maximum water surface elevation at the point in the Gila River nearest the plant site would be 900, which is 51 feet below the plant grade for Unit 3.

2.4.4.2 Unsteady Flow Analysis of Potential Dam Failures

The dam failure hydrographs developed in the preceding section were used as the input hydrographs to the valley topographic relief encountered in the Gila River and its tributaries.

Domino-type failure of all dams was studied with timing such that the peak discharges from each of the four rivers arrive at

the point in the Gila River nearest the plant site simultaneously.

Data developed by the U.S. Army Corps of Engineers for the Gila and Salt Rivers were used to calculate diminution of peak discharge from the dam failure flood waves during the time of travel. The Corps of Engineers synthesized a PMF for the Gila and Salt River systems. Routing the PMF hydrograph downstream caused a diminution in peak discharge from approximately 5 to 10%.(3)

Diminution of peak discharge during time of travel of the dam failure waves through the valleys would be greater than during a PMF. This conservative approach assumed the percentage diminution of flow would be the same as developed by the Corps of Engineers for a PMF in the Salt River. Diminution of peak discharge between McDowell Damsite (proposed dam) and the mouth of the Salt River during a PMF would be 10% of discharge at McDowell Damsite. From the mouth of the Salt River to Gillespie Dam, the diminution of peak discharge during a PMF was computed as 5.2% of peak discharge at the mouth of the Salt River.(3) Applying these figures to the peak discharge remaining in the Salt River from multiple dam failures indicates a peak discharge at the point in the Gila River nearest the plant site would be on the order of 3.0 million cubic feet per second.

Diminution of peak discharge in the Gila River from assumed failure of Coolidge Dam was computed on a mileage basis from the Army Corps of Engineers figures for the Salt River. The Salt River data indicated a diminution of peak discharge

amounting to 0.21% of peak at the entrance to the valley for each mile of river channel in the valley. Flow in the Gila River Valley travels 90 miles from the entrance to the valley to the point opposite the plant site. At 0.21% per mile, total diminution of peak discharge would be 19% of the 2 million cubic feet per second entering the valley. Computed peak discharge reaching the point nearest the plant site was approximately 1.6 million cubic feet per second.

Diminution of peak discharge of the flood wave arising on the Agua Fria River was calculated at 10% of peak discharge entering the valley using 0.21% per mile loss for the 49 miles of valley through which the flood wave travels. Accordingly, of 1,460,000 cubic feet per second hydrograph peak entering the valley, a peak of approximately 1,300,000 cubic feet per second would reach the point in the Gila River nearest the plant site. A less conservative approach would be to utilize the "Inundation Studies" by the Bureau of Reclamation, U.S. Department of the Interior,(39) which estimates approximately 2,660,000 cubic feet per second would reach the point in the Gila River nearest the plant site.

Diminution of peak discharge of overspill from the Salt River entering Gila River Valley would be extremely high, since it would spread out approximately 15 miles while flowing overland. The amount of diminution of peak discharge is likely to be 50%, but a more conservative approach would be to use a figure of 25%. Of the 400,000 cubic feet per second of overspill, peak discharge in the Gila River arriving at the point nearest the plant site was calculated as 300,000 cubic feet per second. The SPF as determined by the Army Corps of Engineers on the

Gila River below the mouth of the Agua Fria River is 370,000 cubic feet per second, and at Gillespie Dam, 350,000 cubic feet per second.[3] For the river point nearest the plant site, a figure of 360,000 cubic feet per second was considered reasonable for peak discharge of the SPF.

Source of Peak	Peak Discharge (10^6 ft^3/s)
Agua Fria flood wave	2.66
Salt/Verde flood wave	3.00
Gila (Coolidge Dam) flood wave	1.60
Gila River SPF	0.36
Total	7.62

Thus, with simultaneous arrival of the peak discharges from multiple dam failures on the four rivers during a SPF at the point in the Gila River nearest the site, the total cumulative peak discharge is approximately 7.6 million cubic feet per second.

2.4.4.3 Water Level at the Site

Using the cross-section data and inundation maps[39][40] of the Salt, Verde and Agua Fria river systems, a slope-area computation indicates that a floodwater surface elevation of 900 would accommodate a peak discharge of 7.6 million cubic feet per second at the selected point in the Gila River, 51 feet lower than the plant grade for Unit 3. Accordingly, a peak discharge of 7.6 million cubic feet per second resulting from domino-type failure of dams in the Gila River system

upstream from the site with timing such that the peaks from each river arrive simultaneously at the point in the Gila River nearest to the plant site during a SPF, will in no way endanger the plant.

Wind waves superimposed upon these water surface elevations will not affect the site.

2.4.5 PROBABLE MAXIMUM SURGE AND SEICHE FLOODING

The plant site is near no large bodies of water for which surge or seiche flooding would apply. The potential for flooding surge or seiche does not exist in this area.

2.4.6 PROBABLE MAXIMUM TSUNAMI FLOODING

The site is near no large bodies of water for which tsunami flooding would apply. The potential for flooding by tsunami does not exist in this area.

2.4.7 ICE EFFECTS

There are no historical data to indicate the possibility of site flooding due to ice jams. Ephemeral desert streams in the site area are not subject to ice formation, due to the infrequency of flow and the desert climate.

Climatological data for Phoenix for a 13-year period indicate that the maximum daily temperature has exceeded 32F on every day of the 13-year period of record. For the same period of record, the maximum number of days per year that the daily minimum temperature was 32F and below was 14 days.(26) Outdoor safety-related facilities are protected from sub-freezing

temperatures. Pipes are installed underground. The mass of water in the essential spray ponds and safety-related tanks will not freeze because subfreezing temperatures have too short a duration. Holes are provided in selected risers in the spray piping of each spray pond to drain standing water, in the exposed piping, to preclude freezing.

2.4.8 COOLING WATER CANALS AND RESERVOIRS

2.4.8.1 Canals

No cooling water canals are utilized on this project.

2.4.8.2 Reservoirs

2.4.8.2.1 Essential Service Spray Ponds

The only reservoirs used to impound safety-related plant cooling water are the essential spray ponds. Two rectangular ponds are provided for each unit (subsection 9.2.1).

The maximum water surface and adjacent grade elevations for the ponds are shown in figure 2.4-4. The ponds are designed as Seismic Category I structures to remain functional following the safe shutdown earthquake (SSE).

2.4.8.2.2 Station Makeup Reservoirs

Makeup water is stored onsite in two independent below-grade impoundments east of the power block area as shown in figure 2.4-2. They are of approximately 85-acres and 45-acres in surface areas.

85-Acre Reservoir: Total surface area corresponding to normal operating evaluation is 85 acres with an active storage capacity of approximately 2191 acre-feet.

Total reservoir capacity is the capacity from the bottom of each reservoir (elevation 909.0 feet for 45-acre and elevation 910.5 for 85-acre) to the maximum water level (elevation 952.5 feet.) Operational capacity for each reservoir is the capacity from elevation 922.5 feet to elevation 952.5 feet. Operational capacity is calculated from elevation 922.5 feet because this is the minimum water level necessary to operate the pumps in the intake structure of each reservoir. During normal operating conditions, each reservoir operates at or below the normal operating capacity. During plant outages or in emergencies, the reservoirs may operate at the maximum operating capacities. The normal operating capacity for each reservoir is from elevation 922.5 feet to elevation 951.0 feet. The maximum operating capacity for each reservoir is from elevation 922.5 feet to elevation 952.5 feet. The total (both reservoirs combined) normal and maximum operating capacities for the 45-acre and 85-acre reservoirs were calculated and elevation-area-capacity (EAC) curves were developed (see Figure 2.4-22a, 2.4-22b, and 2.4-22c).

At normal operating water surface elevation of 951 feet, the average water depth in the reservoir is 29.5 feet. The area capacity curve for the 85-acre reservoir is shown in figure 2.4-22a. An additional 1.5 feet of depth is provided to contain the 6-hour PMP and to accommodate occasional excess flow from the reclamation plant during outages or in emergencies. A minimum 2.5-foot freeboard is provided to

accommodate waves and runup. Operation during outages or emergencies with levels between the normal and maximum operating levels (elevations 951.0 to 952.5 feet) is acceptable since there remains sufficient volume in the impoundment to accommodate the PMP. In the unlikely event of the reservoir being overtopped, flow would be directed south towards the Gila River, away from the PVNGS power block, due to site topography. Design details for the reservoir are given in figure 2.4-23.

The reservoirs are connected with a siphon line and, if necessary, the reservoirs may be used concurrently (water drawn from both reservoirs). The combined area capacity curves for the 45-acre and 85-acre reservoirs are shown at figure 2.4-22c.

45-acre Reservoir: Total surface area corresponding to normal operating elevation is 43 acres with active minimum storage capacity of 1,823 acre-feet. (The surface area at the crest elevation of 955 feet is 45.11 acres, the surface area at the maximum operating water elevation of 952.5 feet is 43.79 acres, and the surface area at the normal operating water elevation of 951 feet is 43 acres). The area capacity curve for the reservoir is shown in figure 2.4-22b for the 45 acre reservoir. An additional 1.5 feet of depth is provided to contain the 6-hour PMP and to accommodate occasional excess flow from the reclamation plant during outages or in emergencies. A minimum 2.5 foot freeboard is provided to accommodate waves and runup. Operation during outages or emergencies with levels between the normal and maximum operating levels (elevations 951.0 to 952.5 feet) is acceptable since there remains sufficient volume in the impoundment to accommodate the PMP. In the unlikely event of the reservoir being overtopped, flow would be directed south

towards the Gila River, away from the PVNGS power block, due to site topography. Design details for the 45-acre reservoir are given in figure 2.4-23.

Evaporation rates for the site area were developed using the published data listed in references 27, 28, 29 and 30. The average lake evaporation rate is 72.4 inches per year as shown in table 2.4-22. Average precipitation for the site vicinity is 7.4 inches per year as given in table 2.4-23. Based on the above, a net evaporation rate of 65 inches per year is used in the reservoir designs.

2.4.8.2.3 Evaporation Ponds

The circulating water system blowdown and waste water from other miscellaneous station sources are discharged into the evaporation ponds at an average annual flow rate of 2,530 gallons per minute with all three units operating 100% of the year. The cooling tower water chemistry is controlled at the reclamation plant process operating parameters. However, prior to being discharged into the evaporation ponds, all potentially radioactive inputs will be tested for radioactivity.

Table 2.4-22

AVERAGE MONTHLY LAKE EVAPORATION RATE NEAR SITE VICINITY

Month	Inches	Month	Inches
January	2.2	July	9.9
February	3.1	August	9.0
March	5.0	September	6.9
April	6.6	October	5.3
May	9.0	November	3.3
June	9.9	December	2.2
Total 72.4			

Those wastes exceeding the release limits stated in the Offsite Dose Calculation Manual (ODCM) will be sent to the liquid radwaste system for processing before being discharged.

Total dissolved solid content of the influent ranges from 7,000 to 30,000 mg/l. The influent carries approximately 150 tons of solids (dry weight) per day per unit into the ponds.

The evaporation ponds are designed to retain residual solids. The net lake evaporation rate for fresh water in the site area is 65 inches per year (as described in paragraph 2.4.8.2.2). Due to the continuous evaporation process from the pond, a consequent buildup of solids results in a progressive decrease in the evaporation rate. This decreased rate is provided for in the design of the evaporation ponds.

Analyses indicate that approximately 1000 acres of pond is sufficient for three units over the plant life, assuming no blowdown treatment or sludge removal.

The evaporation ponds are developed in stages as required. Approximately 250 acres of pond was constructed initially; this provided sufficient capacity for approximately 4 years from the startup of Unit 1. Then the second pond of approximately 235 surface acres was constructed in 1988 along the east side of Pond No. 1. The pond was built with a leak collection system. In 2009, rehabilitation activities started on Pond No. 2 to remove the original HDPE liner, add a composite liner, add a Leachate Collection and Removal System (LCRS), and to rework all of the embankments for construction of two internal embankments. The internal embankments divide the pond into three segments: Pond 2A (117 acres), Pond 2B (87 acres) and Pond 2C (30 acres). Pond No. 2 shares the east embankment of Pond No. 1 to the west. Pond No. 3 is an approximate 180-acre earth embankment structure constructed in late 2009. Pond No. 3 was designed with an internal divider embankment to provide operational flexibility. The divider is aligned north and south and splits the pond into two near-equal halves, Pond 3A and Pond 3B. Pond No. 3 shares the south embankment of Pond No. 1 to the north. The internal embankments divided Pond 1 into 3 segments: Pond 1A (131 acres), Pond 1B (77.5 acres) and Pond 1C (52.5 acres) during the rehabilitation.

A composite liner system in Ponds 1, 2 and 3 consists of:

- Native soil
- Compacted embankment and subgrade
- Soil cement sideslope armoring
- Continually monitored leachate collection and removal system (LCRS)

- Geosynthetic Clay Liner (GCL)
- Secondary 60-mil HDPE geomembrane
- Geonet drainage layer and
- Primary 60-mil HDPE geomembrane

Subject to the results of continuing studies of blowdown treatment methods and pond sludge removal alternatives, additional ponds may subsequently be constructed in a similar manner. The site contains sufficient area to accommodate the ultimate pond size should this be required. The locations of the evaporation ponds are shown in figure 2.4-2.

Interior pond side slopes are four horizontal to one vertical for Pond 1 and four horizontal to one vertical for Ponds 2 and 3. Design details for the evaporation ponds are given in figure 2.4-25 and 2.4-25a.

A reserve storage capacity of 1.50 feet of pond depth is provided to contain a 6-hour thunderstorm PMP and occasional plant waste water discharge during startup. In addition, a minimum of 5 feet of freeboard is provided to accommodate waves and runup based on the Bureau of Reclamation minimum criteria.

Since the ponds are designed to retain the waste water, including PMP, over the plant life, no spillway or outlet structures are provided.

2.4.9 CHANNEL DIVERSIONS

The source of cooling water for PVNGS, including a source of makeup for the essential spray ponds, is treated sewage effluent primarily from the city of Phoenix 91st Avenue treatment facility with effluent input capability and also from

other smaller facilities enroute. The effluent is conveyed to the site through approximately 35 miles of pipeline, and treated in the onsite water reclamation facility to meet plant water quality requirements. Onsite storage reservoirs provide for a continuous water supply in the event of scheduled or unscheduled interruptions or reductions in the normal water source.

Since the conveyance line, water reclamation plant, and reservoirs are not specifically designed against failure under extreme environmental conditions, the normal water source is subject to possible interruption. However, the essential spray ponds are designed to provide storage of safety-related water necessary for safe shutdown, and the ponds will not be subject to loss of function due to any interruptions in the water source.

Table 2.4-23

2.4.10 FLOODING PROTECTION REQUIREMENTS

The site is subject to potential flooding from East Wash and Winters Wash as discussed in subsection 2.4.3. Flood protection will be achieved by site grading such that all Seismic Category I facilities will be located beyond the extent of PMF.

The ground elevation along the west side of the site will be raised, as indicated on figure 2.4-4, to limit the extent of PMF on the site. A maximum of about 10 feet of compacted fill will be placed in the cooling tower areas, such that ground between the peripheral road and the power block areas will be above the PMF levels. A drainage channel designed to carry 50-year flood flows will convey flood waters from the northern portion of the site, west of the peripheral road to a discharge point south of the power block area.

East Wash has been realigned along the eastern edge of the site to maximize use of the site for other facilities and to limit the extent of the PMF. The normal channel of East Wash has been blocked by an embankment between the two hills on the northern edge of the site. This embankment forces flood flows around the small hill in the northeast corner of the site and cuts off any flow through the old channel. An additional embankment has been constructed along the eastern edge of the site to prevent flooding of the site proper. This change in drainage is illustrated in figure 2.4-2. Both embankments will be constructed to elevations sufficient to prevent any overtopping by a PMF and associated wave runup and wind setup. The East Wash embankments have been constructed of material

excavated from the reservoir and power blocks. The elevation of the north-facing embankment is approximately 983 feet msl, and the elevation of the east-facing embankment starts at about elevation 972 and gradually drops to approximately 935 feet msl to meet existing contours at the southern end.

The embankments are designed to withstand static and dynamic effects of floods corresponding to the PMF. The outer faces of the embankments are protected from erosion by providing a riprap zone. The maximum water velocity during the PMF is estimated to be 6 feet per second. A Manning's "n" value of 0.030 is used in computing the maximum water velocity for erosion design only. The maximum water elevations during the PMF, including wind wave and runup, at selected cross-sections along Winters Wash and East Wash are discussed in paragraph 2.4.3.6.

The design of erosion protection for East Wash was based on references 31, 32, and 33. Side slopes of three horizontal to one vertical, estimated angle of repose of riprap material of 40 degrees with the specific weight estimated at 155 pounds per cubic foot were used for analyses. The computed values of design shear and local boundary shear are 3.6 and 3.1 pounds per square foot, respectively. Using a velocity of 6 feet per second, 10 feet maximum water depth, and an average stone diameter of 12 inches, the value of local boundary shear is 0.8 pounds per square foot, which is less than the design local boundary shear. The dumped riprap shall be 1.5 feet thick and provided with a filter blanket.

Details of riprap placement, riprap toes, depth of flow at PMF, and filter blanket are shown in figure 2.4-18. The erosion protection is provided to 2 feet above the PMF elevation, including the effects of wind and wave runup.

Rip-rap for the east side of evaporation pond No. 2 was designed in accordance with Bureau of Reclamation criteria.

2.4.11 LOW WATER CONSIDERATIONS

Plant water demands for the nonsafety-related cooling water system are normally met using effluent primarily from the city of Phoenix 91st Avenue Sewage Treatment Plant with effluent input capability also from other smaller plants enroute. The effluent is conveyed to the site by means of a pipeline and pumping facilities and is treated in the onsite water reclamation plant to meet plant water quality requirements. Onsite makeup reservoirs provide for a continuous water supply in the event of temporary interruptions in the normal water source. Groundwater from onsite wells is used for other plant water uses as discussed in paragraph 2.4.13.2.

The safety-related ultimate heat sink consists of two essential spray ponds (ESPs). The combined water inventory in the ESP is sufficient to provide a 26-day cooling capacity without water makeup. However, makeup water is provided by either the domestic water system (onsite wells) or the water storage reservoirs.

2.4.11.1 Low Flow in Streams

Low flow in streams will have no effect on safety- or non-safety-related systems.

2.4.11.2 Low Water Resulting from Surges, Seiches, or Tsunamis

This section does not apply.

2.4.11.3 Historical Low Water

This section does not apply.

2.4.11.4 Future Control

This section does not apply.

2.4.11.5 Plant Requirements

The safety-related ultimate heat sink consists of two ESPs which have a combined water inventory sufficient to provide a 26-day cooling capacity without water makeup. The ESPs will not be subject to loss of function due to any interruptions in the water source. Refer to paragraph 9.2.5.2.

2.4.11.6 Heat Sink Dependability Requirements

Each generating unit has two Seismic Category I essential spray ponds that provide the ultimate heat sink for cooling auxiliary systems required for safe reactor shutdown. The essential spray pond system is described in subsection 9.2.5. The spray ponds operate in an emergency situation and in conjunction with a normal reactor shutdown. During normal operation, the spray

ponds are operated in support of several auxiliary systems including emergency diesel generators, shutdown cooling, essential chillers, fuel pool cooling, and nuclear cooling water priority loads, as well as for chemistry control, and testing.

Separate makeup water lines are provided to each spray pond from two independent water supply sources; i.e., the station makeup water reservoirs and the domestic water system. None of the makeup water sources are safety-related since the two spray ponds for each unit contain sufficient water in storage to permit safe shutdown and cooldown of the unit and to maintain it in a safe shutdown condition for 26 days. The independent makeup water sources described above ensure a continued capability after 26 days in the safe shutdown condition.

Plant firewater requirements and sources are described in subsection 9.5.1. Firewater is not drawn from the ultimate heat sink.

2.4.12 DISPERSION, DILUTION, AND TRAVEL TIME OF ACCIDENTAL RELEASES OF LIQUID EFFLUENTS IN SURFACE WATERS

The circulating water system blowdown and waste water from other miscellaneous station sources are discharged through piping systems into the onsite evaporation ponds. Since the ponds are designed to retain the waste water, including water from a PMP, over the plant life, accidental releases of liquid effluents in surface waters are not expected to occur.

2.4.13 GROUNDWATER

2.4.13.1 Description and Onsite Use

2.4.13.1.1 Geologic Setting

The site area (5-mile radius) is in the Lower Hassayampa-Centennial groundwater basin. This basin lies within the townships T.2N, T.1N, T.1S, and the northern half of T.2S, in Ranges R.3W through R.7W (figure 2.4-26) encompassing an area of about 400 square miles.

The hydrogeologic profile of the site area is defined by three major sedimentary units, each having distinctly different lithologic and hydrologic characteristics. These units, found in most Central Arizona water basins (U.S. Bureau of Reclamation, 1977)[34], are identified herein as:

- Upper Alluvial Unit
- Middle Fine-Grained Unit
- Lower Coarse-Grained Unit

The generalized hydrogeologic profile of the site area is depicted in figure 2.4-27. A description of the sediments as they relate to the groundwater regime of the site is presented in the following paragraphs. A detailed description of the site geology is presented in paragraph 2.5.1.2.

2.4.13.1.1.1 Upper Alluvial Unit. This unit consists of primarily silty and gravelly sands of varying proportions with interlayered, discontinuous lenses of clays and silty clays. This unit, equivalent to lithozone 5 (see paragraph 2.5.1.2.3), extends to a depth of about 30 feet to 60 feet beneath the

site. Individual layers are about 3 to 10 feet thick and are characteristically moderate to poorly bedded. The stratification is typical of sediments deposited in a high-energy fluvial environment. Primary sedimentary structures identified during the detailed geologic mapping of power block excavations (appendix 2D) consist of channel cut and fill features.

The permeability of the upper alluvial unit soils was determined by inflow and outflow (pumping) type field tests. The typical horizontal permeability of these deposits is about 10 gallons per day per square foot ($5x10^{-4}$ centimeters per second). Because of the extensive stratification, the vertical permeability (not measured) can be expected to be significantly lower than the horizontal permeability.

2.4.13.1.1.2 Middle Fine-Grained Unit. This unit consists of massive, continuous layers of clays and silty clays, interbedded with thinner layers and scattered lenses of clayey silt, clayey sand, and silty sand. The thickness of the unit is about 250 feet. The upper contact of the middle fine-grained unit is equivalent to a well-defined boundary between two distinctive depositional environments and can be clearly identified across the site. Locally, the contact is transitional where a few scattered lenses of silt and fine sand are encountered. A structure contour map of the top of the middle fine-grained unit is presented in figure 2.4-28. The middle fine-grained unit corresponds to lithozones 3 and 4 of the geologic model (see paragraph 2.5.1.2.3). The distinction between the two zones in the middle fine-grained unit is based

on subtle but definite differences in geotechnical and hydrologic properties. Silty clays of medium plasticity predominate in the upper zone (lithozone 4), while clays of somewhat higher plasticity predominate in the lower zone (lithozone 3 -- the Palo Verde clay). The two zones are separated by a relatively continuous coarse-grained soil layer.

The permeability characteristics of soils in the upper portion of the unit were evaluated by both laboratory and field tests (appendix 2G). The vertical permeability, determined by laboratory tests, is on the order of 0.001 gallons per day per square foot ($5x10^{-8}$ centimeters per second). The horizontal permeability, determined by field tests, is approximately one order of magnitude higher. The permeability characteristics of the Palo Verde clay were evaluated only by laboratory tests. Measured permeabilities in the vertical and horizontal directions are on the order of 0.0005 gallons per day per square foot ($2.5x10^{-8}$ centimeters per second) and 0.01 gallons per day per square foot ($5x10^{-7}$ centimeters per second), respectively.

2.4.13.1.1.3 Lower Coarse-Grained Unit. In general, the lower coarse-grained unit is described as a "variably cemented conglomerate which lies directly on the undifferentiated basement complex".[(34)] In the site area, the lower coarse-grained unit consists of a tilted interbedded sequence of volcanic flows and flow breccias, tuffs, tuffaceous sandstones, and coarse-grained arkosic sandstone. The flow breccias (which may be interpreted as the "variably cemented conglomerate") are common throughout the sequence (lithozone 0). Locally mantling

this volcanic/sedimentary section are deposits of moderately-to well-lithified fanglomerates (lithozone 1). The entire sequence is overlain by an unlithified to poorly-cemented silty sand, sand, and gravelly sand (lithozone 2) (refer to figure 2.4-27).

The permeability of the regional aquifer was assessed by reviewing irrigation well pumping records (see paragraph 2.4.13.2) and performing an aquifer pumping test (appendix 2G). Yields from irrigation wells which tap the regional aquifer range from 400 to 2800 gallons per minute. The average specific capacity is 35 gallons per minute per foot of drawdown. The aquifer pumping test, performed on an existing irrigation well (B-1-6 - 34abb) resulted in a calculated transmissivity of 100,000 gallons per day per foot and a storage coefficient of 0.005. The pumping rate during the test was 2360 gallons per minute.

2.4.13.1.2 Groundwater Conditions

In the site area, the groundwater reservoir consists of an extensive regional aquifer and a local perched water zone.

2.4.13.1.2.1 Regional Aquifer. In the site area, the lower coarse-grained unit, described in the preceding section, comprises the regional aquifer that extends to over 400 square miles. The regional aquifer is bounded by the mountain masses that encompass the Lower Hassayampa Centennial area (figure 2.4-26).

The primary recharge source to the regional aquifer in the site area is underflow from upper Hassayampa Valley, north of the

site area. The general flow direction is north to south. Reversal of flow direction occurs locally where the groundwater levels are depressed due to pumping for irrigation purposes. Infiltration of precipitation, surface runoff, and return flow from irrigation in the vicinity of the site comprise a small portion of the total recharge of the regional aquifer.

Discharge from the regional groundwater reservoir occurs as underflow to Arlington Valley (to the south of the site) and pumpage from irrigation wells. A detailed discussion of water use in the vicinity of the site is provided in paragraph 2.4.13.2.

Piezometric levels in the vicinity of the site are at depths ranging from 100 to 250 feet below the ground surface. A water level contour map of the regional aquifer in the lower Hassayampa-Centennial area was constructed by the U.S. Geological Survey[35] and is reproduced in figure 2.4-29. The most conspicuous hydrological features indicated by the water level contours are the large cone of depression beneath the site, and a broader but shallower cone of depression south of the site. A smaller cone of depression also occurs immediately north of the Palo Verde Hills. The cones of depression have been formed by long-term pumpage from irrigation wells in the area (see paragraph 2.4.13.2). Artesian conditions prevail within the aquifer in the site area. Confinement is generally provided by the middle fine-grained layer.

2.4.13.1.2.2 Perched Water Zone. The Palo Verde site is situated in an area that was under cultivation from about 1950 to late 1975. Water for crop irrigation was pumped from the

regional aquifer. Most of the water was consumed by the crops (primarily cotton) through evapo-transpiration. The remainder of the water percolated through the upper alluvial sediments and perched on top of the underlying aquitard (middle fine-grained unit). The shape of the perched mound is consistent with the shape of the irrigated area within the site (see figure 2.4-30). Water table conditions prevail within the perched water zone.

During the 25-year period of agricultural activity at the site, the prime source of recharge of the perched water zone was excess irrigation water that percolated through the upper sediments. Since 1975, when agricultural activity stopped within the site, the only source of recharge has been precipitation and surface runoff. However, as evidenced by the sharp decline in perched water levels since 1975 (3 feet per year average -- refer to paragraph 2.4.13.2) local natural recharge is insufficient to maintain the perched mound. The decay of the perched water mound is caused mainly by radial flow outward from the center of the mound and some downward leakage through the aquitard.

2.4.13.1.3 Onsite Use

A detailed discussion of present and projected groundwater use, as well as its effect on groundwater levels, is presented in paragraph 2.4.13.2.

2.4.13.2 Sources

2.4.13.2.1 Regional Water Use

Water for irrigation is the major use of groundwater in the lower Hassayampa-Centennial area. An average of 78,000 acre-feet per year was pumped during the period 1966 through 1972. The water for municipal and domestic use, also obtained from the groundwater reservoir, is very small. Annual pumpage for municipalities, livestock, or industrial purposes is less than 1% of the total.

The production history of wells in the lower Hassayampa-Centennial area is compiled in table 2.4-24. The table lists well locations for known active wells and the annual pumpage rate for each well for the years 1966 through 1972. The location of these wells is shown in figure 2.4-31. A steady decline of the water levels in the area began about 1950 due to the increase in pumping of groundwater for agriculture. The water level has declined by as much as 100 feet near the centers of cones of depression during the past 25 years (see figure 2.4-32). The water level decline is attributed to pumping of wells and the resultant spread of the cones of depression and consequent interference effects between wells.

2.4.13.2.2 Onsite Water Use

During the 25-year period (1950-1975) of agricultural activity at the site, water was pumped heavily from the regional aquifer, resulting in the localized depression of water levels depicted in figure 2.4-29. The locations of irrigation wells in the site area and its vicinity are shown in figure 2.4-33.

In 1972, four existing irrigation wells within the PVNGS property yielded a total of 7542 acre-feet of water. The site wells yielded a total average of 6000 acre-feet per year from 1966 through 1972. Most of the water (83%) was pumped from wells (B-1-6)34abb and 34acc.

Irrigation stopped in late 1975, a few months prior to the start of construction. Well No. (B-1-6)34abb has been used since as the primary well for construction water supply with (B-1-6)27ddc as the backup well. During the period 1976 through 1978, the combined pumping rate of these two wells has been about 350 acre-feet per year (see table 2.4-25). This quantity corresponds to approximately one-twentieth of the annual groundwater withdrawal from onsite wells during the last few years of irrigation.

The impact of groundwater withdrawal on regional aquifer water levels is demonstrated in the hydrographs of onsite wells (figure 2.4-32). Water levels declined steadily during the 25-year period (1950-1975) of agricultural activity. During this period, water level declines in the wells ranged from 50 to 100 feet. Since 1975, water levels have risen in response to the cessation of agricultural pumpage. The significant reduction (from 6000 to 350 acre-feet per year) in annual groundwater withdrawal rates has resulted in water level rises of about 20 feet in 3 years.

Table 2.4-25

WELL PUMPING RATES DURING CONSTRUCTION

Well No.	Annual Pumpage in Acre Feet		
	1976	1977	1978
(B-1-6)34abb	287	283	314
(B-1-6)27ddc	48	68	58
Total	335	351	372

As noted in paragraph 2.4.13.1, agricultural activity also created a perched water mound above the aquitard beneath the site. Perched water levels have been monitored since late 1973. Hydrographs for perched water level monitoring wells are presented in figures 2.4-34 through 2.4-38. The locations of these wells are shown in figures 2.4-30 and 2.4-39. During the last 2 years of irrigation (1974 and 1975), perched water levels remained essentially constant (except for seasonal fluctuations), indicating that approximately steady-state conditions had been reached. A steady decline in perched water levels has been observed since 1975 when agricultural activities ceased in the site area. The average rate of perched water level decline since 1975 has been about 3 feet per year. Most hydrographs show a decrease in the rate of water level decline with time.

2.4.13.2.3 Projected Groundwater Use and its Impact on Water Levels

During plant operation, groundwater from the regional aquifer will be used only for the domestic water supply. The domestic water requirement for three units is estimated to be about

1000 gallons per minute (1600 acre-feet per year). This rate of groundwater withdrawal is about one-fourth the withdrawal rate during the last few years of irrigation.

The effects of onsite pumping for the domestic water supply on regional aquifer water levels were evaluated by an analysis presented in the PVNGS 1, 2, and 3 PSAR. The analysis was based on values of transmissivity (100,000 gallons per day per foot) and storage coefficient (0.005) determined by a pump test conducted on the production well (B-1-6-34abb). For the projected pumping rate of 1600 acre-feet per year, the predicted drawdown in the production well after 35 years of operation is 30 feet. By the same analysis, the predicted drawdown at distances of 0.5, 1, 2, 5, and 10 miles is 10.6, 9.1, 7.5, 5.3, and 3.7 feet, respectively.

These predictions are very conservative because they do not incorporate the compensating effects of cessation of irrigation in the site area. As noted in paragraph 2.4.13.2.2, a significant rise in water levels has been observed since 1975 due to the reduction of onsite pumping rates from about 6000 acre-feet per year (related to agricultural activity) to 350 acre-feet per year during construction. Because of this reduced pumping rate, regional aquifer water levels are expected to continue to rise during construction. When all three units are in operation, and the pumping rate is increased to 1600 acre-feet per year, water levels can be expected to decline, but at a rate slower than that observed during irrigation (prior to 1975). The net impact of pumping for plant operations is, therefore, expected to be even smaller than that predicted by the analysis presented in the PSAR.

2.4.13.2.4 Recharge From Local Sources

To analyze the long-term seepage effect on the movement of the perched-water table, a digital simulation was performed. Figure 2.4-42 shows the general configuration of the water storage reservoir and evaporation pond used in this analysis. The time-dependent, two-dimensional flow of groundwater in a nonhomogeneous and isotropic aquifer is governed by the following equation:

$$\frac{\partial}{\partial x}\left(T\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial y}\left(T\frac{\partial h}{\partial y}\right)=S\frac{\partial h}{\partial t}+Q \qquad (9)$$

Terms in this relationship, along with others used in the text, are defined as follows:

x,y = Cartesian coordinates

T = aquifer transmissivity = $k_h h$

h = thickness of horizontal flow zone

S = aquifer storage coefficient

t = time

Q = net groundwater loss rate per unit area

$K_{(h)}$ = horizontal permeability (hydraulic conductivity)

There is no general solution to the above equation; however, numerical solutions can be obtained. Prickett and Lonnquist[36] have developed a digital computer simulation code through a finite difference approach at the Illinois State Water Survey. Many different types of groundwater simulation conditions were presented in their report. The Water Table Condition Code,

which was designed to simulate groundwater mound decay and recharge, was used in this study.

A. Assumptions Used in Simulation

Water was assumed to seep from the bottom of the 80-acre water storage reservoir at the rate of 75 feet per year and be immediately transported down to the aquitard surface. Seepage from the storage reservoir continued in the simulation at the rate of 75 feet per year until the perched-groundwater mound rose to the bottom of the reservoir, at which time the seepage decreased linearly to zero as the groundwater mound surface approached the maximum reservoir water level. The simulation was insensitive to the initial seepage rate because the perched mound rose to the reservoir bottom in a matter of months. From then on the seepage rate declined, being controlled by other site parameters.

Inflow to the evaporation pond was assumed to be 954 gallons per minute per unit as the respective units start up in May 1983, May 1984, and May 1986. When the groundwater mound was below the bottom of the evaporation pond (elevation 920 feet above msl), the incoming blowdown was assumed to seep into the ground. When the groundwater mound rose above the bottom of the evaporation pond, an annual evaporation rate of 72 inches was assumed.[37] Evaporation was only considered when water was standing in the evaporation

pond. Seepage was decreased linearly in the same manner as in the storage reservoir.

Leakage through the fine-grained aquitard was allowed to occur in the simulation in the downward direction only. The complication of some actual horizontal movement within the aquitard was avoided by considering only vertical permeabilities and gradients. Leakage through the aquitard was simulated using the following equation:

$$Q_n = \left(K_v / m'\right) \Delta h A_s \qquad (10)$$

where:

Q_n = infiltration rate through the aquitard

K_v = vertical permeability of the aquitard

m' = thickness of the aquitard

Δh = head difference across the aquitard

A_s = area of a grid square

K_v and m' are obtained from field data.

B. Summary of Simulation Conditions and Assumptions

- Time zero was October 1976.
- Each time step represented 30 days.
- Grid points were 1000 feet apart in the north-south and east-west directions.
- Both the storage reservoir and evaporation pond were assumed to be unlined.

- Storage reservoir was assumed to be full at Unit 1 startup in May 1983.
- Each grid point in the storage reservoir was initially assumed to seep 75 feet per year multiplied by the area in square feet of that grid square within the reservoir and above the aquitard until the groundwater mound rose to the reservoir bottom. At that point, seepage began to decrease linearly to zero as the groundwater mound approached the maximum water surface elevation of the reservoir.
- The bottom of the storage reservoir was taken as 921 feet above msl with a water surface of 950 feet msl.
- The evaporation pond was assumed to receive 954 gallons per minute per unit as the respective units start up in May 1983, May 1984, and May 1986.
- When the groundwater mound was below the bottom of the evaporation pond (elevation 920 feet msl), all of the incoming blowdown was assumed to seep into the ground. When the groundwater mound rose above the bottom of the evaporation pond, an annual evaporation rate of 72 inches was assumed.[37]
- K_h of the upper coarse-grained material was represented by 10 gallons per day per square foot.
- K_v of the aquitard was represented by 0.001 gallons per day per square foot.

- The storage coefficient S of the upper coarse-grained material was assumed to be 0.2.
- Aquitard surface contours, figure 2.4-28.
- Aquitard thickness contours, figure 2.4-39.

C. Site Parameters

In the seepage model, the horizontal permeability (hydraulic conductivity) of the upper coarse-grained soil layer was represented by a value of 10 gallons per day per square foot (5 x 10^{-4} centimeters per second). Similarly, the vertical permeability of the fine-grained soil layer (aquitard) was represented by a value of 0.001 gallons per day per square foot (5 x 10^{-8} centimeters per second). These values were selected after a thorough evaluation of field and laboratory permeability test data developed at the site for this purpose. The selection process is described in detail in PVNGS 4 and 5 PSAR, Appendix 2Y. Permeability test data are presented in appendix 2G.

D. Groundwater Level Prediction

Predicted groundwater levels, as shown in figure 2.4-40, from the digital simulation are 915, 909, and 909 feet for Units 1, 2, and 3, respectively. The design groundwater levels of the units are 927, 924, and 921 feet for Units 1, 2, and 3, respectively. Throughout the operating life, therefore, water levels under each unit are predicted to stay below design groundwater levels.

The analysis of long-term seepage effects was based on an evaporation pond location as indicated in figure 2.4-42. If eventual construction of some or all of the evaporation pond was further south than shown on figure 2.4-42 or at a bottom elevation less than 920 feet msl, water levels under the units would be lower than those predicted here. This conclusion is based on the following facts:

- The distance from the evaporation pond to the units would be increased by moving the ponds southward
- The aquitard surface slopes to the south
- Lowering the pond bottom elevation would lead to a decreased head difference between the water level in the pond and the design structural integrity levels under the units.

2.4.13.3 Accident Effects

Contaminated water, if accidentally spilled during plant operation, may seep through the ground surface. For this postulated occurrence, the contaminated water will infiltrate downward through the unsaturated soil and reach the perched water table about 40 feet below the land surface. It will then disperse into the perched groundwater. Further downward movement of water from the base of perched water zone is restricted due to the presence of the Palo Verde clay layer about 200 feet below the ground surface. For the conservative analysis used in this study it is assumed that seepage could occur through the Palo Verde clay layer. Consequently, two

systems are analyzed for the possible effect of a contaminated water spill; the perched water zone and the underlying regional aquifer. The impact of such postulated accidental see pages on the groundwater system, and, in particular, on the existing wells located in the 5-mile zone around the site area, is analytically predicted and its consequences are assessed.

2.4.13.3.1 Inventory of Existing Wells in the Site Vicinity

There are 18 groundwater wells located within 2 miles and another 69 wells located between 2 and 5 miles of the plant site. Among them, 17 of the wells have depths less than 200 feet and draw their water from the perched water zone, while the remaining 70 wells draw their water from the regional confined aquifer below the Palo Verde clay layer.

2.4.13.3.2 Accidents Leading to Liquid Spills

The PVNGS is designed for zero release (releases less than the LLD values shown in the Offsite Dose Calculation Manual (ODCM)) of radioactive liquids of plant origin at or beyond the site boundary during normal operation. None of the defined accidents will be likely to result in any liquid release to the groundwater in the site area. However, to be conservative, it is assumed that the 808,850-gallon refueling water tank (RWT) (volume represents the maximum free space within the RWT tank source terms in table 2.4-26) and its surrounding walls fail, and the contents are instantaneously released to the groundwater. The computations were performed to determine the contaminants concentration at the nearest exclusion boundary on the downgradient groundwater flow direction of the perched

water and regional aquifers. Another possible point of discharge to ground water is the evaporation pond. Computations were performed for liquid releases due to pond liner failure. This calculation determined that effluent concentrations would be less than those associated with the RWT failure.

2.4.13.3.3 Analytical Approach to the Contaminant Movement

Water from a failure of the refueling tank (RWT) on the ground is assumed to percolate through the unsaturated soil before mixing with perched water. When the contaminated liquid reaches the perched water surface, dispersion takes place.

This methodolgy calculates radionuclide concentrations in a potable water supply well due to a catastrophic rupture and liquid spill from the Refueling Water Tank (RWT). The well draws its water from the perched water aquifer at the nearest exclusion area boundary (EAB) in the direction groundwater flow.

Radionuclide Concentration at EAB Perched Water Zone

A vertically averaged groundwater dispersion model with a horizontal area source is used as it is defined in reference 38. This model is for calculating the concentration in the aquifer at some point gradient of a release (e.g., water supply well), and it is the solution for the limiting case of unidirectional saturated convective transport with three dimensional dispersion in an isotropic aquifer:

Table 2.4-26

RADIONUCLIDES AND ACTIVITIES IN REFUELING WATER TANK

(Sheet 2 of 2)

Nuclide	Half-Life	RWT Inventory (Ci)[a]
Fe-59	45 days	6.62E-03
Co-58	71.4 days	1.85E-01
Mn-54	313 days	2.39E-01
Cr-51	2.78 days	3.40E-02
Zr-95	65.5 days	2.84E-04

a. Based on 60 Ci total RWT inventory excluding tritium.

$$\frac{\partial c}{\partial t} + \frac{U\partial c}{R_d\partial x} = \frac{D_x\partial^2 c}{R_{d\partial x}{}^2} + \frac{D_y\partial^2 c}{R_{d\partial y}{}^2} + \frac{D_z\partial^2 c}{R_{d\partial z}{}^2} - \lambda c \qquad (11)$$

where:

c is the concentration in the liquid phase (Ci/cm^3),

D_x, D_y, D_z are the dispersion coefficients in x, y, z directions (cm^2/s), is the decay coefficient (1/s),

U is the seepage velocity in x direction (cm/s),

R_d is the retardation factor (dimensionless).

Solution to this equation can be found in terms of Green's functions as follows:

$$c_i = \frac{1}{neR_d} X(x)Y(y)Z(z) \qquad (12)$$

where:

Ci is the concentration at any point in space for instantaneous one curie release, and n_e is effective porosity;

where, for a horizontal area source of length l and width w centered at (0, 0, 0) in an aquifer of constant depth b:

$$X = \frac{1}{2l}\left\{\mathrm{erf}\,\frac{\left(x+\frac{1}{2}\right)-\frac{Ut}{R_d}}{\sqrt{4\frac{D_x}{R_d}t}} - \mathrm{erf}\,\frac{\left(x-\frac{1}{2}\right)-\frac{Ut}{R_d}}{\sqrt{4\frac{D_x}{R_d}t}}\right\}\exp(-\lambda t) \qquad (13)$$

$$Y = \frac{1}{2w}\left\{\operatorname{erf}\frac{\left(\frac{w}{2}+y\right)}{\sqrt{4\frac{D_y}{R_d}t}} + \operatorname{erf}\frac{\left(\frac{w}{2}-y\right)}{\sqrt{4\frac{D_y}{R_d}t}}\right\} \tag{14}$$

$$Z = \frac{1}{b} \tag{15}$$

Seepage velocity is defined as (U_i):

$$U_i = \frac{V_x}{n_e} \tag{16}$$

where V_x is the flux that can be approximated by:

$$V_x = -K\frac{dH}{dx} \approx -K\frac{\Delta H}{\Delta x} \tag{17}$$

where $\frac{\Delta H}{\Delta x}$ is the hydraulic gradient in the direction of flow that represents elevation head through distance in the x direction (dimensionless). K is respectively permeability (cm/s).

Retardation factor is defined as (R_d):

$$R_d \approx 1 + \frac{\rho}{n}K_d \tag{18}$$

where n is the total porosity, ρ is the bulk density (gm/cm^3) and K_d is the distribution coefficient (ml/g). Retardation coefficients of unity has been used for this analysis (i.e., no retardation).

Dispersion coefficient is defined as (D_i):

$$D_x = \alpha_L U_x \text{ and } D_y = \alpha_T U \tag{19}$$

Where α_L and α_T are the longitudinal and transverse dispersivities respectively.

Radionuclide Concentration in Regional Aquifer

The liquid from Refueling Water Tank (RWT) which migrates to the perched ground water zone, could percolate vertically downward through the several soil layers and reach the regional aquifer approximately 150 ft. below ground surface. The Middle Fine Grained Unit lies between the perched water zone and the regional aquifer. It is divided into the Upper Middle Fine Grained Unit and Lower Middle Grained Unit. The Upper Middle Fine Grained Unit is divided into 3 layers each 40 ft. thick for the purpose of this evaluation. The Lower Middle Fine Grained Unit is the Palo Verde Clay layer. The transport time through each vertical layer is determined based on the layer's thickness, its permeability, and the vertical hydraulic gradient

$$\tau = \left(\sum_{i}^{N,3} \left(\Delta h_i \right) / U_i \right) \qquad (20)$$

Where:

τ is the total transport time through vertical layers (day), Δhi is the thickness of each layer (ft.), U_i is seepage velocity each layer (ft./ day) as defined below;

$$U_i = K_i \times \left(\left(\frac{\Delta H}{\Delta x} \right) / \left(n_e \right) \right) \qquad (21)$$

Where;

K_v is the vertical permeability (ft./day), $\frac{\Delta H}{\Delta x}$ is the vertical hydraulic gradient (dimensionless) and n_e is the effective porosity (dimensionless).

2.4.13.3.4 The Results of Analysis

2.4.13.3.4.1 Unsaturated Flow. There are more than 40 feet of unsaturated soil above the perched water zone. Percolating this unsaturated soil, the spill will be dispersed and diluted. However, to be conservative, no credit has been given to the dilution capability or percolation through the unsaturated soil in the following calculation.

2.4.13.3.4.2 Perched Water Zone. It is conservatively assumed that the spill will not be diluted or dispersed before it reaches the perched water zone. In the event of either a slow leak or a tank and wall failure, the liquid would spread to some negligible depth over the ground surface. For a conservative analysis, a depth of 6 inches is assumed which will occupy a 500-square foot area. The horizontal conductivity or permeability of the upper coarse grained soil layer was determined to be 10 gallons per day per square foot (489 feet per year or 5×10^{-4} cm/s) and the effective porosity was determined to be 0.37.

The maximum possible groundwater gradient was chosen by assuming that groundwater was at the design water elevation of 921 feet at Unit 3 power block and that groundwater was at the aquitard surface at the site boundary elevation of 905 ft. On a line 270° from Unit 3, the gradient over the 2930 feet to the

site boundary was 0.0055 foot per foot. This yields a down-gradient flow velocity of 7.64 feet per year.

The long half-life radionuclides, Cs-137, Co-60, Sr-90 and H-3 are the only isotopes that may reach the perch water zone, the results are summarized as follows:

It can be seen that any spill in the perched zone that reaches the exclusion boundary will be below any maximum permissible concentration in water (MPCw) listed in 10CFR20, Appendix B, Table II[41].

Radionuclide	Half life	RWT Inventory	Time to reach Max Concentration	Maximum Concentration at EAB potable water source	Criteria[a]
	Years	μCi	Year	μCi/ml	μCi/ml
H-3	12.3	2.00E+09	180	8.9E-09	3.0E-05
Sr-90	28.9	6.74E+02	240	2.4E-12	3.0E-09
Cs-137	30.2	3.9E+07	245	1.8E-07	2.0E-07
Co-60	5.3	1.31E+05	125	7.3E-18	3.0E-07

a. One percent of the 10CFR20 appendix B. Table II. Column 2, 1981.

2.4.13.3.4.3 Regional Water Aquifer. It is assumed that the perched water percolates through the Palo Verde clay layer into the regional aquifer. The regional aquifer is located below the perched water zone. It is approximately 150 ft. below the perched water zone; see figure 2.4-27 for details. Vertical permeability for upper middle fine and middle fine and bottom layers are estimated to be 5.67E-3, 2.83E-4 and 5.67E-3 ft./day respectively. The Palo Verde clay layer permeability is 1.843E-5 ft./day. The effective porosity is estimated at 0.37.

A conservative and average hydraulic gradient of 0.0055 feet per feet was determined from the regional water level contours of figure 2.4-29.

The contaminated liquid will be greatly decayed before it proceeds to the Palo Verde clay layer about 200 feet below ground surface. The maximum concentration along the top of the Palo Verde layer without radioactive decay can be obtained from equation 20 and 21 in the vertical direction.

Taking into account the time required to reach this maximum value at the top of clay layer. Concentration of radio isotopes at the regional aquifer would be much less than the perched water zone and well within the one percent limit of 10CFR20 Table II, MPCs.

These calculations present a conservative study, since the dilution capability of the unsaturated soil and the ion exchange process with soil have been neglected. Thus, the accidental spill would result in minimal effect on the environment.

2.4.13.4 Monitoring or Safeguard Requirements

Effects of plant operation on the groundwater system are expected to be minor. The groundwater level and groundwater quality will be monitored to detect the effects, if any, of plant operation.

2.4.13.4.1 Groundwater Level Monitoring

The groundwater levels of both shallow perched zone and deeper regional aquifer will be monitored as described in permits as required by Arizona Statues and Administrative Codes.

2.4.13.4.2 Groundwater Quality Monitoring

The groundwater quality monitoring program is described in permits as required by Arizona Statues and administrative codes.

2.4.13.5 Design Bases for Subsurface Hydrostatic Loadings

The following design groundwater elevations are used as the basis for calculating groundwater-induced hydrostatic loadings on subsurface portions of safety-related structures:

Structure	Design Groundwater Elevation (ft)	Plant Grade at Structures (ft)
Unit 1	927	957
Unit 2	924	954
Unit 3	921	951

The groundwater level beneath each unit is predicted to remain well below its respective design groundwater elevation during the 40-year plant life (paragraph 2.4.13.1.2).

2.4.14 TECHNICAL SPECIFICATION AND EMERGENCY OPERATION REQUIREMENTS

No technical specification and/or emergency operation requirements are necessary.

2.5 GEOLOGY, SEISMOLOGY, AND GEOTECHNICAL ENGINEERING

Summary of Geotechnical Methodology

This section presents the geologic, seismic, and foundation engineering data developed for PVNGS. The location of the site is shown on figure 1.2-1.

The purpose of this program was to thoroughly investigate the regional and site geology, seismology, and foundation conditions in accordance with the criteria outlined in Appendix A, Seismic and Geologic Siting Criteria for Nuclear Power Plants, of 10CFR Part 100, and to demonstrate that a nuclear facility can be safely constructed at the site.

The investigation of the site consisted of the following:

- Research of pertinent published and unpublished geologic, seismologic, and hydrologic literature of Arizona and adjacent areas (see also appendix 2A, Question 2A.4)

- Consultation with numerous local geologists from the universities and various public agencies who are familiar with particular areas

- Review of existing and specially prepared aerial photography and other remote sensing imagery

- Reconnaissance and detailed geologic mapping of the site and vicinity at scales of 1 mile, 2000 feet, 1000 feet, and 500 feet to the inch

- As-graded geologic mapping of excavations for Category I structures, at scales of 10 feet, 5 feet, and 1 foot

- to the inch, and inspection of non-Category I excavations

- Subsurface investigations which include:

  - Drilling of approximately 630 borings to depths ranging from 25 to 720 feet for geologic and engineering data

  - Logging of selected borings with high resolution, downhole geophysics

  - Seven detailed cross-hole seismic surveys in and adjacent to the power block areas to define the in-situ engineering characteristics of the site soils

  - Excavation of 32 backhoe trenches totaling about 1800 linear feet

  - Twenty-one seismic refraction geophysical profiles (hammer energy source) totaling about 32,500 feet; three refraction profiles (explosive energy source) totaling about 49,600 feet

  - Reconnaissance and detailed gravity and magnetic geophysical surveys covering a 10-mile radius of the site

  - Installation and monitoring of perched and regional groundwater observation wells on and adjacent to the site

- Six multiposition extensometers and 18 mechanical rebound anchors to monitor pre- and post-construction related heave and settlement
- One large tank percolation test, three pumping tests in the perched water zone, one regional aquifer pump test, and approximately 25 in-situ injection permeameter tests to determine aquifer characteristics
- Excavation of three large-diameter (6 feet) borings to depths of about 40 feet to obtain bulk undisturbed samples for engineering testing

- Geologic sample analyses which include:
  - Lithologic analysis of thin-section samples of bedrock
  - Potassium-argon age dating of volcanic rock samples
  - Analysis of approximately 550 samples of basin sediments for paleomagnetic polarity
  - Palynology studies of 20 samples of basin sediments
  - X-ray crystallography of selected clay samples
- Engineering testing of foundation materials for static and dynamic properties. Types of tests include:
  - Moisture content and dry density
  - Atterberg limits for selected samples

- Consolidation
- Triaxial shear (dynamic and static)
- Standard penetration (for granular materials within zones of possible liquefaction)
- Relative density
- Direct shear
- Unconfined compression
- Expansion or swell

Soil sampling was initiated in the plant area in April 1973 and continued periodically through December 1978.

Of the more than 630 borings drilled during the site investigations, approximately 575 have been drilled within the site property and at site-specific power block areas. The remainder have been drilled around the site property at spacings ranging from 750 feet to 1 mile and extending up to 5 miles from the plant location.

The investigation of PVNGS conforms to accepted standard practice within the geology/engineering professions and to NRC acceptance criteria defined at the time of the investigations. Sampling of undisturbed soils and soft sediments, for geologic and engineering requirements, was performed with a 12-inch drive sampler; a standard 18-inch, split-spoon drive sampler; a 30-inch pitcher tube; a 12-inch diameter plastic cylinder for hand-excavated samples; and an NX core barrel. The soil samples were taken continuously or at intervals of 5 feet down to a depth of 100 feet, intervals of 10 feet down to a depth of

200 feet, and intervals of 20 feet down to a depth where material suitable for coring was encountered, or to specific completion depth determined by geologic or engineering considerations. The sampling procedures were dependent on expected loading conditions related to building geometry. Samples taken for the general suite of engineering tests of static and dynamic properties were taken from pitcher tube, 2.5-inch (inner diameter) drive sampler, and large-diameter, hand-excavated samples. Standard penetration tests onforming to American Society for Testing Materials (ASTM) specifications were done with an 18-inch, split-spoon sampler.

Trenches were oriented to intersect photo lineations or suspicious linear relationships found during the field investigation. Trenches were usually excavated to depths within the capabilities of the excavating equipment. The walls of the trenches were inspected for geologic evidence of faulting or other potentially hazardous geologic conditions. Scales of the trench logs ranged from 5 feet to the inch to 2 feet to the inch.

In order to monitor the effects of construction excavation activity on the site soils and their response to structural loading following construction, a soil heave and settlement monitoring program has been established at PVNGS. The instrumentation installed prior to construction consists of 18 mechanical rebound (MR) anchors (six in each unit) and six electrical read-out multiple position extensometers (MPEs) (three in Unit 1, one in Unit 2, and two in Unit 3). The MPEs are used to supplement the MRs during the rebound phase but

their primary function is to monitor construction and post-construction settlement recompressions. Based on the data obtained to date, heave/settlements are much less than predicted, on the order of one-third. Heave monitoring results verify that the heave/settlement analyses and the settlement design criteria based on these analyses are very conservative. The subsidence monitoring network consists of survey monuments located within the site boundary on soil. The survey monuments are surveyed relative to benchmarks established on bedrock north and southwest of the site. Data through March 1978 indicate no subsidence. Two strong motion accelerometers were installed at the site in 1975 to monitor earthquake-induced ground motion at the site. The instruments were removed from service in 1985. The trigger threshold for the instruments was 0.009g. The instruments were never triggered during the period of time that they were installed. Refer to paragraph 3.7.4.2 for a description of the permanent seismic instrumentation.

The changes in soil condition caused by construction of the plant are essentially those produced by the earth-moving operations required to grade the area. The moderate-to-high strengths exhibited by the soils indicate that engineered temporary and permanent slopes at the site are designed and constructed with reasonable allowable slope inclinations to minimize erosion and slope failures. Fills, constructed of soils from onsite excavations and borrow areas, are compacted in accordance with criteria provided in the PVNGS 1, 2, and 3 PSAR, Appendix 2T. Fill and cut slopes will be stable under seismic conditions and will be protected against erosion.

Summary of Geology, Seismology, and Earthquake Engineering

The site is situated within the Basin and Range physiographic and tectonic province of southwestern Arizona.

The geology within a 25-mile radius of the site (site vicinity) is characterized by mountain ranges which are relatively short, irregular, and stand sharply above broad alluvium-filled basins. The rocks of these mountains vary from deformed crystalline rocks of Precambrian age to volcanic and sedimentary rocks of middle Tertiary age. Alluvium and volcanic rocks in the broad basins are Miocene to Holocene in age, based on potassium-argon age dates of basalt interbeds. The rocks of the site area (5-mile radius) consist of:

- Precambrian metamorphic and granitic rocks
- Miocene volcanic and interbedded sedimentary rocks
- Basin sedimentary deposits on the order of 200 to 500 feet thick consisting of lithified fanglomerate, unlithified fan, alluvial, and lacustrine deposits with basalt interbeds.

The dominant structure of the site is homoclinal folding of the volcanic bedrock 15 to 23 degrees to the southwest. The over-lying basin sediments are flat-lying and undeformed. Only one northwest trending fault, displacing the volcanic bedrock, has been observed within a 5-mile radius of the site. This fault does not displace Miocene fanglomerate.

The Palo Verde clay, a lithologically and geophysically distinct lacustrine member of the basin sediments, is

stratigraphically below and thus older than the base of the Arlington basalt flow (about 2 million years, based on potassium-argon age dates). The Palo Verde clay can be continuously traced in borings across the site and at least 5 miles to the southeast and northeast of the site with no evidence of faulting since the clay was deposited more than 2 million years ago.

The geotechnical investigation at the site indicates that:

- There are no capable faults within 5 miles of the site
- Geologic conditions at the site are favorable for construction of the plant
- Foundation conditions are favorable for construction of the plant

The historic seismicity of Arizona has been characterized into four general zones:

- Zone A, the southern San Andreas Shear Zone, is approximately 120 miles from the site with a maximum historic earthquake of magnitude 7.1
- Zone B, the Pinacate volcanic area, is about 70 miles from the site with a maximum historic earthquake of about 4.9
- Zone C is more than 70 miles from the site at its nearest point and has produced a maximum earthquake, not associated with a fault, of magnitude 5.6. The

maximum earthquake associated with a fault is the 1887 Sonoran earthquake (estimated magnitude 8.0)

- Zone D, a nearly aseismic zone in which the site is located, with a maximum historic earthquake of about magnitude 4.5

The safe shutdown earthquake (SSE) assumed to be of magnitude 8.0 and to be located 72 miles from the site, is postulated to be similar to the 1887 Sonora earthquake whose estimated magnitude was recently revised downward to 7.4[1]. Through use of attenuation curves, extrapolation of response spectra, and analysis of intensity data, 0.2g is considered a conservative representation of the severity of vibratory ground motion for the SSE.

2.5.1 BASIC GEOLOGIC AND SEISMIC INFORMATION

2.5.1.1 Regional Geology

2.5.1.1.1 Regional Physiography

2.5.1.1.1.1 General. The area within the site region (200-mile radius) includes most of Arizona, part of southeastern California, southern Nevada, and northern Mexico (figure 2.5-1). The major physiographic provinces within the 200-mile radius of the site include the Colorado Plateau, Transition Zone, Basin and Range, Peninsular Ranges, and the Transverse Ranges (figure 2.5-1). For Arizona, physiographic province boundaries and descriptions follow Fenneman[2] and Wilson[3]. Province boundaries in California are taken from Fenneman[2], Oakeshott[4], and Jahns[5]. A detailed description

of the physiography of the site vicinity (25-mile radius), which is in the Basin and Range province, is given in the description of the site geology (paragraph 2.5.1.2.1).

2.5.1.1.1.2 Colorado Plateau Province. The Colorado Plateau province is centered near the four corners of Arizona, Utah, Colorado, and New Mexico and is bounded on the north by the Central Rocky Mountains, on the east by the Southern Rocky Mountains and Rio Grande Valley, and on the west and south by the Basin and Range and Transition Zone provinces (figure 2.5-1). The southwestern province boundary in the site region is a series of rugged cliffs, up to 1500 feet in height, trending northwest across Arizona. Within the site region, the Colorado Plateau is subdivided into the Grand Canyon, Mogollon Slope, and Navajo Country regions (figure 2.5-1).

The Grand Canyon region includes several individual plateaus which are elongated in a north-south direction. Highest of these is the Kaibab Plateau which has been incised by the Colorado River to form the Grand Canyon. The relief decreases west of the Kaibab and Coconino Plateaus. To the east, these plateaus descend to the Marble Platform. The Grand Canyon region is separated from the adjacent Basin and Range province by the Grand Wash Cliffs, a major physiographic break. The southeastern edge of this region contains the high mountains and volcanoes of the San Francisco Peaks volcanic field.

The Mogollon Slope is bordered by the Mogollon Rim on the south and the Little Colorado River on the north (figure 2.5-1). The relief generally declines northward from the uptilted Mogollon

Rim toward the Little Colorado River and Black Mesa Basin. The southeast edge of the region is covered by the White Mountains-Mogollon volcanic field.

The Navajo Country area includes plateaus, mesas, and canyons of the Plateau interior north and east of the Little Colorado River. The generally flat-lying terrain is interrupted at Hopi Buttes by the necks of eroded volcanoes which protrude above the general level of the plateau.

2.5.1.1.1.3 Transition Zone. The Transition Zone lies between the Colorado Plateau and the Basin and Range province[3] (figure 2.5-1). The strata and structure of the Transition Zone are similar to the southern Colorado Plateau except for a greater abundance of faulting. Physiographically it differs from the plateau because of its more rugged topography with steep-sided mountains locally rising as high as the plateau rim. The topography commonly reflects the influence of underlying bedrock in that mesas occur in areas underlain by the sedimentary and volcanic rocks, sharp and rugged terrain in metamorphic rocks, and rugged to rounded topography in granitic rocks.

2.5.1.1.1.4 Basin and Range Province. The Basin and Range province is the most extensive province in the site region and encompasses southern and western Arizona, Nevada, western Utah, southeastern California, and northern Mexico. Physiographic boundaries of the Basin and Range province are generally broad

transitions which are not precisely definable, especially between the Basin and Range and Colorado Plateau.

Most of the province (for example, the Great Basin region in Nevada and western Utah) is characterized by subparallel, steep-sided, linear mountain ranges separated by relatively flat, alluviated basins which abut the ranges with a sharp break in slope. The linearity of the mountain ranges has resulted largely from block faulting, and many mountain ranges are bounded by faults or fault-line scarps. Many basins or groups of basins have interior drainage with central playas.

In the site region, the Basin and Range province is subdivided into the Arizona Mountains and Sonoran Desert subprovinces.

A. Arizona Mountains

The ranges of the Arizona Mountains comprise the Mexican Highlands, which trend northward out of Mexico, and similar but northwest-trending mountain blocks between the Transition Zone and the Sonoran Desert (figure 2.5-1). Topography is generally rugged, suggesting that tectonic activity has occurred more recently here than in the Sonoran Desert. The ratio of the area of the ranges to basins is approximately 1 to 1.

B. Sonoran Desert

The Sonoran Desert includes the deserts of southeastern California and southwestern Arizona. The region is typified by low-relief mountains and extensive

pediments and open drainage(6). The heterogeneous trends of mountain ranges in this region contrast with the pronounced northerly trends in the Nevada-Utah and Mexican Highlands portions of the province. Mountain ranges rarely have peaks higher than 4000 feet. The topography appears old and subdued compared to the Nevada-Utah and Arizona Mountains portions of the Basin and Range province. Basins are the dominant landscape features and several, including the Tucson and Phoenix Basins, contain alluvial accumulations thicker than 2000 feet. The area of the ranges totals only about one-fifth of the total subprovince area indicating long periods of erosion of a relatively stable landscape.

2.5.1.1.1.5 The Salton Trough. The Salton Trough province lies southwest of the site, south and southwest of the eastern Transverse Ranges, and west of the Basin and Range province. The Salton Trough comprises the Coachella Valley, Imperial Valley, and the Gulf of California (figure 2.5-1). The trough boundaries are along mountain ranges bounded by major northwest-trending fault zones, the San Andreas on the northeast, and the San Jacinto, Elsinore, and Sierra Juarez on the southwest. The northern Salton Trough is separated from the Gulf of California by the Colorado River delta, the sediments of which have created a closed inland basin to the north, much of which is below sea level. Colorado River flood water poured into the trough in 1905 initiating the present Salton Sea. However, strand lines, shell deposits, and

calcareous deposits around the rim of the trough indicate the existence of previous Holocene and Pleistocene lakes. As a result of prevailing northwesterly winds, active and inactive sand dunes are common south of the Salton Sea on the east side of the Imperial Valley. The Gulf of California is an elongate body of water between the Mexican mainland and the Baja peninsula. Maximum depth of the seafloor is about 11,500 feet but the northern portion, within the site region, is much shallower, no more than about 1600 feet deep. The floor of the trough is marked by bathymetric depressions which get progressively smaller towards the head of the Gulf; only one of these basins, Wagner Basin, is within the 200-mile site region radius.

2.5.1.1.1.6 Peninsular Range Province. The Peninsular Range province occupies the southwestern corner of California and forms the "backbone" of the Baja Peninsula. It is characterized by northwesterly trending mountain blocks of granitic rocks which are terminated on the north by the Los Angeles Basin and the east-west trending ranges of the Transverse Ranges province. The site region includes only the eastern portion of the Santa Ana block; the eastern margin of which drops off steeply to the floor of the Salton Trough in spectacular scarps about 6000 to 9000 feet high.

2.5.1.1.1.7 Transverse Ranges Province. The Transverse Ranges province of southern California is an elongate series of mountain ranges trending east-west. The eastern edge of the

province (the Little San Bernardino Mountains) extends into the site region where it is bounded on the north by the Mojave Desert, the east by the Sonoran Desert, and on the south by the Salton Trough.

The mountain ranges of the province are rugged and are separated by narrow to moderately-narrow valleys. These east-west oriented physiographic features are transverse to the general northerly grain of most ranges in the western U.S.

2.5.1.1.2 Regional Stratigraphy and Lithology

2.5.1.1.2.1 Geologic Setting. The stratigraphy and lithology in the site region are extremely complex (figure 2.5-2) but can be simplified by grouping areas with similar geology into large provinces. In many cases these geologic provinces coincide quite closely with tectonic provinces and physiographic provinces because of the intimate relationship between physiography, lithology, and geologic structure. However, the physiographic boundaries are not always perfectly coincidental with geologic and tectonic boundaries for provinces with the same name (for example, the Basin and Range province). Figure 2.5-3 shows the major tectonic provinces in the site region and the following discussion groups lithologic and stratigraphic descriptions according to these provinces.

The PVNGS site is within the portion of the Basin and Range tectonic province generally referred to as the Sonoran Desert (figure 2.5-3). The Basin and Range province is bounded about 40 miles northeast of the site by the Colorado Plateau tectonic

province and by the Salton Trough tectonic province about 120 miles to the southwest. The Peninsular Ranges tectonic province lies beyond the latter province along the California and Baja California coasts about 180 miles from the site.

2.5.1.1.2.2 Colorado Plateau. The rocks exposed on the Colorado Plateau are relatively undeformed Paleozoic to early Tertiary rocks (figure 2.5-2). The southwest portion of the Colorado Plateau, within the 200-mile radius surrounding the site, is characterized by a thick sequence of slightly deformed Paleozoic marine sandstone, mudstone, and limestone unconformably overlying highly deformed Precambrian rocks.

The older Precambrian rocks of schist, granite, quartzite, and meta-volcanics are unconformably overlain by up to 4000 feet of younger Precambrian to Permian units of shale, limestone conglomerate, and sandstone. The deposition of the Paleozoic sediments found on the Colorado Plateau was greatly influenced by the Defiance-Mazatzal land mass which transected Arizona with a northeast-southwest trend throughout much of Paleozoic time. Deposition on the flanks of this mass resulted in progressively thicker deposits to the northwest and southeast. The younger strata are nearly horizontal over large areas with broad regional flexures, monoclinal folds, and igneous domes. These strata are broken by faults, joints, and a multitude of dikes. Cenozoic intrusive rocks occur as stocks, laccoliths, and bysmaliths. Late Tertiary extrusions of basaltic lava and pyroclastic rocks cap much of the plateau periphery[3].

Cenozoic sedimentary deposits are well represented in the northern portion of the Colorado Plateau but are missing in the site region. Within the site region, late Cenozoic rocks consist primarily of Tertiary and Quaternary volcanic rocks. The volcanic activity appears to have been localized by Laramide and later tectonic influences because the volcanic cones, necks, plugs, and diatremes are thought to be localized at intersections of deep structural features(3).

The San Francisco volcanic field consists of large central volcanoes surrounded by a multitude of small cinder cones and vents. The central San Francisco Mountain, and the surrounding Kendrick, O'Leary, Sitgreaves, Bill Williams, and Mormon Mountain vents erupted 86 cubic miles of basalt, andesite, latite, dacite, and rhyolite flows and pyroclastic rocks, during Pliocene and early Pleistocene time(7).

2.5.1.1.2.3 Basin and Ranges. The Basin and Range province, west and southwest of the Colorado Plateau, comprises more than 50,000 square miles in Arizona. It is composed of fault-block mountain ranges generally oriented northwest-southeast, northeast-southwest and north-south with the northwest-southeast trends somewhat predominant. The rocks of this province range from intensely deformed Precambrian metamorphic rocks to undeformed Pliocene and Quaternary sedimentary and volcanic rocks (figure 2.5-2). The rocks were folded, faulted, and intruded throughout Precambrian and early Tertiary time but it was the block-fault activity and volcanism during the middle

to late Tertiary that gave the province its distinctive physiography and geology.

The rocks exposed in the Basin and Range province in the site region (Sonoran Desert region) are grouped into eight sequences:

- Older Precambrian granite and schist
- Younger Precambrian granite and schist
- Paleozoic sedimentary rocksMesozoic-early Tertiary sedimentary and igneous rocks
- Mesozoic to early Tertiary crystalline rocks
- Tertiary volcanic and sedimentary rocks
- Late Tertiary-Quaternary volcanic rocks
- Tertiary-Quaternary continental deposits

The Mesozoic and older rocks are discussed in detail in the PVNGS 1, 2, and 3 PSAR(8). The Tertiary and younger volcanic and sedimentary rocks are discussed in detail herein because they determine the important geologic relationships in the site area.

Tertiary volcanic rocks generally range in composition from rhyolite to andesite whereas the late Tertiary-Quaternary volcanic rocks are predominantly basalts. In the Sonoran Desert, volcanic eruptions were small and limited to the vicinities of the Batamonte and Childs Mountains near Ajo, near Gila Bend, Arlington, Gillespie Dam, Crater Mountains, and the Sentinel Plain. Dating by potassium-argon techniques(8)

indicates ages of 16 to 28 million years before present (m.y. BP) on the deformed Tertiary volcanic rocks near Gillespie Dam and the Palo Verde Hills. Ages on the undeformed basalt flows are:

- Sentinel 1.71 ±0.25 million years
- Gila Bend 2.2 to 6.4 million years
- Gillespie Dam 1.3 to 4.2 million years
- Arlington 1.2 to 3.2 million years

The Tertiary to Quaternary continental deposits are predominantly sedimentary deposits with some associated volcanic rocks which were deposited in structural basins characteristic of the present Basin and Range physiography. These basin-fill deposits consist of alluvial fan, fluvial floodplain, and lakebed deposits. The potassium-argon age dating of the four basalt flows which overlie the continental deposits indicate a late Pliocene or early Pleistocene minimum age for basin-fill deposits in southwestern Arizona.

2.5.1.1.2.4 Transverse Ranges. The eastern extremity of the Transverse Ranges of California lies slightly within the site region. The Transverse Ranges, as the name implies, are oriented transversely (east-west) to the northwest trending Sierra Nevada and Coastal Ranges. The total length of the province is approximately 300 miles, from the region offshore of Point Conception in south-central California to the Eagle Mountains, 50 miles from the Colorado River. The eastern

segment is separated from the larger western segment of the province by the San Andreas fault set.

The eastern Transverse Ranges are composed primarily of crystalline basement rocks (figure 2.5-2). The Little San Bernardino, Pinto, and Eagle Mountains primarily consist of biotite quartz monzonite of Mesozoic age, referred to as the Cactus Granite, which contains numerous inclusions of metamorphic rocks. Some large areas are underlain by gneiss, schist, amphibolite, quartzite, and other metamorphosed rocks of possible Precambrian age(9).

2.5.1.1.2.5 Salton Trough. The Salton Trough province is a downwarped, downfaulted, and laterally translated structural trough which contains highly seismically active faults of the San Andreas Shear Zone. The strata of this province consist primarily of late Tertiary to Quaternary continental alluvial, aeolian, lacustrine, and marine sediment (figure 2.5-2) which reach thicknesses in excess of 16,000 feet in the central Imperial Valley(10). Quaternary volcanic extrusions occur at the south end of the Salton Sea and at Cerro Prieto in Mexico. The northern trough is underlain and bounded by Mesozoic and older Crystalline rocks. The Gulf of California comprises up to 3000 feet of modern marine sediment overlying oceanic basalts of Pliocene to Holocene age(11).

2.5.1.1.2.6 Peninsular Ranges. The Peninsular Ranges province occupies the southwestern corner of California and extends southeastward into Baja, California. The Peninsular

Ranges within the site region consist primarily of Mesozoic (90 to 100 m.y. BP) batholiths ranging from gabbro to granite in composition. The batholiths extend at least 500 miles down the Baja Peninsula but may extend much farther under the concealment of younger volcanic rocks.

These plutonic bodies intruded Jurassic and Triassic rocks which now comprise schists, quartzites, and marbles, and some shales and volcanics. Younger rocks are largely sedimentary, partly marine and partly continental, and range in age from late Cretaceous to Pleistocene. The marine rocks are exposed mostly at the northern end of the province and along the coast. Continental deposits were laid down in inland basins. Volcanic rocks are about middle Miocene age but are very limited in extent.

2.5.1.1.3 Regional Tectonics

2.5.1.1.3.1 Introduction. Tectonic features of the region are depicted in figures 2.5-3 through 2.5-7. Tectonic features in the region surrounding the site (200-mile radius) are depicted on figure 2.5-4. Faults and folds are shown on figure 2.5-5. Quaternary faults are shown on figure 2.5-6. The tectonic features shown in these figures are grouped according to broad generalized characteristics into five major tectonic provinces (figure 2.5-3): the Colorado Plateau, Basin and Range, Salton Trough, Transverse Ranges, and Peninsular Ranges.

Several large regional structural lineaments have also been postulated in the site region by various authors. These

features are the San Andreas Shear Zone, Death Valley-Furnace Creek Shear Zone, Walker Lane-Las Vegas Shear Zone, Texas Lineament, and Jerome-Wasatch Structural Zone (figure 2.5-7). Some of these features are capable faults and seismically active (San Andreas Shear Zone) whereas others may be partly capable (Death Valley-Furnace Creek Shear Zone), and others may represent ancient geologic and tectonic trends which no longer act as throughgoing tectonic features (for example, the Texas Lineament).

2.5.1.1.3.2 Tectonic Provinces.

A. Basin and Range Province

The largest tectonic province in the site region, and the one in which the site is located, is the Basin and Range province. This province extends over large portions of the western United States including southern Oregon and Idaho, Nevada, western Utah, south-eastern California, southern Arizona, southwestern and central New Mexico, and northern Mexico. This region has been considered as one structural province because of similarity of Cenozoic tectonic features and tectonic mechanisms[12]. However, more than a decade of research and tectonic syntheses subsequent to Hamilton and Myers[12], for example,[13-23] have shown that late Cenozoic tectonic processes provide a basis for subdividing this large province into smaller neotectonic zones or seismotectonic zones. In the following discussion,

some of the important neotectonic zones are discussed but the basic tectonic province approach used in the PVNGS 1, 2, and 3 PSAR[8] remains unchanged because it still represents a conservative framework within which to determine seismic design parameters.

The Basin and Range province is typified by elongate mountain ranges separated by broad alluvial valleys. The boundaries between the valleys (basins) and mountains (ranges) are generally quite abrupt and commonly represent faults. These boundary faults are predominantly normal faults.

The province has experienced numerous orogenic episodes since Precambrian time. The younger major episodes of deformation within the province occurred in early Mesozoic (Nevadan Orogeny), late Cretaceous, early Tertiary (Laramide Orogeny), and middle Tertiary-late Tertiary (Basin and Range disturbance) times. The Paleozoic and Mesozoic compressional orogenic features are largely obscured by extensional Basin and Range-type block faulting which has separated the former contiguous terrain into numerous widely spaced blocks. This extensional tectonic phase may have begun as early as Eocene or Oligocene times[12][24] but the present episode of Basin and Range-type faulting began in the middle Miocene time[20]. The extent of tectonic activity in late Cenozoic time varies throughout different areas of the province. The distribution of Quaternary faults (figure 2.5-6)

shows that the Quaternary activity in the site region was largely restricted to the

Nevada-Utah (Great Basin), Mojave, and Mexican Highlands regions of the province. The predominance of north-northeast oriented normal faulting in the Great Basin (Nevada and Utah), north-south oriented normal faulting in the Mexican Highlands, northwest-trending strike-slip structures in the Mojave Desert, northwest-trending normal faults associated with abundant volcanic activity along the southern and southwestern edge of the Colorado Plateau, and very little Quaternary faulting in the Sonoran Desert region indicates that each of these regions have been under different tectonic regimes or have reacted differently to pervasive regional stresses during Quaternary time. The relatively heterogeneous structural fabric of the Sonoran Desert region, its relatively subdued physiography, and its near lack of Quaternary faulting indicate that this province escaped the Quaternary tectonic activity occurring in its bordering provinces.

The subdued Basin and Range topography of the Sonoran Desert region is separated from the well developed Basin and Range topography in the Great Basin by a transverse tectonic zone across the southern tip of Nevada. This transverse zone was first noted by Slemmons(25) who thought that it might represent the southern edge of the Basin and Range province. This

zone has been termed the Southern Nevada Seismicity Zone by Smith and Sbar[17] and Smith[26] who were impressed by the abundance of seismicity in the region. Anderson[27] noted that the geologic and geophysical data indicate a "major structural corridor" that transects the northerly trending structural grain. Howard, et al,[21] noted the difference in fault characteristics between the Great Basin and Sonoran Desert regions and placed a boundary between the two which coincides with the southern edge of the transverse zone. Focal mechanism solutions[28] in this area indicate both strike-slip and normal faulting mechanisms which are indicative of a stress regime which is somewhat different from the central Great Basin to the north and its eastern and western boundaries[29].

The only area within the Sonoran Desert region that demonstrates any appreciable seismicity or Quaternary faulting is the Pinacate volcanic area along the Mexico-Arizona border. This volcanic field is the largest family of Holocene volcanoes in the Sonoran Desert region and also the youngest. Some of the volcanoes have erupted within the last few thousand years[30][31]. The lavas and pyroclasts are chiefly basalt which have emanated from a number of deep-seated volcanoes as gaseous, violent eruptions[31]. Short, et al,[32] suggest that the origin of this volcanism is related to the rifting processes that

created the Gulf of California. The volcanic field lies astride the projection of the eastern edge of the Salton Trough and is directly northeast of a dense cluster of earthquakes near Wagner Basin beneath the waters at the head of the Gulf of California (figure 2.5-2 and subsection 2.5.2). These earthquakes probably represent activity on a small seafloor spreading center in Wagner Basin, between transform faults within the San Andreas Shear Zone[33]. There are a few, very small capable and Quaternary faults in the Pinacate region[8][21] which are related to young volcano-tectonic activity[29].

The southeastern corner of the province, in south-eastern Arizona, southwestern New Mexico, and northern Sonora and Chihuahua, Mexico is referred to as the Mexican Highlands region. The Mexican Highlands region is distinguished from adjacent regions by its well developed north-south trending Basin- and Range-type physiography which is a result of earthquake activity and geologic structural trends[21][34]. These trends are accompanied by predominantly north-south trending Quaternary faults, several of which are of great length but there is only one instance of historic surface rupture. This occurred during the 1887 Sonoran earthquake (paragraph 2.5.2.1.4.2). Similar to the Great Basin portion of the tectonic province, and in contrast to the Sonoran Desert region, the Mexican Highlands region has a ratio of

basin area to mountain area of about 1 to 1. This ratio, the relatively youthful geomorphic appearance of the basins and ranges, and the recency of faulting suggest that this region has undergone much more recent tectonism than the adjacent Sonoran Desert region.

B. Colorado Plateau Province

The Colorado Plateau province occupies the four adjacent corners of Colorado, Utah, Arizona, and New Mexico. This province comprises flat-lying, relatively undeformed, Paleozoic through early Tertiary strata overlying deformed Precambrian basement. This province is the remnant of a formerly much more extensive continental terrain which has been chipped away at the edges by extensional tectonics[35-38]. In general, the Colorado Plateau is topographically high and does not display much internal Quaternary geologic deformation. Most of the present tectonic activity occurs along its boundaries in zones such as the Wasatch-Hurricane frontal fault system on the west, the southern Rocky Mountains and Rio Grande rift on the east, and the Transition Zone-Arizona Mountains physiographic province/subprovince on the south and southwest.

The continental crust comprising the Colorado Plateau is 27 miles thick and is shieldlike, whereas the normal faulted regions surrounding the plateau have

thinner crusts[35]. Prior to Miocene time, the area of the Basin and Range province was topographically high relative to the Colorado Plateau. Between about 18 and 10 m.y. BP, the situation reversed and the Colorado Plateau has remained high ever since[37].

C. Salton Trough

The Salton Trough province is a structural trough between the Basin and Range and Peninsular Ranges provinces. The Salton Trough deepens gradually to the south and appears to be structurally continuous with the Gulf of California[39]. This trough is bordered by and contains the most seismically active faults in the site region; the San Andreas, San Jacinto, and Elsinore fault sets (paragraph 2.5.2.2.2).

The San Andreas fault is generally considered to be the contact between the North American and Pacific plates (paragraph 2.5.1.1.5) and as such is highly seismically active with several historic surface ruptures and abundant evidence of repeated movement during Quaternary time on its northern segment. However, the vast majority of seismicity in the Salton Trough clusters around the San Jacinto fault set[40] and strands of the San Jacinto fault set such as the Coyote Creek, Superstition Hills, and the Imperial faults have been historically active. This higher rate of activity indicates that the San Jacinto fault

set is the most important plate-boundary fault within the Salton Trough.

The three major fault sets in the Salton Trough and the numerous faults lying between are herein referred to as the southern San Andreas Shear Zone. The principal movement along this system is right-lateral but lateral crustal inhomogeneities and unfavorable structural trends set up a very complex stress-strain system and thus other types of movements occur locally, such as reverse faulting in the "big bend" area of the Transverse Ranges and normal faulting along the southern margin of the trough. Displacement of several hundred miles along this shear zone was documented by Hill and Dibblee(41), but it was not until plate tectonic concepts were developed that the broader aspects of this fault system as a transform-fault plate boundary were understood(42). The San Andreas Shear Zone has been episodically active along the northern portions of its trace since before Late Cretaceous time(43). However, in southern California, the most severe, if not the first, displacements have occurred since Miocene time(44-48). Much of this movement has occurred within the last 4 to 6 m.y. when spreading activity opened the Gulf of California(11)(13)(49).

The northeastern boundary of the Salton Trough (San Andreas Shear Zone) is along the San Andreas fault

set, which comprises the Mission Creek, Banning, and the San Andreas faults, between the floor of the trough and the adjacent mountain ranges (figure 2.5-6). The San Andreas fault set cannot be traced south of the Salton Sea on the basis of surface geology or seismicity and numerous speculations have been advanced on the location and even the very existence of the southern extension of the San Andreas. There appears to be two viable hypotheses; either it terminates near the southern end of the Salton Sea with major activity shifting to the Imperial fault, or it continues directly southeastward where its active nature is masked by the mobile sand dunes and rapid alluviation of the Colorado River. The Algodones fault in the Yuma, Arizona area lies along the southeasterly projection of the San Andreas and has been hypothesized as its direct continuation(50). Merriam(51) postulated that the San Andreas continues well into Mexico east of the Gulf of California. Geophysical and geotechnical studies in the Yuma, Arizona area(52) show that the Algodones fault has been active in late Pleistocene time but that its displacement is down to the east in a dip-slip sense. This sense of displacement does not favor the hypothesis of the Algodones fault as the southeastern extension of the San Andreas, but the location of the Algodones fault and its recent activity suggest that it probably functions as one of

the eastern bounding faults of the Salton Trough and thus it should be considered as one of the faults in the San Andreas Shear Zone.

D. Transverse Ranges Province

The east-west structural trend of the Transverse Ranges is a notable exception to the general northerly and northwesterly trend of most western United States mountain belts. Quaternary left-lateral and reverse faults, similar earthquake focal-mechanism solutions, and east-west trending fold axes indicate that the province is under a north-south compressional stress regime. The San Andreas fault separates the Transverse Ranges into eastern and western segments and movement along the San Andreas plate boundary may have played a role in formation of the east-west trends(13)(15). The eastern segment has the same compressional tectonic patterns as the western segment but these patterns appear to be caused by movement between different crustal blocks on each side of the San Andreas.

The eastern Transverse Ranges province bounds the Mojave block on the south. The major faults in the eastern Transverse Ranges province are the Quaternary-age, east-west trending Pinto Mountain and Blue Cut faults. The frontal fault is a reverse fault along which the San Bernardino Mountains have been uplifted from the Mojave Desert. The Pinto Mountain fault has

a cumulative left-lateral displacement of about 10 miles[53]; and the Blue Cut fault shows 3 to 4 miles of left slip[54]. Abundant seismic activity, displacement of alluvium, and uplift of the San Bernardino Mountains[55] indicate active tectonic forces in the province and along its boundaries.

E. Peninsular Ranges Province

The Peninsular Ranges occupy the southwestern part of the state of California and most of the Baja California peninsula. In California, mountains that comprise the Peninsular Ranges are the San Jacinto, Santa Ana, Santa Rosa, and Laguna Mountains. These ranges trend northwest-southeast and are separated by the major, northwest-striking, San Jacinto and Elsinore fault sets. These fault sets are members of the San Andreas Shear Zone, thus the northeastern portion of the Peninsular Ranges physiographic province is not part of the Peninsular Ranges tectonic province as defined herein. The Elsinore fault set forms the boundary between the San Andreas Shear Zone and the Peninsular Ranges which, under this definition, consists predominantly of the Santa Ana block, a stable, massive, continuous Mesozoic plutonic massif forming the backbone of the California and the northern Baja Peninsular Ranges. Such a division of tectonic provinces is consistent with Richter's zones[56] and the Peninsular Ranges province corresponds to his Coastal Stable Block.

The Santa Ana block is nearly aseismic and is bounded on the west by the Santa Monica to Baja zone of deformation and on the south by the numerous faults associated with the San Miguel, and Agua Blanca fault zones in Mexico. These Mexican faults have been identified as capable faults on the basis of Quaternary displacement and seismicity[57]. The province's eastern bounding fault, the Elsinore fault, aligns with the Laguna Salada fault near the U.S.-Mexico border and lies just within the site region. The low level of Quaternary and historic tectonic activity renders this fault subordinate to the San Andreas and San Jacinto fault sets[38][58], but it is considered a capable fault (paragraph 2.5.2.2.2).

2.5.1.1.3.3 Major Tectonic Lineaments. Four major structural zones or tectonic lineaments have been postulated to trend through the site region. These features are:

- The San Andreas Shear Zone
- The Death Valley-Furnace Creek Shear Zone
- The Jerome-Wasatch Structural Zone
- The Walker Lane-Las Vegas Shear Zone and Texas Lineament

The San Andreas Shear Zone (figure 2.5-7), lying about 120 miles southwest of the site, is the most pronounced tectonic lineament in western United States and has been postulated to be a transform fault system along the Pacific-North American

plate boundary (paragraph 2.5.1.1.3.2). It is a zone of active right-lateral shear with displacements in southern California estimated to be in excess of 190 miles[59] and about 350 miles in northern California[41], and a high rate of historic seismicity.

The northwest-trending Death Valley-Furnace Creek fault system is a right-lateral shear system in the Death Valley, California region -- its type locality. Hunt[60] and Hamilton and Myers[12] postulate an extension of the Death Valley-Furnace Creek fault zone toward the southeast into southern California and Arizona. However, the extension is based solely on small local displacements at scattered localities and diffuse seismicity in the southwest corner of Arizona. There is no geologic expression of this zone in Arizona and recent, more detailed tectonic studies[61][62] in the eastern Mojave Desert show that the Death Valley-Furnace Creek fault zone does not extend very far southeast of the eastern Garlock fault-Avawatz Mountain region.

The Jerome-Wasatch structural zone comprises several different tectonic elements along the Colorado Plateau-Basin and Range boundary, the Arizona Mountains-Transition Zone along the southern boundary of the Colorado Plateau, and the linear mountain ranges in the Mexican Highlands region. Neotectonic syntheses[21][22] show these areas as discrete zones and do not consider the lineament to represent a continuous, through-going fault zone.

The Walker Lane-Las Vegas Shear Zone is a discontinuity between the north-northeast trending basins and ranges of the Great

Basin in Nevada and the northwest-southeast trending ranges of the Owen's Valley-Death Valley region. The feature is primarily a late Tertiary, right-lateral feature[63] and is not associated with any concentration of seismicity or Quaternary faulting; thus is not an active or capable fault zone.

The Texas Lineament is a diffuse zone of structural disturbance that was postulated to trend northwest from southwestern Texas[64] across southwestern New Mexico and central Arizona, and which has been further postulated by some authors to ultimately connect with the Walker Lane-Las Vegas Shear Zone[60]. Various authors have commented on the lineament's characteristics, continuity, association with active faulting, association with copper mineralization belts and its sense of movement [17][60][63-76]. The geologic evidence for the location, trend, and even the existence of the Texas lineament through New Mexico and Arizona is scanty and ambiguous and this ambiguity allows an abundance of permissive arguments. Evidence suggests that it is an ancient feature which no longer acts as a through going tectonic element. Several lines of evidence indicate that these are not young fault zones. The most notable negative arguments are:

- Age relationships of the mineral deposits appear to relegate its activity to Laramide time[77].
- Reconstruction of the late Cretaceous-early Tertiary Cordilleran Orogeny[63] shows no indication of a major throughgoing transcurrent fault.

- The Las Vegas Shear Zone which supposedly connects the lineament with the Walker Lane has not shown any activity in Quaternary time. Where it is postulated to transect the Rio Grande Rift, it does not affect Tertiary-Quaternary north-south tectonic features associated with the rift.

2.5.1.1.4 Regional Geologic History

The regional geologic history can be divided into three major intervals; pre-Laramide, Laramide, and post-Laramide.

2.5.1.1.4.1 Pre-Laramide Interval. The pre-Laramide interval (Precambrian-late Mesozoic) in the site region was generally a period of synclinal sedimentation in the Sonoran and Californian geosynclines. Periods of major tectonic deformation in the Precambrian, the Mazatzal Revolution (1200 m.y. BP), and the Grand Canyon disturbance (late Precambrian), disrupted sedimentation by igneous intrusive activity, uplifting, faulting, and folding. Paleozoic geosynclinal sedimentation was interrupted by episodes of uplift and erosion in the Cambrian, Devonian, and Mississippian periods.

During the Triassic-Jurassic period, the Nevadan Orogeny caused a disruption of the Cordilleran geosyncline and a major uplift and erosional unconformity in pre-Cretaceous rocks.

2.5.1.1.4.2 Laramide Interval. The Laramide Orogeny began in late Cretaceous and extended into earliest Cenozoic time.

Laramide folding and faulting were relatively minor on the Colorado Plateau but were intense in the Basin and Range province[3]. Laramide igneous activity was marked by the emplacement of batholiths, stocks, dikes, plugs, and volcanic rocks, especially within the Basin and Range province. Within the Colorado Plateau province, the Laramide orogeny produced folds and faults which created a basin or trough area surrounded by newly formed mountains. Deposition continued in this basin until Eocene time.

2.5.1.1.4.3 Post-Laramide. In post-Laramide time, structural movements, volcanic and igneous activity, erosion and sedimentation all acted upon preexisting geologic features to form the present plateaus, mountains, valleys, and drainage patterns[78].

Regional uplift, as well as flexing and faulting, increased during the Miocene and culminated in the Miocene or early Pliocene. The effects included the gentle northeast tilting of the Colorado Plateau and further arching in the Transition Zone(3). During this time the Colorado Plateau and the Basinand Range area became separate features(79).

This uplift served to disrupt the southwesterly drainage. Gorges were cut in the rising mountains before complete disruption occurred, and some of these gorges form a part of the present drainage system. Formation of the present Basin and Range topography in the southern part of the state disrupted drainage diverting it into newly formed basins.

Pediments and other erosion surfaces were locally developed before the Pliocene basin fill accumulated.

Continuing structural movement, volcanic activity, and diversion of waters during the Pliocene resulted in complex changes of the drainage pattern. The reduction of stream gradients or blocking of valleys allowed the deposition of hundreds to thousands of feet of sediments during much of the Pliocene. The character and stratigraphic relationships of these sediments suggests that much of the material was brought into the valleys by through-flowing rivers. Coarse deposits in the form of alluvial fans and pediment gravels were shed from the mountains in middle and late Pleistocene time[78]. Holocene deposition of alluvium continued locally, but the presence of surficial Pliocene-Pleistocene basalt flows indicates that Holocene sediments are thin in many parts of southwestern Arizona and that most basin fill may actually be Pliocene and Pleistocene in age rather than Holocene as shown on many published geologic maps.

2.5.1.1.5 Regional Tectonic History

A clear understanding of the tectonic evolution of the south-western United States can only be approached through an understanding of global tectonic events. The complex geology of the western United States is due to a long history of complex plate tectonic events requiring that orogenic belts be viewed as collages of diverse tectonic elements jumbled together in many possible ways and with a great deal of overprinting of different structural and metamorphic events.

The Precambrian and Paleozoic history is fragmental and too far in the past to be of much consequence to the safety of the Palo Verde site; thus it is highly summarized below. It is primarily the middle Cenozoic to Holocene tectonic activity that is responsible for formation of the features present today in southwestern Arizona.

Western North America appears to have been the passive trailing edge of a lithospheric plate during Precambrian and early Paleozoic time[80]. Exactly when subduction began under western North America is not clear. Churkin[81] argues that subduction and the opening and closing of marginal ocean basins began as early as the Ordovician; the Devonian-Mississippian Antler orogeny, which occurred from Nevada north to the Yukon, suggests that plate convergence had begun at least by Devonian time. However, andesitic volcanism, generally considered indicative of subduction, did not occur extensively until Permian through Cretaceous time. By late Jurassic time, a broad, high magmatic arc edifice had developed along the site of the present Sierra Nevada, and granitic batholiths formed beneath, especially in Late Cretaceous time[82]. Essentially conformable Cretaceous, Paleocene, and Eocene strata with similar bedding characteristics in western California suggest continuation of the Mesozoic subduction regime until about 40 m.y. BP[83].

Major tectonic reorganization occurred in middle Tertiary time, not only in the western United States but throughout the whole circum-Pacific area. In the Pacific Northwest, the north-south trending Cascade volcanic belt was superimposed across older

arcuate, eastwardly convex structures. Basin and Range block faulting began to segregate a previously continuous broad Laramide uplift comprising much of the western United States[37]. Also, the most severe -- if not the first -- displacements along the San Andreas fault system began in Miocene time[44][45][47][48]. These middle Cenozoic tectonic events, combined with similar accelerated tectonism and volcanism in areas such as the Alaska-Aleutian area, Japan, Mexico, Central America, and South America suggest a major middle Cenozoic change in sea-floor spreading[84]. Atwater[13] postulated that the major changes in the western United States were due to the encounter of the Americas plate with the East Pacific spreading center. Herron[85] demonstrated that the present East Pacific ridge has developed in the past 30 m.y. at the expense of a former north-northwest trending ridge, and Handschumacher[86] documented a major reorganization of the spreading regime in early Miocene. The geologic record in the western United States suggests that the Basin and Range disturbance was not a single episode but apparently consisted of two or three phases. The earliest extensional phase in the Great Basin area in the Oligocene and early Miocene (42 to 18 m.y. BP) may have been oriented quite differently than today's[24]. Middle Miocene (17 to 14 m.y. BP) extension was oriented S68°W-N68°E (±5°) about 45 degrees counterclockwise from the present direction of extension which is oriented about N65°W-S65°E (±20°)[20].

About 4 to 6 m.y. ago, sea-floor spreading activity abruptly began in the region of the Gulf of California[13][86],

establishing the San Andreas Shear Zone as the plate boundary. This spreading activity changed the stress regime in southern California and Arizona, creating the Transverse Ranges and initiating eastward movement of the Mojave block which effectively neutralizes the Sonoran Desert block's extensional tectonic regime[15][87]. In very recent time (late Holocene), the major plate-boundary movements appear to have shifted westward from the San Andreas to the San Jacinto fault set.

At present, the major tectonic mechanisms operative in the southwestern U.S. are extension in the Great Basin and Rio Grande Rift-Mexican Highlands regions and shearing along the San Andreas Shear Zone.

2.5.1.1.6 Regional Geophysics

Regional gravity and aeromagnetic maps reflect the known regional geologic conditions[8]. Both maps show the Sonoran Desert area to be a region of relatively randomly oriented, low-gradient trends representative of heterogeneous faultblock structures masked by large thicknesses of sediments. In contrast, the southeastern part of the state and a curvilinear area across central Arizona from the New Mexico border to the Utah border are regions of high contrast, more-linear trends representative of more rugged terrains of surface and near-surface rocks. The gradients in the northeastern corner of the state are relatively smooth and reflect the relatively homogeneous structure of the Colorado Plateau.

2.5.1.1.7 Regional Subsidence

Regional subsidence due to processes such as tectonic down-warping is not prevalent in the site region, but subsidence due to compaction of basin fill due to lithostatic loading and groundwater withdrawal does occur in local areas throughout the site region.

Tectonic downwarping suggested by Cooley[88], in the form of a large syncline extending northwesterly from the Tucson area through the Phoenix area and westward toward the site, does not extend into site area and thus does not represent a hazard to the Palo Verde site. The very existence of such a zone of subsidence is questionable because it crosses known structural trends and is not consistent with any known or postulated tectonic stresses.

Subsidence that occurs when groundwater is withdrawn from basins, allowing the sediments to consolidate due to loss of pore fluid, is generally slow and generally does not result in great amounts of subsidence. Sometimes, however, surface cracks, land-surface tilting, and rapid subsidence occur and these processes could present a hazard. Areas of subsidence and ground cracking in the site region due to groundwater withdrawal (Eloy-Picacho, Luke Air Force Base, Las Vegas, Nevada) have been analyzed[8] and the analyses have shown that certain conditions must exist to permit consolidation. The areas most affected by subsidence are basins filled with great thicknesses (greater than 2000 feet) of permeable, low density alluvial sediments where large amounts of groundwater are

withdrawn resulting in water level declines on the order of 100 feet or more[89]. Comparison of these conditions (both gross field characteristics and laboratory test results) to conditions in the site region (table 2.5-1) reveal that subsidence is not a hazard at the site (paragraph 2.5.4.1).

2.5.1.1.8 Miscellaneous Regional Geologic Hazards

Geologic studies in the region surrounding the site have shown that there is no potential hazard due to processes such as salt diapirism, landsliding, ground collapse due to cavernous or karst terrain, and unusual weathering or erosion.

2.5.1.2 Site Geology

2.5.1.2.1 Site and Site Vicinity Physiography

The site is located in one of the intermontane valleys of the Sonoran Desert region of the Basin and Range physiographic province. This valley, known as the Tonopah Desert, is broad and relatively flat-floored, with through-flowing, intermittent drainage graded to the Gila River, the regional trunk stream. The site lies between two major intermittent drainages, the Hassayampa River on the east and the Centennial Wash on the southwest. These two drainages are within 3 to 5 miles of the site and drain toward the northern bend of the Gila River near Arlington. The major surrounding mountain ranges are the Palo Verde Hills to the west, the Belmont Mountains to the north, the White Tank Mountains and Buckeye Hills to the northeast and southeast, and the Gila Bend Mountains to the south. Like most mountain ranges in the Sonoran Desert, the flanks of the

surrounding mountains consist of pediment and alluvial fan surfaces that grade gently to the basin floor. The basin floor slopes gently southward from about 1500 feet above sea level at the edge of the Belmont Mountains to about 800 feet elevation along the course of the Gila River southeast of the site. The site is nestled between outliers of the Palo Verde Hills on a flat surface, at about 950-foot elevation, herein referred to as the Palo Verde Hills Basin. The nearest edge of the Palo Verde Hills is about 2 miles west of the site; the outliers are low-relief, rounded knobs protruding through the alluvium north and south of the site. The Palo Verde Hills range in elevation from about 1200 feet directly adjacent to the site to more than 2100 feet at their highest point about 5 miles northwest of the site. The basin floor is dissected by several small ephemeral streams which flow southward and are integrated with the Gila River, about 10 miles southeast of the site. The natural, intermittent flow of water in the washes has now been interrupted by an agricultural irrigation system and by PVNGS construction activities. The micro-relief system, leveled in local areas by agriculture, consists of small rills and gullies that carry the normal runoff into the washes.

Table 2.5-1

COMPARISON OF GEOLOGIC AND HYDROLOGIC CONDITIONS, LUKE AIR FORCE BASE AREA, LAS VEGAS VALLEY, PALO VERDE HILLS AREA (Sheet 1 of 2)

	Luke AFB (Eaton, et al., 1972)[a]	Las Vegas (Mindling, 1971)[b]	Palo Verde Site
Thickness of basin sediments	Greater than 2350 feet	Greater than 4000 feet	480 feet
Thickness of compres-sible sediments	Not available	500+ feet	250 feet (includes very stiff clay and dense granu-lar soils
Depth interval from which water is derived	300 to 1400 feet	200 to 700 feet	700 to 1000 feet (from confined, bedrock aquifers below compres-sible sediments)

a. Eaton, G. P., Peterson, D. L., and Schumann, H. H., 1972, Geophysical, geo-hydrological and geochemical reconnaissance of the Luke Salt body, central Arizona: U. S. Geol. Surv. Prof. Paper 753, 28 p.

Table 2.5-1

COMPARISON OF GEOLOGIC AND HYDROLOGIC CONDITIONS, LUKE AIR FORCE BASE AREA, LAS VEGAS VALLEY, PALO VERDE HILLS AREA (Sheet 2 of 2)

	Luke AFB (Eaton, et al., 1972)[a]	Las Vegas (Mindling, 1971)[b]	Palo Verde Site
Drawdown	250+ feet	180+ feet	In site area for the period 1955 to 1975, approximately 40 to 50 feet
Subsidence	0 to 3 feet	0 to 5 feet	None
Earth fissures	Three areas of fissuring related to large scale withdrawal of groundwater. Fissures possibly associated with differential consolidation over crest of the Luke salt body and compressibility differences in subsurface deposits.	Four areas of fissures localized by differential consolidation across older compaction fault scarps.	None

2.5.1.2.2 Site Vicinity Geology and Relationship to Regional Geology

2.5.1.2.2.1 Site Vicinity Stratigraphy. Figure 2.5-8 is a geologic map and simplified stratigraphic column of the area within a radius of 25 miles of the site (site vicinity). Figure 2.5-9 shows geologic cross-sections illustrating the subsurface geologic relationships of the site vicinity.

The geologic formations within the site vicinity are typical of the Sonoran Desert subprovince and include highly deformed metamorphic and granitic rocks of Precambrian age and moderately deformed volcanic and sedimentary units of Tertiary age in the mountains, and undeformed volcanics and sediments of Pliocene to Holocene age in the basins. The metamorphic and granitic rocks are termed basement and the moderately deformed volcanic and sedimentary units are termed bedrock, and the undeformed volcanics and sediments are termed basin sediments.

The emplacement of Precambrian plutons of granitic and gabbroic composition are generally associated with the culmination of the Mazatzal Revolution, and resulted in the metamorphism of surrounding rock to schist and gneiss(3).

The metamorphic rocks are the oldest rocks in the site vicinity and are subdivided into three subgroups: greenschist facies metamorphics, metadiorites, and gneissic, granitic and hornfelsic rocks.

The greenschist metamorphic rocks make up only a small fraction of the rocks in the site vicinity. They crop out 5 miles west of Gillespie Dam and on the east flank of Saddle Mountain. The

metadiorites are rare intrusive bodies found only in conjunction with the greenschist metamorphics in the Gillespie Dam area. The gneissic rocks are the predominant metamorphic subgroup in the site vicinity and compose about one-third of the Belmont Mountains and all of the White Tank Mountains. A large segment of the Gila Bend Mountains, 20 miles west of Gillespie Dam, is composed of gneiss. Scattered outcrops of gneiss are also exposed 2 miles south of Gillespie Dam. The granitic rocks are represented by granite and quartz monzonite, including aplite and alaskite, outcrops in the eastern portion of the Belmont Mountains, Maricopa Mountains, the entire Buckeye Hills, and in the Gila Bend Mountains. Although not exposed in the Palo Verde Hills, granitic basement rocks were encountered in exploratory borings beneath the site property (figure 2.5-10).

Bedrock in the site vicinity consists almost entirely of Tertiary volcanic rocks and Tertiary volcano clastic and sedimentary rocks unconformably overlying the Precambrian basement rocks (figure 2.5-9). The age and composition of these rocks are similar to those throughout the entire Basin and Range province. Tertiary sedimentary and volcanic rocks are exposed in the western portion of the Belmont Mountains and the south-central flanks of the Gila Bend Mountains. Sedimentary rocks in the Gillespie Dam area consist of arkosic conglomerate, lahar deposits, tuffaceous sandstone, and cross-bedded sandstone. The Tertiary sedimentary members of the sequence are interbedded with the Miocene andesite and basalt flows, flow breccias, and pyroclastic rocks. The Gila Bend

Mountains are primarily composed of andesite and basalt which range in age from 19 to 28 m.y. BP. In the Palo Verde Hills, basaltic andesite, diabase, and basalt, with minor amounts of interbedded tuff, are approximately 17 to 21 m.y. old.

Basin filling deposits overlying the Tertiary volcanic-sedimentary bedrock sequence are talus, colluvium, alluvial fan, basin alluvium, lacustrine, and fanglomerate. Ages of alluvial fan deposits on the surrounding mountain flanks range from Tertiary to Holocene, based on potassium-argon ages of overlying basalt flows. Two series of alluvial fan deposits (QTfn and TVfn) are stratigraphically below the Arlington and Gillespie basalt flows and, therefore, are late Pliocene in age (greater than 2 m.y. BP). Massive, extensive clay deposits penetrated by numerous water wells in the Phoenix and Gila Bend basins attain a thickness of more than 700 feet between Phoenix and Litchfield Park and 850 feet in the Gila Bend Basin. These clay deposits are usually continuous across individual basins but there is no direct evidence that they are continuous between adjoining basins.

Late Tertiary and early Quaternary basalt flows interbedded with and overlying the basin sediments are the youngest volcanic rock units in the site vicinity. Four extensive olivine-basalt flows overlie Gila River terrace deposits and alluvial fan deposits. Whole-rock, potassium-argon ages of these flows are:

- Gillespie: 1.3 to 4.2 million years (nine samples) -- average age 3.3 million years

- Arlington: 1.2 to 3.2 million years (six samples) -- average age 2.2 million years
- Sentinel: 1.71 ±0.25 million years (one sample)
- Gila Bend: 2.5 to 6.5 million years (three samples) -- average age 4.5 million years

The youngest volcanic flows appear to be similar to widely scattered geomorphically young vents and flows throughout the Sonoran Desert subprovince. These volcanics are generally shown on published maps(90) as Quaternary basalts, but the age data given above shows them to be earliest Quaternary and/or latest Tertiary in age.

2.5.1.2.2.2 Site Vicinity Structure.

A. General

The structure of volcanic bedrock in the Palo Verde Hills is homoclinal with the volcanic flow-bedding striking approximately N40°W and dipping 15 to 23°SW. To the north of the 5-mile radius, scattered northerly and northeasterly dips have also been noted. These dips suggest small intraformational folding probably associated with irregularities on the original surface of flow deposition or proximity to one of the numerous vent or source areas.

B. Faults

Published detailed geologic maps of Arizona and Maricopa County do not indicate any faults within the site

vicinity. The existence and position of mountain-basin boundary faults (figures 2.5-8 and 2.5-11) have not been directly documented in the site vicinity and are only inferred from published regional geologic maps and gravity data(8)(88)(91). The existence of these inferred and hypothetical faults in the site vicinity is based on extrapolations of regional Basin and Range-type geologic characteristics. Our investigations could find no surface or near-surface evidence of these faults; therefore, if they are assumed to exist, they are in older rocks at depths beyond the reach of state-of-the-art geotechnical methods and would not be considered capable faults under existing criteria.

Techniques used to investigate these inferred faults included interpretation of aerial photographs, ERTS-1 imagery, and side-looking radar imagery; reconnaissance and detailed geologic mapping; detailed borehole and trenching investigations; and gravimetric and surface magnetic surveys. The detailed geophysical surveys were able to detect only a few of these inferred faults within 15 miles of the site (figures 2.5-8 and 2.5-11) and inferred and hypothetical faults and lineaments were shown not to be capable faults on the basis of:

- The existence and continuity of the Palo Verde Clay (LZ-3 described in paragraph 2.5.1.2.3) which underlies the Palo Verde Hills Basin without any signs of disruption by faulting.

- The continuation of the distinctive Palo Verde Clay, in the subsurface, to Arlington and Gillespie Dam where it is overlain by basalt flows dated as about 2 m.y. old (paragraph 2.5.1.2.2.1); based on the principle of stratigraphic superposition, the Palo Verde clay and any faults underneath it are much older than the basalts.

- The presence of extensive elevated terraces along the Gila River which overlie the trends of several faults and lineaments and were found to be undisturbed; a prominent 40-foot terrace is overlain by both the Arlington and Gillespie basalt flows indicating the terrace is greater than at least 2 m.y. old.

Reconnaissance and detailed geologic mapping by Fugro within the site vicinity and the site have revealed a few small faults (figures 2.5-11 and 2.5-12) which were not shown on published maps; but these are Tertiary in age and, except for one, are outside of the 5-mile radius. None of these faults displace late Quaternary rocks[8].

LANDSAT, aerial photograph, field reconnaissance studies, compilation of unpublished data, and published maps by M. Cooley during the period 1963 to 1974 has led to publication[88] of a "Map of Arizona

Showing Selected Alluvial, Structural, and Geomorphic Features." The faults shown by Cooley[88] are "known and

inferred faults" which, according to him, were active mostly during the Miocene Epoch. In general, his faults coincide with buried faults shown on previously published maps (see figures 2.5-4 and 2.5-11). The areas of these faults were investigated during the fault and lineament analysis and no displacement or disturbance of late Tertiary or Quaternary strata or geomorphic features could be found.

See also appendix 2A, Questions 2A.11, 2A.13, 2A.15, and 2A.16.

C. Lineaments

Lineaments observed in the site vicinity are shown on figure 2.5-13. These lineaments were observed on aerial photographs, side-looking radar imagery, and space photographs and imagery. These features were investigated and none were found to represent geologic structure.

Photogeologic lineaments identified in the Belmont and White Tank Mountains (figure 2.5-13) were found to be restricted to deformed Precambrian crystalline rocks with no evidence of Quaternary displacement[8].

The Gila River lineament trends N70°E about 8 miles south of the site. This lineament defines the north side of the Buckeye Hills along the straight east-northeast-trending segment of the Gila River and projects toward Saguaro Lake east of Phoenix. To the west, the lineament aligns with the straight course of

the Gila River and projects toward Yuma. A similar subparallel lineament exists on the south edge of the Buckeye Hills and appears to converge with the Gila River lineament near Phoenix (figure 2.5-13). Detailed geologic investigations along these lineaments did not disclose any faulting which could be associated with the lineament. In the vicinity of the site, the lineament is chiefly the result of the linear Gila River along the north side of the Buckeye Hills. The straightness of the river is controlled by the straight northern edge of the Buckeye Hills which is probably a remnant of middle to late Tertiary Basin and Range block-faulting[(91)]. Features near the east end of the Gila River lineament, such as faulting at Saguaro Lake, are cut off by northwest striking faults and thus are not continuous to the west and do not represent faulting associated with the lineament. Indirect evidence for uplifted early Tertiary conglomerate was observed at Tempe, but no fault or indication of geologic structure could be found.

Eberly and Stanley[(92)] postulated that the Gila River between Phoenix and Yuma coincided with an ancient northeast-southwest trending structural trough. This trough, however, is transected by late Miocene north-west-southeast trending block faults and thus is no longer an active structural feature. The Gila River follows the trough to the Colorado River and appears to be the reason for the apparent prominence of the Gila

River lineament. The inactivity of the trough as a tectonic element is further substantiated by its being overlain by at least two extensive Pliocene and Pleistocene basalt flows at Gila and Sentinel. Both of these flows have been inspected in detail and were shown to be continuous and unbroken across the lineament[8]. Detailed geomorphic studies were conducted on the elevated terraces of the Gila River from Hassayampa south to Gila Bend. Both the Arlington basalt flow and the Gillespie flow overlie a prominent terrace (40-foot terrace) indicating the terrace is no younger than late Pliocene (2 to 3 m.y. ago). Leveling surveys on terrace benches between Arlington and Enterprise Ranch show no evidence of deformation or displacement of the terrace across the projected lineament.

Investigation of the Gila Bend lineament (figure 2.5-13) shows that it is the result of alignment of the western margin of the Maricopa Mountains, the portion of the Gila River south of Gillespie Dam, the eastern margin of the Gillespie basalt flow, and vegetation in the mouth of Centennial Wash. No surface evidence could be found to indicate that major through-going faults or Quaternary faults are associated with this lineament. Like the Gila River lineament, the Gila Bend lineament is an area of continuous undisturbed Quaternary-Tertiary terraces and the Pliocene Palo Verde clay demonstrating that if the lineament were structurally controlled it would be older than at least 2 million years. Thus, it

appears that a chance arrangement of the unrelated features has created an alignment, but one which is not a surface expression of geologic structure.
The Harquahala lineament trends approximately N45°W and can be interpreted to be about 100 miles long, although it is not distinct for that entire length (figure 2.5-13). Its expression is purely topographic and it does not disrupt Quaternary formations such as the Gila Bend basalt flow, the river terraces near Gila Bend, or the sediments filling Harquahala Valley.

Approximately 7 miles southeast of the site, a short northeast trending lineament called the Arlington lineament projects toward the Arlington basalt flow (figure 2.5-13). The lineament is approximately 2.5 miles long, is defined by an abrupt change in vegetation, and terminates at the basalt flow. The area around the lineament and basalt flow was mapped in detail and no evidence could be found for disturbance or faulting of the surface of the basalt. A backhoe trench was excavated across the projection of the features at the west edge of the basalt flow. Prebasalt strata, including buried paleosols form distinctive horizons, which could be directly correlated or stratigraphically overlapped along the full length of the trench. Because the unbroken strata are older than the overlying Arlington basalt (about 2 m.y. BP), the undeformed prebasalt strata demonstrate that no faulting or

deformation has occurred along the Arlington lineament for more than 2 million years.

D. Joints

Regional Basin and Range joint-trend investigations[93] attributed systems of north to northwest, east to northeast, and east-west joint trends to regional Laramideage and Basin and Range tectonism[8]. No evidence has been observed of joints or fractures in the basin sediments.

2.5.1.2.3 Site Stratigraphy

The rocks of the site area are divided into three groups: the basement complex, bedrock, and basin sediments. The areal distribution of these rocks is shown on figure 2.5-12. Figures 2.5-14 and 2.5-15 show several typical geologic cross-sections through the site area. Figure 2.5-15 shows one of these cross-sections enlarged and figure 2.5-16 is a generalized cross-section. Figure 2.5-17 is a stratigraphic chart.

A. Basement Complex

Precambrian granitic and metamorphic rocks are called the basement complex. Metamorphic rocks, chiefly amphibolite schist, are exposed in outcrop on the southwest and west flanks of the Palo Verde Hills approximately 7 miles west and northwest of the site (figure 2.5-8). The basement complex is not exposed at the ground surface within the site area, but granitic

rocks encountered in boreholes at the site (figure 2.5-10) indicate that the basement rocks extend under the site. The basement rock is weathered to as much as 60 feet below its upper contact.

B. Bedrock

Miocene volcanics and interbedded sedimentary rocks unconformably overlying the basement complex are termed bedrock. Figure 2.5-18 is a structure contour map of the bedrock surface below the site. Bedrock is well exposed in the Palo Verde Hills as massive flows, plugs, dikes, and flow breccia, with scattered, discontinuous interbeds of tuff and tuffaceous sandstone (figure 2.5-12). Within exploratory drill holes, arkosic conglomerate at least 140 feet thick was found in the volcanic rock section near the unconformity with granitic basement rocks. Driller's logs from water wells in the northern part of the Palo Verde Basin suggest the volcanic-sedimentary bedrock sequence may reach thicknesses greater than 1400 feet (near borehole PV-21) and contain numerous interbedded sandstone and conglomerate layers.

The volcanic bedrock varies, in order of relative abundance, from basalt to diabase to andesite to dacitic welded tuff and quartz-latite tuff. Whole-rock potassium-argon ages from seven localities range from 17.7 to 20.3 m.y. old[8].

The interbedded arkosic conglomerate includes red to brown argillaceous quartz sandstone, lithic sandstone, and granitic pebble-cobble conglomerate. Clasts are primarily of feldspar, quartz, and granitic debris. Tuffaceous zones are also noted within the unit and reach thicknesses of at least 107 feet. Ferruginous cement is common throughout the unit as are calcareous zones.

C. Basin Sediments

Lithified and unlithified sediments overlying the basement and bedrock groups have been divided into six lithologic units or zones (abbreviated LZ) (figures 2.5-16 and 2.5-17).

In order of descending stratigraphic position and increasing age, the stratigraphic subdivisions of the basin sediments at the site area are:

- LZ-6 Fan deposits (Pleistocene to Holocene)
- LZ-5 Upper sand and gravel
- LZ-4 Upper silty clay
- LZ-3 Palo Verde clay (upper Pliocene)
- LZ-2 Lower silt and lower sand and gravel
- LZ-1 Fanglomerate (Miocene-Pliocene)

LZ-2 through LZ-5 are unlithified units of Pliocene and Pleistocene age, and together with more recently deposited LZ-6, are designated the "alluvial sequence".

LZ-1 is lithified and in most respects is a rock formation. The average thickness of the alluvial sequence is approximately 320 feet with a variation of thickness in the site area of approximately 100 feet.

LZ-1: The Tertiary fanglomerate contains rounded to angular clasts of predominantly andesite and basalt in a well-cemented matrix of sand, silt, and occasionally tuffaceous sand. The fanglomerate is exposed along the lower slopes of the Palo Verde Hills unconformably overlying the volcanic bedrock. In the subsurface the fanglomerate fills bedrock depressions but is generally absent on the highest bedrock surfaces (figure 2.5-10). Thickness of the fanglomerate ranges from about 35 to 285 feet. A basalt interbed in the fanglomerate showed evidence of horizontal cleavage and a brecciated contact indicating the basalt is a flow that was deposited during deposition of the fanglomerate. The basalt has been dated as 16.7 m.y. BP, indicating a middle Miocene age for the fanglomerate.

LZ-2: LZ-2 unconformably overlies the fanglomerate and consists of uncemented sand and gravel grading upward into sandy and clayey silt. This unit is generally light brown and contains scattered caliche stringers. The gravel clasts are commonly volcanic rocks, but granitic gravel and cobbles are also present.

LZ-3: The Palo Verde clay is the most distinctive lithologic zone in the alluvial sequence. It is

continuous throughout the site property and extends at least 5 miles southeast and northeast of the site (figures 2.5-19 through 2.5-22). It is generally 80 to 100 feet thick with a maximum known thickness of 136 feet (figure 2.5-23). In addition to its lithology, the Palo Verde clay is readily distinguished from other units in the alluvial sequence by a distinctive natural gamma response (figures 2.5-10 and 2.5-15). Nine subunits within the Palo Verde clay were identified through detailed analysis of natural gamma, gamma-gamma, neutron-neutron, neutron-gamma, spontaneous potential, and resistivity logs (figure 2.5-15). Horizons located by geophysical interpretation are usually accurate within 2 feet but where the geophysical subunits were compared with continuous core or closely spaced samples, the resolution of subunits was found to be within a few inches.

The Palo Verde clay appears to have been deposited under lacustrine or playa conditions. The lower contact is generally gradational and the clay is commonly interlayered with silt or sand near its base. The upper contact of the clay is distinct and in several borings the top of the clay is marked by a paleosol suggesting a relatively long period of landscape stability prior to deposition of overlying sediments.

LZ-4: An upper silty clay unit, 150 to 200 feet thick, contains brown to red-brown silty clay, clayey silt, and silt with lenses of fine-grained sand and silty sand.

Coarse-grained sand and gravel up to 20 feet thick are found at the base of this unit at many locations. The unit is generally calcareous with irregular caliche stringers and nodules. It is continuous throughout the site area and over bedrock highs where the Palo Verde clay is not deposited (figure 2.5-10). Stratigraphic Unit E, the uppermost subunit of this lithologic zone was exposed in power-block excavations (appendix 2D). The west and northwest boundaries of the Palo Verde clay interfinger with coarser alluvial fan and basin sediments before reaching the Palo Verde Hills volcanic bedrock.

The Arlington basalt flow (about 5 miles southeast of the site) unconformably overlies the coarse-grained sediments of LZ-4 and a silt unit which is equivalent to at least the lower portion of LZ-5.

LZ-5: Lithologic Zone 5 ranges from 25 to 53 feet thick in the northwest, thins to 10 or 12 feet farther south, and is not present beneath the Arlington basalt to the southeast. It is generally much coarser grained than the underlying units, although it also contains silt, clayey silt, and silty clay in thin irregular beds. LZ-5 and the upper portion of LZ-4 (stratigraphic unit E) have been mapped in detail in the powerblock excavations (appendix 2D). Geologic inspection and mapping indicate that the geology and stratigraphy exposed during construction confirm geologic interpretations made during PSAR[8][94] investigations.

South and southwest of the Palo Verde Hills, a surficial unit described on the geologic map (figure 2.5-12) as Tertiary-Quaternary fan deposits (QTfn), includes gravel and sandy clayey gravel which appear to be derived primarily from the Saddle Mountain and Palo Verde Hills area. These deposits grade south-eastward into the basin fill deposits and are considered to be time-equivalent to the Tertiary-Quaternary basin fill (QTbf) deposits in the site area.

LZ-6: The younger fan deposits are 8 to 15 feet thick and range in composition from brown sand, sandy silt, and sandy gravel to brown gravelly silt with interbedded sand. These deposits are chiefly volcanic rock fragments derived from the nearby hills and quartz, granitic, and metamorphic debris derived from the Belmont Mountains and areas to the north.

The younger fan deposits occur in the site area as erosional remnants of fan deposits east of the site area in the Hassayampa River drainage. The stratigraphic relationship between the younger fan deposits and the underlying basin fill is best seen at the Arlington basalt where the flow separates the under-lying basin fill deposits from the overlying younger fan deposits.

2.5.1.2.4 Site Geologic Structure

The geologic structure of the bedrock and basement complex in the site area has been investigated by detailed geologic mapping of surface outcrops, trenching, boring, seismic

refraction, gravity, magnetic, and downhole geophysical surveys. Analysis of structure within the basin sediments is based on correlation of lithology using samples from exploratory borings, high-resolution downhole geophysical logs, and excavations at and adjacent to the site.

The faults in the vicinity of the site (25-mile radius) were discussed in paragraph 2.5.1.2.2. In that section two basic classifications of faults were discussed; mappable and inferred or hypothetical faults. These faults are shown on figure 2.5-11 which also shows that one mappable and four hypothetical or inferred faults are within the 5-mile site area radius. The one mappable fault within the 5-mile radius is in Miocene volcanic rock about 3 miles west of the site (figures 2.5-11 and 2.5-12). This fault is exposed for about 2000 feet and is overlain by fanglomerate (Tvfn) on the southeast (figure 2.5-12). The age of the overlying fanglomerate is 16.7 m.y. (Miocene) based on potassium-argon dating of a basalt interbedded within the fanglomerate. Numerous trenches dug across the fault (see figure 2.5-12) could find no evidence of post-Miocene movement.

Geophysical anomalies about 4.5 to 5 miles north of the site (figure 2.5-12) were inferred to be faults(8). These features do not displace the Pliocene-Pleistocene basin sediments and therefore are not capable faults.

In paragraph 2.5.1.2.2.2, faults inferred by Cooley(88) were shown as generally coinciding with hypothetical faults on other published regional maps(91). However, two of Cooley's inferred

faults are not shown on published maps, and trend through the site area radius (figure 2.5-11). The fault inferred to lie beneath the site has been shown by detailed field mapping, borehole lithologic, seismic refraction, downhole geophysical, gravimetric, and magnetic studies not to displace the Palo Verde clay or younger strata. The fault inferred north of the site extends southeastward from near a linear volcanic dike complex at the southern tip of the Big Horn Mountains past the site along the highway to the Arlington Basalt flow. Directly north of the site, it coincides quite closely with the Tertiary-age buried faults postulated from gravity data (figure 2.5-11). Detailed borehole lithologic, geophysical, and paleomagnetic studies have shown that this buried fault does not displace the ground surface or the Pliocene-age Palo Verde clay (figure 2.5-19). The fault was most likely inferred on the basis of linear alignment of Tertiary (19 to 20 m.y.) volcanic features in the Big Horn Mountains, natural drainages, Tertiary volcanic hills at the north edge of the site, and manmade trails and highways. The linearity and alignment of the natural features in the Big Horn Mountains and those north of the site could be attributed to the existence of ancient faults. The bend in the "fault", as shown by Cooley(88), suggests two different faults and the difference in structural trends between the Big Horn Mountains segment and the Palo Verde Hills segment (figure 2.5-11) supports this view. The linearity of the Big Horn Mountains is due to the presence of a linear dike extrusion. Published maps(91) indicate that the Big Horn Mountains are bounded by a buried fault on the

southwest side rather than through the range as shown by Cooley. The location of a fault on the southwest would suggest that it is a basin-bounding fault, and this is more consistent with known geologic relationships in the Sonoran Desert where it is thought that Tertiary volcanics were block-faulted into basins and ranges in late Tertiary time. Regardless of the existence or exact location of the inferred faults, geologic studies in the site area demonstrate that they do not displace late Pliocene or Pleistocene strata. If the fault extends toward and under Arlington basalt flow, as inferred by Cooley, it would be a pre late-Pliocene fault because it does not displace the Palo Verde clay or the Arlington basalt flow.

Two photo lineations lie at the northern edge of the site property line (figure 2.5-12). These short lineations were identified from low level (1000 feet to the inch), color, aerial photographs of the site area. One lineament coincides with a short section of stream channel and an indistinct northwest trending alignment of vegetation for a distance of about 5000 feet, approximately 0.75 mile northeast of the site. A second lineation corresponds to a straight segment of stream channel about 4500 feet long, approximately 0.5 mile northwest of the site. Backhoe trenches excavated across these lineaments exposed continuous, undeformed Quaternary strata. There was no evidence of faulting or other structural origin for these lineations.

2.5.1.2.5 Site Geologic History

Pre-Laramide geologic history is discussed in paragraph 2.5.1.1.4 and no new information can be added to that discussion from results of site area investigations.

Some of the volcanic and sedimentary rocks in the site area had been considered Laramide in age, but recent potassium-argon radiometric dating indicates that most of these rocks are of middle Tertiary age(8).

Tectonic activity, which resulted in the current Basin and Range physiographic and structural features, began in middle Tertiary time, after the Laramide orogeny, and culminated in middle Miocene to middle Pliocene time with large-scale tilt-block faulting of the basement complex and Tertiary volcanic and sedimentary sequences. Basin and Range tectonism continued at a diminished rate through the end of Pliocene time.

During and after the development of the mountain ranges and intermontane basins into approximately their present configuration, alluvial fans and pediments developed at the bases of the ranges. These pediment-fan systems provided considerable detritus to the basins and are probably the oldest, clearly post-orogenic deposits in the site area. Alluvium accumulating in the basins during the post-orogenic Pliocene period covered the pediments and basin bounding faults. In the site region, alluviation did not exceed about 1000 feet, but in the adjacent Phoenix Basin more than 2000 feet of sediment accumulated. Closed-basin conditions existed in the site region until late Pliocene time with several

hundred feet of fine-grained basin fill accumulating under playa-like conditions. The Palo Verde clay was deposited in such an environment in late Pliocene time; it is now overlain by 150 feet of sediments containing well developed paleosols and local calcareous zones.

Through-flowing drainage developed in late Pliocene time when the basins became full. The Gila River was integrated through the site area as it flowed west from the Phoenix Basin into Arlington Valley through an outlet on the east side of the Gila Bend Mountains. Apparently the last episode of local uplift occurred prior to extrusion of the Gillespie basalt flow as indicated by older Gila River gravels tilted about 25 degrees to the south. The tilted late tertiary gravels are most likely the result of local faulting in the Gillespie Dam area.[(8)]. Following this localized faulting, stability continued as indicated by well-developed paleosols on an erosional surface between the tilted gravels and subsequently deposited, horizontally stratified, Gila River deposits and the overlying Gillespie basalt flow, (about 3.3 m.y. old).

The Gila River has undergone several episodes of downcutting since its initial integration, probably the result of climatic as well as localized tectonic changes. One episode of down-cutting had already occurred prior to the eruption of the Arlington basalt flow, about 3 m.y. ago. Both of these flows occurred while the river was at a level 40 feet above the present level; they locally constricted the river channel, with the Gillespie flow probably damming the river for a short time and forcing it to cut a new outlet through Miocene basalt east

of the former channel. This higher river level was a major base level in the site area throughout much of Pleistocene time. Tributary streams of the Gila River and tributary pediment-fan systems along mountain fronts were graded to this level both in pre- and post-basalt flow time. The Hassayampa River probably did not enter the site area until after extrusion of the Arlington flow; Hassayampa alluvium blanketed the fine-grained basin fill, the Gila River gravel, and the northern half of the Arlington basalt flow. This large alluvial blanket was apparently graded to the 40-foot level of the Gila River.

A second downcutting occurred in Pleistocene time (post-Arlington basalt) with a corresponding base-level change. The coarse-grained Hassayampa material overlying the fine-grained basin fill in the site area was dissected and partially removed. Tributary system incision caused wide-spread degradation of alluvial fans.

The third downcutting probably began in late Pleistocene time and is continuing today.

Aggradation during the Pleistocene was largely limited to fluvial deposits in local floodplains and windblown deposition. A mantle of fine-grained windblown material covered the site area and sand dunes derived from the Gila River floodplain developed locally in the site area.

2.5.1.2.6 Miscellaneous Site Geologic Hazards

The detailed geologic and engineering analysis of the site area has shown that there are no hazards due to geologic processes such as subsidence (paragraph 2.5.4.1.1), salt dissolution or diapirism, liquefaction (paragraph 2.5.4.8), erosion, landsliding, collapse due to cavernous or karst terrain, or to man's activities such as fluid and mineral extraction or dam breakage.

2.5.1.2.7 Site Geophysical Surveys

The following geophysical surveys were conducted at the site and the surrounding area:

- Surface magnetometer
- Gravimetry
- Crosshole seismic velocity
- Downhole seismic velocity
- Downhole geophysical logging

Gravity and magnetic surveys of the site area and up to 10 miles from the site[8] indicate that the Palo Verde Hills represent a positive basement block bounded by a gravity low to the northeast and southwest. To the north and northeast the gravity contours indicate a steep gravity gradient interpreted to represent buried northwest-trending normal faults. These features are interpreted to be subparallel and approximately 10 miles in length but are overlain by unfaulted Palo Verde clay beds (paragraph 2.5.1.2.4).

2.5.1.2.8 Engineering Geologic Evaluation of Local Features Which Affect Seismic Category I Structures

There is no reported or observable physical evidence indicating adverse response or failure of bedrock or basin sediments during prior earthquakes. The continuity of the Palo Verde clay (paragraph 2.5.1.2.3) indicates the site area has been tectonically stable and unfaulted for at least 2.8 million years, and historic seismicity indicates the site has been subjected only to very mild ground shaking during the last 100 years (paragraph 2.5.2.1.3).

Seismic Category I foundations are on undeformed basin sediments with a minimum thickness of about 200 feet. These sediments are firm, consolidated, continuous, and show no evidence of shears, faults, joints, folds or other tectonic features (paragraph 2.5.1.2.4 and appendix 2D).

No zones of structural weakness, crushed, or disturbed materials have been identified in the basin sediments underlying the site. Zones of alteration and irregular weathering profiles also are not present in these units (paragraph 2.5.1.2.4 and appendix 2D).

Bedrock is not exposed in the powerblock area and is not present at depths which could adversely influence the foundations (appendix 2D). There is no evidence of unrelieved residual stresses in the bedrock or in the basin sediments.

A detailed description of the rock and soil properties underlying the site is in subsection 2.5.4 and appendix 2D.

There is no evidence of subsidence in the site area such as basin downwarps, fissures, or cracks. The closest known occurrence of land subsidence and earth fissuring is in the Luke Air Force Base region, about 25 miles east of the site. A comprehensive analysis of areas of known subsidence and comparison of those areas to the site area has shown that land subsidence and earth fissures should not be anticipated at the site (paragraphs 2.5.1.1.7 and 2.5.4.1.1).

No mineral extraction has taken place in the area of the site and none is anticipated. However, according to the Arizona Oil and Gas Commission, two applications are on file to drill exploratory test holes in the site vicinity. Table 2.5-2 lists the location and status of the applications.

Groundwater withdrawal has been analyzed (subsection 2.4.13) and does not represent a hazard.

2.5.1.2.9 Groundwater

A detailed discussion of site groundwater conditions is presented in subsection 2.4.13.

a. Due to proprietary nature of exploration drilling, drill logs are not available for public inspection until one year following submittal of logs to the Arizona Oil and Gas Commission.

2.5.2 VIBRATORY GROUND MOTION

2.5.2.1 Seismicity

2.5.2.1.1 Data Base

Data describing the earthquake history of the region surrounding the Palo Verde site are found in a number of sources. A basic compilation of historical records of earthquakes in the region is the catalog of Townley and Allen[95] which lists earthquakes for 1769 through 1928. In 1971, Sturgul and Irwin[96] published an "Earthquake History of Arizona and New Mexico, 1850-1966". They supplemented the Townley and Allen data with subsequent reports of earthquakes that had been felt and some instrumentally determined epicenters to bring the

list up to 1966. Annual issues of "United States Earthquakes" by the U.S. Department of Commerce, beginning in 1928, contain about 30 additional small shocks that were not included in the Sturgul and Irwin catalog. A worldwide seismicity catalog on magnetic tape is maintained by the National Oceanic and Atmospheric Administration (NOAA), and the catalog is updated periodically. The most recent Arizona catalog, "Arizona Earthquakes 1776-1980", has been compiled by DuBois, et al[97].

Figures 2.5-24 and 2.5-24a show the locations of the maximum intensities assigned for shocks felt (Modified Mercalli Intensity IV or more) in the site region.

The source for instrumentally determined seismicity data in the Arizona region is currently the National Geophysical and Solar-Terrestrial Data Center (Boulder, Colorado) operated by NOAA. A catalog has been compiled of the reported, instrumentally determined epicenters in the region since 1927. The catalog is periodically updated. There are certain limitations to the data, but the data are necessarily the best available because Arizona does not have a local network of seismograph stations. For many years, a seismograph station established at Tucson in 1925 was the only station within the state. Several stations were installed near Lake Mead at Boulder City, Nevada in 1942 during the dam construction, and were operated for many years. A similar station has been installed at Glen Canyon Dam. In 1963, the Tonto Forest Seismological Observatory was established with a sophisticated array of seismometers. However, this project was oriented towards teleseismic data and no attempt was made to locate local tremors. An amateur

station was operated by W. L. Groene with relatively sophisticated equipment near Phoenix from 1967 until his death in 1975. Arizona State University staff were performing studies of local seismicity through early 1976. Since that time the studies have been terminated, their station has been inoperative, and no results have been reported.
Table 2.5-3 lists the locations of the stations in Arizona. Other stations throughout the western United States provide useful records for any larger events that might occur. Parts of the Imperial Valley and the Gulf of California are within 200 miles of the Palo Verde site; instrumental observations of shocks in these areas are gathered by the Southern (California Seismograph Network, California Institute of Technology, and U.S. Geological Survey) and to a lesser extent by Scripps Institute of Oceanography and the University of Mexico. Epicenter data for the region are shown in figure 2.5-25.

2.5.2.1.2 Limitations of the Data

Historical records can give an incomplete picture of the regional seismicity. The location of a shock often cannot be determined more accurately than to say it occurred near a community reporting the strongest effects from ground shaking. In addition, other shocks may have occurred in sparsely populated areas and may not have been reported. However, the historical records do provide a good measure of any large, damaging earthquakes that might have occurred. Maximum intensities, assigned on the basis of historical records, are

often uncertain because many earthquake accounts tend to be highly subjective.

Several restrictions should be considered when using the NOAA data for instrumentally determined epicenters: location accuracy, detection threshold, and magnitude assignment. The NOAA data have a detection threshold judged to be about magnitude 4.5 prior to 1945 and about 4.0 thereafter. Detection threshold means that, while smaller events are sometimes reported, the catalog may not contain a complete record of the smaller shocks. Locations are reported only to the nearest 0.1 degree (about 6 miles) prior to July 1968, and the accuracy of most events before the early 1950s may be only 1/4 to 1/2 degree (about 17 to 33 miles). These uncertainties in epicenter locations require that the data be used mostly to define seismic zones (refer to paragraph 2.5.2.3) rather than to delineate individual, active tectonic structures. The Imperial Valley in California is less restricted by this requirement because of better station coverage and surface ruptures associated with some of the larger earthquakes. The third consideration is that of magnitude assignment, in that many of the earlier events, especially those prior to 1945, do not have magnitudes recorded in the NOAA catalog. However, it is unlikely that earthquakes with magnitudes greater than 4.5 to 5.0 would appear without an assigned magnitude. Similarly, these events are probably of at least 3.5 to 4.0 magnitude so that they would have been recorded sufficiently well by the regions' seismograph stations to be included in the NOAA catalog.

Table 2.5-3

SEISMIC STATIONS IN ARIZONA[98] (Sheet 1 of 3)

Station	Location	Elev (ft)	Remarks
Glen Canyon Dam, GCA	36°58'25" N 111°35'35" W	4393	SP Benioffs; 3-component installed in 1960.
Sunset Crater, SCN	35°22'08" N 111°32'33" W	6959	An SP instrument installed in 1970 by the National Park Service. Inadequate timing for use in locating events. Inoperative since late 1977.
Mummy Mountain Observatory, MMO	33°33'16" N 111°57'28.6" W	1398	Private station operated by Mr. W. L. Groene from May 1967 to January 1973.
Tucson, TUC	32°18'35" N 110°46'56" W	3232	In 1962, the WWSSN standardized instruments were installed
Tucson, TUO	32°14'48" N 110°50'06" W	2526	The station was established with two Bosch-Omori's in 1909. Two Wood-Anderson seismographs were

Notes: (1) The Southern California Seismographic Network has operated stations in the extreme southwest corner of Arizona; but the operations have not been for extended periods of time, and the locations are not included in this table.

(2) Teledyne-Geotech operated stations at 16 sites for various short periods up to about 18 months between 1961 and 1968; locations are not included in this table.

Table 2.5-3

SEISMIC STATIONS IN ARIZONA[98] (Sheet 2 of 3)

Station	Location	Elev (ft)	Remarks
Tucson, TUO Continued			installed in 1925. A Benioff short-period system was added in 1936, later supplemented with a Long-Period galvo.
Tuscon, TUT	32°20'06" N 110°43'24" W	4721	SP tetemetered to Tucson, 1958-1962.
Tonto Forest Observatory TFO	34°16'04" N 110°16'13" W	4895	Installed in 1963 with a 37-element, 30-km-diameter array of short-period (SP) instruments; a linear, cross array of 21 SP elements; and a 50-km-diameter, 7-element (3 comp), long-period (LP) array. Intended primarily for teleseismic data, but local seismic events were noted. Closed 1975.
Tonto Hills Observatory, THO	33°52'31" N 111°52'35" W	3720	Private station operated by Mr. W. L. Groene since January 1973, when it replaced the Mummy Mountain Observatory started in May 1967. Inoperative since 1975.
Arizona State University	33°25' N 111°57' W	1162	An LP instrument since 1971. Inoperative since 1976.
Boulder Dam, BDA	36°00'56" N 114°44'12" W	778	A Benioff SP operated from 1941 to 1961.

Fortune Mine, FTM	32°33'17" N 114°20'01" W	863	SP telemetry to Pasadena since 1975.
Laguna Mts., LGA	32°45'35" N 114°29'34" W	223	SP telemetry to Pasadena since 1975.
San Luis, SLU	32°30'06" N 114°46'38" W	135	SP telemetry to Pasadena since 1973.
Yuma Desert, YMD	32°33'17" N 114°32'41" W	249	SP telemetry to Pasadena since 1975.

2.5.2.1.3 Selection of Events Affecting the Site

With the above considerations in mind, the data describing the earthquake history of the site are presented in the following way. A distinction is made between small, local earthquakes and larger, more distant earthquakes. The site history is well-described by considering all shocks within a radius of 50 miles and only those earthquakes of magnitude 6.0 or larger at distances from 50 miles to 200 miles. The limit for events of magnitude less than 6.0 is derived from the work of Schnabel and Seed[99] who predict that the upper bound for maximum accelerations produced by a magnitude 6.0 earthquake at a distance of 50 miles is less than 0.1g. Thus, the site has experienced only minor levels of shaking (compared to the seismic design level) from shocks occurring more than 50 miles away and having magnitudes less than 6.0.

2.5.2.1.4 Large Earthquakes in the Site Region

A list of all large earthquakes affecting the site is given in table 2.5-4. Events of magnitude 6.0 and above to a distance of 200 miles are included and some more-distant shocks, 1887 and 1966, that are significant for the site. For events that predate instrumental observations, recorded magnitudes are not available. However, because a magnitude 6.0 earthquake usually produces a maximum epicentral intensity of at least VII or greater, earlier events of intensity VII and greater have been included in the list. The site intensities shown in the table for earthquakes since 1928 were estimated using the reports published in "U.S. Earthquakes". For shocks before 1928, site

intensities were estimated by comparison with later, better-known events.

Earthquakes occurring in the Imperial Valley and the Colorado delta dominate the list of table 2.5-4. Generally, the maximum magnitudes seem to be no larger than 7.1. Considering the earthquakes of 1852, 1934[2], 1940, and 1956, there have been five events in the magnitude range 6.7 to 7.1 during a period of at least 128 years up to the present. The recurrence rate for these shocks is on the order of once every 25 years, but their occurrence is irregular, as shown in the above dates. For earthquakes of magnitude 6.0 and greater, the data suggests a 7-year recurrence interval. It is emphasized that these rates do not imply periodic occurrence of earthquakes but only reflect the average level of recent seismic activity on a portion of the San Andreas Shear Zone at its closest approach to the site.

Four earthquakes in table 2.5-4 originate in the band of seisicity that cuts across Arizona almost diagonally from northwest to southeast (Zone C, figure 2.5-25). The earthquakes in 1906 and 1910 probably affected the site only slightly and were probably smaller than magnitude 6.0, but they are included to be complete. A 1923 earthquake near Granados, Mexico is not listed because there are no records indicating it affected the site area (paragraph 2.5.2.1.4.2). The 1912 shock is beyond 200 miles, but its location is very uncertain.

Table 2.5-4

LARGE EARTHQUAKES (MAGNITUDE 6.0 OR GREATER)

WITHIN 200 MILES OF THE PALO VERDE SITE (Sheet 1 of 4)

The other event is the 1887 Sonora, Mexico earthquake which occurred approximately 300 miles from the site and is beyond the usual range of consideration (NRC criteria). However, the 1887 earthquake occurred within a seismic zone that is within the 200-mile range, and its magnitude was estimated at about 7.7 to 8.0 (Richter, personal communication, 1974). More recent work places the magnitude at about 7.75 - 7.5[1][98][100][101].

Two of the large earthquakes in the region are of particular significance to the evaluation of the Palo Verde site. The 1852 Fort Yuma earthquake and the 1887 Sonora earthquake are discussed in the following sections.

2.5.2.1.4.1 Fort Yuma Earthquake of November 28, 1852. The literature contains various references to strong shocks felt at the frontier post of Fort Yuma on November 9, 1852; Novemer 28, 1852; and in December 1853[95][96][102]. Because conflicting dates and locations were reported, a study of orignal documents was undertaken by Balderman, et al[103]. The results of their study indicated the following:

> A major earthquake was reported near Yuma, Arizona, in November 1852. Because of the sparse population and frontier conditions in this region at that time, reports of the earthquake were incomplete and partially inaccurate. Subsequent accounts in historic earthquake catalogs repeated erroneous reports on the data, locations, and intensity of the Fort Yuma earthquake. Review of original earthquake accounts indicates that the Fort Yuma earthquake occurred about noon on November 28, 1852. Analysis of the regional geology suggests that the earthquake would have been associated with the seismically

> active Salton Trough. Comparison of effects of the Fort Yuma earthquake with those of subsequent large earthquakes in the region indicates that the event probably was located about 25 to 50 miles southwest of Yuma and had a probable magnitude of 6 to 7.

Major Samuel P. Heintzelman, post commander, noted in his diary: "At 20 minutes past 12 ... we had a violent shock of an earthquake last (sic) half a minute ... first a considerable shock, then a slight lull and then quite severe. Sufficient to have shaken down a house of several stories of the ordinary construction." Another officer at the post, Lieutenant Thomas W. Sweney wrote: "... Hendershott and myself ... rushed out of the house and had enough to do to prevent our falling down, the earth shook so. Large openings were made in the ground all around us, and water and steam thrown up in large quantities."

At Volcano Lake (near Cerro Prieto in Mexico, about 45 miles southwest of Fort Yuma), eruption of large steam geysers accompanied the earthquake. Steam rose to a height of 1000 feet as estimated by Major Heintzelman and probably much higher as concluded by Balderman, et al[103]. The earthquake also caused a large rockfall in California, at Chimney Peak (now called Picacho Peak) about 17 miles north of Fort Yuma. However, high cliffs and vertically oriented jointing in the rocks are present, such that the rockfall may not be a good intensity indicator. The lower Colorado River was considerably affected by caving river banks, changing water depths, and changing channel position. All the effects mentioned here, as well as others, are discussed in detail by Balderman, et al[103].

Figure 2.5-26 shows the estimated location for this earthquake. Most writers have estimated the maximum epicentral intensity as IX (for example, [95] and [102]), but Sturgul and Irwin[96] give XI for the larger of the "two shocks."

2.5.2.1.4.2 Sonora Earthquake of May 4, 1887. The Sonora earthquake occurred along the eastern side of San Bernardino Valley in northeastern Sonora, Mexico (figures 2.5-6 and 2.5-27). The epicenter has been estimated to be about 35 miles south-southeast of Douglas, Arizona along the east side of the San Bernardino Valley. The town of Bavispe, largest in the region, was totally destroyed, and 42 people were killed. Maximum epicentral intensities of VII-IX are reported in History of U.S. Earthquakes[102], but values of IX-X are estimated by DuBois, et al[98] based on, (1) extensive ground fissures caused by lurching, (2) 30 to 47 miles of primary fault rupture, and (3) observed groundwaves. High intensities must have been localized because towns 9 miles north and 3-1/2 miles south of Bavispe were practically undamaged[95].

The earthquake was felt over an area of about 450,000 square miles (figure 2.5-28) bounded by Mexico City to the south, El Bolson de Mapimi and El Paso to the east, Santa Fe and Prescott to the north, Yuma to the northwest, and the Gulf of California to the west[104].

Aguilera describes the fault as 30 miles in length, with an average offset of 7 feet, and a maximum offset of 26 feet. Based on recent field studies, Sumner[105] has described the faulting that accompanied the Sonora earthquake as "... a

normal sense of movement ... with vertical offsets of as much as 4 meters (13 feet) and a fault trace 50 kilometers (31 miles) long". Herd[101] believes the surface rupture was about 45 miles long, an estimate similar to that of Gianella[106]. Natili and Sbar[1] describe the faulting as 80 kilometers long (50 miles) with an average displacement of 3 meters (10 feet), and propose the name Pitaycachi fault. The fault scarp is still preserved in many localities after more than 90 years because of the desert climate and soil cementation with caliche. There is no indication of surface faulting extending as far north as the Mexico-U.S. border. Sumner's map of the faulting is shown in figure 2.5-27.

MacDonald[107] estimated that ground fissures and cracks were distributed over an area 350 miles long by 100 miles wide (about 35,000 square miles). His estimate is in doubt because he observed ground cracks only along the road between Tepic and Tombstone (approximately 120 miles) and along another road about 35 miles west. Because the Tepic-Tombstone road traverses the epicentral area, the long cracks reported by MacDonald are consistent with details from the more precise and authoritative report by Aguilera[104]. However, MacDonald's description of cracking and damage outside the epicentral area is not consistent with other reports.

Goodfellow's report[108] of the Sonora earthquake indicated no damage to buildings of "any stability" in Tombstone and noted no ground fissures. He did report, "in Sulphur Springs Valley, about 25 miles east of here, some fissures occurred in the bed

of an old stream". Sulphur Springs Valley is approximately 25 miles west of San Bernardino Valley, the epicentral area of the earthquake.

Descriptions of cracking by Aguilera[104] clearly indicate that large cracks did occur, probably as a result of consolidation and lurching of alluvium. Aguilera points out that the largest and greatest number of fissures occurred in the San Bernardino Valley, and that similar cracks appeared farther south and in the nearby Sulphur Springs Valley. There is no evidence in the published reports or the newspaper accounts that significant cracking occurred outside the general vicinity of the epicenter.

Richter[56] refers to a matching fault scarp on the east side of the northern Sierra Tejas Mountains in Chihuahua. Apparently it was reported to Goodfellow by another observer that a duplicate fault existed east of the Espuelas and Pitaycachi Mountains; however, this fault was never confirmed by either Aguilera or Goodfellow, and there is no evidence of scarps on the eastern part of the Sierra Tejas Mountains.

A recent compilation and review (figure 2.5-28a) of the various intensity reports is given in DuBois, et al[98]. Magnitude estimates based on seismic movement calculations place the magnitude at about 7.25 - 7.5[1][97][100]. The 1887 Sonora earthquake has been considered a rare event because of its size and its occurrence within a zone of apparently low seismicity. Townley and Allen[95] state that investigations (not cited) subsequent to the shock revealed that earlier ruptures had

taken place along the same fault zone. MacDonald[107] experienced the shock and reported that "no other earthquake had occurred within the memory of the inhabitants or in their tradition." A recurrence interval on the order of thousands of years between major earthquakes near the site of the 1887 earthquake has been estimated by Sumner[105] after field studies in the area. Herd[101] saw evidence of at least two and possibly three pre-1887 surface ruptures along this fault and estimated that the last one occurred about 10,000 to 15,000 years ago and the earlier ones several hundreds of thousands of years earlier. Bull and Pearthree[109] estimate that the youngest previous earthquake occurred more than 100,000 years ago.

At least one earthquake in this region has caused extensive damage and casualties but is not included in most earthquake catalogs. On December 20, 1923 an earthquake caused extensive damage and 12 casualties in the villages of Huasabas and Granados (intensity IX) in Sonora, Mexico very near to the locality of the 1887 event[98]. The shock was felt in Douglas, Arizona but affected an area much smaller than the 1887 earthquake. The rediscovery of the 1923 shock suggests that damaging earthquakes in this region of Sonora may be more frequent than previously believed.

2.5.2.1.4.3 Isoseismal Maps. Isoseismal maps for many earthquakes are gathered together for convenience in figures 2.5-28 through 2.5-39E. The selection includes all earthquakes for which isoseismal maps have been prepared and whose areas of perceptibility (felt by persons) included, or came near, the

Palo Verde site area. Also included are isoseismal maps for a number of other earthquakes in the western U.S. that are referenced in other parts of this text in discussions on seismic zones, attenuation effects, etc. Many of the maps are found in annual issues of "U.S. Earthquakes"; these and other sources are indicated on the figures. The following earthquakes are included in the selection:

- 1872, Owens Valley, California
- 1887, Sonora, Mexico
- 1906, San Francisco, California
- 1906, Flagstaff, Arizona
- 1907, Morales, Mexico
- 1910, Cedar Wash, Arizona
- 1912, Lockett Tanks, Arizona
- 1916, St. Michaels, Arizona1918, San Jacinto, California
- 1922, Miami, Arizona
- 1931, Snowflake, Arizona
- 1931, Cottonwood, Arizona
- 1932, Gabbs, Nevada
- 1934, Colorado Delta, Mexico
- 1938, Buckhorn, New Mexico
- 1939, Hoover Dam, Arizona
- 1940, El Centro, California
- 1942, Superstition Mountains, California
- 1947, Manix, California

- 1948, Desert Hot Springs, California
- 1949, Desert Center, California
- 1950, Calipatria, California
- 1951, Calipatria, California
- 1952, Kern County, California
- 1954, Borrego Springs, California
- 1955, Brawley, California
- 1956, North Central Baja California, Mexico
- 1958, Northeast Baja California, Mexico
- 1959, Kanab, Utah
- 1963, Globe, Arizona
- 1966, Colorado River Delta, Mexico
- 1968, Borrego Mountains, California
- 1969, Warner Springs, California
- 1969, San Carlos, Arizona
- 1971, San Fernando, California
- 1975, Brawley, California
- 1976, Prescott, Arizona
- 1976, Chino Valley, Arizona
- 1977, Standing Rock, New Mexico
- 1979, Yucca Valley, California
- 1979, Calexico, California

These isoseismal maps and the individual reports that were used in preparing the site intensity column in table 2.5-3 indicate that the maximum intensity experienced by the site has been V.

This intensity has been experienced three or four times; two of these were direct reports from the town of Palo Verde. In all cases, these intensities were developed by earthquakes origiating in the California Imperial Valley region.

2.5.2.1.5 Small Earthquakes in the Site Vicinity

Figures 2.5-24 and 2.5-24A show the historically-reported earthquakes since 1852, and figure 2.5-25 shows 50 years of instrumental data and some larger, older shocks. These data show no instrumentally determined epicenters and only a few historical reports of small shocks felt within 50 miles of the site. However, the limitations discussed in paragraph 2.5.2.1.2 must be kept in mind. In particular, the NOAA data are incomplete for earthquakes with small magnitudes. The distribution and significance of any microseismic activity near the site can only be speculative for the present. However, some limited instrumental observations in the area are useful in placing an upper bound on the level of microseismic activity in recent years.

2.5.2.1.5.1 Accounts of Local Shocks Felt. The catalogs by Sturgul and Irwin[96] and DuBois, et al.[98] lists only a few local earthquakes felt at towns within 50 miles of Palo Verde: one report in 1875 at Maricopa Wells (about 25 miles south of Phoenix) and reports at Phoenix in the years 1906 and 1937. "U.S. Earthquakes" for 1935 adds several small shocks felt at Phoenix. Although the 1976 Prescott earthquake is well beyond 50 miles from the site, it is included here because of its

size, M_L = 5.2 (PAS), and its proximity to the boundary of the seismic zone containing the site. Various other shocks at locations such as Flagstaff and Williams in northern Arizona or Globe and Whitewater in eastern Arizona have been perceived in the site vicinity, but their epicenters are clearly within seismic Zone C.

A. Maricopa Wells, 1875

A small event was reported for December 15, 1875, at 2:45 p.m. near Maricopa Wells (now Maricopa) approximately 25 miles south of Phoenix[95]. No accounts of ground shaking or damage to document this event could be found by DuBois, et al.[97].

B. Phoenix, Arizona, 1906

On April 18, about 5:48 a.m., a slight shock occurred with motion west to east. At 5:59 a.m., another shock of intensity II (Rossi-Forel) occurred[95]. No other accounts are given in the published reports. Examination of the Phoenix Republican for the period April 18 to April 24 disclosed no historical accounts.

These shocks should not be confused with the great San Francisco earthquake which occurred about 35 minutes earlier on the same day. The time differential is too great even for the normal travel time of 5 to 7 minutes for surface waves[56] from the San Francisco earthquake, unless there are major errors in the times noted at Phoenix. Furthermore, Phoenix is 250 miles beyond the farthest extent of reported shaking from the San

Francisco earthquake, and no exceptionally strong aftershocks are reported along the southernmost portion of the fault rupture. DuBois, et al.[98] questions the validity of a local shock in Phoenix on this date.

C. Phoenix, Arizona, 1937

On July 21, at about 4:55 p.m. (MST), one short, heavy thud occurred, with slight upward motion, then "settling quiet". The event is said to have disturbed small objects and to have been felt by all. One observer described the thud as sounding like a heavy charge of powder in soft ground. The event frightened no one[96].

There were no newspaper accounts of this event in the Phoenix, Arizona Republican (July 21-28), the Tucson Citizen Daily Star (July 21-24), or the Yuma Daily Sun (July 21-24). DuBois, et al.[98] suggests these reports may, in fact, represent an earthquake the day before at Seligman, Arizona and not effects felt in Phoenix.

D. Cave Creek, 1974 (formerly termed New River earthquakes)

Two small shocks were felt at Cave Creek, about 60 miles northeast of Palo Verde; the first on December 19 at 8:01 p.m. (MST) with intensity VI and a magnitude of M = 2.5, and the second on December 23 at 10:47 p.m. (MST) with intensity V and magnitude of about 3.0[98]. Intensity VI from a magnitude 2.5 earthquake seems quite unusual. Intensities II and III for these shocks were reported at New River 12 miles to the west-northwest

(U.S. Earthquakes, 1974; and W. A. Sauk, personal communication).

E. Prescott, Arizona, 1976

A magnitude 5.2 earthquake (M^L = 5.2, M^b = 4.9) occurred at 5:05 p.m. (MST) on February 3 about 20 kilometers north-northwest of Prescott (34° 40' N, 112° 30' W)[110]. The fault did not rupture the surface, and focal mechanism studies are not conclusive. The preferred focal mechanism solution[111] is right-lateral motion on a steeply dipping plane trending N 80° E or left-lateral motion on a steeply dipping plane trending N 15° W. Eberhart and Phillips, et al,[112] derived a solution with a preferred fault plane striking N 60° W and dipping 40° southwest. Aftershocks continued until February 23.

Strong-motion instruments in the Prescott Veterans Administration Hospital recorded short accelerograms, but the two accelerographs at the Palo Verde site were not triggered. In the epicentral area, where the maximum intensity reached VI (Modified Mercalli), objects were thrown from shelves, but no significant structural damage was reported[111]. Intensities were IV or less in the Phoenix area. An isoseismal map for this shock is included in paragraph 2.5.2.1.4.3.

F. Phoenix, Arizona, 1983

A small shock was reported felt in Phoenix metropolitan area at about 8:15 a.m. (MST) on January 28, 1983. According to news accounts, the event was recorded on a university of Arizona seismograph registering a magnitude of about 2.5. Felt reports indicate intensities ranged from II to III.

2.5.2.1.5.2 Instrumental Data Relating to the Presence of Microseismicity. Arizona lacks a local network of seismograph stations that is necessary to systematically detect and locate small-magnitude earthquakes. Some limited instrumental observations that have been made can be useful in estimating the levels of seismicity. Figures 2.5-24, 2.5-24A, and 2.5-25 show that the site vicinity has experienced a low level of seismicity in historic times, and paragraph 2.5.2.3.4 describes the area as being in a tectonic zone characterized by low seismicity. The objective of the analyses in the following paragraphs is to establish an upper limit to the rate of occurrence of small shocks in the site vicinity. First, records from an amateur seismograph station near Phoenix were studied to determine how many shocks might have come from the area around the site (based on S-P intervals) and what magnitude corresponds to the smallest detectable shock. Then, phase arrival times for selected shocks that were also recorded at the Tonto Forest Observatory array were obtained so that possible locations for the shocks could be further limited. These studies indicated that no more than three shocks, and

probably only one shock, with magnitudes greater than 1.7 occurred in the site vicinity over a period of nearly 5 years.

A. S-P Intervals at Tonto Hills Seismograph Station.

Mr. Willard L. Groene operated excellent amateur seismograph observatories in the Tonto Hills and the Mummy Mountains near Phoenix from 1967 until his death in 1975. The Palo Verde site is about 65 miles from the Tonto Hills Observatory (THO); thus, earthquakes within 25 miles of the site will have S-P intervals in the range of 8 to 17 seconds when recorded at THO. These intervals are obtained from the travel-time tables of Richter (1958) and checked against a velocity model from a refraction survey between Gila Bend and Phoenix, Arizona by Warren[(113)]. A total of 21 events with acceptable S-P intervals were recorded in Mr. Groene's catalog for a 5-1/2-year period from July 1967 through February 1973. In addition, there were eight otherwise acceptable events that were known to be mining blasts. These blasts suggest that some of the other events might also be unidentified mining blasts rather than natural earthquakes. The lower limit of detection for events in the site area and recorded at THO is estimated to be magnitude 1.7 at 40 miles (the nearest distance of approach) and 2.2 at 90 miles (the farthest distance). An operating gain of 500,000 was occasionally used, but such a level was generally too noisy, and 100,000 was the usual magnification. After

looking at representative THO records, a basic assumption is made that an earthquake must register with a maximum amplitude of at least 3 mm zero-to-peak to be reliably identified as an earthquake. Signals with smaller maximum amplitudes might be observed, but their corresponding P-wave arrivals would be difficult to separate from the background noise. The definition of local magnitude involves the instrumental characteristics of the Wood-Anderson torsion seismograph. Although the response characteristics of the THO short-period seismograph are not identical to those of the Wood-Anderson torsion seismograph, the two responses are close enough that the peak amplitudes can be assumed to occur at nearly the same frequency on both systems for small, local earthquakes.

Then the registration of earthquakes on the two systems will differ in proportion to their magnifications (gain). Finally, magnitudes corresponding to 3 millimeter amplitude on the THO records and the appropriate distances are estimated using Richter's[56] fundamental definition of magnitude modified for the magnification of the THO instruments:

$$M = \log \frac{A' \times 2800}{100{,}000} - \log A_o$$

A' is the measured amplitude, A_o is a reference amplitude dependent on distance and given in a table by Richter[56]. Because of the logarithmic nature of the

magnitude scale, the magnitude estimates given above are not strongly dependent on the assumptions used.

The THO data suggest that about four or five events per year in the magnitude range of 1.7 to 3.0 occur at such a distance from THO that they could have originated within 25 miles of the site. Earthquakes of magnitude larger than 3.0 would probably have been identified as such during the period of the data. Any, or all, of the events could have originated in other equally distant locations, and some events may be mining blasts. The following section shows that a much lower level activity is appropriate for the site.

B. Approximate Locations of Some Local Events.

The preceding analysis naturally leads to the question of whether further constraints might be placed on the occurrence of microearthquakes in the site vicinity. Additional data are available from the Tonto Forest Observatory (TFO) for the period September 1967 through July 1972. The Tonto Forest Observatory was a large (tens of kilometers across), experimental array of seismographs designed to study seismic waves from distant earthquakes worldwide. Local earthquakes were noted and their arrival times logged, but the determination of epicenters was not attempted. Normally two seismograph stations are inadequate to determine an epicenter. In this case, the TFO array provides additional information in the form of the

approximate azimuth from which the seismic waves arrive as well as their arrival times, so that crude estimates of epicenter can be made. In principle, the difference in arrival times at two stations can reduce possible epicenter locations to a particular curved line if the seismic velocities are known and the hypocentral depth is known or can be fixed. For a simple case in which velocity is constant and there is no source-depth effect, the appropriate curve is one branch of a hyperbola symmetric about the line joining the two recording stations (analogous to LORAN radio positioning). For any realistic model of crustal velocity structure and a fixed hypocentral depth, the curves are not simple, and they may involve two different wave phases at the two recording stations such as direct P and refracted P. Epicentral distances from the seismograph stations, calculated from S-P intervals, reduce the locus curve to two points. Finally the azimuth information from one station determines the correct point.

A velocity model was chosen on the basis of central Arizona crustal structures as determined by Warren[113]. Then a map was constructed showing the travel-time differences for possible epicenters in the site vicinity. Mr. Groene's station catalogs were reexamined and the Tonto Forest Observatory data were examined to identify all events with the appropriate time differences during the period September 1967

through July 1972. A larger area around the site, radius 65 miles, was included in this analysis. From these logs only 12 events were found with acceptable time differences (3-1/2 to 15-1/2 seconds) and TFO data arriving second (TFO is more distant from the site). An additional five events were noted for which the time differences were too large, 17 to 69 seconds, for any possible epicenter. These spurious data result from timing or picking errors, and imply the possibility of similar errors in some of the other events.

A detailed discussion of the velocity model, the derivation of the travel-time difference map, the significant features of the map, and the parameters of each of the 12 acceptable events is contained in paragraph 2.5.2.5.4.5 of the PVNGS 1, 2, and 3 PSAR. In summary, the analysis showed that eight of the events were clearly away from the site vicinity, two events were indeterminant because of inadequate or conflicting data and only a single event could be shown to have occurred in the site vicinity. The single event was recorded July 2, 1972 at 1829 (GMT); its location would appear to be about 10 to 15 miles north of the site, but the uncertainty is on the order of 25 miles. No felt reports for this event are cited by DuBois, et al[98].

The analysis of travel-time differences suggests that no more than three earthquakes (one reasonably certain and two indeterminant) in the magnitude range 1.7 to 3.0 occurred in the site vicinity during a period of nearly 5 years. Only one of these earthquakes can be shown to have occurred in the site vicinity. These data indicate very low levels of seismic activity near the site, but the levels cannot be established conclusively because the observation periods are short in relation to the recurrence intervals of the earthquakes.

2.5.2.1.6 Strong Motion Data

Very few accelerographs have been installed in Arizona and the neighboring portions of Nevada because of the low levels of seismicity. Recent regulations have caused accelerographs to be placed in Veterans Administration hospitals, some dam sites, and the Palo Verde site. Conversely, many accelerographs have been installed in the neighboring portions of California and Yuma, Arizona because of high seismicity associated with the San Andreas fault system and related features. The Arizona station locations are listed in table 2.5-5 and all locations are shown on figure 2.5-40.

No significant accelerograms have been recorded in Arizona. The 1976 earthquake near Prescott triggered accelerometers at the VA hospital in Prescott, but the epicentral distance was about 20 miles and maximum acceleration levels were only 0.045g[111]. Recordings at epicentral distances of only a few

miles are desirable for Prescott-sized earthquakes, magnitude 5.2, because such earthquakes may affect design criteria only if they are considered to occur nearby.

The 1940 Imperial Valley earthquake wrote accelerograms in California (none in Arizona) with maximum accelerations of 0.35g at an epicentral distance of 5.8 miles[114] and 0.001g at about 180 miles in the Los Angeles area (U.S. Earthquakes, 1940). Los Angeles and the Palo Verde site are at comparable distances from the Imperial Valley. During the 1968 Borrego Mountain earthquake, the maximum recorded accelerations were 0.13g at El Centro 45 miles from the epicenter (closest record); about 0.005g was measured at Mohave Generating Plant, Nevada (Arizona border) at a distance of 170 miles, and the levels in the Los Angeles area were 0.004 to 0.015g[115]. The 1979 Imperial Valley earthquake had a maximum acceleration locally of over 1.0g, but did not trigger accelerographs in the Los Angeles area that had trigger levels of about 0.01 to 0.02g nor did the event trigger either of the two accelerographs (with trigger levels of 0.009g) operating at PVNGS.

Because the maximum earthquakes which control the seismic design criteria for the Palo Verde site are large (a magnitude 8.0 shock along the southern portion of the San Andreas fault, or a magnitude 8.0 Sonora-type earthquake), there are no appropriate accelerograms from the site region. The necessary data from other areas are introduced as they are needed in paragraph 2.5.2.6. There are also many accelerograms of small shocks in the Imperial Valley recording because of the dense

network of stations or as the results of special studies. These records are not listed here because they do not have an impact on the development of the seismic design criteria.

2.5.2.1.7 Earthquake-Induced Geologic Failures

No geologic failures caused by ground shaking are known to have occurred within 100 miles of the Palo Verde site during historic times. The 1976 Prescott earthquake, magnitude 5.2, did not cause any recognized failures nor are any suspected after intensive field investigations. The larger earthquakes of seismic zones B and C might be capable of inducing some slumping or rockfalls under suitable conditions, although no instances are known. MacDonald[107] reported that the 1887 Sonora earthquake caused ground cracks in Tombstone.

Table 2.5-5

a. Agencies: ACOE, Army Corps of Engineers
USBR, U.S. Bureau of Reclamation
VA, Veterans Administration

MacDonald's report is not confirmed by Goodfellow[108], and Tombstone is more than 200 miles from Palo Verde.

The 1852 Fort Yuma earthquake, located in the lower Imperial Valley, caused liquefaction around Fort Yuma and a rockfall at Picacho Peak (then called Chimney Peak) about 17 miles north of the fort. Numerous other geologic failures have occurred in portions of the Imperial Valley and Colorado Delta that are within 200 miles of the Palo Verde site. Faulting has ruptured the surface during earthquakes in 1934 on the Colorado Delta, 1940 near El Centro, 1968 at Borrego Mountain, 1975 near Brawley, and probably others. Sand boils, indicative of liquefaction, have been induced by the larger earthquakes such as 1852 Fort Yuma, 1940 Imperial Valley, and 1968 Borrego Mountain.

2.5.2.2 Geologic Structures and Tectonic Activity

2.5.2.2.1 Tectonic Provinces and Tectonic History

Regional geologic and tectonic structures are shown on figures 2.5-4, 2.5-5, and 2.5-6. Figure 2.5-25 shows the spatial relationship between Quaternary faults and earthquake epicenters. Figure 2.5-3 shows the major regional tectonic provinces within the site region based on gross similarities of geologic and tectonic features. These provinces are the Basin and Range, Colorado Plateau, Salton Trough, Transverse Ranges, and Peninsular Ranges. The geologic and tectonic characteristics of these provinces and the regional tectonic history describing present and past stress regimes that

distinguish the various tectonic provinces are described in paragraphs 2.5.1.1.3 and 2.5.1.1.5. The following paragraphs describe the capable faults found in these provinces.

2.5.2.2.2 Capable Faults

2.5.2.2.2.1 Introduction. The major capable faults within the site region (200-mile radius) are in southeastern California, the Grand Canyon region, and in Sonora, Mexico. There are no capable or Quaternary faults within the site vicinity (25-mile radius).

Figure 2.5-6 shows the known capable faults (less than 500,000 years old) and the Quaternary faults (500,000 years to about 1.8 or 2 million years old) in the site region. These faults are described below under the headings of the tectonic provinces in which they occur.

2.5.2.2.2.2 Salton Trough. The Salton Trough tectonic province has, by far, the largest and most historically active capable faults. These faults trend southeasterly through the trough and are generally considered to be members of the San Andreas Shear Zone (see figure 2.5-7). The major faults within this Shear Zone are:

- The Mission Creek, Banning, and southern San Andreas faults which make up the southern San Andreas fault set
- The San Jacinto, Superstition Hills, Coyote Creek, Clark, Buck Ridge, Hot Springs, Imperial, and Cerro Prieto faults which comprise the San Jacinto fault set

- The Elsinore and Laguna Salada faults which make up the southern end of the Elsinore fault set
- Other faults, lying between the above major fault sets, such as the Brawley and Calipatria faults at the southern end of the Salton Sea, the Algodones near Yuma, and the Sierra Juarez fault zone in Baja California, Mexico

The San Jacinto fault set is principally a group of right-lateral, strike-slip faults and fault zones with a cumulative displacement of about 15 miles(116). The feature extends from the head of the Gulf of California to the Transverse Ranges north of the city of San Bernardino, California, a distance of about 250 miles. The rate of slip on the San Jacinto has been estimated at about 0.1 to 0.5 inch per year(117)(118). Seismic activity in the site region is concentrated in the central Salton Trough in the vicinity of the San Jacinto fault set. The largest historic earthquakes in the site region occurred in the vicinity of the San Jacinto fault set and were the magnitude 7.0 Imperial Valley earthquake of 1940 and the magnitude 7.1 and 7.0 earthquakes near the head of the Gulf of California in 1934. The 1940 event was associated with surface rupture of the Imperial fault which amounted to about 19 feet of displacement. The 1934 events have not been associated with any known faults, but surface cracks were noted shortly after the shock had occurred. In contrast, the southern San Andreas fault set has not been associated with a large number of earthquakes. However, minor surface ruptures occurring in 1868

and 1968 and geomorphic expression of faulting indicate that the fault is active and its great length (totaling about 600 miles when connected with its central and northern segments) suggest that it is capable of generating great earthquakes. The slip rate on the Cholame to Cajon Pass segment is about 1.3 to 2.4 inches per year[119]. Rates on the southern segment appear to be much slower and a major earthquake has not occurred in several hundred years[120]. A major earthquake occurred on the northern segment of the fault zone in the San Francisco area in 1906. This earthquake registered a magnitude of 8.3 with maximum displacement of about 21 feet. An earthquake in 1857 which ruptured the central segment of the fault zone between Cholame and Cajon Pass, a distance of about 200 miles, may have had displacements of about 30 feet[121]. Comparison of these large displacements has led to magnitude estimates of 8.0 to 8.5 for the 1857 earthquake.

The southeasterly continuation of the San Andreas fault set past the Salton Sea has been the topic of much debate among geoscientists. There is little geomorphic evidence of a southeasterly continuation, but direct alignment with the Quaternary Algondones fault in the vicinity of Yuma, Arizona has led Olmstead, et al[50] to postulate an association of the two. Kovach, et al[39] postulated a subsurface fault in the vicinity of Sand Hills but did not believe that it was a direct continuation of the San Andreas. Merriam[51] has suggested that the San Andreas fault set continues through the Yuma area into Mexico east of the Gulf of California. Detailed geotechnical studies[52] near Yuma, Arizona have shown that the Algodones

fault is capable, but that its history of movement has been primarily dip slip with the northeast side of the fault down. Such a displacement is not compatible with the hypothesis that it is a direct continuation of the San Andreas fault, which is a right-lateral fault, but rather that it is just one of the bounding faults of the Salton Trough. The extension of faults of the San Jacinto set toward the head of the Gulf of California along with the high rate of seismicity on the San Jacinto set indicate that most of the plate movement is taken up along the younger, more active, San Jacinto fault set.

The Elsinore fault set is a zone of fractures extending about 200 miles from the Whittier branch near Los Angeles to the Laguna Salada fault in Baja California. Near the Mexico-U.S. border, the fault traces are mostly concealed by the alluvium of Imperial Valley. Cumulative, strike-slip displacement on the Elsinore fault set probably is small compared to the San Jacinto and San Andreas fault sets[58]. Historic surface rupture has not been recognized on the Elsinore fault set, but appreciable low-magnitude seismicity occurs along the fault. The slip rate on the Elsinore fault zone has been estimated at about 0.03 inch per year[117].

2.5.2.2.2.3 Transverse Ranges. Offset Quaternary sediments indicate Quaternary activity on the Pinto Mountain fault, the largest fault in the eastern Transverse Ranges. This fault is about 65 miles long, strikes nearly east along the north flank of the Pinto Mountains[122], and extends about 20 miles into the 200-mile radius. Offset streams and lithologic contacts

indicate up to 10 miles of left-lateral movement on this fault with the maximum displacement near the central portion of the fault[53]. There have been no known surface ruptures on this fault, but a magnitude 5.9 earthquake in 1949 occurred near its eastern end. However, it has not been established whether this earthquake was associated with the Pinto Mountain fault or one of the northwest striking faults of the Mojave block.

2.5.2.2.2.4 Colorado Plateau. The major capable faults in the Colorado Plateau province are the southern ends of faults that form the boundary between the Colorado Plateau and Basin and Range provinces in Utah. Major Quaternary faults in this transition zone are the Hurricane, Main Street, Toroweap, Sevier, and Wasatch faults. These faults coincide with the Intermountain Seismicity Belt[17] and various geophysical anomalies which indicate a major change in crustal and upper mantle characteristics under the region[14][38]. Major capable faults in this system that extend into the 200-mile radius are the Main Street, Hurricane, and Toroweap, all of which lie in the western Grand Canyon region (figure 2.5-6). No historic surface ruptures have been recorded on these faults, but displaced Quaternary features have been interpreted to be as young as late Pleistocene[123] and possibly Holocene[124][125]. Historic seismicity in this region is widely scattered. The maximum historic earthquake in this southern region of the Hurricane-Wasatch fault system was a magnitude 5.6 event near the Arizona-Utah border in 1959 (figure 2.5-25). The maximum earthquake associated with this same zone of faults to the

north was a 1901 event near Richfield, Utah with a magnitude estimated to be 6.7[126]. However, the lengths and displacements of faults along the Wasatch front suggest that earthquakes as large as 7.1 to 7.5 may be expected[127][128].

A zone of short, northwest-southeast trending Quaternary and capable faults extends from the southern end of the Grand Canyon region to the southeastern corner of Arizona (figure 2.5-6). These faults coincide with the Transition Zone and Basin and Range (Arizona Mountains) physiographic provinces (figure 2.5-1).

Most of these faults are minor features with the longest being about 27 miles in length.

2.5.2.2.2.5 Basin and Range. Capable and Quaternary faults are rare within the Basin and Range tectonic province in the site region. The greatest concentration of capable faults within the province occurs in the Mexican Highlands region of southeastern Arizona and Mexico (figure 2.5-6). Faults in the Mexican Highlands are very minor features within the site region where they do not exceed about 10 miles in length. Howard, et al[21] characterized these faults as "small cracks and faults associated with groundwater withdrawal which may be partially of tectonic origin." Similarly trending features in Mexico extend as far south as Guaymas (26° N lat) along the western edge of the Sierra Madre Occidental Plateau and are much longer. The great 1887 Sonoran earthquake occurred on one of these faults (Pitaycachi fault). Long faults of the type generally considered capable of generating great earthquakes,

such as the Sonoran event, are not present north of the Mexican border (figure 2.5-6).

The capable and Quaternary faults within the Sonoran Desert region of the Basin and Range province are widely scattered, short, and have very small displacements. Known capable faults are the Blythe and Chemhuevi grabens in California, the Sand Tank Mountain fault in Arizona, and several small unnamed faults near the Arizona-Mexico border(129) and within the Pinacate volcanic field. The Pinacate area is a very unusual area for the Sonoran Desert region because it has a relatively high concentration of minor Quaternary faults (figure 2.5-6). The longest of these faults is only about 4 to 6 miles long. These faults are commonly restricted to the young volcanic flows and generally do not displace Quaternary sedimentary formations surrounding the volcanics. This suggests that they are local volcano-tectonic features rather than surface manifestations of larger through-going subsurface faults.

2.5.2.3 Correlation of Earthquake Activity with Geologic Structures or Tectonic Provinces

The spatial distribution of instrumentally determined epicenters, figure 2.5-25, clearly shows that seismic activity is concentrated in certain areas and relatively rare in others. The locations of these earthquakes can be described in terms of geologic structures and the tectonic processes responsible for those structures. However, the locations of the epicenters have some unavoidable uncertainties, as discussed in paragraph 2.5.2.1.2, so that most earthquakes cannot be

attributed unequivocally to a particular fault. Instead, the general distribution of seismicity is described in terms of seismic zones, and particular shocks as belonging to a particular zone. A seismic zone is meant to generally encompass an area with relatively similar characteristics of its geology and seismicity.

In the Palo Verde region, the seismological data represent too short a time period to be fully representative of all the earthquake processes that might occur. Therefore, the seismicity data alone do not provide complete, distinct boundaries for the zones. Similarly, many of the geologic and tectonic characteristics are gradational rather than abrupt near zone boundaries. For these reasons, the seismic zones identified in this study have some approximate boundaries.

Within a 200-mile radius of the site, four seismic zones can be recognized. These zones have been identified as Zones A through D because there is no generally recognized nomenclature. The Palo Verde site is within Zone D which extends beyond 200 miles from the site. Therefore, Zone E is also discussed to define fully the bounds of Zone D. The geologic and tectonic characteristics of these zones have been discussed in detail, with some references to seismicity, in paragraph 2.5.1.1.3. The following sections will describe the seismological data for each zone.

2.5.2.3.1 Seismic Zone A

The most conspicuous feature of the seismicity distribution, figure 2.5-25, is the concentration of activity in the southwest quadrant from the site at distances beyond about 120 miles. This seismicity is related to faults of the San Andreas Shear Zone in the Salton Trough and to the eastern portions of the Transverse Ranges and the Mojave block. Zone A extends to the northwest and to the southeast considerably beyond the 200-mile radius of the Palo Verde site region. Because the level of seismicity in the San Andreas Shear Zone is high, only earthquakes of magnitude 4.0 and greater have been shown in figure 2.5-25.

Zone A is dominated by the San Andreas Shear Zone which is the boundary between the American crustal plate to the east and the Pacific crustal plate to the west. This plate boundary is the major tectonic feature of the site region. These two crustal plates are in motion so that the Pacific plate is moving northwest relative to the American plate at the rate of a few inches per year. The major fault displacements and the largest earthquakes are associated with right-lateral, strike-slip faults that trend northwesterly. Allen(130) pointed out changes in the characteristic seismicity along this plate boundary. Some portions generate great earthquakes, magnitude 8+, such as in 1906 at San Francisco (rupture from Cape Mendocino to Hollister) and 1857 at Fort Tejon (rupture from Parkfield to Cajon Pass). Other portions, such as the length from Hollister to Parkfield (lying between ruptures of the two great

earthquakes), are characterized by only moderate shocks, magnitudes up to about 6.0, and episodes of aseismic creep. North of the Transverse Ranges in central and northern California, relative plate motion is predominantly along the San Andreas fault, a zone no more than a few kilometers wide. South of the Transverse Ranges, the plate boundary becomes a broad zone of faulting that includes the San Andreas, San Jacinto, and Elsinore fault sets. There have been no great earthquakes (magnitude 8.0 or larger) historically on the southern portion of the San Andreas fault.

In the northern Gulf of California, seismic activity is very high, but lower levels are indicated southward in the vicinity of the islands of Angel de la Guarda and Tiburon. This difference may represent a change in tectonic characteristics, or it may simply reflect incomplete observation of the area.

Near 33° 30' N, the boundary of Zone A has been taken along a more northerly trend to include seismicity associated with the eastern Transverse Ranges and the Mojave block. These areas are intimately related to the plate boundary tectonics, but they are secondary to the San Andreas Shear Zone. Geologic and seismotectonic studies[21][22] support separate seismotectonic zones for the Transverse Ranges and the Mojave block. However, these zones have not been considered separately in keeping with the somewhat generalized nature of the seismicity zones. The largest earthquake in these portions of Zone A was the 1947 Manix earthquake with a magnitude of 6.2. Capable faults are long enough to produce shocks up to about magnitude 7.0,

considerably smaller than those postulated for the San Andreas fault.

In general, seismic Zone A is the plate boundary and its associated seismic activity. There are some geologic and seismic data to suggest limits of the zone along the plate boundary such as the Transverse Ranges to the north and the major gulf islands to the south, but these limits are not considered further here. A great earthquake, magnitude 8+, has been assumed credible along the San Andreas fault at the eastern margin of the Salton Trough, and further consideration of the extent of Zone A would have no impact on the design criteria.

Seismic activity is high in Zone A with several earthquakes in the magnitude range of 6.5 to 7.1 such as in 1852, 1903, 1915, 1934, 1940[56], and 1979. Earthquake swarms such as the Brawley swarm in 1975[131] and 1976[132] and the Gulf of California swarm in 1969[33] are a characteristic feature of the Imperial Valley and Colorado Delta areas. Quaternary movement is evident on many faults within the zone, although most historic surface ruptures have been along the San Jacinto fault set (including the Coyote Creek and Imperial Faults). The 1934 ruptures were on a presumed extension of the San Jacinto fault set. Minor surface offsets have occurred on other faults. Rupture on the San Andreas fault near the north end of the Salton Sea is reported for an 1868 earthquake[95] but the size of the earthquake has been questioned[133]. The San Andreas fault is considered to be the only fault capable of

producing a magnitude 8+ earthquake in this zone. At its closest approach to the site, the fault is on the order of 120 miles distant. The San Andreas fault has not been mapped in areas south of the international border, and may not extend south of the Salton Sea (paragraph 2.5.2.2.2). Seismicity in the area continues southward along the San Jacinto fault set.

2.5.2.3.2 Seismic Zone B

Seismic Zone B is a roughly circular zone of epicenters about 80 miles in diameter and lying astride the Arizona-Sonora border (figure 2.5-25). This zone was first recognized on the basis of the distribution of epicenters reported in the USGS catalog, and its limits were drawn to simply envelope the seismicity. Subsequent analysis of the seismological data indicated that many of the epicenters should be relocated southward in, or very close to, seismic Zone A. However, a significant number of the events have no indication of mislocation and must be presumed correct for this study. This area is centered on the Pinacate volcanic field which has been the site of numerous late Quaternary age volcanic eruptions. Small earthquakes, of the type mentioned previously which could not be relocated from this area, could be related to the volcano tectonic processes of the volcanic field.

The largest historic earthquake in Zone B was a magnitude 4.9 shock (previously listed as 5.0 in NOAA file) on March 15, 1958 with a reported epicenter near the south end of the Mohawk Mountains (NOAA: 32.5°N, 113.5°W), but the epicenter could be in error by 30 to 40 miles. DuBois, et al[98] eliminates this

event from the Arizona catalog because the instrumental data were "unconvincing" and there were no felt reports. All of the earthquakes reported for this zone have magnitudes of 4.0 or greater, if a magnitude is reported. Smaller events have not been registered well enough at regional seismographs to permit epicenter determinations.

The quality of the epicenter locations in Zone B was examined in detail. Each earthquake was checked for entries in the International Seismological Summary (ISS), U.S. Earthquakes, and Seismological Notes in the Bulletin of the Seismological Society of America. This study indicated that all of the epicenters in Zone B have large location uncertainties, about 15 to 30 miles generally, and sometimes much larger. Furthermore, the ISS data strongly suggest that many of the epicenters reported in the USGS catalog have a consistent northeast bias and should be located farther to the south within or very close to Zone A. Figure 2.5-41 shows how the ISS determinations relocate some of the epicenters in Zone B. Earthquake locations, as determined independently by the ISS, are available for events in or near Zone B only since 1964 when ISS began to include smaller events. Earthquakes occurring prior to 1964 probably present the same location difficulties as those studied here. Several factors indicate problems in determining these epicenters. Standard deviations for the ISS locations were large, 0.3 to 0.5 degree, even though ISS used more data than was available for determinations in the NOAA catalog. The usable data are from stations to the northwest, north, and northeast of Zone B leaving an angular gap of about

200 degrees. S-wave arrivals are available from only Barrett and Pasadena, both of which are on nearly the same azimuths from the epicenters. Travel time residuals of about -8 seconds at Barrett and +5 seconds at Pasadena indicate difficulties with the travel-time tables or phase identification.

Table 2.5-6 provides a tabular comparison of the epicenter determinations. Individual earthquakes are discussed in paragraph 2.5.2.6.3 of the PSAR[8]. The ISS epicenters are preferred because more data were available and certain earthquakes with swarm-like association were placed by the ISS in an area characterized by earthquake swarms. This location problem seems to be limited to the Zone B shocks; three shocks in central Arizona have consistent locations by USGS and ISS (within 10 miles), and a fourth shock has locations that differ by about 30 miles.

In summary, many of the epicenters in Zone B should probably be relocated farther south into Zone A. The epicenters that have similar locations by NOAA and ISS, or remain stationary from lack of any comparative data, are in an area with evidence of young volcanic activity. Since there is not conclusive evidence for relocating all the Zone B shocks southward into Zone A, Zone B and the original epicenter location have been retained as a conservative approach to seismic consideration of this area.

2.5.2.3.3 Seismic Zone C

Seismic Zone C is a band of rather diffuse seismicity extending diagonally across Arizona from its northwest corner (figure 2.5-25). Since the beginning of seismic instrumentation in Arizona, there have been a moderate number of earthquakes (shown in table 2.5-7) with magnitudes less than 4.0, four earthquakes with magnitudes from 4.0 to 4.9, and five earthquakes with magnitudes from 5.0 to 5.6. This distribution of magnitude with number of events (relatively few small shocks with respect to the number of larger shocks) is attributed to a deficiency in recording smaller shocks rather than an unusual recurrence relationship.

Zone C corresponds to a transition zone between the Colorado Plateau to the northeast and the Sonoran Desert portion of the Basin and Range province to the southwest. This area was called the Arizona Mountain Belt by Howard, et al[21]. This transition zone is characterized by Quaternary and capable faults and volcanism in addition to its seismicity. The geologic description of the zone is presented in paragraph 2.5.1.1.1.3.

In the PSAR studies[8] and figure 2.5-25 herein, seismic Zone C broadens to the south and includes the area of the 1887 Sonora earthquake. For a conservative estimate of the safe shutdown earthquake (SSE) (see paragraphs 2.5.2.4.3 and 2.5.2.6), a Sonora-type earthquake has been postulated on other Quaternary faults in Zone C. Recent studies[21] suggest the existence of a Mexican Basin and Range province (a subdivision of the Basin

and Range province) in which the Sonora earthquake occurred. Identification of the Mexican Highlands as a separate province may be important to understanding the regional tectonics. However, this interpretation has no adverse impact on the previous estimates[8] of seismic hazard at the Palo Verde site, because the nearest boundary of the province is at a distance

Table 2.5-6

EARTHQUAKES OCCURRING WITHIN SEISMIC ZONE B

						DuBois[a]					NOAA[b]

comparable to that used before to evaluate the effects of a Sonora-type earthquake. The Mexican Highlands are defined mostly in terms of their geologic characteristics because there is very poor seismographic coverage for small shocks, and only a few earthquakes are known there.

The 1887 and 1923 Sonora earthquakes are described in paragraph 2.5.2.1.4.2. Only two other small shocks are listed in the NOAA catalog for the Mexican Highlands area (north of 31° 30' N). A shock with no assigned magnitude occurred just south of the Arizona border in 1961 and was felt in Bisbee with intensity II. In 1977, there was a magnitude 4.6 shock very close to the epicentral area of the 1887 earthquake.

Excluding the Mexican Highlands, the largest earthquake that has been recorded in Zone C is a July 21, 1959 shock with a magnitude of 5.6. The earthquake occurred near the Arizona-Utah border (37°N, 112-1/2°W) and was felt most strongly in the communities of Kanab, Utah and Fredonia, Arizona. In both places, the shock was felt by all and there were some fallen bricks and cracked plaster. The epicenter of this shock is probably not determined more closely than 20 to 30 miles as suggested by the precision of the coordinates assigned.

The northern portion of Zone C in Arizona has experienced four other earthquakes with magnitudes of 5.0 or greater: January 7, 1945 (M=5.1), October 13, 1959 (M=5.0), a January 25, 1906 shock near Flagstaff whose magnitude is not known but probably exceeds 5.0 as indicated by intensity reports (U.S. Earthquakes), and an August 18, 1912 shock north of the San

Francisco mountains with a reported intensity of X. In the southeastern portions of Zone C, there have been two shocks with magnitudes greater than 5.0: September 17, 1938 (M=5.5) near the Arizona-New Mexico border and December 25, 1969 (M=5.1) near Globe, Arizona.

The 1976 Prescott earthquake, M=5.2, occurred very close to the boundary between seismic Zone C and D as drawn here. Recent seismotectonic studies[22] suggest that the boundary (approximate at best) of Zone C is farther westward and that the Prescott earthquake should be identified with Zone C. These same interpretations would include the northern portions of Zone C (and the 1959 event) in a zone extending northward coinciding with the Intermountain Seismic Belt. Then, the largest event recorded in Zone C becomes the magnitude 5.5 shock near the Arizona-New Mexico border.

2.5.2.3.4 Seismic Zone D

After the prominent concentrations of seismicity have been recognized as seismic Zones A, B, and C, the remainder of the region within 200 miles of the site has very sparse seismic activity and is termed Zone D. Seismic Zone D generally corresponds to the Sonora Desert portion of the Basin and Range province. The mountain ranges here are small and relatively low-relief; there is little Quaternary faulting known (figure 2.5-25). The geologic characteristics of Zone D are described in paragraphs 2.5.1.1.3.2 and 2.5.2.2.2.5 as part of the Basin and Range province.

Earthquakes are infrequent in Zone D and no shocks larger than magnitude 4.5 (as shown in table 2.5-8) have occurred here. The magnitude 5.2 Prescott earthquake in 1976 is considered to be associated with seismic Zone C. Other moderate shocks have been located within this zone. The largest is a 1956 earthquake of magnitude 4.5 (or possibly smaller) with a poorly known epicenter about 50 miles west or northwest of Tucson. The general location of this 1956 earthquake, the precision of its coordinates, and the lack of any felt reports suggest considerable uncertainty in the epicenter, perhaps 20 to 40 miles. None of the shocks in Zone D have caused surface ruptures or other phenomena indicating geologic failure. In evaluating the seismic hazard for Zone D, shocks as large as magnitude 4.5 were considered at distances as close as 5 miles to the site (see paragraph 2.5.2.6). Closer distances are excluded because detailed geologic studies in the site area, out to 5 miles, have shown the absence of any capable faults.

Since the PSAR studies(8)(94), several small changes have been suggested in the description of seismic Zone D as a result of additional data and interpretations, but none of these impact the seismic design criteria. As mentioned above, the boundary with Zone C may be a little farther westward than originally drawn, and the Prescott earthquake then is associated with Zone C. The 1956 earthquake, M=4.5, did not have an assigned magnitude in the earlier NOAA catalog listing; it is currently listed as M=5.0, but analysis of original Pasadena seismograms indicates that the correct value should be no more than 4.5, including uncertainties.

2.5.2.3.5 Seismic Zone E

Seismic Zone E is a band of seismicity trending northwestward across southern Nevada and into central Utah. This zone is about 100 miles wide and has been called the Southern Nevada Transverse Zone(17)(25)(26). The zone is transverse to most of the structural grain of the region, and the tectonic significance of the trend is poorly understood. Although seismic Zone D, containing the site, extends 200 miles northwest from the site, Zone E is included here because it bounds the site zone and separates the site zone from Nevada Basin and Range tectonics further to the north.

There is pronounced increase in the level of seismic activity in Zone E as compared to Zone D. In addition, moderately large earthquakes have occurred there: a magnitude 6.1 (U.S. Earthquakes) or 5.6(134) earthquake shook southern Nevada near the Utah border on August 16, 1966, with a maximum intensity of VI in the epicentral region. The seismicity cluster around Lake Mead has been attributed to reservoir filling(97)(135)(136). In addition, numerous small earthquakes induced locally by large nuclear explosions at the Nevada Test Site have been attributed to tectonic prestress(137). These two examples indicate stressed conditions in Zone E, but there are no data for comparison in other areas of the region.

An alternate interpretation of regional tectonics and seismicity by the NRC staff in their Safety Evaluation Report of the PVNGS 1, 2, and 3 PSAR adopts a single province of basins and ranges from Mexico, through Arizona and Nevada, and extending partially into Utah and Oregon. At the same time, this approach recognizes that:

- Major seismic events are associated with large, recognizable Quaternary faults.
- Large Quaternary faults are present in Sonora, Mexico and are numerous in Nevada.
- Large Quaternary faults are demonstrably absent in the Basin and Range areas of Arizona.
- Only a few Quaternary faults of any size have been recognized in the Basin and Range areas of Arizona.

As a result, both interpretations lead to essentially the same estimate of the seismic hazard for the Palo Verde site. The differences are a matter of degree in the requirements to characterize separate zones.

2.5.2.4 Maximum Earthquake Potential

The level of maximum vibratory ground motion that might occur at the site is determined by considering the largest earthquakes that might credibly occur in each of the seismic zones. The following sections discuss the maximum earthquake for each zone; discussions of the seismicity and tectonics of the zones are found in paragraphs 2.5.2.3 and 2.5.1.1.3,

respectively. When attenuation of strong ground motions because of distance from the epicenter is considered (paragraph 2.5.2.6), the most severe case at the site is found to be the postulated occurrence of a Sonora-type (1887) earthquake located 72 miles from the site. This case results from considering an epicenter approximately 250 miles northwest of the 1887 event along a series of north-west trending valleys and associated Quaternary and capable faults which project north from Mexico toward the Grand Canyon region (paragraph 2.5.2.4.3). Since submittal of the PSAR(8)(94), geologic and earthquake studies(18)(21)(22) have continued to substantiate the neotectonic contrasts between the Mexican Highlands subprovince and the Transition Zone, both of which are generally included by seismic Zone C. Because of these contrasts, the USGS(21) characterized the Mexican Highlands as distinct from the Arizona Mountains (Transition Zone) in terms of the nature and distribution of young faults. The USGS recognition and documentation of this distinction reinforces the very conservative procedure used to locate a Sonora-type earthquake over 250 miles from the 1887 rupture. The nearest approach of the Mexican Highlands subprovince to the site is about the same as the epicentral distance already postulated in the maximum earthquake analysis.

2.5.2.4.1 Seismic Zone A

The San Andreas fault, from the Transverse Ranges southward, is the only fault in Zone A that is considered capable of producing a great earthquake with a magnitude of 8.0. Such an

earthquake may represent a conservative assumption because there has been very little historic activity along this portion of the San Andreas fault, and there has been a high level of earthquakes (up to magnitude 7.1) on the nearby San Jacinto fault set (paragraphs 2.5.2.2.2.2 and 2.5.2.3). At its closest approach to the site, the San Andreas fault is at a distance of about 120 miles. A level of vibratory ground motion less than 0.10g at the site is expected from an earthquake of magnitude 8+ at a distance of 120 miles (paragraph 2.5.2.6). Because the San Andreas fault and the postulated maximum earthquake lie along the edge of the zone nearest to the site, all other shocks in the zone would produce lesser levels of shaking at the site.

2.5.2.4.2 Seismic Zone B

This zone shows evidence of Quaternary fault activity, but epicenter uncertainties prevent assignment of shocks to particular causative faults. For maximum earthquake considerations, the shocks are presumed capable of occurring anywhere within this zone and in particular at the edge of the zone closest to the site. The largest earthquake observed in Zone B was a magnitude 4.9 shock in 1958. The maximum earthquake is taken to be a magnitude 5.0 shock with its epicenter at the edge of the zone and approximately 65 miles from the site. The maximum earthquake would cause a 0.02g level of vibratory ground motion at the site based on Donovan's[138] attenuation relationship. Capable faults are not

extensive enough to suggest that larger shocks should be expected.

2.5.2.4.3 Seismic Zone C

Determination of the maximum earthquake for Zone C involves two cases depending on the interpretation chosen for the tectonic relationship of the 1887 Sonora earthquake (see paragraphs 2.5.2.3.3 and 2.5.2.3.6). In the first case, Zone C comprises the band of seismicity crossing Arizona diagonally, and the 1887 Sonora earthquake is contained in a separate zone, the Mexican Highlands of the Basin and Range province. For this case, the maximum earthquake recorded in Zone C is a 1959 shock with magnitude 5.6; several other shocks greater than magnitude 5 have also occurred. The geologic and seismologic data are not adequate for this area to correlate individual shocks with particular faults, so a magnitude 5.6 earthquake is presumed possible at the closest approach to the zone to the site, more than 70 miles. Shaking from such an earthquake would be on the order of 0.03g at the site(138).

For the second case, Zone C is considered to widen southward and to contain the epicentral area of the 1887 Sonora earthquake. Then the occurrence of a Sonora-type earthquake of about magnitude 8.0 at some location closer to the site represents the maximum earthquake for Zone C. Faults about 200 miles long are needed to generate a magnitude 8.0 earthquake(139)(140) and no such Quaternary age faults are present within the Arizona portion of Zone C. However, there are several long, northwest trending valleys with associated

Quaternary and capable faults along a trend that projects northward from Mexico to the Grand Canyon region. Associating a great earthquake with these unconnected, Quaternary faults represents a very conservative assumption. The closest approach of these faults to the site is 72 miles. Evaluating a magnitude 8.0 earthquake at a distance of 72 miles provides a 0.20g estimate for vibratory ground motion at the site (paragraph 2.5.2.6). This level of shaking at the site is more severe than that of all other postulated earthquakes that might credibly occur in the site region.

2.5.2.4.4 Seismic Zone D

In Zone D, the largest earthquake must be presumed to occur at a random location because the geologic and seismologic data are generally not adequate to prove otherwise. However, detailed geologic investigations in the immediate vicinity of the site have precluded the existence of any capable faults within 5 miles of the site (paragraph 2.5.1.2.3). Shocks as large as magnitude 4.5 have occurred within Zone D: 1956, M=4.5 about 110 miles southeast of the site. The maximum earthquake for Zone D is taken to be a magnitude 4.5 shock at a distance of 5 miles. Such an earthquake would cause a level of vibratory ground motion at the site of less than 0.15g (paragraph 2.5.2.6).

DuBois, et al[97][98] have identified a few earthquakes in Zone D occurring prior to instrumental observations and for which they assign intensity VI. These authors have associated intensity VI with the magnitude range from 4.0 to 4.9.

However, for the particular intensity VI shocks in Zone D, the reported effects clearly suggest the lower portion of the intensity VI effects range. Thus, these shocks do not provide clear evidence for magnitudes greater than 4.5.

The 1976 Prescott earthquake, magnitude 5.2, occurred within the Colorado Plateau tectonic province very near the boundary between seismic Zones C and D. Although not identified with a particular fault, the earthquake is considered to be associated with a group of Quaternary faults(111) typical of the southwestern edge of the Colorado Plateau. Therefore, the event was not used to fix the magnitude of the randomly occurring earthquake in Zone D which is within the Sonoran Desert portion of the Basin and Range tectonic province.

2.5.2.4.5 Seismic Zone E

Seismic Zone E is beyond 200 miles from the site and would not generate vibratory ground motion at the site comparable to that from great earthquakes at much closer distances.

2.5.2.5 Seismic Wave Transmission Characteristics of the Site

Ground motions which would result at the site from the postulated maximum earthquake were assessed by the extrapolation of real earthquake accelerograms recorded on soils generally similar to those at the site rather than by using wave transmission methods. This approach does not depend upon seismic compressional and shear wave velocities, bulk densities, soil properties and classifications, shear

moduli and their variation with strain level and water table elevation. Site conditions, and the extent they influence ground motions, are accounted for as part of the procedure to select representative accelerograms. Paragraph 2.5.2.6.1 provides a summary of this methodology; paragraph 2.5.2.6.6 provides a discussion of amplification potential at the site.

2.5.2.6 Safe Shutdown Earthquake

The SSE has been selected as an event similar in size to the 1887 Sonora earthquake of magnitude 8.0 occurring at a distance of 72 miles northeast of the site. The selection of the SSE is conservative and is described in paragraph 2.5.2.4. The level of vibratory ground motion associated with this event was found to be conservatively represented by horizontal and vertical design response spectra normalized to 0.20g with the characteristics recommended in NRC Regulatory Guide 1.60 (figures 2.5-94 and 2.5-95). See section 3.7 for the seismic design basis SSE value.

The vibratory ground motion determined for the SSE is based essentially on free-field surface motions. Accordingly, it is applicable to the grade level of the plant. In a conservative manner, the SSE level of acceleration and the associated design spectra are applied to both the plant grade and the foundation level for the purpose of structural design and soil-structure interaction analyses.

As postulated in paragraph 2.5.2.4, there are two other sources capable of generating strong ground motion at the site. They are the San Andreas Shear Zone and an earthquake of magnitude 4.5 randomly located no closer than 5 miles from the site.

The San Andreas Shear Zone is not capable of producing vibratory ground motion at the site as strong as that of the SSE because the magnitude 8.5 maximum earthquake on the San Andreas Shear Zone would be located at a considerably greater distance from the site (120 versus 72 miles) than the SSE of magnitude 8.0.

A simplified evaluation of the level of shaking that could be expected at the site during an earthquake of magnitude 8.5 at a distance of 120 miles on the San Andreas Shear Zone can be obtained using the following attenuation relations:

	Maximum Ground Acceleration
Schnabel and Seed[99]	
Average	Less than 0.05g
Housner[141]	Less than 0.10g
Donovan[138]	0.06g

	Maximum Ground Acceleration
Esteva[142]	0.02g
Davenport[143]	0.04g

All of these values of maximum acceleration indicate shaking at the site considerably less severe than that represented by the recommended 0.20g NRC design spectra.

An earthquake of magnitude 4.5 in the vicinity of the site is also not capable of producing stronger vibratory ground motion at the site than the postulated SSE. The values of acceleration obtained in this case from the attenuation relations are:

	Maximum Ground Acceleration
Schnabel and Seed[99]	
Average	Less than 0.11g
Housner[141]	Less than 0.15g
Donovan[138]	0.10g
Esteva[142]	0.04g
Davenport[143]	Not applicable in near field

All these values are also representative of less severe shaking than the recommended 0.20g NRC design spectra. See also appendix 2A, Question 2A.5.

2.5.2.6.1 Basis of Approach

The design level of vibratory ground motion associated with the SSE (as expressed by the design response spectra) has been established by the extrapolation of response spectra of accelerograms recorded during past earthquakes. The results obtained by this method are corroborated with the results of methods which establish peak accelerations from attenuation relationships (paragraph 2.5.2.6.3) or intensity observations (paragraph 2.5.2.6.5). These latter two methods, involving the use of peak acceleration, have been used on other, previously

licensed nuclear power plants to determine the design level of vibratory ground motion associated with the SSE.

The response spectra of selected accelerograms of past earthquakes in the western United States were extrapolated to the conditions of the postulated SSE. The earthquake accelerograms were selected on the criteria that the recording conditions of the actual accelerograms should have, to the maximum extent possible, the same magnitude, source-site distance, local soil, and fault characteristics as the postulated SSE event for which design spectra are to be generated. Such criteria minimize the degree of scaling and extrapolation required and provides the greatest degree of assurance that the results reflect the postulated SSE realistically.

The approach is technically sound and leads to realistic results for the following reasons:

A. The selection of design spectra is based on examination of spectra over the entire frequency range of interest, rather than on the peak acceleration. Peak acceleration is only one point on the spectrum and is a poor measure of the strength of motion, except at very high frequencies. The same comment holds with respect to maximum ground velocity and displacement, which are not related, except in a statistical sense, to points on the design spectrum. (The peak ground displacement does control the spectrum at very long periods, but these are beyond the range of interest).

B. By making a selection of accelerograms recorded under circumstances as comparable as possible to the postulated SSE, the extrapolation and the associated inaccuracies are minimized. The scaling of accelerograms and spectra for magnitude and distance is by necessity an approximate operation, as any examination of basic data will show. The closer the characteristics of the actual earthquake are to those of the postulated earthquake, the more reliable the results.

C. The method is complete in the sense that existing records from all major U.S. earthquakes are the base of data from which selected records are drawn; while at the same time the existing records are limited enough so that no obvious significant data will be overlooked.

D. The approach does not depend on concepts such as bedrock motion, period of soil, depth to bedrock, and soil damping that are ill-defined or not as yet measured(144). Site conditions, and the extent they influence motions, are accounted for as part of the records selection procedure, except in the case of very soft soils.

Because of the limited data, some scaling of the response spectra with respect to magnitude and distance is necessary. The attenuation relations developed by Schnabel and Seed(99), Housner(141), and Donovan(138), were used to perform the scaling. These attenuation relations were used because they yield values

of maximum acceleration which are indicative of the severity of shaking. Donovan's relation was also considered to be one of the most appropriate of the statistical relationships for use with this procedure.

In the scaling procedure, the attenuation relations are considered correlations of the severity of the vibratory ground motion (as represented by the whole response spectrum) with magnitude and distance, and not merely as predictions of maximum ground accelerations. The scaling factor is obtained by dividing the acceleration that corresponds to the distance and magnitude of the postulated SSE, by the acceleration that corresponds to the distance and magnitude of the accelerogram being scaled. The distance associated with the accelerogram being scaled is the distance from the recording station to the center of energy release. An average depth of 10 miles has been assumed for the postulated event.

2.5.2.6.2 Safe Shutdown Earthquake Level of Vibratory Ground Motion

Table 2.5-9 identifies the accelerograms of past real earthquakes that are considered appropriate for extrapolation to represent the postulated SSE, an earthquake of magnitude 8 at a distance of 72 miles from the site. The two recorded horizontal components and the vertical component of motion were used in the extrapolation. In every case, the more conservative scaling factors obtained from the Schnabel and Seed[99], Housner[141], and Donovan[138] average attenuation curves

were used to scale the existing records to the postulated conditions.

The four records in table 2.5-9 generated by the Kern County earthquake of 1952, are the accelerograms whose recording conditions most closely resemble the conditions of the postulated earthquake. The Kern County earthquake was of high magnitude (7.7), similar to the magnitude of the postulated SSE event (8.0). The distance of the recording stations to the central portion of the causative fault are very similar to the source-site distance postulated for the SSE (60 and 80 miles versus 72 miles). Both the recording stations and the site are located on firm and moderately deep alluvium.

The two records from the San Fernando earthquake of 1971 were selected because they are the records with the highest acceleration levels recorded at distances comparable to that of the postulated SSE (68 and 78 miles versus 72 miles). However, they are not as representative as the records from the Kern County earthquake because considerably more scaling is necessary for magnitude (from 6.5 to 8.0 magnitude) resulting in large scaling factors (3.38 and 3.79).

Large scaling of the records to account for magnitude produces results that are very conservative because the attenuation relations used were obtained from data taken from small to moderate magnitude earthquakes; the application of these relations to large magnitude earthquakes requires an extension of the empirical relationships beyond the limits of the recorded data. It is widely agreed by researchers[139][145], and

acknowledged by the authors of the attenuation relations used, that such an extension results in values that are much higher than would actually be expected. This situation does not invalidate the scaling technique, it merely indicates that under these circumstances, the scaling is very conservative. It also indicates, however, that the records from the 1971 San Fernando earthquake, because they need large scaling for magnitude, are less representative of the SSE shaking than those from the Kern County earthquake. This is probably true with respect to both the general level of the response spectra and their relative frequency content.

Figures 2.5-42 through 2.5-47, which include the scaled spectra of the records from the Kern County earthquake (more representative set), indicate that 0.20g horizontal and vertical NRC Regulatory Guide 1.60 design spectra are a very conservative envelope of the level of ground shaking to be expected at the site due to an earthquake of magnitude 8.0 at a distance of 72 miles. For the period range of 0.5 second and less, the recommended design spectra are 1.5 to 4 times higher than the peaks of the scaled spectra. Figures 2.5-42 to 2.5-44 indicate that the conservatism of the recommended horizontal design spectra increases with increasing levels of damping. At the 10% damping level, which is on the order of the damping used for structure-foundation interaction, the scaled spectra do not reach the design spectrum at any period. The peaks that exceed the 0.20g NRC spectrum at 2% damping (figure 2.5-42) for periods between 0.6 to 2 seconds do not indicate less conservatism because considerably higher levels of damping

determine the vibratory response of the structures due to soil-structure interaction.

Table 2.5-9

SCALING FACTORS FOR ACCELEROGRAMS USED IN THE EVALUATION OF THE SSE DESIGN RESPONSE SPECTRA LEVEL[a]

Earthquake Record	Recorded Magnitude	Distance Between Recording Station and center of Energy Release (mi)		Scaling Factor for Record		
		Horizontal	Depth	Schnabel and Seed Average Attenuation Curves (1973)	Housner's Attenuation Curves (1965)	Donovan's Attenuation Relation (1973)
From the Kern County Earthquake of 1952						
Santa Barbara	7.7	60	10	0.88	0.80	0.98
Pasadena	7.7	80	10	1.57	1.69	1.33
Hollywood Storage Basement	7.7	80	10	1.57	1.69	1.33
Hollywood Storage P.E. Lot	7.7	80	10	1.57	1.69	1.33
From the San Fernando Earthquake of 1971						
San Bernardino	6.5	68	4	3.13	3.38	2.0
San Juan Capistrano	6.5	78	4	3.79	Beyond range	2.34

a. The largest of the three scaling factors computed for each accelerogram was used in the actual scaling of the accelerogram to simulate a magnitude 8.0 earthquake, 72 miles from the site.

At 10% damping (figures 2.5-44 and 2.5-50) there are no portions of the scaled response spectra that exceed the 0.20g NRC spectrum for either the records from the Kern County earthquake of 1952 or the San Fernando earthquake of 1971. At 5% damping (figures 2.5-43 and 2.5-49), only a few peaks of the scaled spectra slightly exceed the 0.20g NRC design spectrum; however, the 0.20g design spectrum envelops the scaled spectra well above the 84.1 percentile level implicit in the NRC Regulatory Guide 1.60.

Figures 2.5-48 through 2.5-53 show a comparison of the scaled response spectra of the records from the San Fernando earthquake listed in table 2.5-9 with the recommended 0.20g design spectra. They indicate that the 0.20g spectra are also a conservative envelope of these scaled records (especially at 5 and 10% damping, figures 2.5-49 and 2.5-50).

2.5.2.6.3 Maximum Accelerations Based on Attenuation Relations

The procedure described in paragraph 2.5.2.6.1 reflects the best use of the existing accelerogram data and provides a rational and conservative estimate of the design spectra associated with the SSE at the site. In utilizing this procedure, the most appropriate existing accelerograms recorded during past earthquakes have been scaled to the magnitude and distance associated with the postulated SSE.

The procedure results in a more representative determination of the maximum vibratory ground motion at the site than would be obtained by directly normalizing NRC Regulatory Guide 1.60

design spectra to peak acceleration values obtained from the different attenuation relationships presented in literature. Nevertheless, to demonstrate the reasonableness of the applicant's procedure, this paragraph presents comparisons of results with those obtained from a direct application of some pertinent attenuation curves. The peak ground accelerations estimated at the site for the postulated SSE are listed below:

	Magnitude 8.0 at a Distance of 72 Miles
Schnabel and Seed[99]	0.07g
Average	
Housner[141]	0.11g
Donovan[138]	0.09g
Esteva[142]	0.04g
Davenport[143]	0.17g
Cloud and Perez[125] Envelope	0.07g

It should be noted that all these attenuation curves were obtained from data taken from small to moderate magnitude earthquakes. The application of these curves to larger magnitude earthquakes requires an extension of the empirical relationships beyond the limits of the recorded data. It is widely agreed by researchers[139][145] that such an extension results in ground accelerations that are much higher than would actually be expected. Nevertheless, it can be seen that the peak ground accelerations shown above indicate the conservatism of the 0.20g NRC Regulatory Guide 1.60 design spectra determined by the procedure described in paragraph 2.5.2.6.1.

2.5.2.6.4 Attenuation of Vibratory Ground Motions in Arizona

The attenuation curves used in specifying the SSE have been derived mostly from instrumental data from California earthquakes. Thus, their use deserves justification for Arizona application. This aspect of the seismic evaluation in different geographic areas is important since it has been postulated by some investigators[147] that seismic shaking is attenuated more slowly with distance in the eastern United States than in the west. Because instrumental data are lacking in Arizona, the available intensity data were reviewed and found to support two lines of reasoning with similar results.

The first relates to the shape of isoseismal lines from single large events which affect both areas (California and Arizona). Shown in figures 2.5-31, 2.5-32, 2.5-35, and 2.5-38 are isoseismal maps for large earthquakes in the Imperial Valley Region in 1934 and 1940, the Desert Hot Springs earthquake of 1948, and the Borrego Mountain earthquake of 1968, respectively. The limits of the felt area are about equidistant in the northwesterly direction in California, and in the easterly direction into Arizona. This radius is not exactly constant, but such is common for events within California. If the crust under the southwestern corner of Arizona possessed attenuation properties greatly different from those in California, the limiting distance of perceptibility would be considerably less or considerably more in Arizona than in California. At most, these examples would admit to about 20 to 25% difference in distance, but this amount is not significant in light of the small number of events large enough

to be felt in both areas and the irregular shape of the isoseismal lines in general.

The second method compares the area enclosed by the isoseismals produced by earthquakes of the same magnitude in Arizona and California. Of particular interest, because of the 1887 Sonora earthquake, are events in the central seismic zone (Zone C) of Arizona. Although there are five moderate events (1938, M=5.5; 1945, M=5.1; 1959, M=5.0; 1959, M=5.6; and 1976, M=5.2), only the 1938 event near the Arizona-New Mexico border, the 1959 event on the Arizona-Utah border, and the 1976 event north of Prescott, Arizona have reported isoseismal data. The 1938 event, magnitude 5.5, is reported as having affected 8000 square miles. The 1959 event of magnitude 5.6 was also reported to have been felt over 8000 square miles; however, if the felt reports are plotted (figure 2.5-37), the felt area is indicated to range from 15,000 to 32,000 square miles. The 1976 Prescott event was reported as being felt over 9000 square miles. For comparison, the felt areas as reported in the publication, Earthquake History of the United States (1973), for California events in the magnitude range of 5.4 to 5.8 were plotted against magnitude in figure 2.5-54. Shown also are open symbols representing the Arizona events described above. There is great scatter in these data, but the Arizona data do fall within the California data.

These two studies indicate that the attenuation of ground motion in Arizona is approximately the same as that for California.

Furthermore, the observations of damage and shaking during the 1887 Sonora earthquake towards Arizona and to the west of the fault break clearly indicate that the attenuation of vibratory ground motion in these directions is the same order as has been experienced in California. (The detailed discussion and data supporting this conclusion can be found in paragraph 2.5.2.10.4 and Appendix W of the PVNGS 1, 2, and 3 PSAR). Consequently, the use of attenuation relations based on California data is adequate for Arizona.

2.5.2.6.5 Estimations of Vibratory Ground Motion from Intensity Observations

This paragraph is presented also as a corroboration that the recommended 0.20g NRC design spectra are a conservative representation of the maximum level of shaking for the site. It is pointed out, however, that intensity scales are not a scientifically quantitative measure, and so the results obtained by their use are not as reliable as those obtained by the extrapolation of real earthquake response spectra. The Modified Mercalli (MM) intensity to be expected at the site during an earthquake of magnitude of 8.0 at a distance of 72 miles, as determined from figure 2.5-55(148), is between VI and VII. The curves in figure 2.5-55 are based on data for southern California earthquakes(149)(150)(151). They are, however, considered applicable to Arizona in view of the data presented in paragraph 2.5.2.6.4. The conservatism of the estimated intensity VII is apparent in the isoseismal maps of the high magnitude earthquakes in California shown in figures 2.5-29,

2.5-30, and 2.5-36. In every case, the highest intensity at a distance of 72 miles is MM VII, with the exception of the intensity VII-VIII indicated for the Yosemite Valley during the Owens Valley earthquake of 1872. This intensity is based on the poetic description of the earthquake by the explorer John Muir who indicates only the falling of rocks from the almost vertical granite walls of the canyon; no damage to his cabin is mentioned(152). Only intensities VI-VII of the

Rossi-Forel scale (which is equivalent to MM VI), were reported to distances of 72 miles from the San Andreas fault during the 8.3 magnitude San Francisco earthquake of 1906; this is considered to be the most representative because of relatively good documentation and because it was caused by a high-angle fault as is the fault system producing the SSE.

The intensity VII reported for Visalia during the 1872 Owens Valley earthquake is considered to be overestimated because it is based on the following description of damage:

> "People ran into the street; front wall of brick saloon moved 1 inch; fissures of 1 inch or more opened in clay ground." From the Los Angeles Evening News of 3/27/1872 (R. Greensfelder, 1974 personal communication)

The values of maximum ground acceleration that have been associated with the modified Mercalli intensity VII by a number of authors are (see Table 1 of reference 153 for citations):

Ishimoto (1932)	0.05g
Kawasumi (1951)	0.09g
Hershberger (1956)	0.13g
Richter (1958)	0.07g

Neumann (1954)	0.13g
Medvedev and Sponheuer (1969)	0.05g-0.10g
Japan Meteorological Agency (Okamoto, 1973)	0.04g-0.10g
Trifunac and Brady (1975)	0.13g

All these values are below the 0.20g recommended for the SSE.

2.5.2.6.6 Amplification Potential at Site

This paragraph addresses three points concerning the treatment of soil amplification and other potential site effects by the procedure used to determine the SSE level of design spectra (see paragraph 2.5.2.6.1).

A. For alluvial deposits as firm as those at the Palo Verde site, effects of local site conditions upon the ground motion are much less significant than effects of source mechanisms and travel paths.

B. The procedure incorporates potential site effects, and other effects, in the most fundamental way, by making full use of available measured data obtained under comparable conditions.

C. The use of a soil column analysis to calculate the site vibratory ground motion would be inappropriate.

Regarding item A above, the measured wave velocities at the site (table 2.5-10) indicate that the surface materials are somewhat firmer than at El Centro, California, and are also comparable to the surface deposits in other places in southern California, such as the Pasadena and Los Angeles basins. At

the El Centro site, a detailed analysis of 15 measured strong-motion records, including the 1934 and 1940 events, showed conclusively that consistent local site effects, if any, are overshadowed by variations in the motion attributable to variations in the source mechanism and travel path[130]. This study of a single site for several earthquakes is complemented by Hudson's[154] study of records obtained on many sites in the Pasadena area for the San Fernando earthquake. In this later study, it was found that the motion bore no simple relationship to depth of alluvium or rock types. There were no characteristics of the motion that could be ascribed to local site conditions.

Table 2.5-10

P-WAVE VELOCITY (fps) PROFILES AT THE SITE

AND STRONG MOTION RECORDING STATIONS IN SOUTHERN CALIFORNIA

Depth (ft)	Palo Verde Site	El Centro	Pasadena	Santa Barbara	Hollywood Storage	San Bernardino
10	1900	1200	1000	2500	1090	1300
20	1900	1200	2200	4100	2400	1300
50	2100	1200	2200	4100	2400	5200
75	5000	5900	2200	4100	2400	5200
100	5500	5900	5300	5200	2400	5200
150	5700	5900	5300	5200	2400	5200
200	5700	5900	5300	5200	5000	5800
250	6100	5900	5300	5200	5000	5800
300	6500	5900	5300	5200	5000	5800

NOTE: No P-wave velocity profile for San Juan Capistrano.

In addition, motions in the Los Angeles area during the San Fernando earthquake, and at sites where four earthquakes have been recorded[155], show no effects on the motion that are identifiable with local conditions. There are indications, however, from Hanks[156], that the surface wave motions of long period were enlarged in passing laterally from basement rock and firm sediments into the softer sediments of the southern Los Angeles basin. This occurred during the San Fernando earthquake at distances from 20 to 40 miles from the fault.

These surface waves appear to be responsible for the peaks at periods of 3 to 4 seconds in the response spectra at sites in southern Los Angeles studied by Crouse[157], and may also be the source of the long-period motions discussed by Scott[158] for sites at Long Beach and Vernon. This very general effect of basin-wide conditions on the amplitude of surface waves in the San Fernando earthquake is the only observed "site effect" and does not, in general, occur at frequencies that are important in nuclear power plant design.

With regard to item B above, by beginning with records of ground motion obtained under as comparable conditions of epicentral distance, local site conditions, and source mechanisms as possible, the applicant's procedure considers the effects of these features directly. For example, selecting records at comparable distances and from comparable sites in the San Fernando earthquake ensures that surface-wave effects of the type noted above are correctly accounted for. (They are not of major importance in this application, however, because of their long periods.)

With respect to local site conditions, table 2.5-10 shows that the sites where the records selected for extrapolation to represent the SSE (table 2.5-9) were obtained have wave propagation characteristics that are comparable to those at the Palo Verde site. It is noted that many of the records used to establish the shape of the spectra set forth in Regulatory Guide 1.60 were obtained on firm alluvium.

Regarding item C above, the use of soil-column analysis to study site effects is inappropriate for a number of reasons. First, the soil-column analysis assumes vertically propagating shear (SH) waves as the only mode of wave propagation. This is a gross simplification that neglects the contribution of surface waves and body waves coming at other angles of incidence. Secondly, there are essentially no measurements of strong motion obtained at depth that can serve as reliable excitations for such models. Thus, the excitation must be estimated from motions obtained at the ground surface which is a circuitous way of determining ground surface motion. Finally, the two properties of the soil column that are paramount in determining its calculated effects on surface motions are the fundamental frequency and the damping in the fundamental mode. The fundamental frequency is determined, in large part by the depth of the column, with larger periods associated with deeper soil columns. However, at the El Centro site, no specified site period can be identified either from strong-motion records or from microtremor recordings(159), and no such site periods are present in the records studied by Hudson(154) and Crouse(157). The amount and type of damping associated with the soil column analysis is uncertain and is based primarily on empirical data having wide scatter.

In view of the oversimplifications and uncertainties inherent in a soil column analysis, it is thought preferable to make a more direct extrapolation from measured data.

2.5.2.7 Operating Basis Earthquakes

The level of vibratory ground motion selected as the OBE is represented by the 0.10g design response spectra presented in figures 2.5-96 and 2.5-97. This earthquake level is half that of the postulated SSE (0.20g spectra) as required in 10CFR Part 100, Appendix A. The level of shaking represented by the 0.10g design response spectra is greater than the shaking levels that may be reasonably expected to occur at the site during the operating life of the plant. This conclusion is based on the following:

- Low seismicity of the region
- Absence of capable faults within approximately 70 miles of the site
- Results of probabilistic analyses contained in Algermissen and Perkins[160][161] and ATC.[162]

According to these references, the accelerations at the site with a 10% probability of being exceeded in 50 years (which corresponds to an average return period of 475 years) are less than 0.05g. See section 3.7 for the seismic design basis OBE value.

2.5.3 SURFACE FAULTING

2.5.3.1 Geologic Conditions of the Site

The geologic conditions of the region surrounding the site (200-mile radius) are discussed in paragraph 2.5.1.1. A more detailed discussion of the geology in the site vicinity and its

relation to the regional geology is presented in paragraph 2.5.1.2.2. Geologic conditions of the foundations of PVNGS Units 1, 2, and 3 are described in subsection 2.5.4 and appendix 2D.

In summary, the distinctive Palo Verde Clay underlying the site has been shown to be greater than 2.8 million years old and its unfaulted nature provides the basis for proving that there are no capable faults within 5 miles of the site.

2.5.3.2 Evidence of Fault Offset

2.5.3.2.1 General

Techniques used to determine the presence or absence of fault displacements at or near the ground surface within the 5-mile radius of the site, and in adjacent areas outside this radius, included: analysis of stereo, vertical, aerial photographs; ERTS-1 imagery, and side-looking radar imagery; detailed geologic field mapping; trench and foundation excavations; lithologic and high-resolution, geophysical, borehole correlations; gravimetric and magnetic surveys; and seismic refraction surveys. These studies have shown that there is no evidence of capable fault offset at or near the ground surface within a 5-mile radius of the site.

2.5.3.2.2 Mappable Faults

Detailed geologic mapping within the 5-mile radius revealed only one mappable fault (figures 2.5-11 and 2.5-12). This fault is in the Miocene volcanic bedrock about 3 miles west of

the site, strikes northwest, and has been traced for approximately 2000 feet. The fault plane is vertical and is indicated by a crushed zone of volcanic rock 1 to 3 feet wide. This fault has been investigated in closely-spaced backhoe trenches ranging from 15 to 200 feet apart[8]. Plunges of slickensides in four trench exposures of the fault indicate that the sense of movement is dip slip. Based on the orientation of slickensides and a distinctive 30 to 50-foot-wide tuff unit exposed on both sides of the fault, displacement is calculated to be about 50 to 75 feet. The fault was traced to a point where it is overlain by Tertiary fanglomerate (Tvfn). A trench exposing the fault at this point clearly demonstrates that the fanglomerate is not displaced. The age of the fanglomerate is 16.7 million years (Miocene) based on a potassium-argon date of a basalt interbed (paragraph 2.5.1.2.1).

2.5.3.2.3 Inferred Faults

Gravity and magnetic surveys in the site area reveal two anomalies inferred to be buried faults. These inferred faults are from 4.5 to 5 miles north of the site, trend northwest to eastwest, and are approximately 10 miles long (figures 2.5-11 and 2.5-12). These features do not displace the ground surface or the thick sequence of Pliocene and Pleistocene basin sediments, including the Palo Verde clay (figure 2.5-19): thus, they must be older than the Palo Verde clay (greater than 2.8 million years).

2.5.3.2.4 Lineaments

Several lineaments were noted within 10 miles of the site (paragraph 2.5.1.2): two short ones within the 5-mile radius (figure 2.5-12), one about 7 miles southeast of the site, and two about 8 miles south of the site coinciding with alignments of the Gila River (figure 2.5-13). Detailed investigations (paragraphs 2.5.1.2.2.2 and 2.5.1.2.4) revealed that none of these lineaments represent capable faults.

2.5.3.3 Earthquakes Associated with Capable Faults

Figure 2.5-25 shows that there are no capable faults or historic earthquakes within 5 miles of the site.

2.5.3.4 Investigation of Capable Faults

There are no capable faults within 5 miles of the site.

2.5.3.5 Correlation of Epicenters with Capable Faults

The absence of capable faults within 5 miles of the site precludes the correlation of epicenters with capable faults.

2.5.3.6 Description of Capable Faults

There are no capable faults within the 5-mile radius of the site (paragraph 2.5.3.2).

2.5.3.7 Zone Requiring Detailed Faulting Investigation

There is no zone requiring detailed faulting investigation.

2.5.3.8 Results of Faulting Investigation

This paragraph is not applicable because there is no zone requiring detailed faulting investigation (paragraph 2.5.3.7).

2.5.4 STABILITY OF SUBSURFACE MATERIALS AND FOUNDATIONS

2.5.4.1 Geologic Features

2.5.4.1.1 Subsidence Potential

There is no physical evidence or published information that indicates any occurrence of subsidence in the site area (5-mile radius). Mineral resources are not known to exist within the site area and geologic conditions beneath the site are not conducive to formation of mineral resources. Therefore, any subsidence due to extraction of mineral resources is precluded. The potential for subsidence due to groundwater withdrawal at the site is not significant because of a favorable combination of three factors:

- Projected groundwater level changes beneath the site are small (see paragraph 2.4.13.2).
- The thickness of unlithified deposits beneath the site is less than 480 feet; less than half of this thickness corresponds to deposits below the regional water level.
- The compressibility of the unlithified deposits at the site is small (see paragraph 2.5.4.10.1).

Although the potential for subsidence is considered to be minor at this site, detailed analyses were performed to verify this condition. Conservative parametric analyses of the effects of

hypothetical (not anticipated) water level declines were presented in the PVNGS 1, 2, and 3 PSAR. The potential for deep-seated subsidence due to declines in the piezometric level of the regional aquifer was discussed in paragraph 2.5.1.1.6, Listing G.3, of the PVNGS 1, 2, and 3 PSAR. The elastic compression of the sedimentary and volcanic rocks comprising the regional aquifer was conservatively estimated to be about 2, 3, and 4 inches for hypothetical water level declines of 250, 350, and 450 feet, respectively.

The potential for subsidence due to dewatering of the perched water zone was discussed in Appendix 2T (Section 2T.7) of the PVNGS 1, 2, and 3 PSAR. Based on the very conservative groundwater assumption that hydrostatic conditions prevailed below the perched water zone, and using conservative compressibility parameters for the soils, total subsidence due to complete dissipation of the perched water zone was estimated to be in the range of 6 to 10 inches. However, based on the more realistic groundwater model presented in paragraph 2.4.13.1, dewatering of the perched water zone is not expected to result in subsidence. Since the fine grained soils encountered below approximately 50 feet act as the aquitard for the perched water zone, dewatering of this perched zone can be expected to cause a slight reduction in effective stresses within and below the aquitard resulting in a slight amount of heave, not subsidence. Some evidence of this is provided by excavation heave and subsidence monitoring data presented in paragraph 2.5.4.13. Maximum heave/rebound measured at the bottom of power block excavations at Units 1, 2, and 3 ranged

between 2 and 3 inches. While the subsurface conditions are similar under all three units, the amount of measured heave increased with the degree of dewatering. Dewatering was not required at Unit 1, while total water levels were lowered approximately 20 and 30 feet at Units 2 and 3, respectively. Similarly, survey data from the subsidence monitoring network, away from the influence of excavations, show no measurable subsidence over a 2-year period from 1977 to March 1979 (see paragraph 2.5.4.13.2.2) even though perched water levels declined about 5 feet over the same period and about 15 feet since 1975. These observations confirm that declines in perched water levels do not result in subsidence at this site.

2.5.4.1.2 Loading History of Foundation Materials

Historic erosion/deposition at the site has provided for the development of uniform sequences of dense or stiff soils that have been naturally consolidated during loading cycles. The mode of deposition and mineralogical composition of the soils and rock underlying the site is described in paragraph 2.5.1.2.2. Historic seismicity indicates that the site soils have been subjected to mild dynamic loading due to events with epicentral locations far removed from the site (paragraph 2.5.2.1). However, no evidence of seismically-induced ground failure has been observed at the site. The site has not been adversely subjected to other forms of loading phenomena such as glaciers or tidal effects or meteor impact.

2.5.4.1.3 Localized Soil and Rock Structures

Bedrock is not exposed in the site-specific area nor at depths which would influence the foundations due to joint patterns or fracturing. Category I structures are founded either on engineered backfill or undeformed basin sediments (paragraph 2.5.4.3 and appendix 2D) with a minimum thickness in the power block areas of about 200 feet (paragraph 2.5.4.2). No zones of structural weakness, such as crushed or disturbed materials caused by shears, faults, and folds, have been identified in the basin sediments underlying the site. No abnormal zones of alteration, irregular weathering profiles or seams, and lenses of weak materials are present in the soil and rock units beneath the powerblock areas.

2.5.4.1.4 Unrelieved Residual Stress

No bedrock is exposed at the foundation elevation of Category I structures (appendix 2D). There is no evidence to indicate that there are unrelieved residual stresses in the bedrock.

2.5.4.1.5 Rock and Soil Response Characteristics

There is no evidence that the characteristics of rocks or soils at the site are such that they may result in hazardous foundation conditions. The dense rock is consolidated and soils are generally overconsolidated (paragraph 2.5.4.2). No abnormal water content in the site soils or rock has been observed or is expected during the operational life of the facility (paragraphs 2.4.1.3 and 2.5.4.2). No significant

quantity of soluble minerals exists at the site (paragraphs 2.5.1.2).

The response of rock and soil to natural loading conditions, i.e., seismic events and anticipated static loads induced at the site, is expected to be favorable (paragraphs 2.5.4.8 and 2.5.4.10).

2.5.4.2 Properties of Subsurface Materials

Soil properties presented herein were derived from investigations conducted at five unit areas which included the location of two potential units (Units 4 and 5). Licensing activities for these two potential additional units have been terminated.

The engineering properties of subsurface soils were investigated by drilling, sampling, laboratory testing, and geophysical testing techniques. A summary of the generalized stratigraphy and associated engineering properties is presented in this section. Specific details of the drilling and sampling program are presented in paragraph 2.5.4.3. Details of the laboratory testing program and of the geophysical exploration are presented in appendix 2E and paragraph 2.5.4.4, respectively.

Profiles depicting the generalized stratification of subsurface materials at the units down to bedrock (approximately 300± feet deep) are shown on figures 2.5-56 through 2.5-58. The actual detailed soil stratification of the upper 65± feet is shown in the detailed excavation mapping of each of the

powerblock excavations, presented in appendix 2D. The stratigraphy disclosed by the mapping is consistent with that derived from borehole information.

2.5.4.2.1 Layer Descriptions

To determine representative engineering properties, the subsurface profile has been subdivided into three soil depth zones representing different depositional environments and generally exhibiting different engineering characteristics. For discussion purposes, these zones are defined as the upper zone (0 to 30 feet), intermediate zone (30 to 55± feet), and lower zone (55 to 300± feet). These depth zones correspond approximately to the following geologic lithozones and stratigraphic members presented on the geologic profiles and maps of excavations:

Depth Zone (feet)	Geologic Lithozone	Stratigraphic Members
Upper (0 to 30±)	Upper LZ5	A and B
Intermediate (30 to 55±)	Lower LZ5 (Transition)	C, D, and Upper E
Lower (55 to 300±)	LZ4 and LZ3	E, F, G, H, I, J, and K

The upper zone contains granular soils deposited in a high energy environment. Such deposits primarily consist of relatively well-graded silty and clayey sands with some fine gravel. Relatively uniform, fine, and medium sand layers are also present to a lesser extent. With the exception of the

upper 2 or 3 feet which are generally loose, the deposit is generally medium dense to dense. Zones of caliche cementation are common.

The intermediate zone represents a gradational interface between the upper coarse-grained pluvial deposits and the underlying, fine-grained lacustrine deposits. It consists of crudely stratified clay, silt, and sand layers of limited lateral extent. The clays are generally medium plastic, hard, and exhibit extensive calcareous cementation. Gradational mixtures of fine sands, silts, and clays of low plasticity are also common within the transition zone. Such soils, classified as SM-ML and SC-CL, are generally stiff to hard and exhibit localized calcareous cementation. Layers of sands with low silt and clay content (typically less than 30% fines) are also encountered within the transition zone. The sands within the intermediate zone are generally medium dense to very dense.

The intermediate zone generally increases in thickness and complexity of layering from Unit 1 southward. At Unit 1, the transition between the upper coarse-grained and lower fine-grained zones is very abrupt in most areas and the intermediate zone is discontinuous in those areas. At Units 2 and 3, the intermediate zone generally occurs within the interval of approximately 30 to 50 feet deep, immediately above the well-defined stratigraphic member E contact.

The lower zone deposits primarily consist of medium to highly plastic, hard clays. Sands and silts comprise a very small portion of the formation. Layering within the deposits is

uniform and relatively flat. Several major layers are traceable across the site.

2.5.4.2.2 Static Soil Properties

The results of the field and laboratory testing program were used to evaluate the engineering properties of site soils. Typical static material properties for site soils are presented in figure 2.5-59. Grain size and plasticity characteristics of the various soil layers are presented in figures 2.5-60 through 2.5-62. Results of standard penetration tests in granular soils beneath Units 1, 2, and 3 are presented in figure 2.5-63. A summary of shear strength test results is presented in figure 2.5-64. The resulting strength parameters used in design are summarized in figure 2.5-59.

2.5.4.2.3 Dynamic Soil Properties

See paragraph 2.5.4.7.

2.5.4.3 Exploration

2.5.4.3.1 General

An extensive subsurface exploration program was conducted to provide regional engineering and geology data for making preliminary site selection, and to provide detailed data at the site-specific areas after the unit locations had been finalized. The subsurface investigation included:

- 578 borings ranging in depth from 5 to 721 feet
- 3 backhoe trenches

- High resolution downhole geophysical logging
- seismic refraction lines (3 at site-specific areas)
- 4 outflow type borehole pump tests
- 27 inflow type borehole permeability tests

Site plans showing the locations of exploratory borings, trenches, and seismic refraction lines are presented in figures 2.5-66 through 2.5-68. An extensive tabulation of details concerning the subsurface exploration is presented in appendix 2F; included are details about drilling and trenching, such as coordinates, elevations, depths, drilling methods, sample types, and purpose.

Details concerning the geophysical investigation are presented in paragraph 2.5.4.4. Details concerning the borehole permeability testing are presented in appendix 2E. Exploratory borings were sealed by continuously grouting to prevent hydraulic communication between aquifers.

2.5.4.3.2 Subsurface Profiles

Geologic profiles illustrating the generalized stratigraphy under the power block areas are presented in figures 2.5-56 through 2.5-58. Detailed stratigraphy of the upper soils in the Units 1, 2, and 3 power block areas is presented in the geologic mapping of the power block excavations (appendix 2D).

2.5.4.4 Geophysical Surveys

Compressional and shear wave velocity surveys were performed at each unit to evaluate the low strain amplitude dynamic

characteristics of foundation soils and to establish the general occurrence of predominant soil layers. These surveys were accomplished using refraction, downhole, and crosshole testing methods. The methods used to conduct these tests, together with test results, are briefly summarized in the following paragraphs. Detailed information about test procedures, test results, interpretation of results and discussion of results is given in Appendix 2U of the PVNGS 1, 2, and 3 PSAR and the PVNGS 4 and 5 PSAR.

2.5.4.4.1 Refraction Surveys

Refraction tests were conducted at the Units 1, 2, and 3 locations (figure 2.5-68). Five source points were used during each refraction test. Explosive charges were used as energy sources. Geophone receivers were located at 20-foot intervals over a 250-foot spread distance.

Results of the refraction tests are summarized in figure 2.5-69. Three to four major velocity units can be identified in these profiles. Compressional wave velocities beneath the units vary from about 1100 feet per second near the ground surface to 5000 feet per second or more below the apparent groundwater table (60 to 80 feet below the ground surface at the time of the refraction tests).

2.5.4.4.2 Downhole Surveys

Downhole travel time measurements were made at the Units 1, 2, and 3 locations (figure 2.5-68). The energy was generated on the ground surface by striking a concrete block embedded in

surficial soils with a sledge hammer. Wave arrivals were recorded at 10-foot depth intervals in a borehole located about 30 feet from the source. Measurements were made to depths of 300 feet or more. Travel times for depths less than 200 feet were corrected to an equivalent vertical time according to the ratio between the slant distance and the vertical distance.

Travel times from the downhole tests are plotted as a function of depth in figure 2.5-70. Compressional and shear wave velocities derived from the time-distance relationships are noted in each plot. Velocity values at each unit increase with depth. Shear wave velocities typically vary from about 1000 feet per second in the upper 50 feet to 4000 feet per second or more at a depth of 4000 feet. Compressional wave velocities vary from 1300 to 2000 feet per second in the unsaturated, upper 50 feet of the soil profile to velocities in excess of 7000 feet per second at depths greater than 300 feet. The water table typically was interpreted to occur at depths of 50 to 80 feet on the basis of a sharp increase in compressional wave velocities (from about 2400 feet per second to slightly more than 5000 feet per second).

2.5.4.4.3 Crosshole Surveys

Crosshole tests were conducted at six locations (figure 2.5-68). Explosive and mechanical source mechanisms were employed during crosshole testing to enhance identification and interpretation of wave arrivals. Receiving holes were typically located in a linear pattern on both sides of the source hole. Arrays generally covered approximately

80 feet with adjacent receiving holes being 10 to 35 feet apart. Crosshole tests were normally performed at 10-foot depth intervals from depths of 10 feet to depths of 300 feet or more.

Results from the crosshole tests performed at Units 1, 2, and 3 are plotted as a function of depth in figure 2.5-71. These velocity values were used with elastic theory to compute shear moduli, Young's moduli, bulk moduli, and Poisson's ratio, as presented in tables 2.5-11 through 2.5-13.

As shown in figure 2.5-71, shear and compressional wave velocities generally increase uniformly with depth. Shear wave velocities vary from about 1000 feet per second in the upper 50 feet to values in excess of 2000 feet per second at 300 feet. Compressional wave velocities increase from about 1500 feet per second in the upper 50 feet to in excess of 6000 feet per second at a depth of 300 feet. These shear and compressional wave velocities are generally consistent with those recorded during the downhole program, suggesting that little material anisotropy exists. The water table, indicated by compressional wave velocities of approximately 5000 feet per second, is at 50 to 80 feet below the ground surface. These observations are also consistent with those recorded during downhole and refraction surveys.

2.5.4.5 Excavations and Backfill

2.5.4.5.1 Extent of Excavations, Fills, and Slopes

There are no Seismic Category I excavations at the site. Temporary excavations related to construction of plant facilities are backfilled before the plant is in operation. Therefore, the stability of temporary excavation slopes will not affect the safe operation of the plant.

The existing ground surface at the site is relatively flat, and only minor grading is required in the vicinity of the plant facilities.

The excavation details for Units 1, 2, and 3 temporary powerblock excavations are presented in figures 2.5-72, 2.5-73, and 2.5-74. Temporary excavations have slopes ranging from approximately 1-3/4:1 to 1:1 (horizontal to vertical).

See also appendix 2A, Questions 2A.7, 2A.9, and 2A.10.

2.5.4.5.2 Dewatering and Excavation Methods

Dewatering was carried out during excavation of the powerblock areas at Units 2 and 3. To facilitate construction activities, the ground water level was kept at a depth of at least 1 foot below final grade. Dewatering operations did not have any adverse effects on the underlying foundation soils. Dewatering was accomplished by use of open trenches and sumps.

The foundation excavations were made with conventional earth moving equipment in soils. Foundation excavations at the base of slab were protected against disturbance by use of a 3-inch

concrete mud mat, and where overexcavation was done, the excavation was backfilled with lean concrete or processed sand to the specification indicated in paragraph 2.5.4.5.3.

Foundation heave and settlement of critical structures in the Units 1, 2, and 3 excavations were measured by:

- Multiposition extensometers anchored at various depths between bedrock and the bottom of the excavation
- Mechanical rebound anchors located near the bottom of the excavation

Details and results of the heave/settlement monitoring program are presented in paragraph 2.5.4.13.

2.5.4.5.3 Backfill

Soil backfill placed adjacent to Category I structures and pipelines meets the requirements of the PVNGS 1, 2, and 3 PSAR. The shape of construction excavations and the extent of backfill at each powerblock is shown in figures 2.5-72, 2.5-73, and 2.5-74. During backfilling, fills were benched into firm, undisturbed native soils along construction slopes. This was done in order to remove any loose, eroded soil at the construction slope surface, and to facilitate uniform compaction to the edges of the backfill.

Structural backfill under Category I structures consists primarily of excavated granular soils. Suitable granular soils are abundant in the upper granular strata to depths of approximately 50 feet in the unit areas. Material gradation

specifications are presented as a grain size band in figure 2.5-75. Structural backfill is compacted to a density of 95% of the maximum dry density determined in accordance with ASTM D1557. The above gradation and compaction requirements were developed as a result of extensive static and dynamic

laboratory testing of remolded granular soils from Units 1, 2, and 3.

Physical properties of the upper sand strata which are the source of Seismic Category I backfill material are presented and discussed in paragraph 2.5.4.2. Details and results of the testing program performed to evaluate structural backfill and formulate compaction and gradation requirements are presented in a report(163).

A test fill program(164) which complies with the PVNGS 1, 2, and 3 Safety Evaluation Report was also performed to develop compactive effort requirements. This report was submitted to and approved by the NRC.

2.5.4.6 Groundwater Conditions

A detailed description of groundwater conditions at the site is presented in subsection 2.4.13. A discussion of the effects of groundwater conditions on the loading and stability of structures and foundation materials is presented in the following paragraphs.

2.5.4.6.1 Groundwater Conditions Relative to Plant Facilities

The groundwater studies discussed in subsection 2.4.13 indicate the presence of a deep regional aquifer and a local perched water zone beneath the site. Piezometric and water table elevations for these two groundwater bodies are presented in figures 2.4-29 and 2.4-30, respectively.

The regional water levels are typically at depths in excess of 200 feet below the ground surface. Therefore, fluctuations in these water levels, will not have a significant effect on the stability of critical plant structures. The subsidence potential due to water level changes in the regional aquifer is discussed in paragraph 2.5.4.1.1.

The perched water zone, on the other hand, is in direct contact with some of the structures in Units 2 and 3 (below all structures in Unit 1). The presence of a perched groundwater condition at the site has prompted the assessment of four safety-related considerations:

A. The potential for liquefaction of granular soil within the perched zone (refer to paragraph 2.5.4.8)

B. The potential for subsidence due to dewatering or dissipation of the perched zone (refer to paragraph 2.5.4.1.1)

C. Hydrostatic loading on the walls of Category I structures in contact with the perched groundwater zone (refer to paragraphs 2.4.13.5 and 2.5.4.10.3)

D. Flotation of Category I structures (refer to paragraph 2.4.13.5)

The design water levels presented in paragraph 2.4.13.5 conservatively envelope all anticipated groundwater level fluctuations at the site.

2.5.4.6.2 Control of Groundwater Levels

Groundwater levels at the site are not expected to exceed design levels during the operational life of the plant. Therefore, special measures to control groundwater levels are not deemed necessary.

2.5.4.6.3 Dewatering During Construction

Dewatering of excavations is discussed in paragraph 2.5.4.5.2.

2.5.4.6.4 Groundwater Conditions Experienced During Construction

Refer to paragraph 2.5.4.5.2 for a discussion of groundwater conditions during construction.

2.5.4.6.5 Permeability Tests

Permeability tests are presented in appendix 2G. Results of the tests are discussed in paragraph 2.4.13.1.

2.5.4.6.6 Groundwater Fluctuations

A detailed discussion of water level fluctuations within and around the site area is presented in paragraph 2.4.13.2.

2.5.4.6.7 Periodic Monitoring of Local Wells and Piezometers

A detailed discussion of the groundwater monitoring program is presented in paragraph 2.4.13.4.

2.5.4.6.8 Direction of Groundwater Flow, Gradients, and Velocities

Direction of groundwater flow, including contour maps which indicate gradients and velocities, is discussed in paragraph 2.4.13.1.

2.5.4.7 Response of Soil and Rock to Dynamic Loading

PSAR studies for Units 1, 2, and 3 included an assessment of soil response during dynamic loading. This assessment involved the determination of low-strain amplitude, in situ shear moduli at each unit, and the evaluation of the manner in which shear moduli and material damping (expressed as a percent of critical damping) vary with the level of shearing strain. The results of these assessments were used together with earthquake information in the computer program SHAKE to perform dynamic response studies at each unit. Details of these assessments and studies are briefly summarized in the following sections. Soil-structure interaction analyses and the response of buried pipelines and earthworks during earthquake loading are described in paragraph 3.7.2.4.

2.5.4.7.1 In Situ Shear Modulus Profiles

In situ values of low-strain amplitude (less than 0.001%) shear modulus (G_{max}) were established at each unit by determining shear wave velocities from seismic crosshole tests and then using elastic theory to compute shear moduli. Figure 2.5-76 shows the resulting in situ modulus profiles for each unit. The shaded zone superimposed on the profiles

defines the limits on moduli used in dynamic response studies, as will be discussed subsequently.

All modulus values are plotted together in figure 2.5-77 to show the general similarity in modulus values at the site. The low-amplitude, in situ shear modulus profiles are similar in trend as well as in magnitude.

The low-amplitude shear moduli derived during the laboratory testing program are also shown in this figure for comparative purposes. The difference between average laboratory and field values of shear modulus will be discussed in the next paragraph.

2.5.4.7.2 Laboratory Dynamic and Cyclic Tests

Twenty-three sets of resonant column and strain-controlled cyclic triaxial tests were performed on undisturbed samples of sands, silts, and clays from the Units 1, 2, and 3 power block areas. In addition, 26 sets of tests were performed on materials from Units 1, 2, and 3 compacted to 95% relative compaction (ASTM D1557). These laboratory tests were performed to establish the relationships between shear modulus ratio (G/G_{max}) and shearing strain level and between material damping ratio and shearing strain. The manner in which the dynamic and cyclic tests were conducted, as well as individual test results, are presented in Appendix 2T of the PVNGS 1, 2, and 3 PSAR.

Data from individual tests were combined to establish composite modulus-strain and damping-strain relationships for the following six conditions:

- Undisturbed silts, very fine sands and coarser sands originating in the upper 50 feet
- Undisturbed clays originating in the 50- to 100-foot depth interval
- Undisturbed clays originating in the 100- to 150-foot depth interval
- Undisturbed clays originating at depths greater than 150 feet
- Remolded silts and sands originating in the upper 50-feet of soil profile

Composite curves for undisturbed and remolded samples are shown in figures 2.5-78 and 2.5-79, respectively.

Low amplitude values of shear modulus (G_{max}) were also obtained during the laboratory program. These moduli are compared to shear moduli obtained from seismic crosshole tests in figure 2.5-77. This comparison indicates that the laboratory moduli are typically less than the field moduli by a factor of 1.5 to 2.5. The difference in moduli is attributed to unavoidable disturbance to samples which occurs during any sampling operation. Because of this difference, composite modulus ratio plots were generally used to define the shape of the modulus-strain relationship for dynamic response studies; the magnitude

of the modulus curve was keyed to the low-amplitude shear moduli determined from the seismic crosshole tests.

2.5.4.7.3 One-Dimensional Response Studies

One-dimensional ground response studies were performed to assess the manner in which shearing stresses developed at depth for different types and levels of earthquake shaking. The shearing stress determinations served as a basis for determining the liquefaction potential of sands, silty sands, and sandy silts, as discussed in paragraph 2.5.4.8. The results of the dynamic response studies are not used as a basis for establishing the horizontal and vertical design response spectra for the SSE as discussed in paragraphs 2.5.2.6.1 and 2.5.2.6.6.

The computer program SHAKE[165] was used to perform the ground response studies. The program computes response of a system of homogeneous visco-elastic layers of infinite horizontal extent subjected to vertically traveling shear waves. The program is based on the continuous solution to the wave equation adapted for use with transient motions through the Fast Fourier Transform algorithm. The nonlinearity of the shear modulus and damping is accounted for by the use of equivalent linear soil properties using an iterative procedure to obtain values for modulus and damping compatible with the effective strains in each layer. The following assumptions are implied in the analysis:

A. The soil system extends infinitely in the horizontal direction.

B. Each layer in the system is completely defined by its value of shear modulus, critical damping ratio, density, and thickness. These values are independent of frequency.

C. The responses in the system are caused by the upward propagation of shear waves from the underlying rock formation.

D. The shear waves are given as acceleration values at equally spaced time intervals. Cyclic repetition of the acceleration time-history is implied in the solution.

E. The strain dependence of modulus and damping is accounted for by an equivalent linear procedure based on an average effective strain level computed for each layer.

These SHAKE analyses were conducted with five accelerograms. Four of the accelerograms are actual recordings of the 1952 Kern County earthquake scaled to be representative of a magnitude 8.0 event at a distance of 72 miles. These records include the Santa Barbara (S48E) record with a peak acceleration of 0.128g, the Hollywood PE Lot (S00W) record with a peak acceleration of 0.10g, the Hollywood Basement (S00W) record with a peak acceleration of 0.093g, and the Pasadena (S50W) record with a peak acceleration of 0.090g. The fifth accelerogram was the Bechtel record scaled to 0.20g. The Bechtel accelerogram is an artificial record with a spectra which conforms closely to the shape of the standard NRC

spectra. The basis for selecting these records is given in paragraph 2.5.2.6.

The ground response studies included an assessment of the influence of soil-parameter variation. This assessment was accomplished by varying the low-amplitude shear modulus to which the shear modulus ratios (presented in paragraph 2.5.4.7.2) were keyed. The modulus variations included:

- Average low-amplitude in situ moduli
- Average in situ moduli plus and minus 50%
- Average laboratory moduli.

Variations were introduced to assess the possible effects on ground response caused by differences in values of shear modulus. Figure 2.5-76 illustrates the range in modulus values used in dynamic response studies as compared to low-amplitude moduli determined during seismic crosshole tests. Additional details about these studies are discussed in Appendix 2T of the PVNGS 1, 2, and 3 PSAR, and appendix 2A, response to Question 2A.8.

Typical values of maximum shearing stress determined during the ground response studies are presented in figure 2.5-80. These results show that the level of maximum shearing stress varied with earthquake shaking level as well as in situ values of modulus. Shearing stresses for average in situ soil moduli and the Bechtel earthquake record were subsequently used as a basis for evaluating liquefaction potential.

2.5.4.8 Liquefaction Potential

The potential for liquefaction of saturated, cohesionless soils underlying the three units was evaluated by comparing liquefaction strengths obtained from field and laboratory investigations to shearing stresses predicted on the basis of simplified and one-dimensional wave propagation methods. Two different methods were used to predict liquefaction strengths: one based on blowcounts obtained during a field standard penetration testing program, the other based on the results of laboratory testing. The following subsections present a review of soil conditions at the units relevant to a liquefaction discussion, the methodology used during the investigations, and the results of the study. Additional details about liquefaction studies are presented in Appendix 2T of the PVNGS 1, 2, and 3 PSAR.

2.5.4.8.1 Site Conditions

The PVNGS site essentially consists of a relatively thin veneer of dense cohesionless soils, 30 to 60 feet in thickness, underlain by about 250 feet of stiff to hard clays. Cohesionless soils include layers and lenses of sands with some gravels, silty sands, clayey sands, and silts. A third general material type, granular backfill, will be placed beneath and adjacent to some Category I structures. Backfill materials are primarily on site sands with up to 30% fines, compacted to 95% of maximum dry density (determined in accordance with ASTM D1557). Maximum thickness of backfill varies from zero in the free-field to nearly 65 feet around the auxiliary building.

A perched water level presently (1979) occurs about 40 to 70 feet below the ground surface. This water level is attributed to irrigation water perched on top of deeper clay layers. The regional water level is approximately 200 feet below the ground surface. As irrigation has been discontinued in proximity to the site, the perched water level has been receding in recent years (paragraph 2.4.13.2.2).

Although the water level is presently receding or is too deep to consider from a liquefaction standpoint (i.e., within the clay layer), a potential exists for increases in water level due to seepage from evaporation ponds and the water storage reservoir (paragraph 2.4.13.2.3). Analyses of water seepage from these sources indicate that the maximum predicted height of rise in water will be well below design water level, which is at a depth of 30 feet below ground surface. For conservatism, design levels have been specified as a basis for liquefaction analyses presented herein.

Considering the presence of cohesionless soils and the potential occurrence of water within 30 feet of the ground surface, natural and backfill soils located between the depths of 30 and 70 feet are identified as being potentially susceptible to liquefaction during earthquake-induced ground shaking. Soils below the depth of 70 feet are generally stiff to hard over-consolidated clays; and hence, are not of interest in terms of liquefaction. It is worthwhile noting at this point that the amount of potentially liquefiable soils (i.e., cohesionless soils below the design water elevation) beneath Category I structures is generally limited. The

containment and auxiliary buildings are supported directly on hard nonliquefiable soils. Most of the other Category I structures (main steam support structure, control building, fuel building, and refueling water tank) are primarily supported on granular backfill, the maximum thickness of which is 40 feet or less. Only the spray ponds, diesel generator buildings, and condensate tanks are primarily supported on natural sands. The maximum thickness of these potentially liquefiable materials is typically less than 30 feet.

2.5.4.8.2 Blowcount Analyses

The blowcount analysis procedure suggested by Seed, et al[166] was used to assess liquefaction potential of in situ sands. This procedure involved adjusting blowcounts from the standard penetration test to an equivalent overburden pressure of 2 kips per square foot. The adjusted blowcounts were then used to determine the liquefaction strength of the material on the basis of a limiting plot between liquefaction strength and adjusted blowcount, as developed by Seed, et al[166]. Liquefaction strengths were then compared to shearing stresses induced by earthquake ground shaking to determine liquefaction potential.

To be consistent with the methodology used to develop the relationship between liquefaction strength and blowcounts, shearing stresses were computed on the basis of the following equation developed by Seed and Idriss[167]:

$$\tau_{avg} = 0.65\ \gamma_t H \frac{a_{max}}{g}\ r_d$$

where γ_t is the total unit weight of the soil, H is the depth below the ground surface, a_{max} is the peak acceleration at the ground surface, g is the acceleration due to gravity, and r_d is a soil deformability factor. Figure 2.5-81 presents curves used in this methodology to compute normalized blowcount values, liquefaction strengths, and soil deformability.

Blowcount analyses were performed for each unit using average lower bound blowcount values from the sites, existing and design water level elevations, and a SSE maximum ground surface acceleration of 0.2g. The effects of possible low blowcount zones were evaluated by analyzing liquefaction potential for a lower bound blowcount profile, as determined from mean-minus-one-standard-deviation blowcount values.

The results of the blowcount analyses in terms of the factors of safety against liquefaction for design water table elevations (30 feet below the ground surface) are presented in Table 2.5-14. For lower bound blowcount analyses, the minimum factor of safety was 2.0 and occurred at Unit 1. It is worthwhile noting that the water level at the units is predicted to be lower than the design elevation during the design life. As shown in figure 2.5-82, the factor of safety

increases as the design water table elevation drops; hence the actual factors of safety will always be greater than those used for design. It is concluded from these investigations that the factor of safety against liquefaction will be adequate for the SSE.

2.5.4.8.3 Dynamic Response Studies

The dynamic response study involved performing cyclic liquefaction strength tests on undisturbed samples of sands and silts and compacted samples of granular backfill. Liquefaction strengths determined from these laboratory tests were compared to shearing stresses predicted on the basis of one-dimensional computer simulation of site response during earthquake loading to establish liquefaction potential. The one-dimensional computer simulation is described in paragraph 2.5.4.7.4.

Forty-five controlled-stress, cyclic triaxial tests were performed on undisturbed samples obtained from the three units to define the strength of in situ soils; 12 tests were performed on granular backfill compacted to 95% of maximum dry density. Undisturbed samples were generally obtained by Pitcher-tube sampling methods; however, undisturbed block samples were also obtained. Details about the laboratory programs, including individual test results, are presented in Appendix 2T of the PVNGS 1, 2, and 3 PSAR.

Composite plots of liquefaction strengths for granular backfill and for undisturbed sands are shown in figure 2.5-83. Liquefaction strengths in these plots were defined on the basis of either initial liquefaction or 5% peak

Table 2.5-14

SUMMARY OF FACTORS OF SAFETY AGAINST LIQUEFACTION

BY BLOWCOUNT AND LABORATORY ANALYSES

Unit	Design Groundwater Elevation (ft)	Blowcount Analyses			Laboratory Analyses		
		Depth of Minimum FS (ft)	Minimum Factor of Safety		Depth of Minimum FS (ft)	Minimum Factor of Safety	
			Average[a]	Bound[b]		C_r[c] = 0.57	C_r = 0.70
1	927	47	2.9	2.0	35 to 43	1.2	NA
2	924	50	3.4	2.1	40 to 50	1.2	NA[d]
3	921	32	3.6	2.6	42 to 45	1.1	NA
Back-fill-Unit 2	924	NA	NA	NA	40 to 50	1.6	NA
Back-fill-Unit 3	921	NA	NA	NA	35 to 45	1.6	NA

a. Average blowcount values

b. Lower bound blowcount values

c. C_r = laboratory to field correction factor

d. NA = not applicable

to peak strain, whichever came first, and were adjusted to field conditions before assessing liquefaction potential.

This adjustment involved multiplying the laboratory strength curve by 0.57. The resulting field strength curves are shown in figure 2.5-84.

Liquefaction potential was determined by comparing the earthquake induced shearing stress to the adjusted liquefaction strength of the soil. The maximum levels of shearing stress occurred under the SSE shaking level (0.2g) using the Bechtel earthquake. Liquefaction strengths were determined at 15 to 20 cycles of loading. For these studies, a cycle counting procedure suggested by Lee and Chan[168] was used to determine the number of equivalent cycles of loading. Factors of safety against liquefaction, as determined during dynamic response studies, are tabulated in table 2.5-14 for design water table elevations. From table 2.5-14 it can be seen that minimum factors of safety are greater than 1.1 even for conservative values of liquefaction strength and design earthquake. Granular backfill materials exhibited nearly 50% more resistance to liquefaction than natural soils. Figure 2.5-85 shows that the factors of safety by this approach will be even higher when the water table elevation is deeper than the design elevation. It is concluded from this analysis that the potential for liquefaction of cohesionless soils is low.

2.5.4.8.4 Summary of Liquefaction Potential

Liquefaction studies, as discussed in the preceding two paragraphs and as summarized in table 2.5-14, show that:

A. The minimum factors of safety for average blowcount values are equal to or greater than 2.0 at each unit. These factors of safety will represent lower bound values because:

   1. The curve used as a basis for determining liquefaction strengths from blowcount values is a lower bound curve enveloping all recorded data

   2. Analyses were based on design water elevations which are higher than predicted water elevations

B. The minimum factors of safety from dynamic response (laboratory) methods are equal to or greater than 1.1 for undisturbed soils and 1.6 for compacted soils. Values for undisturbed soils will be very conservative because:

   1. In situ strengths will be higher than laboratory strengths because of the unavoidable disturbance which occurs during undisturbed sampling of dense granular soils(169)(170)

   2. Design water elevations exceed those predicted

The above factors of safety are also based on a very conservative SSE (0.2g at the ground surface). More credible levels of earthquake acceleration will result in appreciably lower shearing stresses which will increase the factors of

safety against liquefaction. In summary, all evidence indicates that the cohesionless soils at PVNGS will not undergo liquefaction during the design life of the plant. See also Appendix 2A, Question 2A.8.

2.5.4.9 Earthquake Design Basis

A detailed discussion of the earthquake design basis is presented in paragraphs 2.5.2.6 and 2.5.2.7.

2.5.4.10 Static Stability

Seismic Category I structures were analyzed for stability under anticipated loading conditions. The analyses presented in the following paragraphs include evaluations of bearing capacity, foundation heave and settlement, and lateral earth pressure. In view of the similar subsurface conditions displayed in the geologic profiles (figures 2.5-56 through 2.5-58) for the three units, stability analyses were based on conservative soil parameters representative of all three units. The plant layout and foundation loading information are presented in figure 2.5-86. All Seismic Category I structures utilize mat-type foundations.

2.5.4.10.1 Bearing Capacity

Seismic Category I structure foundations were analyzed for stability against general shear failure under anticipated static and dynamic loading conditions. The effects of confinement due to adjacent structure(s) were conservatively neglected in the analysis.

2.5.4.10.1.1 Soil Model. A two-layer soil model was used for the bearing capacity analyses. The first layer, extending from the ground surface to a depth of 50 feet, consists of native or compacted backfill sands. The second layer, underlying the sands, consists of native clays. Two Category I structures, the containment and auxiliary buildings, are founded directly on the clays. The remaining structures are founded on the sands at depths ranging from 2 to 30 feet below the ground surface. The groundwater level was conservatively assumed to be at a depth of 30 feet below the ground surface which is the design level. Actual groundwater levels are expected to remain well below the design level. The soil parameters used for the analyses are as follows:

	Sand Layer	Clay Layer
Friction angle, degrees	36	0
Cohesion, kips per square foot	0	5.0 (static) 5.5 (dynamic)
Total Unit Weight, pounds per cubic foot	120	N/A
Buoyant Unit Weight, pounds per cubic foot	70	60

The shear strength parameters listed above were conservatively derived from laboratory test results summarized in figure 2.5-64. The undrained shear strength of the clays was increased by 10% for the dynamic analyses to account for the effects of the rapid strain rates induced during dynamic loading. Research data[171-174] indicate that for typical

earthquake loading rates on clays of the type found at PVNGS, at equivalent water contents and under similar stresses and stress histories, the increase in strength over that measured in the standard laboratory static triaxial test will range from about 50 to 150%. Considering that this strength increase does not account for the mass action (inertial effects) of soil under rapid loading, it is seen that the 10% strength increase used for the analyses is very conservative.

2.5.4.10.1.2 Method of Analysis. State-of-the-art methods outlined by Vesic' in the Foundation Engineering Handbook[175] were used to evaluate bearing capacities under static and dynamic loading conditions. Static loads included the dead weight of the structures and ordinary live loads. Dynamic loads additionally included the effects of the SSE as outlined in paragraph 3.7.2.1. The analyses were based on the Buisman-Terzaghi equation modified for eccentric and inclined loading[175]. In its general form the equation is:

$$q_o = \frac{Q_o}{B'L'} = CN_c\zeta_c\zeta_{ci} + qN_q\zeta_q\zeta_{qi} + 1/2_\gamma BN_\gamma\zeta_\gamma\zeta_\gamma i$$

where:

q_o = ultimate bearing capacity

Q_o = ultimate vertical load

B', L' = effective foundation dimensions under eccentric loading; for zero eccentricity, the actual footing dimensions B and L are used (B is the smaller of the two)

c = shear strength intercept (cohesion)

q = effective overburden stress

γ = effective density of soil below foundation level

N_c, N_q, N_γ = bearing capacity factor

$\zeta_c, \zeta_q, \zeta_\gamma$ = foundation shape factors

$\zeta_{ci}, \zeta_{qi}, \zeta_{\gamma}i$ = load inclination factors

For structures founded in the upper sand layer, the bearing capacity was calculated for both a two-layer system (sand over clay) and for a single-layer system (sand only). The lower of the two values was selected as the bearing capacity of the structure in question. The two-layer analysis was based on the following relationship for a dense sand overlying clay:

$$q_o = q''_o \exp\left\{ 0.67 \left[1 + (B'/L') \right] (H/B') \right\}$$

where:

q_o = ultimate bearing capacity

B', L' = effective footing dimensions under eccentric loading. For zero eccentricity, the actual footing dimensions B and L are used (B is the smaller of the two)

H = distance from base of footing to top of underlying clay layer

q''_o = bearing capacity of a fictitious footing of the same size, shape, and lateral loading as

the actual footing, but resting on the clay; q''_o is computed by the modified Buisman-Terzagh: equation presented previously

The effects of the water level were also incorporated in the analysis by defining the unit weight, γ, used in the modified Buisman-Terzaghi equation as follows:

$$\gamma = \gamma' + (z_w / B')(\gamma_m - \gamma')$$

where:

γ' = buoyant unit weight of soil below the water level

γ_m = total (moist) unit weight of soil above the water level

B' = effective width of foundation, and

z_w = distance between the bottom of foundation and water level ($0 < z_w < B'$)

If the base of the foundation is at or below the water surface, γ is equal to γ'. If the base of the foundation is at least one effective foundation width above the water level, γ can be equated to γ_m.

2.5.4.10.1.3 Results. The results of static and dynamic bearing capacity analyses together with structural data used for the analyses are summarized in tables 2.5-15 and 2.5-16, respectively. The computed factors of safety against a bearing capacity failure range between 4.5 and 32.1 for static loading conditions, and between 2.0 and 13.5 for short-

duration dynamic overload conditions. These factors of safety are considered adequate for the types of structures analyzed and meet the design criteria outlined in paragraph 2.5.4.11.

2.5.4.10.2 Heave/Settlement Analysis

A detailed analysis was performed to calculate heave and settlement at various points beneath the power block structures. The analysis incorporated the effects of the magnitude and complex timing of the application and removal of loads imposed by excavated soil, backfill, and a large number of structures. Both time-rate of settlement effects caused by consolidation of saturated fine-grained soils and immediate elastic settlements were evaluated. Details concerning the assumptions and refinements applied to the revised analysis are presented in Appendix 2AA of the PVNGS 1, 2, and 3 PSAR.

Preliminary analyses for Units 1, 2, and 3 indicated that the soil parameters obtained from the laboratory testing on samples from Unit 2 yielded the largest computed settlements. Settlements were calculated using Unit 2 soil parameters and are presented as being conservative estimates for all three units.

Table 2.5-15

STATIC BEARING CAPACITY OF CATEGORY I STRUCTURES

Structure	Average Static Design Load $q_s (k/ft^2)$	Ultimate Bearing Capacity $q_o (k/ft^2)$	Factor of Safety (q_o/q_s)
Containment building	7.9	35.7	4.5
Auxiliary building (deep section)	6.2	34.9	5.6
Main steam support structure	7.1	64.8	9.1
Control building	3.3	45.3	13.7
Fuel building	5.3	54.9	10.4
Diesel generator building	3.1	79.5	25.6
Refueling water tank	4.4	90.4	20.5
Condensate storage tank	3.5	112.4	32.1

Table 2.5-16

DYNAMIC BEARING CAPACITY OF CATEGORY I STRUCTURES[a]

Structure	Equivalent Uniform Vertical Stress q_d (k/ft^2)	Ultimate Bearing Capacity q_o (k/ft^2)	Factor of Safety (q_o/q_d)
Containment building	16.1	32.2	2.0
Auxiliary building (deep section)	10.3	25.8	2.5
Main steam support structure	25.3	60.6	2.4
Control building	9.8	39.8	4.1
Fuel building	19.1	50.3	2.6
Diesel generator building	5.6	75.5	13.5
Refueling water tank	13.2	58.7	4.4
Condensate storage tank[b]	13.2	30.2	2.3

a. Based upon maximum dynamic loads derived from analyses described in section 3.7.

b. Condensate storage tank loads were conservatively chosen to be equal to the dynamic design load for the refueling water tank. Actual loads will be less.

Results of the heave/settlement analysis are presented in figures 2.5-87, 2.5-88, and 2.5-89. These figures present predicted amounts of heave, total recompression settlements, and post construction settlements, respectively. In summary:

A. Heave estimates range to a maximum of approximately 7 inches near the center of the deepest portion of the excavation, underlying the auxiliary building.

B. Estimates of total recompression settlements range from approximately 0.2 inch at the corners of the essential spray ponds to about 7 inches under the containment and auxiliary buildings.

C. Estimates of post-construction total settlements are less than 1-1/2 inches for any structure, and less than 1/2 inch for most structures. Calculated post-construction differential settlements are less than 0.1 inch.

D. Settlements are expected to occur soon after load application and to be well within tolerable limits for the structures involved.

Heave at the base of the powerblock excavations at Units 1, 2, and 3 has been monitored by extensometer installations and by optical surveying means. Results of the heave monitoring program are presented in paragraph 2.5.4.13. The heave measured by both extensometer installations and optical surveying means is on the order of one-third of the magnitude predicted by the heave/settlement analysis.

The response of the site to load changes was, as anticipated, quite rapid due to the overconsolidated nature of the foundation soils. These observations confirm the conservatism of the heave and settlement estimates and support the conclusion that post-construction settlements should be very small and well within tolerable limits.

2.5.4.10.3 Lateral Earth Pressures

Static active and passive horizontal earth pressures have been determined for both in situ soils and backfill. For the analysis of active and passive pressures, a conservative, simplifying choice of $\varnothing = 36°$, $C = 0$, and $\gamma_t = 126$ pounds per cubic foot has been used. Active earth pressures are developed with relatively small wall movements while theoretical passive pressures require much larger wall movements before development. For this reason, the passive lateral pressures recommended for design have been reduced by one-half from Rankine theoretical values. Passive pressures computed based on Rankine theory are very conservative because friction between the soil and walls, that would increase the passive resistance, is neglected. For compacted backfill, the at-rest lateral earth pressure has been calculated assuming an earth pressure coefficient of $K_o = 0.7$ and average unit weight $\gamma^t = 129$ pounds per cubic foot. A summary of recommended static lateral design earth pressure parameters is presented in table 2.5-17.

Table 2.5-17
SUMMARY OF DESIGN LATERAL EARTH PRESSURE PARAMETERS

Case	K	Equivalent Fluid Pressure[a]	
		Above Water Table	Below Water Table
Active	0.26	33	15
Passive	3.85	240	122
Backfill	0.7	80	46

a. Expressed as pounds per square foot per foot of wall height, for horizontal backfill.

2.5.4.11 Design Criteria

Foundation stability and settlement analyses were performed for each structure in the three units. In addition, the overall liquefaction potential at each unit was analyzed. A description of the settlement and bearing capacity analyses are presented in paragraph 2.5.4.10. The liquefaction analysis is presented in paragraph 2.5.4.8.

The following geotechnical design criteria, based on state-of-the-art engineering practice and structural constraints, were followed:

- Bearing Capacity — Factor of safety = 3 for static loading

  Factor of safety = 2 for dynamic loading

• Total Settlement	Post-construction settlements less than 1-1/2 inches for each structure (survey accuracy ± 1/8 inch)
• Differential Settlement	Post-construction differential settlements less than 1/2 inch at a common point between any two adjacent structures (survey accuracy ± 1/8 inch)

2.5.4.12 Techniques to Improve Subsurface Conditions

Soils and underlying rock as described in paragraph 2.5.4.2 are adequate for supporting Category I structures. Remedial or special foundation treatment will not be necessary except for soils at very shallow depths (less than 4 feet) which have been disturbed by agricultural activity. Where these shallow soils are encountered below Category I structures, they will be excavated and replaced with structural backfill compacted as specified in paragraph 2.5.4.5.2.

2.5.4.13 Subsurface Instrumentation

An extensive instrumentation program is being implemented at PVNGS to monitor foundation response and ground movement during excavation, construction, and throughout the life of the plant.

This data is being collected and analyzed primarily to establish the degree of conservatism that exists in the

settlement analysis, which impacts structural and critical piping connection designs.

To compare actual post-construction settlements with the criteria given above, a program of settlement monitoring has been instituted. The locations of settlement markers are shown in engineering drawings 01, 02, 03-C-OOA-030, and the frequency of readings is shown in table 2.5-19. All markers will be surveyed; however, particular attention will be given to those pairs of settlement markers which would indicate differential settlements between structures in the vicinity of critical connections, and those markers which would indicate deformation or tilt within a critical structure (table 2.5-18).

Table 2.5-18

CRITICAL CONNECTION/STRUCTURE SETTLEMENT MARKERS

Deformation	Critical Connection Location/Structure	Settlement Marker Number
Differential settlement	Between auxiliary and control building	21, 22, 36, 37
Differential settlement	Between containment and MSSS	19, 20
Differential settlement	Between containment and fuel building	24, 28, 29
Settlement	Auxiliary building (south side)	21, 22, 23
Tilt	Containment building	20, 24, 25

If actual post-construction settlement reaches 90% of the design criteria values given above, then the frequency of

monitoring for those markers will be increased from that indicated in table 2.5-19 to an interval of 1 month. If no significant settlement occurs over a 3-month period, then the frequency of monitoring at those markers will be quarterly for a year, and then return to the normal frequency in table 2.5-19.

If settlements could impose unacceptable additional stresses within structures or on critical connections, then a remedial action plan would be formulated. Remedial action would necessarily be a function of the nature and location of the problem.

2.5.4.13.1 Instrumentation

The heave, settlement, and subsidence instrumentation consist of four component systems: multiposition extensometers, mechanical rebound anchors, settlement markers, and subsidence network benchmarks. Table 2.5-19 details the type of response being monitored and the frequency of monitoring schedule for each system.

A detailed description of the installation and monitoring of each system is presented in a report submitted previously to the NRC[176]. A brief description of each system follows:

A. Multiposition extensometers (MPEs) with electronic readout capability are utilized to monitor both heave resulting from excavation and recompression settlements resulting from structural loading. As of March 1979, extensometers were installed in six

locations, three near the containment centers of each of Units 1, 2, and 3, two more at selected points in Unit 1, and an additional backup sensor (MPE-6) near the containment center in Unit 3. All but one of the six existing MPE installations monitor relative ground movement between each of three sensors anchored to bedrock. The exception is MPE-6 which contains only one sensor, installed as a backup for a damaged sensor in the adjacent MPE-5 installation. In each extensometer installation the top sensor is anchored at a depth a few feet below the estimated bottom of excavation, in order to monitor the full amount of heave and recompression settlement. Instrument locations are shown in figure 2.5-90.

B. Mechanical rebound anchors (MRAs) are used to monitor heave by optical survey methods. Each MRA installation consists of a 3-foot long stainless steel pipe, embedded in soil at the bottom of a cased borehole. The top of the pin is typically located 2.5 feet below the bottom of excavation and serves as a reference point for elevation measurements. Calibrated aluminum rods are used to reach the pin from the ground surface. As of March 1979, mechanical rebound anchors had been installed at six locations in Units 1, 2, and 3, as shown in figure 2.5-90.

C. Settlement markers are pins installed in structural members of critical structures to monitor settlements by optical surveying methods. Fifty-eight markers are

installed in each powerblock in Units 1 and 2; 56 markers are installed in the powerblock in Unit 3 at locations/elevations shown in engineering drawings 01, 02, 03-C-OOA-030.

D. Subsidence monitoring benchmarks have been established to monitor regional subsidence at the site relative to two benchmarks on rock outcrops. The locations of the benchmarks used are shown in figure 2.5-91.

2.5.4.13.2 Results

As of March 1979, power block excavations for Units 1, 2, and 3 had been completed. Structural construction and backfill placement was underway in Units 1 and 2. Results of excavation heave monitoring at Units 1, 2, and 3 and subsidence onitoring over the entire site are discussed in the following paragraphs.

2.5.4.13.2.1 Excavation Heave. Results of heave/rebound monitoring in the powerblock excavations for Units 1, 2, and 3 were presented and discussed in detail in Appendix 2AB of the PVNGS 1, 2, and 3 PSAR. Briefly, observed maximum heave ranged from 1.8 inches in Unit 1 to 2.4 inches in Unit 3. The foundation soils responded rapidly to overburden removal with the full amount of heave measured within 2 months after completion of the excavation. On the average, observed heave in various parts of the excavations was on the order of one-third of the values predicted by the heave/settlement analysis (see figure 2.5-92).

Table 2.5-19

SUBSURFACE INSTRUMENTATION DETAILS

Instrumentation System Name	Response Being Monitored: Heave Resulting From Excavation	Response Being Monitored: Recompression Due to Structural and Backfill Loading	Response Being Monitored: Regional Subsidence	Minimum Specified Monitoring Frequency-Time Between Readings[a]
Multiple position extensometers (MPEs)	X	X	X	1) Pre-excavation, excavation, pouring of overlying foundations -1 week 2) The following 18 months -1 week 3) Until end of construction -3 months 4) For a 3-year period following end of construction -6 months 5) After last 6-month reading -5 years
Mechanical rebound anchors (MRAs)	X			1) Pre-excavation, excavation -1 week
Settlement markers		X	X	1) 18 months following first concrete placement for a given structure -1 month 2) Until end of construction of the last major power block structure -3 months 3) For a 3-year period following end of construction -6 months 4) After last 6-month reading -5 years
Subsidence monitoring network			X	1) During construction -1 year 2) After end of construction -5 years

a. Settlement monitoring will be increased to 1-month intervals at markers showing greater than 90% of design post-construction settlement criteria. Refer to the discussion in paragraph 2.5.4.13 for the increase in time interval if no significant settlement occurs over a 3-month period.

The difference between predicted and observed values of heave is attributed to conservative compressibility parameters and groundwater assumptions included in the predictive analyses. Based on the results of the heave monitoring data, it is concluded that:

A. The conservatism of the heave/settlement analysis is verified.

B. Recompression settlements can be expected to take place rapidly after load application and be lower in magnitude than the predicted values.

C. Post-construction settlements can be expected to be small and well within tolerable limits.

2.5.4.13.2.2 Subsidence. Movement of the survey benchmarks within the subsidence monitoring network, relative to benchmarks established on bedrock, have been measured to within an accuracy of approximately ±0.25 inch. Results of the subsidence network monitoring program are presented in figure 2.5-93. The benchmark monitoring data exhibits random scatter within the accuracy of the survey and there has been no measurable subsidence over the period monitored.

2.5.4.14 Construction Notes

No construction problems that would adversely affect the safety of the plant facilities have been encountered.

GEOLOGY, SEISMOLOGY, AND GEOTECHNICAL ENGINEERING

2.5.5 STABILITY OF SLOPES

There will be no natural or man-made slopes at the site, the failure of which could adversely affect the safe operation of the plant. Natural slopes are sufficiently distant (at least 3/4 mile) from the nearest Category I structures; therefore, their stability need not be considered. The natural ground surface in the vicinity of the plant is essentially flat with ground surface gradients on the order of 1% or less.

2.5.6 EMBANKMENTS AND DAMS

There will be no Seismic Category I embankments or dams at the site.

RESPONSES TO NRC REQUESTS FOR INFORMATION

APPENDIX 2A

CONTENTS

TABLES

FIGURES

APPENDIX 2A

QUESTION 2A.1 (NRC comment on section 2.5.2.7) (6/18/80) (2.5.2.7)

No probability for operating basis earthquake

RESPONSE: The response is given in amended paragraph 2.5.2.7.

QUESTION 2A.2 (NRC Question 451.2)

Appendix E to 10CFR Part 50 outlines requirements for Emergency Planning and Preparedness. NUREG-0737 and NUREG-0654 provide further guidance on the requirements which include an upgraded meteorological measurements program. Provide a description of your upgraded program to meet these requirements. Include details about any new instrumentation to be installed, the atmospheric transport and diffusion model used in the dose assessment methodology, and data availability to emergency response organizations.

RESPONSE: Refer to amended section 2.3 and section 18.III.

QUESTION 2A.3 (NRC Question 230.1)

Include table similar to table 2.5-2, listing earthquakes in Seismic Zones C and D. Identify and discuss all significant earthquake activity in Seismic Zones B, C, and D, which has occurred since Supplement No. 2 to the Safety Evaluation Reports for Units 1, 2, and 3, published in 1976.

RESPONSE: Tables 2.5-7 and 2.5-8 are provided which list all earthquakes in Seismic Zones C and D. The tables are compiled from the most recent NOAA files available for the period ending 1980 and from local sources. An updated

(through mid-1981) epicenter map and list has been finalized by S. Dubois as part of an NRC funded program. Tables and maps have been updated and are provided in amended section 2.5.

See amended paragraph 2.5.2.3.3.

QUESTION 2A.4 (NRC Question 230.2)

Discuss the following recent studies and their significance to the Palo Verde site:

a. Brumbaugh, D., 1980, Analysis of the Williams Arizona Earthquake of November 4, 1971, Bull. Seism. Soc. Amer., v. 70, 885 - 891.

o. Holzer, T., 1981, Ups and Downs, A Reply to "Is There a Casa Grande Bulge and Will It Cause Earthquakes in Arizona?", Fieldnotes, Arizona Bureau of Geology and Mineral Technology, v. 11, no. 1.

RESPONSE:

a. Brumbaugh, D., 1980:

The Williams earthquake was a 3.7 magnitude event occurring along the edge of the Colorado Plateau about 10 miles SW of Williams, Arizona. The earthquake described in this study is significant mainly because the collection of station data were adequate for a focal mechanism solution, an unusual situation for Arizona.

Brumbaugh's analysis primarily consisted of calculating a new location and focal mechanism solution. Locations for the shock are: ISC, 35.13°N, 112.22°W; NEIS, 35.2°N, 112.2°N, NEIS revised, 25.16°N, 112.25°W, depth restrained to 5 kilometers, M_l = 3.7 from ERL. The new location does not differ significantly (less than 0.05 degrees in any direction) from that shown on figure 2.5-25 of the FSAR. The focal mechanism, based on 16 first-motion readings, is consistent with reverse faulting along a NW trending fault. There are no faults in the vicinity of the epicenter with which the earthquake could unambiguously be associated.

Neither the Williams earthquake nor Brumbaugh's analysis has any direct bearing on the PVNGS. The earthquake was within the belt of small-magnitude earthquakes trending NW-SE across the state and designated as Seismic Zone C

in the FSAR (figure 2.5-25). The orientation of the focal mechanism solution is compatible with the preferred NW-SE orientation of major faults in the region, but the reverse faulting mechanism may be anomalous. Geologic data (nature and orientation of faults and volcanic fields) suggest that this region is under tensional tectonic regime but the axis of extension is ambiguous. Extension appears to be oblique to the major faults with E-W to WNW-ESE orientations being most favorable (Zoback and Zoback, 1980; Schell and Wilson, 1981). Reverse faulting along minor fractures is not completely incompatible with this type of oblique extension. However, the focal-mechanism solution is based on too little data to justify revision of existing tectonic hypotheses and therefore results of such a revision have no significance with respect to PVNGS.

b. Dubois, S., 1981, Historical Seismicity in Arizona Final Report; Arizona Bureau of Geology and Mineral Technology, 845 N. Park Avenue, Tucson, Arizona 85719; 199 pp. Partially funded by USGS Contract No. 14-18-0001-18396 and NRC Contract No. 04-79-212.[a]

This report represents a comprehensive assessment of historical seismicity in Arizona. A comparison of information in the Dubois (1981) report with the PSAR indicates the latest work both confirms and refines

a. Final report of Dubois 1980 study referenced in NRC Question.

the data presented in the FSAR relating to Arizona seismicity. The major items affected are as follows:

- The 1887 Sonora Earthquake has been assigned a magnitude of 7.25 (moment magnitude) whereas a conservative estimate of magnitude 8.0 was assigned to the event in the FSAR.

- The seismic zones shown on Dubois (1981), based solely on historical seismicity, are clearly less conservative with respect to SGE analysis than the Seismic Zonation model presented in FSAR figure 2.5-25. Dubois (1981) shows separate zones of seismicity in the northwest and southeast corners of the state. The FSAR shows Zone C as continuous across the state from northwest to southeast, and the zone is, therefore, clearly more conservative for the risk evaluation. From a scientific viewpoint, a new analysis with the benefit of the upgraded data base might lead to a modification of the zone model presented in the FSAR. However, the FSAR results are conservative with respect to any proposed changes in the seismic zonation.

- If the seismic zones depicted by Dubois (1981) were used to develop the SSE, the SSE (an earthquake similar to the 1887 Sonora earthquake) would be located farther away from PVNGS than the 72 miles now used in the FSAR. Seismic analysis using a greater epicentral distance and a lesser magnitude of 7.25 (Dubois, 1981), would predict significantly

less SSE ground motion than the 0.2g used for seismic design at PVNGS.

- Earthquake epicenters have been redefined and many unverified events have been eliminated. Other seismologic data, such as isoseismal maps, have been added or updated as a result of the study by Dubois.

In summary, this recent assessment of historical seismicity in Arizona strongly suggests that the approach used to define the regional seismicity and to develop the seismic design criteria for PVNGS was, in fact, conservative.

c. Racine, D., et al, 1979:

The microseismicity study by Racine and others identify a number of earthquake epicenters located in the Transition Zone and Colorado. Of particular importance are three clusters of low-magnitude events: one, a cluster of 72 earthquakes located near the Arizona-New Mexico border at latitude 31° north; another cluster on the Arizona-New Mexico border at latitude 36° north include 14 events; and the third, a small cluster of nine earthquakes located about 50 miles west of the Prescott earthquake epicentral area or about 34.6° north and 113.3° west. Racine, et al, feel that the characteristics of the shock indicated them to be earthquakes.

This conclusion was evaluated further because their presence would be significant if the events were earthquakes. An analysis of the clusters was made by

constructing histograms of origin time for each event occurring in the clusters. The results indicated that all events occurred during normal working hours, local time. Also, all magnitudes fall in a very narrow range of 2.2 to 2.9 and do not have a normal logarithmic distribution. Considering these points, and the fact that the clusters occurred in the vicinity of a major mining activity, we conclude the clusters are directly associated with mine blasting and are, therefore, not significant with respect to PVNGS.

d. Dubois, S. and Smith, A., 1980:

The main emphasis of this study is the compilation and critical use of intensity reports for the 1887 Sonora earthquake. There is an extensive table quoting the various reports. Isoseismal maps are drawn and important correlations made between high intensities and valley fill material. The isoseismals are greatly extended to the south to account for reports of Mexico City. However, the isoseismals out to about intensity VIII are reasonably symmetric (although elongated). Perhaps Mexico City, with its special soil column, should have been considered as an anomalous intensity. Their intensity maps show a value of about IV to V at the Palo Verde site.

The 1887 earthquake is assigned a magnitude of 7.25 on the basis of seismic moment $M. = 7.2 \times 10^{26}$

(L = 50 kilometers, W = 16 kilometers, s = $\bar{3}$ m) and the relation $M^1 = 2/3 \log M_o - 10.7$. Because of the

presence of several Quaternary faults in the seismically active zones of Arizona, western New Mexico and the 1887 epicentral area, a "magnitude 7+ should be considered as the likely maximum magnitude for this region." In a conservative manner, the FSAR analysis has assumed an earthquake as large as magnitude 8+ occurring at the closest approach of the active zone (Zone C) to the site. The studies of Dubois and Smith suggest that the magnitude for the Sonora earthquake should be downgraded from the value of 8+ used in the FSAR.

e. Dubois, S. and Sbar, M., 1981:

This paper also reports the magnitude and intensity map results of Dubois and Smith (1980, Special Report No. 3). In addition, intensity data are plotted as a function of distance and compared with some attenuation models. The data (Figure 4) for distances on the order of 70 miles (nearest approach for the SSE) show intensities ranging from VII to X. However, they have used epicentral distances rather than distance to the fault rupture which would be a better choice here. At 70 miles perpendicular to the fault trace (Figure 3), the intensity is VIII. The attenuation data are widely scattered, but seems to favor a western U.S. model (Howell and Schultz, 1975) better than an eastern U.S. model (Bollinger, 1977) for distances beyond about 100 miles. For distances up to about 100 miles, the models are comparable.

They present a preliminary map of historical epicenters (Figure 7) that shows several small earthquakes, intensity II to IV, that are not shown in the FSAR. They did much more extensive search using original sources, and the FSAR only compiled published data. They show the 1852 Fort Yuma earthquake incorrectly at Chimney Peak. They also have two intensity VII events east of Yuma and within Zone D (M - 5 to 5.9) that the FSAR does not show. According to Dubois (personal communication, 1981) the epicenter locations shown in Figure 7 at Chimney Peak and east of Yuma are questionable because of the lack of reliable location data. The final epicenter map in preparation will reflect location changes.

f. Pierce, H., 1979:

Article describes subsidence problems of the Picacho Basin, Arizona. The author suggests that other areas surrounding Phoenix may experience similar problems.

There is no evidence of subsidence in the Palo Verde site area such as basin downwarps, fissures, or cracks (paragraph 2.5.1.2.8, FSAR). Comparison of geologic conditions at the site to geologic conditions in the areas of known subsidence indicate that sediment consolidation is not a hazard at the Palo Verde Nuclear Station (paragraph 2.5.1.17, FSAR). For a more detailed discussion, see following item k.

g. Dubois, S., 1980:

The paper discusses reports by various government agencies and individuals in the Tucson, Arizona area of several reportedly small earthquakes. The investigators evaluated these reports and determined the shock wave travel time between recording stations was too slow to be an earth-propagated event. They concluded that sonic booms generated by supersonic aircraft caused the localized ground vibrations. We agree with the authors. It is conceivable that the strong motion instrument at PVNGS could be triggered by sonic boom-induced ground vibration under optimum atmospheric conditions, but this is of no safety-related significance to PVNGS.

h. Dubois, S., and Smith, A., 1980:

This is a brief description of work-compiling damage reports for earthquakes affecting Arizona. Particular attention is given to older, historic earthquakes that are known only from their felt reports. The paper includes a table of representative earthquakes, but the full results of the study are not included. A preliminary map of all the epicenters is given. A final map and/or listing has not yet been released. These results, when available, will modify the historical seismicity map in the FSAR, but there should be no significant changes in the delineation of seismic zones on the maximum earthquakes chosen. See the comments under preceding Item e.

i. Eberhard-Phillips, et al, 1981:

The earthquake studied in this paper has been called the Prescott earthquake in the FSAR text. The author determined the following parameters: Mb = 4.9, Mo = 1 x 1023, location at 34.7°N, 112.5° W and depth 10 to 15 km, northwest trending model planes with the preferred solution having a strike of 120° and dip of 40° southwest. The location is consisted with the shock possibly occurring on the downdip extension of the Big Chino fault but the location of the fault at 10 to 15 km depth is speculative. A brief microearthquake survey indicated about one recordable shock every 3 days in the vicinity of the Prescott earthquake. Considerable discussion is given concerning the tectonic significance of the earthquake closing with the sentence: "In summary, several different models explain the Chino Valley earthquake and other characteristics of the Transition Zone, but we cannot uniquely explain the tectonics of the area due to insufficient and possibly conflicting data". The results of this paper suggest a fault association for the earthquake, but do not affect any of the implications drawn relative to the earthquake hazard at the Palo Verde site.

j. Sinno, et al, 1981:

This paper describes a refraction experiment that results in a crustal model 23 - 25 kilometers thick, having two layers, and overlying an upper mantle with Pn velocity of only 7.67 kilometers per second. The

refraction profile extended from Parker to Globe and passed about 100 kilometers north of the Palo Verde site. The authors propose that the lithosphere has thinned from 40 to 24 kilometers over the past 5 m.y. and will probably continue to thin. The crustal structure model will not impact any of the seismological studies for the FSAR. In one case, the FSAR assumes a crustal structure to estimate the locations of any near-site shocks, but details of the crustal structure model would not alter the conclusions significantly. Crustal thickness is also a consideration in differentiation of the seismotectonic zones, but the model in this paper is not significantly different as to alter the PVNGS zoning analysis.

k. Holzer, T., Davis, S., and Lofgren, B., 1979:

Modern surface faulting, in the Picacho Basin, has created a scarp ranging from 0.2 to 0.6 m high and approximately 15 kilometers long. The scarp has been steadily increasing in height since it began to form in 1961. Faulting is concluded to be related to groundwater withdrawal. Conclusion based on: (1) scarp is restricted to an area underlain by alluvium in which groundwater levels have declined; (2) faulting post-dates the beginning of water-level declines and associated land subsidence; (3) observed vertical displacements associated with faulting are compatible with results from a model of subsurface faulting in which rupture does not extend beneath the zone affected by stresses related to declines of water levels; and

(4) analysis of levelings of bench marks unaffected by man-induced subsidence indicates minor regional crustal movements that do not appear to be compatible with the magnitude of fault offset. There is no evidence of subsidence in the site area such as basin downwarps fissures, or cracks. The closest known occurrence of land subsidence and earth fissuring is in the Luke Air Force Base region, approximately 25 miles east of the site (paragraph 2.5.1.2.8, FSAR). A subsidence monitoring program has been in effect at the Palo Verde site since early 1977 to meet objectives outlined in PSAR Section 2T.7 of Appendix 2T. Analysis of the results of this continuing program indicate that the data exhibits random scatter with no discernable trends relative to vertical movement on the site (figure 2.5-96, FSAR). Analyses of areas that have undergone surface cracking and subsidence indicate that certain conditions must exist to permit consolidation. The areas affected by subsidence are basins filled with great thicknesses (greater than 2000 feet) of permeable, low-density alluvial sediments where large amounts of groundwater are withdrawn resulting in water level declines on the order of 100 feet or more. Comparison of these conditions to conditions in the site region reveal that subsidence is not a hazard at the site (paragraph 2.5.1.1.7, FSAR).

l. Holzer, T., 1979

Based on leveling surveys in 1905, 1948-49, 1967, and 1977, Holzer estimated that the land surface rose

(elastic expansion) 6 centimeters from 1948 and 1967 in areas northwest and northeast of the town of Casa Grande in southcentral Arizona. He suggested that this rise was the result of removal of 43.5 x 10^{12} kilograms of groundwater and subsequent diminishment of surface stresses. Also, he speculated that in the tectonically active areas, unloading may cause earthquakes.

The results of this paper have no significance with respect to conditions at the PVNGS site. Since initiation of construction, groundwater depletion in the site area is negligible with preconstruction water levels having recovered in the immediate site area (figure 2.4-32). Since monitoring was initiated at the site, (FSAR figure 2.5-94) no measurable subsidence or uplift has been recorded.

m. Sumner, J., 1976:

This paper presents a very brief summary of Arizona earthquakes along with general summaries on causes of earthquakes, seismic measurements, safety and damage prevention, earthquake prediction, and earthquake control in four pages of text. A seismic zone map is presented which appears to be a modification of prior maps in the PSAR; no detailed supporting discussion is given. The zones chosen seem less conservative than the FSAR analysis in terms of estimating seismic hazard at the Palo Verde site. This paper was reviewed for amendments to the PSAR, but was not used in the analysis.

n. Raymond, R., Cordy, G., and Tuttle, G., 1980:

It is apparent the Raymond, **et al**, 1980 paper addresses comments to specific ideas presented in Holzer's (1979) paper, "Elastic Expansion of the Lithosphere Caused by Groundwater Depletion". The authors questioned Holzer's conclusions on the basis that:

1) unadjusted data with varying degrees of accuracy are compared,
2) data points are widely spaced and may have been disturbed or destroyed in some cases,
3) elevation changes are computed in relation to a single benchmark, and
4) leveling errors were evaluated by nominal accuracy methods which yield minimal values of one-half of the permissible error.

The new paper, in itself, has no impact on PVNGS.

o. Holzer, T., 1981:

Rebuttal to Raymond, et al, 1980 paper which questioned the hypothesis of crustal expansion caused by the depletion of groundwater in southcentral Arizona (Holzer, 1979). The main emphasis of Raymond, et al, paper was directed toward the analysis of leveling data that supported hypothesis. Holzer suggests that Raymond, et al, questions were based on 1) misunderstandings of how geodetic data are collected and reduced, and 2) misinterpretations of Holzer's (1979) data. The significance of this paper relative to PVNGS is

discussed in responses to studies 1 and n and reflects the divergent conclusion of the authors.

QUESTION 2A.5 (NRC Question 230.3)

Current staff practice is to approach the development of response spectra by performing statistical analyses on the strong motion records for sites with similar foundation conditions. The applicant used this approach to demonstrate that the safe shutdown earthquake (SSE) response spectrum exceeds the ground motion expected from a magnitude 8 event at a distance of 115 kilometers (72 miles).

The SSE can also be compared to the largest random earthquake near the site - a magnitude (m_b) = 5.0 ± 0.5 event at epicentral distances less than 25 kilometers (15 miles) for records on soil sites similar to Palo Verde. A similar collection of records has been made by Lawrence Livermore Laboratory (LLL, 1979 Draft, Seismic Hazard Analysis: Site Specific Response Spectra Results).

a. Either compare the results of the LLL study to the SSE or perform a similar analysis using mb = 5.0 + 0.5 events and recording sites on soil conditions similar to Palo Verde for epicentral distances less than 25 kilometers.

b. Determine whether the strong-motion records recorded in the Prescott Veterans Administration Hospital for the 1976 Prescott earthquake are consistent with this data set.

RESPONSE:

a. The conservatism of the 0.2g SSE design spectrum with respect to the ground motions from a nearby small-

magnitude earthquake was demonstrated by comparing the SSE and LLL[1] spectra. This comparison, presented in figure 2A-1, shows that the SSE spectrum (0.2g NRC Regulatory Guide 1.60) exceeds the 50th percentile LLL soil-site spectrum at all periods by factors between 2 and 10. The SSE spectrum also exceeds the 84th percentile LLL spectrum at periods longer than 0.05 second. The margin is a factor of approximately 1.3 for periods less than 0.4 second; at longer periods the margin gradually increases from factors of 1.4 to 3.7 at 2.0 seconds. Between 0.04 and 0.05 second, the 84th percentile LLL spectrum is slightly greater than the NRC spectrum, but this is of no practical significance. The conservatism of the 0.2g SSE design spectrum with respect to spectra for a nearby $m_b = 5.0 \pm 0.5$ event is greater than that indicated in figure 2A-1 because the LLL spectra are applicable for events in a larger magnitude range ($m_b = 5.3 \pm 0.5$ range).

b. The February 4, 1976, Chino Valley, Arizona, earthquake with a body-wave magnitude (m_b) of 4.9 occurred 17 kilometers north of the Prescott Veterans Administration Hospital in the Transition Zone between the Basin and Range and Colorado Plateau provinces[2]. The hospital rests on unconsolidated alluvial fan and stream channel deposits. The deposits are intercalated, stratified sand and gravel, and well-graded clayey sand and gravel to a depth estimated between 50 and 100 feet.

These deposits, underlain by Precambrian granodiorite, are unsaturated and above the water table (Blume, 1973).

A Kinematrics SMA-1 accelerograph recorded the motions in the basement of the Veterans Administration Hospital. Maximum accelerations reported by King and Ohm[3] are 0.020g and 0.045g for the two horizontal components and 0.026g for the vertical component, which are well below the SSE level of 0.2g.

The Veterans Administration Hospital accelerogram meets the criteria for the selection of representative records stated in Question 2A.5 (paragraph a). The body-wave magnitude (m_b = 4.9) falls within the specified range (m_b = 5.0 ± 0.5). The epicentral distance (17 kilometers) is less than the specified upper limit (25 kilometers). The local geologies at the Prescott Veterans Administration Hospital and the Palo Verde site[a] are both alluvium, and in this general sense both soil deposits are similar.

RESPONSE: Copies of the requested references have been provided to the NRC.

QUESTION 2A.7 (NRC Question 241.1) (2.5.4.5)

Excavation and Backfill

1. Provide the as-built drawings showing the locations and limits of excavation, fills, backfills of the essential spray pond and structures on plot plans (i.e., figures 2.5-74 through 2.5-76, and figures 2D-1, 2D-3, and 2D-5) and on geological sectional profiles (i.e., figures 2.5-56 through 2.5-58 or figures 2.5-74 through 2.5-76). The structures shown on those figures should be identified. Also, indicate where the as-built condition has been changed from what was proposed in the PSAR and quantitatively justify the change.

2. Provide field control test results, such as field density, moisture content, and gradation tests, obtained during construction.

RESPONSE:

1. The response is given in figure 2A-2.

2. Backfill placed in the power block areas has been extensively tested during placement to ensure that the as-built compacted density and gradation are within specifications. In terms of total volume, the power block backfill was essentially complete as of the end of June 1981, with only small areas in Unit 3 remaining to be filled. The volume of power block backfill placed between start of construction through June 1981 is roughly 1,000,000 cubic yards. Over the same time interval, the approximate number of tests performed on power block backfill is summarized below:

- in-place field density (ASTM D1556) - 10,110
- gradation (ASTM D422) - 8,000
- compaction (ASTM D1557) - 720

Specified acceptance criteria for backfill require that all backfill soils, which did not fall within specified gradation or compaction limits, were removed or reworked until retests indicated compliance to specifications. Gradation tests were performed on material sampled at each density test location except at density test locations in native soils below fills, and at density retest locations, where gradation tests had already been performed. Thus, compliance to specified limits on gradation and compacted density has been documented throughout the power block backfill.

Tables 2A-1 and 2A-2 present a summary of Category I field control tests for the period from January 1, 1981, through March 31, 1981. These tests include measurements for density, moisture content, and gradation. The results of these tests are representative of previous tests performed during construction. Field control test results for the entire construction period are available at the PVNGS site for NRC review.

QUESTION 2A.8 (NRC Question 241.2) (2.5.4.7.3)

As stated in the FSAR, one-dimensional ground response studies were performed to assess the liquefaction potential of the in situ soils. Figure 2.5-78 seems to indicate that a soil column

of 100-foot depth was selected for those analyses. Provide quantitative and qualitative justification for the selection of the maximum cut-off depth of 100 feet (i.e., provide parametric analyses with varying depths to demonstrate that the seismic induced shear stresses would not be affected significantly should 150 feet or 200 feet be selected as the cut-off depth). The soil profile with the appropriate shear moduli and damping values used in all analyses should be provided. The bases for selecting the dynamic properties should be given (including reference to figures or tables where they are presented).

RESPONSE: The liquefaction potential of cohesionless soils was evaluated using the one-dimensional ground response program SHAKE(1) in conjunction with liquefaction strengths obtained by laboratory testing methods. Procedures for making this assessment are summarized in Appendix 2T of the PVNGS 4 and 5 PSAR. The purpose of this documentation is to provide a qualitative and quantitative justification for using a 100-foot soil column when performing the SHAKE analyses.

ANALYTICAL CONCEPT: In an overall sense, the potential for liquefaction at the PVNGS site is of interest only in the upper 80 feet. Soils below this depth are cohesive, and hence, are not of direct concern from the standpoint of liquefaction.

The ground response studies for Units 1, 2, and 3 involved use of an analytical procedure which was essentially independent of the depth of the soil model. This procedure, which is called deconvolution, involved the specification of earthquake acceleration at the ground surface and derivation of compatible ground motions and shear stresses at various depths.

The surface motion was determined by scaling earthquake records from sites with similar soil conditions for earthquake magnitude and distance, as discussed in paragraph 2.5.2.6. An artificial time-history (Bechtel record) scaled for a maximum acceleration of 0.2g was also used for this purpose.

The ground response analyses were conducted using the computer program SHAKE(1). This program is based on the assumptions that the soil profile consists of horizontal layers of linear viscoelastic material and that the earthquake motions result from shear waves propagating vertically from the base of the soil column. Each layer is characterized by a thickness, mass density, shear modulus, and damping factor. Under dynamic excitation, the system satisfies the wave equation. Hence, if motion is known in any one layer in the system, the motion can be uniquely computed in any other layer. In other words, the response for a layer within the soil profile model would be the same whether the motion is deconvoluted directly from the ground surface to the layer, or the motion is deconvoluted to

the base of the soil profile model and the resulting motion at the base is used as a source motion for propagating upward to the layer. This uniqueness in the analysis results from the characterization of layers within the soil model by constant values of shear modulus and damping during excitation by an earthquake record.

Once deformation functions are uniquely described in any analysis, strains and accelerations can then be derived from the displacement functions. A Fast Fourier Transfer algorithm is used to solve the equations of motion for transient excitation, such as caused by an earthquake. The nonlinearity of shear modulus and damping is accounted for by the use of equivalent linear soil properties in conjunction with an iterative procedure to obtain values for modulus and damping compatible with the effective strain in each layer.

QUANTITATIVE CONFIRMATION: To demonstrate the validity of using a 100-foot soil profile, a series of parametric SHAKE analyses were conducted. In these studies the model of the site was extended to a depth of 200 feet. Acceleration and shearing stress profiles were then computed to the base of the model.

The comparative study was performed for Unit 3. Results of previous studies for Units 1, 2, and 3 indicate that this unit is the most crucial of the three. The study was performed using the Hollywood Basement S0°W, the Santa Barbara S48°E, and the synthetic Bechtel earthquake records. These records defined minimum, average, and maximum ground response during previous studies.

26	20	1	128	7.11
27	20	2	129	7.45
28	Base	-	129	7.70

a. Soil types:

1 - clays and silty clays
2 - sands and silty sands

The site model used in the study is presented in table 2A-3. The variation of modulus and damping ratio with shear strain was based on the normalized relationship presented in figures 2A-7 and 2A-8.

The results of the comparative studies are summarized in table 2A-4. As might be expected, these results verify that the depth of the soil model used with SHAKE[1] has no effect on the computed stresses. Any major variation in computed stresses are due to the iterative process involved in the analyses. In the cases analyzed herein, these differences are insignificant (less than ±0.5%).

QUESTION 2A.9 (NRC Question 241.3) (2.5.4)

As shown on figures 2.5-74 through 2.5-76, "As-Built Temporary Excavation Plan and Profile", many buildings are founded on fills with variable thicknesses over excavated slopes. Because the fills and the in situ soils possess different properties; the stability, settlement, and seismic behavior of these buildings are of concern.

1. The construction excavations, as indicated in paragraph 2.5.4.5.1, have slopes ranging from 1-3/4:1 to 1:1 (horizontal to vertical). The stability of those buildings founded on slopes of 1:1, such as control building, must be evaluated. The evaluation should consider that the frictional resistance along the construction slopes could be affected by seepage, the softening of the clayey soils, and the under-compaction of the fill along and adjacent to the construction slopes. Provide the details and results of your analysis for review.

2. Bearing capacity analyses, as stated, utilize a two-layer soil model. Apparently, those analyses do not represent the as-built condition as discussed above. Provide additional analyses with the critical bearing failure surfaces developed along the construction slopes.

3. Since many buildings are founded on fills of various thickness, the post-construction differential settlements are of concern. Provide differential settlement calculations for those buildings, i.e., fuel, control, etc. The documented as-built soil properties should be used for the analyses. In addition, the available data on structural settlements obtained from monitoring instrumentation should be plotted and provided. The structural settlement plots should cover at least two sections for each unit with the main structures identified. Settlement versus time plots for instruments installed at the fuel and control buildings should also be provided.

4. As shown on figure 2.5-74, since the buildings were founded on fills of various thickness, differential settlements, tilting, and potential stability problems are of concern. Provide analyses to demonstrate that: (1) the rotation of those buildings due to differential settlements would not have any significant impact on adjacent buildings or building internals, (2) the lateral earth pressures used in the original design would not be significantly affected if the critical failure plane was along the construction slopes, and (3) the seismic-induced loads and responses would be less or equal to what was calculated in the original design configuration.

RESPONSE: The major slopes of the power block excavations occur in the native sands of the upper 50 feet of the site (see figures 2.5-74 through 2.5-76). Native soils below the base of excavation are predominantly silty clays. Sands excavated from the power block excavations were reused as power block backfill. The shear strength properties of the compacted sands and the native sands are essentially the same, based on laboratory shear tests summarized in figure 2.5-66; thus, a two-layer model consisting of sand over clay was used in stability and bearing capacity analysis.

There is no evidence to indicate a plane of weakness or undercompaction along construction slopes. Any loose or softened native soils were removed during backfilling because fills were benched into firm native soils. Compaction was performed to specified densities, as documented in the response to NRC Question 241.1, part 2. Settlement instrumentation data presented in "Foundation Instrumentation Report Supplement for Responses to NRC Questions 241.3 and 241.4" (sent to the NRC under separate cover), indicates that measured structural settlements are well within design criteria limits and thus show no evidence of back-fill undercompaction.

Although there is no evidence to indicate a plane of weakness along buried construction slopes, the effects of a hypothetical plane of weakness upon structural stability and upon design static and seismic earth pressures were evaluated. The following conclusions were drawn:

- A relatively small portion of both the control building and the containment overlie a small (roughly 16 feet high) backfilled 1:1 construction slope. Both of these slopes are in the native clay soils. A small wedge of granular backfill is confined between the 1:1 slopes and the auxiliary building. Softening and/or undercompaction along the 1:1 slopes would not significantly reduce the overall stability of either the containment or the control building due to the small size of the weakened zone relative to the potential bearing failure surface and the confinement provided by the lower portion of the auxiliary building.

- For static conditions, structural walls were designed to resist at-rest lateral earth pressure exerted by compacted backfill, assuming rigid, nonyielding walls. This design condition conservatively assumed no movement in the soil; therefore, any slippage that might occur along a hypothetical plane of weakness would reduce the earth pressures from the at-rest design value. Thus, the presence of a plane of weakness along construction slopes would have no adverse impact on static earth pressures used in design.

- For seismic conditions, structural walls were designed to resist earthquake-induced loading. A check was made to compare the dynamic wall pressures used in design to the pseudo-static pressures that would result if the wedge of backfill between structural walls and construction slopes were free to accelerate toward the

structure under earthquake loading. To stimulate a hypothetical plane of weakness, it is assumed that no frictional forces could be mobilized along construction slopes. For all structures, the dynamic pressures used in design were larger than the pressures generated by the pseudo-static wedge forces; therefore, the seismic-induced loads used in design will not be increased if a plane of weakness is assumed along construction slopes.

QUESTION 2A.10 (NRC Question 241.4) (2.5)

Essential Spray Pond

1. As shown on figure 2.5-88, the essential spray pond will be excavated. Since the pond is a Seismic Category I structure with man-made slopes or embankments, the design and analysis information for these slopes should be provided. The information required for staff review can be found in either Section 2.5.5 or 2.5.6 of Regulatory Guide 1.70 "Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants."

2. Provide an analysis to demonstrate that the groundwater levels will not be higher than those used in the design and confirmed by data obtained from groundwater level monitoring program.

3. Buried pipelines and associated earthwork should be discussed. This discussion should include the design and construction of the foundation support for the pipelines, excavation, bedding and backfills, compaction requirements, estimated settlements along the pipelines (particularly in

fills). The confirmation test results of moisture, density and compaction during installation should be provided. The settlement monitoring results along the pipelines should also be provided.

RESPONSE:

1. The essential spray ponds are watertight reinforced concrete structures (refer to paragraphs 3.8.4.1.6, 9.2.5.2, and engineering drawing 13-C-SPS-375). The base slab has a minimum thickness of 2 feet and is 3 feet thick under the walls. The walls are 15 feet 6 inches high, extending 8 feet above the plant grade and are 2 feet thick. All vertical and horizontal construction joints located in the exterior walls and base slab have 6 inch dumbbell waterstops. A nonstructural embankment, approximately 4 feet 6 inches high, is provided around the outside walls of the ponds for vehicle access. Failure of the nonstructural embankment would have no impact on the safety function of the ponds. Sections 2.5.5 and 2.5.6 of Regulatory Guide 1.70 do not apply to this nonstructural embankment. The design philosophy is explained in amended paragraph 3.7.2.3.3.

2. Data from the groundwater monitoring program have established the groundwater level to be the same as described in paragraph 2.4.13.4.1.

3. Buried Category I pipelines which service the essential spray pond consist of steel water pipes and concrete encased PVC electrical conduits referred to as

electrical duct runs. These pipelines are supported directly on either native soils, or on compacted power block fill in areas where they cross the power block excavation ramp backfill. A plan view of the spray pond area showing the location of Category I pipelines and power block backfill is presented on figure 2A-5.

Bedding, gradation, and compaction requirements are summarized in figure 2A-6.

All fills placed in the power block excavation are granular soils compacted to at least 95% of the ASTM D1557 maximum density. Compaction requirements, equipment, and procedures are the same for fills underlying structures and for fills supporting pipelines only. Results of field density testing on these fills is presented in the response to NRC Question 241.1, part 2.

Category I pipelines impose very little net load on the foundation soils; therefore, settlements in the spray pond area are caused primarily by the weight of backfill and by spray pond structural loads. Settlements caused by the considerable weight of backfill will be essentially complete prior to installation of the pipelines. This is due to the fact that the backfill will have been placed up to grade for at least 6 months prior to both spray pond and Category I pipeline installation. The predicted rapid rate of backfill-induced settlement is supported by instrumentation data presented in the "Foundation Instrumentation Report"

(sent to NRC under separate cover). Category I pipelines are installed at about the same time the spray ponds are constructed, and after backfill-induced settlements are essentially complete. Category I pipeline settlements will, therefore, be caused primarily by spray pond loading. Pipeline settlements will be maximum at connections to the spray pond structure and will decrease gradually.

With increasing distance from the structure. Total predicted recompression settlements for the perimeter walls of the spray pond are small, ranging from 0.2 to 0.4 inch. These predictions were obtained in a detailed analysis presented in Appendix 2AA, Amendment 18 of the PSAR. Therefore, estimated settlements of Category I utilities are also small, ranging between 0.0 and 0.4 inch.

Because of the very small settlements anticipated along pipelines, no instrumentation has been installed on the pipelines; however, settlement markers have been installed at six locations around the perimeter of the spray ponds. Data from these spray pond settlement markers at Unit 1 are available for the 13-month period beginning roughly 6 months after construction began on the spray ponds. Results are presented graphically in the "Foundation Instrumentation Report." Measured settlements are low, ranging from 0.0 to 0.3 inch; thus, the measured settlements provide evidence that very small settlements have occurred along pipelines in the spray pond area.

<u>QUESTION 2A.11</u> (NRC Question 231.1)

Eberly and Stanley's (1978) paper addresses the structural geology in the site vicinity (within 5 to 10 miles). Discuss the impact and validity of their interpretation of the subsurface with respect to:

a. The existence of mountain-basin bounding faults in the Arlington Gillespie Dam area.

b. The validity of their interpretation of the site vicinity geologic structure as shown on their Figure 8, p. 933.

c. The significance of Eberly's and Stanley's interpretation with respect to site safety.

RESPONSE: The field work and research leading to Eberly and Stanley's 1978 paper was accomplished between 1971 and 1973 and represented about an 18-month effort to synthesize a broader picture of Arizona's Cenozoic stratigraphic and tectonic history than was currently available in published literature. The ultimate purpose of the study was for application to Exxon's oil and gas exploration program. Their study involved:

- incorporation of all previous geologic data
- reconnaissance geologic mapping from 93 outcrop locations
- results of 57 water, gas, and oil borings
- four new test borings
- hundreds of miles of vibroseis reflection profiling

- 57 radiometric age dates

The greatest emphasis of Eberly and Stanley's work was on the correlation of one major and several minor unconformities in the Cenozoic stratigraphic section throughout southwest Arizona. As a result of this broad stratigraphic work, they were able to document two distinct orogenic episodes and provide a chronologic framework for the development of two major structural trends throughout southwest Arizona. Eberly and Stanley interpreted structural trends along their traverses based on seismic lines and reconnaissance mapping. These interpretations were depicted in a series of small-scale, vertically-exaggerated cross-sections which extend east from Yuma along the Gila River and south along the Phoenix-Tucson corridor.

In terms of PVNGS, Eberly and Stanley's Figure 8, page 933, is most significant because it shows the east end of their Section B-B' which extends east-northeast through the vicinity of the Palo Verde Hills. Their structural interpretation of the Saddle Mountain - Palo Verde Hills high is based on reconnaissance mapping of the outcrops, a single Exxon vibroseis reflection profile and a single exploratory boring (Reaves No. 1 Fuqua, [see FSAR figure 2A-3] drilled and abandoned in 1939, total depth 4117 feet) located in Buckeye about 15 miles east of PVNGS. Five normal faults were interpreted across the area between Centennial Wash and the Hassayampa River: two on each side of the horst, apparently defining the "step down" into each adjacent basin, and one normal fault within the horst. All

these faults were interpreted to be northwest trending based on reconnaissance mapping. The quality of the seismic profile and reflectors was considered only fair by Eberly (1981, personal communication), and the prime purpose for placing faults in the vicinity of the Saddle Mountain - Palo Verde Hills high was to account for the tilting of the volcanic units. He believes that the Exxon seismic line showed some permissive evidence for placing faults in the area, but the exact number and location of specific faults, as shown on Figure 9, represents some "artistic license" according to the authors (Eberly, 1981, personal communication).

FSAR figures 2.5-8 and 2.5-9 show tectonic interpretations for the Palo Verde site vicinity based on: 1) the reconnaissance and detailed investigation for PVNGS, and 2) tectonic interpretations from all available geologic sources. Cross-section B-B' on FSAR figure 2.5-9 roughly coincides with the area between Hassayampa and Centennial Wash shown on the Eberly and Stanley Figure 8. FSAR figure 2.5-9, Section B-B', shows or infers five faults: two forming the west boundary of the structural high near Centennial Wash, two forming a graben near the Hassayampa River, and one small fault in the Palo Verde Hills. The original FSAR figure 2.5-9, Section B-B', has not shown the Centennial Wash faults projecting onto the section. The revised figure has corrected this. So, in terms of the numbers and locations of faults considered in the PVNGS site vicinity, Eberly and Stanley do not indicate any essentially unique interpretation. Therefore, the style of

tectonics presented in the FSAR is conservative and, considering scale differences and vertical exaggeration, the PVNGS analysis would be more accurate. The detailed geologic mapping and geophysical surveys conducted in the site vicinity have documented the absence of any surface fault (other than the one noted in the Palo Verde Hills) and have confirmed the general integrity of the Saddle Mountain - Palo Verde structural high.

Regarding the age of the faulting, Figure 8 shows some range bounding faults as displacing the lower sections of Unit 1 which implies tectonic activity ranging from 13 million years to about 10 million years before present (late Miocene block faulting episode or "mid-Tertiary" orogeny). Eberly and Stanley interpret that between 10 and 6 million years ago the period of closed basins ended, streams were integrated and the area began to demonstrate a general tectonic stability. The PVNGS investigations established that major tilting of volcanic units occurred after about 17 m.y. and apparently stopped at about 16 m.y. (age of untilted fanglomerate). Actually, basin faulting must have stopped later but well prior to deposition of the Palo Verde clay (i.e., well before 2.7 m.y.). Therefore, the minimum age of faulting presented in the FSAR is more conservative than Eberly and Stanley's observations.

Eberly and Stanley also discuss the Gila trough and describe it as a "northeast-trending, sediment-filled trench underlying the Gila River Valley east of Ligurta, Arizona (east of Yuma). Thick deposits of Unit 1 indicate that the Gila trough predated late Miocene block faulting.

The block faulting overprinted the older northeast-southwest structural trend, forming horsts and grabens within the Gila trough that are aligned with the northwest-southeast trend of the present day valleys and ranges." Therefore, their study indicates that the northeast structural trends of the Gila trough and the Gila lineament are clearly older than the mid-Miocene block faulting, and, therefore, are not capable or significant to the site.

In total, the Eberly and Stanley paper confirms, in a regional sense, many of the more important findings of PVNGS related to: 1) the general location and distribution of major faults near the Saddle Mountain - Palo Verde Hills high, 2) the age of faulting and basin development, and 3) the age of basin filling, stream integration, and achievement of tectonic stability in southwest Arizona.

There has been no new information presented which would alter the opinions or conclusions of safety at PVNGS and, therefore, there is no impact or significance to the FSAR.

QUESTION 2A.12 (NRC Question 231.2)

Describe your post-1978 Palo Verde 4 and 5 PSAR activities with respect to the geologic and seismological updating of the Palo Verde 1, 2, and 3 FSAR.

RESPONSE: Preparation of the PVNGS Final Safety Analysis Report (FSAR) reflects the thorough assessment, reevaluation, and compilation of previously-submitted data for PVNGS Units 1, 2, and 3 and PVNGS 4 and 5 obtained through March 1979. Following March 1979, an ongoing,

multifaceted program continues to update the geologic seismological and geotechnical engineering data base for subsequent amendments to FSAR. The updating program includes, but is not limited to:

- review and evaluation of geologic and seismologic research developing in the southwest and other regions that may influence geotechnical and conclusion regarding PVNGS.
- review and evaluation of published report, maps, and other records, as they become available, pertaining to the geology and seismology of the southwest.
- periodic personal contact with the various governmental agencies, academic institutions and the private organizations involved in geotechnical projects in the southwest.
- investigation and evaluation of seismic events reported as occurring within Arizona and adjacent regions.
- continuous in-grading geologic inspection and mapping of construction excavations at PVNGS.
- analysis of settlement and subsidence network data and the reporting of results on an interim basis.
- monitoring of regional and perched groundwater conditions in the site area.

QUESTION 2A.13 (NRC Question 231.3)

Figure 2 (page 6) of a November 1979 Department of Energy Report shows two inferred faults in the Hassayampa Plain northeast of the Palo Verde site. Discuss the validity of these faults and their site-safety significance. The DOE report is titled "Geothermal Studies in Arizona with Two Area Assessments (DOE/ID/12009-T4)."

RESPONSE: The existence and location of the intersecting northwest and northeast trending faults shown on Figure 2 of the Geothermal Reservoir Site Evaluation in Arizona were inferred from regional geologic relationships supplemented by some reconnaissance geophysical data and a previous regional lineament study. In the case of both faults, there was no directly mappable geologic or structural discontinuities to confirm their existence (Stone, 1981, personal communication). The actual locations of the faults shown on Figure 2 were inferred from: a) the assumed position and shape of the buried pediment edge along the northeast Belmont Mountains (i.e., the northwest trending fault), and b) buried basin topography interpreted from low resolution gravity and aeromagnetic surveys of the northern Hassayampa Plain (northeast trending fault).

According to the author, Claudia Stone, a second phase of the geothermal study has produced a higher resolution gravity survey of the northern Hassayampa Plain. This latest geophysics is just being analyzed and will be reported in a second publication available before the end of 1981. Although currently incomplete, the revised analysis

will make two important changes to the structural interpretation on Figure 2. First, the northeast trending fault will be removed because the detailed data apparently do not substantiate the inferences of the original study. Second, the buried fault along the north edge of the Belmont Mountains will be sinuous to follow the shape of the pediment rather than straight as now shown (C. Stone, 1981, personal communication). Therefore, we may conclude that the northeast trending fault is not valid.

FSAR figure 2.5-8 shows a northeast trending hypothetical fault along the north boundary of the Belmont Mountains. However, it is located about 2 miles west of the northwest trending fault on Figure 2 of the referenced article. The fault in FSAR figure 2.5-8 was taken from a small-scale tectonic map of North America which placed faults along margins of most major mountain ranges. The accuracy of location of those hypothetical faults is unknown and the geologic reasoning for their location is not described. Therefore, the fault on FSAR figure 2.5-8 represents essentially the same range bounding structure in Figure 2 except that locations of the two faults vary slightly due to map scale and minor interpretive differences. FSAR figure 2.5-8 has been revised to reflect the results of these latest studies.

The ages of faulting are not discussed in detail in the referenced article; however, it was noted that the orientations of the two faults in Figure 2 are representative of the two prominent structural trends in central Arizona: northeast trends are attributed to the

Laramide Orogeny and north-northwest trends are attributed to the mid-Tertiary orogeny. This is consistent with the tectonic history outlined in the FSAR and brackets the age of movement on the younger northwest trending faults from about 13 million years to about 10 million years before present.

Surface studies in the form of aerial photographic analysis, flyover, and ground reconnaissance have not revealed any evidence of Quaternary activity along the northern margin of the Belmont Mountains. Lineaments have been placed along the relatively straight segment of Jackrabbit Wash which parallels the north margin of the Belmont Mountains, but no evidence has been generated by previous studies to indicate that the stream alignment is due to Quaternary faulting.

Therefore, we conclude that the revised maps of the referenced study will be consistent with the geology as represented in the FSAR and that the postulated fault along the northeast margin of the Belmont Mountains is not capable and is not of safety significance to the site.

QUESTION 2A.14 (NRC Question 231.4)

Describe the basis used for categorizing the fault (see FSAR figure 2.5-6) in the Sand Tank Mountains area some 35 miles SE of the Palo Verde site as older than 500,000 years.

RESPONSE: The weight of line used to depict the age of the fault near the Sand Tank Mountains is a drafting error. In the absence of any detailed geologic investigations, we consider the Sand Tank fault as younger than 500,000 years

and FSAR figure 2.5-6 was modified accordingly. Richard Van Horn of the U.S. Geological Survey describes the Sand Tank scarp as follows:

The scarp, about 3 kilometers long and 2 meters high, slopes about 20 degrees west. It is formed on an old alluvial fan that slopes about 2 degrees west-ward. Desert varnish is about half as well developed on the scarp as on the upper surface of the fan. The old fan deposit and the scarp have been eroded by ephemeral streams, which have deposited a younger fan alluvium in the gulches and over the old fan alluvium west of the scarp. The younger fan alluvium over-lies and conceals the scarp at its north and south-ends. No scarp was seen on the young fan. The young fan deposit is not stained by desert varnish.

The scarp is believed to have been formed by a fault that displaced the old fan deposit downward to the west. The fault and downdropped block of old fan deposit have been completely covered by the young fan deposit. Alternative origins for the scarp that were considered and rejected include erosion by the Gila River and subsidence into a depositional basin. The age of faulting was not determined, but is probably Pleistocene.

Since the exact age within the Pleistocene has not been determined and no detailed analysis is available, no definitive statement can be made regarding the capability of the Sand Tank fault. However, for this analysis we have assumed it is capable. In terms of site safety, the existence of the Sand Tank fault, about 35 miles south of

the site, is not considered significant because of the very conservative model used to establish the seismic design for PVNGS. The Sand Tank fault is too short and too distant from the site to represent a surface faulting hazard or to exceed the safe shutdown earthquake. Therefore, there is no impact to the seismic evaluation of the site by assuming that the fault is capable.

QUESTION 2A.15 (NRC Question 231.5)

Detailed geophysical surveys (gravity and magnetic) recently conducted by C. Cloran (Geophysics, Hydrology and Geothermal Potential of the Tonopah Basin, Maricopa County, Arizona, MS Thesis, Arizona State University, May 1977) within 5 miles of the Palo Verde site indicate that the Tonopah Basin is bounded by normal faults. Discuss the impact of Cloran's interpretation of the subsurface with respect to:

a. Site safety

b. The capability (or noncapability) of the basin-bounding faults suggested by Cloran.

c. The validity of the structural interpretation of the Tonopah Desert area as shown on FSAR figure 2.5-8 and other related FSAR figures.

RESPONSE: The masters thesis by Courtney Ann Cloran (Geophysics, Hydrology and Geothermal Potential of the Tonopah Basin, Maricopa County, Arizona, 1977) provides a reasonably detailed geophysical and structural analysis covering about two-thirds of the Tonopah Basin. Cloran performed a gravity and ground magnetic survey on 1 mile and

one-half mile centers, respectively, which refined earlier geophysical work in the area by others including, in part, the work by Sumner for the PVNGS PSAR (i.e., the area north of the Palo Verde Hills and into the Tonopah Desert).

In terms of safety significance to PVNGS, the most pertinent conclusions to Cloran's work were that:

- The Tonopah Basin is a large (15 kilometers) Basin and Range style, block-faulted structure.

- Steep gravity gradients on the basin margins to the north and south indicate steep scarps of normal faults or a series of normal faults. The number of interpreted faults vary depending on the density model, but the position of major structural blocks remain about the same.

- Maximum thickness of alluvium ranges from about 7500 feet to about 10,000 feet.

- The greatest depth of the basin is in the southeast corner and the basin trends about N56°W.

  The basin is bounded on the north by the buried pediment of the Belmont Mountains, to the south by the Saddle Mountains and Palo Verde Hills, to the west by the connection between Big Horn Mountains and the Belmont Mountains, and on the east by the buried granitic high trending south from the southeast end of the Belmont Mountains.

- A prominent nose exists in the southwest part of the Tonopah Basin which may be a northeast trending fault.

- Magnetic anomalies in the northwest part of the Saddle Mountains have been speculated to be faulted volcanic flows which have been intercalated into the basin sediments. The magnetic contours suggest the faults might trend northeast and project into the central basin.
- A water temperature anomaly coincides with the general location and orientation of the northeast trending fault. The northeast trending fault is postulated to act as a conduit to high water transfer.
- There is no discussion in Cloran's study of geologic history, tectonic history of minimum age of last displacement on faults in the Tonopah Basin.

Cloran's interpretation of faults within the Tonopah Basin is based on consistently steep gravity gradients and a few abrupt magnetic anomalies. The basin bounding faults interpreted from gravity data are shown in section (plate 8) using two interpretations of the geophysical model. Model 2 shows the most faults and has been discussed here as the most conservative alternative. Unfortunately, there is no plan which shows the interpreted length and orientation of northwest basin bounding faults between the three cross sections. Similarly, there is no section or plan showing the location, orientation, or length of the northeast trending fault along the "Tonopah Nose" or of the northeast faults defining the abrupt, high-low magnetic anomalies. These locations must be inferred from the text description. Figure 2A-4 is a reduced version of plate 4 showing our

interpretation of Cloran's faults described in the text and cross-sections. In addition, we have superimposed the locations of the inferred and geophysical faults from FSAR figure 2.5-8 for ease of comparison in the following discussion.

The PVNGS geophysical and subsurface investigations concentrate on the southeast edge of the Tonopah Basin closest to the site. Cloran's survey overlapped the northern edge of the PVNGS investigation and covered the remaining southern two-thirds of the entire valley. The two southernmost faults (A and B, figure 2A-4), which were interpreted as basin-bounding structures in the FSAR, appear in good alignment and form a reasonable correlation with Cloran's basin-bounding faults farther northwest (i.e., faults F and G). Fault F, which marks the change in gravity values from about -6 to -12 milligals, seems the most consistent structure and possibly correlative with fault B of the PVNGS investigation. Sumner (personal communication, 1981) has commented that Cloran's gravity contours suggest another alternative interpretation, i.e., a structural change along the 0 milligal line which roughly parallels the northwest trend of the valley. This inferred structure would project into the vicinity of faults A and B and also might be correlative with them. Therefore, a complete acceptance of Cloran's work would suggest at least one and possibly two faults (A and B) may be longer than shown on FSAR figure 2.5-8. Another alternate interpretation could postulate one fault which might correlate to faults A or B.

Along the northern Tonopah Basin, Cloran has interpreted two bounding faults (H and I) at the change in gravity gradient near the -14 milligal contour. Fault H roughly follows the -14 milligal contour and appears to correlate among all three cross sections. The correlation of fault I among all three cross-sections requires cutting across one prominent gradient near section C-C' (Figure 8); therefore fault I may not be as continuous as fault H. FSAR figure 2.5-8 shows a geophysical fault (fault E) about two or three miles north of Cloran's fault (H and I). The existence and location of fault E was based on a single gravity profile performed during the PVNGS investigation which was supplemented by regional gravity data and regional geology. Fault E was interpreted along the steep gravity gradient along the south margin of the Belmont Mountains.

Cloran's work refined the shape and location of the northern basin contours and, as a result, permits a more refined interpretation of basin faulting. Upon reviewing Cloran's work, we agree that the data suggest a range-bounding fault along the northern Tonopah Basin. However, we favor placing the fault in the areas of the steepest gravity gradient; i.e., approximately along the -4 milligal contour (Sumner, 1981, personal communication). This latter interpretation would place the range bounding fault about 1 mile south of and slightly subparallel to fault E and about 1 or 2 miles north of faults H and I. Although the locations of the different interpretations of range-bounding faults may vary by a few miles, the general concept of a bounding fault along the northern edge of the Tonopah Desert has been

accepted and considered in the FSAR. In addition, the FSAR has considered a hypothetical fault from published tectonic maps along the entire southern boundary of the Belmont Mountains (FSAR figure 2.5-8).

The "Tonopah Nose" was interpreted by Cloran from the abrupt kink in gravity contours in the southwest corner of the basin (Figure A). Based on the text description, there was a northeast trending fault interpreted along the aligned contours of the kink. Although the original gravity readings and station data are not available and have not been analyzed, it is clear that the contours have been pulled out of position by an anomalous reading on one station. This leads us to suspect the accuracy of the station readings of elevations and, as a result, to question the existence of the "Tonopah Nose".

The shorter, east-west trending geophysical faults near the center of Tonopah Basin (faults C and D) correlate, in one instance, with a basin fault shown on Cloran's section A-A' (plate 8). Fault D has no obvious correlation to any structure shown on Cloran's section B-B'. Fault C, if projected west, would generally align with several short northeast faults that Cloran interpreted at the southwest margin of the basin; however, there is no basis for a reliable correlation.

In summary, it can be said that Cloran's work has expanded the geophysical interpretation of the Tonopah Basin, and in terms of the basin-bounding faults nearest the site, has shown that one of the southern basin faults might be

continued 8 to 10 miles farther northwest. The interpretations between Cloran and PVNGS studies regarding faults forming the north margin of the Tonopah Basin agree in principle as to the existence of a basin-bounding fault, but these interpretations have placed the faults at different locations (a few miles apart) and slightly subparallel in orientation. Cloran's work has identified some short northeast trending faults near the southwest edge of the basin which would project toward Saddle Mountains. These latter faults are the only really new interpretations introduced. It is important to note that these interpretations of northeast trending faults are somewhat suspect because; 1) the high-magnetic anomalies used to infer the faults occur near great thicknesses of basalt near Saddle Mountain, and 2) the kink in the gravity contours used to infer the "Tonopah Nose" is based on a single station anomaly. It is a reasonable alternative to postulate the presence of northeast trending dikes which are known to produce similar magnetic patterns.

Regarding the impact of this information to site safety, we can conclude:

- Cloran's work has not identified any new structures which are closer to the site or project toward the site from those structures already presented in FSAR figure 2.5-8.

- The original PVNGS analysis considered the impact of basin-bounding faults along the north and south margin of the Tonopah Basin (i.e., those determined from direct

investigation or from faults inferred on other tectonic maps). The FSAR model is conservative and its safety significance has not been changed by Cloran's studies.

- The unbroken correlation of the Palo Verde clay across the southern basin-bounding faults (A and B) still demonstrates no movement in at least 2.7 million years. This age is valid regardless of how far the faults might project to the northwest (i.e., correlate with faults F and G).

- Potential northern basin-bounding faults were evaluated with various remote sensing techniques, reconnaissance geologic mapping, and geomorphic evaluations. It was concluded that there are no signs of displacement of any Quaternary formations along the south edge of the Belmont Mountains or the pediment.

- The postulated northeast trending faults interpreted by Cloran are subordinate to the northwest basin bounding faults in terms of length and inferred amounts of displacement. Although there is no discussion of the tectonic history of the basin or evaluation of ages of fault development and last movement, these northeast trending faults fit a regional tress pattern in central Arizona which usually places the northeast faults as Laramide structures. As a result, they precede the mid-Tertiary orogeny and are older than the northwest trending faults. There is no surface expression of the northeast trending faults nor is there any evidence

raised by Cloran's work that would suggest that they should be considered capable.

In direct answer to the three questions raised by the NRC, we conclude:

a) There is no impact to site safety or to the geotechnical evaluation from Cloran's work.

b) The basin bounding faults as postulated by Cloran are not considered capable in terms of NRC siting criteria.

c) The structural interpretation shown on FSAR figures 2.5-8 and 2.5-9 is still valid in terms of the basic basin geometry and the significant structural features of safety significance to the site. There will be the addition of some details from Cloran's work to make the data base more complete.

QUESTION 2A.16 (NRC Question 231.6)

Geologic features, which may possibly be faults, have been recently identified within approximately 8 to 13 miles of the Palo Verde Nuclear Generating Station by a geologist with the Arizona Bureau of Geology and Mineral Technology. Preliminary estimates indicate that at least some of the features (faults) may be of tectonic origin and may be capable - ranging from 10,000, perhaps 50,000 years old. Conduct field studies and investigations as necessary in order to better understand the nature and age of the reported faulting. For any feature which is determined to be a fault, determine whether it is capable. If capable, determine the effect, if any, on the seismic design bases for the Palo Verde plant.

RESPONSE: Christopher Menges, Research Geologist for the Arizona Bureau of Geology and Mineral Technology, identified a series of anomalous, scarp-like features near the Hassayampa River about 12 miles north-northeast of the Palo Verde Nuclear Generating Station.

Mr. Menges' discoveries were an outgrowth of a two year statewide study of Quaternary faulting in Arizona funded by the U.S. Geological Survey. His preliminary work, which included photointerpretation, aerial overflight, and reconnaissance ground-field checks, provided data suggestive, although not diagnostic, of a fault origin for the Hassayampa scarps. These data included: 1) linear topographic scarps oriented oblique to local drainage throughout much of their extent, 2) approximately the same surface, as indicated by relative degree of soil and pavement development, above and below many of the topographic scarps, and 3) disruption of drainage and local sedimentation at or adjacent to the scarps.

Menges also noted that certain characteristics of the scarps made interpretation of the origin difficult and problematic, especially compared to other well-documented fault scarps in Arizona. These characteristics included the position of the scarps relative to the direction of the pediment (i.e., the scarps were nestled among inselbergs), the funnel-shaped aerial pattern, and the subparallel orientation of the scarps to the pediment and adjacent piedmont drainage. Because the surface evidence was ambiguous and the scarp morphology suggested a late Pleistocene age of scarp formation, a field program was

undertaken to clarify the origin and significance of the scarps to PVNGS. The field program was designed and conducted in cooperation with Menges and he was directly involved with the location of trenches and interpretation of results.

Figure 2A-9 shows the location of the Hassayampa scarps originally interpreted by Menges. Their degree of certainty based on anomalous characteristics and field checking is also indicated by appropriate symbols. Based on the field evidence and the degree of certainty, the scarps were considered in two groups: 1) the westernmost group of relatively short scarps (1-2 miles in length), and 2) the eastern group of relatively long scarps (3-5 miles in length).

The western group of scarps, although shorter, had been field checked and contained the most anomalous characteristics. Therefore, they were the most prominent and were the most likely to be of fault origin. The eastern group were not field checked and were so closely associated with active drainage channels that they were considered by Menges to be less likely of fault origin. As a result, the subsurface investigation concentrated on the most diagnostic and anomalous scarps of the western group and the results of that study were used to refine the interpretation on the remaining scarps.

The investigative program included:

- several meetings between APS, their geologic consultants and the Arizona Bureau of Geology and Mineral Technology;
- research and analysis of U-2 and Army Map Service aerial photography of the Hassayampa area;
- aerial flyovers by helicopter and fixed wing aircraft at low sun angle conditions;
- field reconnaissance of scarp areas with and without Menges;
- selection of trench locations with Menges;
- excavation of two backhoe trenches across the most prominent and diagnostic scarps;
- Analysis and documentation of the excavations with Menges and the NRC geologist.

Figure 2A-9 shows the location of the western scarps and the two trenches investigating them.

Trench PV-BH-32 was excavated across a north-northwest trending scarp in an area where the scarp separated the elevated, paved fan surface from the lower, more recent alluvial plain. In this area the scarp angle dips to the west and ranges from a few degrees to a maximum of 9 degrees. The trench ranged in depth from about 12 to 16 feet and revealed six distinctive stratigraphic horizons.

At least four horizons could be traced continuously throughout the full length of the trench (figure 2A-10).

For the most part the contacts could be identified within an inch and could be confidently correlated across the trench without any evidence of warping or displacement. Since the strata are nearly horizontal, the uppermost gravelly sand unit gradually pinched out to the west against the erosional scarp. The lowest clay unit was only exposed in the deepest part of the excavation.

The lithologies exposed in trench PV-BH-32 range from coarse gravelly sands to fine grain deposits of silt and clay. In general, the lithologic groupings from top to bottom of the trench are: 1) reddish brown, gravelly sand which forms the desert pavement on the upper paleosurface, 2) massive gray brown silt, 3) thick sequences of fine to coarse well-stratified gravelly sands and sandy gravels, and 4) brown to red brown silty clay.

There is evidence of soil development on the existing paleosurface in the form of red oxidation zone and a slight calcareous development at the base. A possible paleosol may exist at the upper surface of the lowermost silty clay. Otherwise, none of the intervening contacts appear to represent surfaces of long-term stability. The strongly oxidized soils on the eastern side of the trench are discontinuous to the west because of the modern alluviation by the regional drainage.

Trench PV-BH-33 was excavated across a broad scarp connecting two levels of paved surfaces which were known to have similar soil profile development. The actual scarp was

about 4 to 5 degrees, necessitating a relatively long trench (about 225 feet) (figure 2A-11).

Essentially, trench PV-BH-33 showed a similar lithologic grouping as PV-BH-32, i.e., from top to bottom: 1) red brown gravelly silty sand than was strongly oxidized, 2) gray brown massive silt and sandy silt, 3) brown, well stratified gravelly sands and sandy gravels. At the west end of PV-BH-33, these three main stratigraphic divisions extend uninterrupted throughout the length of the scarp, i.e., from about station 00 to 150. The contacts are distinct and can be located within 1 inch. The lower sand and gravel unit is commonly well stratified, and contains many continuous distinctive subunits too numerous to be included as detailed in the log on figure 2A-11. As in trench PV-BH-32, the major continuous contacts have minor irregularities due to erosion, but are continuous and essentially horizontal across the scarp area.

Throughout the entire lithologic section, the eastern end of trench PV-BH-33, starting from about station 150, shows the influence of strong lateral variation in deposition. Prominent channeling and in-filling has created cut and fill structures and interfingering between fine and coarse grain units (figure 2A-11). All of the areas between stations 145 and 175 were carefully inspected and logged in detail for any indication of faults or shears. Numerous interbeds within the main lithologic units were traced to show direct or overlapping continuity of the strata. Interfingering contacts were carefully inspected for any sign of shearing or other surfaces which might suggest a fault. In each case

the abrupt termination of contacts is due to normal erosional/depositional processes. These conclusions were confirmed by continuity of subunits above and below such features.

Trenches PV-BH-32 and 33 begin on the same elevated paleosurface and extend across the scarps to lower, more recent surfaces. In terms of relative elevation between the two trenches, level surveys indicate that the highest paleosurface (i.e., the point of highest ground surface encountered by the trenches) varies from 100 (assumed) in PV-BH-33 to 96.5 in PV-BH-32 or about 3.5 feet difference in about 1200 feet of horizontal distance.

Based on lithology and soil profile development, each of the trenches terminates in a different lower surface. PV-BH-32 terminates in a Holocene surface at about relative elevation 92.5. PV-BH-33 terminates on a late Pleistocene surface at elevation 93.

In terms of relative elevations on the main stratigraphic division between the two trenches:

	PV-BH-32 east end	PV-BH-33 west end
Ground Surface	96.5	100.0
Contact between sandy gravel and massive gray brown silt	94.0	97.5
Contact between massive gray brown silt and stratified sand and gravels	88.2	91.7
Contact between stratified sand and gravel and red brown clay	79.5	not exposed

Therefore, there is a remarkable consistency in the elevation of the paleosurface between the two trenches and that consistency (about 3.5 feet difference) is maintained between the major stratigraphic divisions exposed in both trenches.

The results of the trenching were definitive in establishing the following characteristics about the scarp origin:

1) There are distinctive strata within the alluvial deposits underlying the scarps whose contacts can be clearly identified to within at least 1 inch.

2) The stratigraphic horizons are continuous, unwarped, and unbroken throughout the length of the trenches. Where local lateral variation has made direct correlation of gross contacts difficult, there are numerous subunit contacts which can be correlated or overlapped to confirm stratigraphic continuity.

3) The continuity of the stratigraphy confirms that the origin of the scarps cannot be due to faulting or any other tectonic cause.

Regarding the origin of the scarps, our observations are in general agreement with the revised interpretations of Menges; viz., the data suggest the following history:

1) The primary surficial deposits which currently form the upper surface for the scarps were deposited, as a minimum, in late Pleistocene time. Estimates of 55,000 - 100,000 years have been made by Menges based on soil development.

2) The observed scarp was formed by downcutting or lateral cutting in late Pleistocene (30,000 - 80,000 years) along a channel system which is no longer present.

3) Subsequent changes to the pediment drainage network by stream capture and alterations in the Hassayampa River.

4) Late Pleistocene to Holocene slope degradation and stabilization followed by soil formation which have produced the presently observed geomorphic and soil stratigraphic characteristics at the scarp.

The results of the trenching demonstrated that similar sequences of nontectonic events can explain the formation of other anomalous features in the eastern scarp group of the Hassayampa scarp system. Specifically, the field inspections of the eastern scarps showed the following:

1) The most obvious scarps nearest the Hassayampa River coincide exactly with the margins of the flood channel of Jackrabbit Wash. The scarps are smoothly arcuate in plan and have steep scarp angles up to 35 to 40 degrees indicating active influences of erosion. Tributary drainages across the scarp have carved deep embayments and have made nearly all the scarps irregular with no evidence of disruption of tributary drainages or their associated alluvial deposits.

2) In contrast, the scarps farther west from the Hassayampa River and Jackrabbit Wash are shorter,

more subtle and range in angle from 10° to 30°. The scarps occur along the edges of older, elevated alluvial fan deposits which have been incised by tributary drainages to the Hassayampa River. Similar to the scarps which were trenched (PV-BH-32 and 33), the paleosurface in the eastern scarp area has been preserved and the paleoslopes stabilized along the drainage divides between the tributary basins. Hand leveling shows that the preserved paleosurfaces are of uniform elevation across the drainages and could not have been differentially uplifted. In detail, the scarps are not linear and there has been no direct observation of faulting.

In addition, this region was closely inspected during the early site selection studies for PVNGS by two nationally recognized experts in tectonic geomorphology; viz., Dr. Lawrence Lattman and Dr. Roy Shlemon. Neither expert noted any anomalous conditions in this area to suggest faulting. We believe these latest studies confirm the original interpretation and give support to the conclusion that the scarps in the Hassayampa region are due to normal processes of basin deposition and erosion.

The final conclusion reached by this study is that the scarps interpreted by Menges are due to erosion and preservation of paleosurfaces. The trenches established conclusively that faults are not associated with the scarps and that nontectonic explanations must account for their origin. Menges has reviewed all the data and concurs with this conclusion. As a result, since no faults are

associated with the scarps, the scarps have no safety significance to the site and the original interpretation of the geomorphology of the site vicinity as presented in the FSAR has been confirmed.

APPENDIX 2D
GEOLOGIC MAPPING OF EXCAVATIONS FOR CATEGORY I STRUCTURES

2D.1 INTRODUCTION

2D.1.1 PURPOSE

This appendix presents the results of the detailed geologic inspection and mapping of excavations for Category I structures at the Palo Verde Nuclear Generating Station (PVNGS). The purpose of the inspection and mapping program at PVNGS is to establish and document in detail the subsurface geologic conditions in the power block areas to confirm that conclusions regarding geologic and geotechnical properties made during earlier investigations are valid.

2D.1.2 SCOPE AND METHODOLOGY

The scope of the documentation of geologic conditions in these excavations included:

- Detailed mapping of geologic units in the walls and floors of each excavation at a scale of 1 inch = 10 feet
- Identification of soils exposed in the excavation
- Detailed logging of areas requiring special attention at scales of 1 inch = 1 foot or other appropriate scales
- Verification by the NRC staff of preliminary maps, profiles, and detailed logs during their onsite inspection of the power block excavations

- Finalization of the as-graded geologic maps and production of a brief report of the geology of each unit. The methodology employed during mapping operations was as follows:
- Divide the excavation into map areas based on slope configurations
- Locate survey control points to establish control for the base map
- Map the geology to identify the major stratigraphic units and locate the contacts between them
- Tag key points along contacts for surveying
- Plot surveyed points on base maps and sections of the map units at a scale of 1 inch = 10 feet (these plotted points were used for location control during mapping)
- Prepare detailed graphic logs of areas requiring special attention by establishing a control grid system across the area and making measurements to critical points

2D.1.3 SUMMARY OF RESULTS

The results of detailed mapping in the power block excavations demonstrate that the geology exposed in the walls and floors of the excavations conforms to the geologic model of the powerblock areas developed from surface and subsurface data during earlier siting studies. The models were reported in the PVNGS Units 1, 2, and 3 PSAR. The geologic units exposed in the excavations are lithologic zones (LZs) 5 and 4

(figures 2.5-16 and 2.5-17). The only deviation from the earlier geologic model is the character of stratigraphic unit C. This unit has been removed locally by erosion prior to or during deposition of the over-lying coarse-grained sands and gravels of stratigraphic unit B, and thus it is discontinuous throughout the area. The original model showed stratigraphic unit C as a continuous layer in the power block area.

No safety-related geologic features such as faults, subsidence, liquefaction, or other tectonic features or processes were revealed by mapping. The contact between stratigraphic units D and E was well defined and could be traced continuously around the base of the excavations. The continuity of the D/E contact, which is also the contact between LZs 5 and 4, demonstrates an absence of faulting of sediments older than 500,000 years (figure 2.5-17).

Preliminary copies of all maps, cross-sections, and detailed logs for Units 1, 2, and 3 were presented to the NRC staff during their onsite inspections of the excavations (September 1976, May 1977, September 1978). Following an examination of the maps and cross-sections and visual inspection of the geology, the excavations were approved by the NRC for construction.

2D.1.4 GEOLOGY

2D.1.4.1 Geologic Models

The geologic models were developed from surface and subsurface investigations conducted during the siting study and borehole foundation investigation for PVNGS (refer to subsection 2.5.1).

The initial geologic investigation of the PVNGS site determined that the stratigraphic column beneath the site could be divided into three major groups:

- Precambrian metamorphic and granitic rocks - designated basement rock
- Miocene volcanic and interbedded sedimentary rock - designated bedrock
- Middle Miocene to Holocene basin sediments consisting of alluvial, colluvial, fluvial, and lacustrine basin-filling deposits, with local interbeds of Pliocene-lower Pleistocene volcanic flows

The areal distribution of these groups is shown in figures 2.5-2, 2.5-8, and 2.5-12 and in cross-section (figure 2.5-9). Age data and brief lithic descriptions are shown on figure 2.5-17. The rocks and sediments of the basin sediments (QTbf) which overlie the basement and bedrock groups were further subdivided into six LZs using data from continuously sampled borings. The stratigraphic relationships between these lithologic zones are shown in figure 2.5-17. From youngest to oldest, the lithologic zones identified during the siting study within the basin sediments are:

- LZ-6 Fan deposits (Pleistocene to Holocene)
- LZ-5 Upper sand and gravel deposit
- LZ-4 Upper silt deposit
- LZ-3 Palo Verde clay (upper Pliocene)

- LZ-2 Lower silt and lower sand and gravel deposits
- LZ-1 Fanglomerate (Miocene-Pliocene)

LZ-2 through LZ-5 are unlithified zones of Pliocene and Pleistocene age, and together with the overlying deposit, LZ-6, were designated the "alluvial sequence".

A total of 17 horizons, designated A through M, were recognized in the alluvial sequence (LZ 2-6) beneath the PVNGS units.

These horizons are referred to as "stratigraphic units" in this appendix. The upper five stratigraphic units, A through E, are exposed in the power block excavations. Table 2D-1 summarizes the approximate thickness of these stratigraphic units and the major soil types. Stratigraphic units A through D correspond to LZ-5. They are coarse-grained soils with only the relatively thin, discontinuous, stratigraphic unit C containing any appreciable amount of clay. Stratigraphic unit E is a fine-grained sequence of silts and clays corresponding to the upper portion of LZ-4. The contact between the fine-grained stratigraphic unit E and the overlying coarse-grained material of stratigraphic unit D forms a major change in the stratigraphic column beneath the PVNGS site.

APPENDIX 2D

Table 2D-1

STRATIGRAPHIC UNITS A THROUGH E BASED ON BORING LOG INFORMATION

Stratigraphic Unit	Approximate Thickness (ft)	LZ Desig-nation	Soil Type
A	5 to 17	LZ-5	Sandy silt, silty sand, gravelly silty sand, clayey sand
B	10 to 24	LZ-5	Sand with silt, sand
C	3 to 8	LZ-5	Sandy clay, clayey sand
D	3 to 20	LZ-5	Gravelly silty sand, sandy gravel, clayey sand, silty sand, sandy silt
E	20 to 32	LZ-4	Silty clay, clayey silt

2D.2 PVNGS UNIT 1

2D.2.1 GENERAL

Stratigraphic units A through E can be recognized in the walls of the excavation, and demonstrate stratigraphic continuity beneath PVNGS Unit 1. The most easily defined contact lies between stratigraphic units D and E. This contact marks a major change in the basin stratigraphic column, separating light-colored sand and gravel (LZ-5) above from the dark-colored silt and clay (LZ-4) below. The contact is marked by numerous small erosional cut-and-fill sedimentary structures, but due to the sharp contrast in both color and lithic type, the contact can be precisely located to within a few inches. Detailed geologic mapping (figure 2D-1) shows that the contact extends around the Unit 1 excavation, unbroken, demonstrating an absence of faulting in the basin sediments.

Except for stratigraphic unit C, the 40 to 45 feet of sediments which lie above the D/E contact are coarse-grained and represent moderate to high energy alluvial depositional environments not unlike that occurring in the area today. Portions of stratigraphic unit C have been removed by erosion locally. Both erosional and gradational depositional features separate the stratigraphic units. Stratigraphic unit C consists of silty sand, sandy clay, clayey silt, and clayey sand and may be the result of deposition in a shallow playa or fluvial overbank deposits in abandoned stream channels and depressions.

Stratigraphic units C and D were combined to form a composite map unit designated CD on the preliminary as-graded geologic

map and profiles presented to the NRC regulatory staff at the time of their onsite inspection of the Unit 1 excavation. However, stratigraphic units C and D are shown separately in this appendix (figure 2D-1) to present the geology beneath PVNGS Unit 1 in as much detail as possible. This format does not alter any of the contacts shown on the preliminary geologic map.

2D.2.2 STRATIGRAPHY

2D.2.2.1 Geologic Models

Stratigraphic unit A is the uppermost map unit exposed within the PVNGS Unit 1 excavation. The average thickness of this unit is approximately 11 feet. The predominant soil types include brown, sandy and clayey silt, clayey sand, silty sand, sandy clay, and locally, gravelly sand. The coarse-grained soils are generally dense, noncalcareous to slightly calcareous, and consist of poorly sorted, angular to subangular, very fine-grained to coarse-grained quartz and lithic rock fragments. The largest clasts within the sands are 2 inches in diameter. The fines vary from about 12 to 35% of the coarse-grained soils.

The fine-grained soils have a low to medium plasticity and are stiff to hard. Silt, grading to very fine sand, is the most abundant fine-grained material. The soils are calcareous and contain abundant caliche nodules and root casts.

Individual soil types within stratigraphic unit A are discontinuous both horizontally and vertically and frequently grade into one another. No subunits of stratigraphic unit A

were differentiated in the PVNGS Unit 1 excavation. The stratigraphic unit's lower contact is undulatory and gradational with the underlying sediments.

2D.2.2.2 Stratigraphic Unit B

Stratigraphic unit B consists of gray to brown, silty sand and gravelly sand which is in conformable, gradational contact with the overlying stratigraphic unit A sediments. The average thickness of this unit is approximately 16 feet. Sands within stratigraphic unit B are loose, noncalcareous to slightly calcareous and consist of poorly to moderately sorted, angular to subangular, very fine-grained to coarse-grained quartz and lithic sand. Fines within the sands vary in percentage from about 12 to 25%. The sand grains of this unit grade from very fine to coarse and become cleaner with depth. Near the lower contact of the unit, the sands contain 10 to 30% gravel. Cross-bedded gravels and coarse-grained sands usually occur as fill in erosional channels cut into stratigraphic unit B sands. Lenses of finer grained clayey material also occur within the sands of stratigraphic unit B.

The fine-grained clayey soils have a low to medium plasticity, are very stiff to hard, and are slightly to highly calcareous. The sand in the fine-grained soils varies from about 10 to 40%. The soils are of limited horizontal and vertical extent, discontinuous, and frequently contain caliche nodules. The large, more-continuous, fine-grained beds are shown as B_1 on the as-graded map (figure 2D-1).

The contact of stratigraphic unit B with unit C is erosional with much of stratigraphic unit C being removed by erosion when unit B was deposited. This is suggested by erosional channels cut into stratigraphic unit C and by deposits of stratigraphic unit B in direct contact with unit D. Where unit C was not removed by erosion, the B/C contact is marked by a caliche unit.

2D.2.2.3 Stratigraphic Unit C

Stratigraphic unit C is 3 to 6 feet thick where exposed in the Unit 1 excavation. The predominant soil types found within this unit are brown to red-brown, silty clays, sandy clays, clayey silts, and clayey sands. The fine-grained soils are very stiff, have medium plasticity, are locally calcareous, and contain about 12 to 30% fine-grained sand. These fine-grained soils are capped by a 1- to 2-foot-thick discontinuous zone of hard, dense, white caliche and clay (figure 2D-1).

The fine-grained sediments found in stratigraphic unit C represent low energy depositional conditions such as presently occurs in shallow playa lakes or topographically low areas which collect overbank flood deposits. The interfingering bedding relationships with the overlying stratigraphic unit B sands indicate fluctuating water levels within the depositional basin.

Much of the contact between stratigraphic units B and C is erosional and reflects high energy deposition of stratigraphic unit B. Where stratigraphic unit C has not been completely removed by erosion, the contact with the underlying sands,

silts and clays of stratigraphic unit D is depositional. Geologic map area 21 (figure 2D-2) was mapped in detail because of a discontinuity in the caliche horizon C_1 and the underlying unit C. The discontinuity was determined to be an erosional irregularity not related to tectonic processes; units E and A are undisturbed above and below the area.

2D.2.2.4 Stratigraphic Unit D

Stratigraphic unit D is about 2 to 12 feet thick and is predominantly brown to red sand, silty sand, and gravelly sand. The sands are dense, noncalcareous to slightly calcareous and consist of poorly sorted, angular to subangular, very fine-grained to coarse-grained quartz and lithic rock fragments. The sands also contain cobbles to 10 inches in diameter and about 12 to 35% fines. The sands within stratigraphic unit D are locally cross-bedded. Locally discontinuous, thin lenses of stiff to hard clay and silt of low to medium plasticity are found interbedded with the coarse-grained material.

Individual horizons within this map unit are discontinuous both horizontally and vertically and commonly grade into one another. Lenses of brown silty clay and clayey silt, designated as D_1 on the as-graded geologic map (figure 2D-1), were mapped to clarify contact relationships. These fine-grained soils have a low to medium plasticity and are stiff to very stiff.

Stratigraphic unit D can be distinguished from stratigraphic unit B by its darker brown to red color, the higher percentage

of clay and silt, the presence of numerous soil horizons, and by its much more dense nature. The contact between stratigraphic unit D and the underlying soils and clays of unit E is a very sharp erosional contact marked by numerous and fill features.

2D.2.2.5 Stratigraphic Unit E

Stratigraphic unit E consists of homogeneous, dark-red-brown, silty clays and clayey silts with a lens of very fine-grained sand up to 4 feet thick. Maximum thickness of this stratigraphic unit exposed in the Unit 1 excavation is 28 feet. The silts and clays are very stiff to hard, exhibit medium to high plasticity, are noncalcareous to moderately calcareous, and contain scattered caliche nodules and up to 10% sand. Contacts between the silts and clays are highly gradational so it was not practical to separate these materials on the map. One silty sand horizon, designated E_1, was mapped in this unit. Sand within this horizon is brown to gray, dense, slightly calcareous, and contains poorly sorted, angular to subangular, very-fine- to medium-grained quartz and lithic sand.

2D.3 PVNGS UNIT 2

2D.3.1 GENERAL

Stratigraphic units A through E are recognized in the walls of the excavation and demonstrate stratigraphic continuity beneath PVNGS Unit 2 (figure 2D-3). The most obvious stratigraphic feature is the contact between stratigraphic units D and E. As

in the PVNGS Unit 1 excavation, this contact marks a distinctive change in the stratigraphic column, separating light-colored sand and gravel (LZ-5) above from the dark-colored silt and clay (LZ-4) below. The contact is erosional and marked along its length by numerous, small cut-and-fill structures, but due to the sharp contrasts in both color and lithic type across the contact, it can be located to within a few inches. The contact extends around the PVNGS Unit 2 excavation in a continuous, unbroken manner, demonstrating the absence of faulting in the basin sediments (figure 2D-3).

Except for stratigraphic unit C, the 40 to 45 feet of sediments which lie above the D/E contact are coarse-grained and represent moderate to high energy depositional environments. Strati-graphic unit C consists of silty and sandy clay, clayey silt, and clayey sand and may represent playa deposits or overbank sediments deposited in topographically low areas of the depositional basin. The PVNGS Unit 2 excavation exhibits the same erosional characteristics discovered in the PVNGS Unit 1 excavation. Both erosional and gradational contacts separate the stratigraphic units above the D/E contact. Cross-beds, cut-and-fill sedimentary structures, and other primary depositional features were identified during the detailed mapping. No evidence of faulting, liquefaction, or subsidence was observed.

2D.3.2 STRATIGRAPHY

2D.3.2.1 Stratigraphic Unit A

Stratigraphic unit A is the uppermost unit exposed within the PVNGS Unit 2 excavation. The average thickness of this unit is approximately 10 feet. The predominant soil types include brown, brownish yellow, and yellowish red, sandy and clayey silt, silty and sandy clay, silty and clayey sand, and gravelly sand. The coarse-grained soils are slightly dense to dense, calcareous, and consist of poorly sorted, angular to subrounded, very fine- to coarse-grained quartz, lithic and mica sands and gravels. The percentage of low- to medium-plasticity fines varies from about 21 to 35% in the coarse-grained soils.

The fine-grained soils have low to medium plasticity and are moderately firm to hard. Silt, grading to very fine-grained sand, is the most abundant fine-grained material. The fine- to coarse-grained sand within the fine-grained soils varies from 10 to 50%. These soils are calcareous with abundant caliche nodules and root casts.

Individual soils within stratigraphic unit A are discontinuous both horizontally and vertically and frequently grade into one another. Two subunits within stratigraphic unit A, designated A_1 and A_2 on the geologic map (figure 2D-3), were differentiated in the PVNGS Unit 2 excavation. The subunits comprise silty sands (A_2) and gravelly sands with occasional lenses of gravel and (or) silt (A_1). Subunit A_1 lies at the top of the stratigraphic unit A and is continuous around the PVNGS Unit 2 excavation. The lower contact of A_1 is erosional and commonly

has cut-and-fill sedimentary features. Subunit A_2 occurs as a lens near the base of stratigraphic unit A. The lower contact of stratigraphic unit A is undulatory and gradational into the underlying sediments.

2D.3.2.2 Stratigraphic Unit B

Stratigraphic unit B consists of gray to yellow brown, silty sand, sand, and gravelly sand which are in conformable, gradational contact with the overlying stratigraphic unit A sediments. The thickness of this unit varies from about 10 to 28 feet. Sands within stratigraphic unit B are loose to moderately dense, noncalcareous to slightly calcareous, and consist of poorly to moderately sorted, angular to subangular, fine- to coarse- grained quartz and lithic sand. Fines comprise from about 12 to 25% of the sands and exhibit low plasticity. The sands of this unit have fewer fines and grade from
fine-grained to coarse-grained as depth increases. Near the lower contact of the unit, the sands contain 10 to 35% gravel. Locally cross-bedded, coarse-grained gravels and sands are usually deposited as fill in erosional channels within the stratigraphic unit B sands. Lenses of fine-grained material occur locally within the sands of stratigraphic unit B.

The fine-grained soils have low to medium plasticity, are stiff, and are slightly to highly calcareous. Percentage of sand in the fine-grained soils varies from about 10 to 40%. The soils are of limited horizontal and vertical extent, discontinuous, and frequently contain caliche nodules. Local discontinuous lenses of silty clay, clayey silt, silt, sandy

silt, and gravelly sand are shown on the as-graded geologic map (figure 2D-3) as B_1 and B_2.

As was the case in the PVNGS Unit 1 excavation, the lower contact of stratigraphic unit B in the PVNGS Unit 2 excavation appears to be both erosional and depositionally contemporaneous with the underlying sediments. Large cut-and-fill structures are found along this contact and have removed much of unit C whereas in other areas the sediments of stratigraphic units B and C appear to be interbedded. A large cut-and-fill feature exposed on the bench near geologic map area 37 shows sands of stratigraphic unit B filling an old channel incised into stratigraphic units C and D.

2D.3.2.3 Stratigraphic Unit C

Stratigraphic unit C is thin, varying from about 4 to 10 feet in thickness where exposed in the PVNGS Unit 2 excavation. The predominant soil types within this unit are brown to reddish brown silty clays, sandy clays, clayey silts, and clayey sands. The fine-grained soils are very stiff, have medium plasticity, are locally calcareous, and contain about 12 to 30% fine-grained sand. The 1- to 2-foot-thick zone of hard white caliche and clay(C_1) capping the fine-grained soils in the PVNGS Unit 1 excavation is not present in the PVNGS Unit 2 excavation.

As in the PVNGS Unit 1 area, much of the contact between stratigraphic units B and C is erosional and reflects the high energy depositional conditions of stratigraphic unit B. As a result, stratigraphic unit C has been completely removed by

erosion in portions of the PVNGS Unit 2 excavation. The contact between stratigraphic units C and D is depositional.

2D.3.2.4 Stratigraphic Unit D

Stratigraphic unit D varies from 2 to 18 feet in thickness and is predominantly brown to red sand, silty sand, clayey sand, and gravelly sand. These sands are loose to dense, noncalcareous to slightly calcareous, and consist of poorly-sorted, angular to subangular, very fine-grained to coarse-grained quartz and lithic rock fragments. The sands also contain cobbles up to 10 inches in diameter and about 12 to 35% fines. Sands within stratigraphic unit D are locally cross-bedded. Locally discontinuous, thin lenses of stiff to hard clays and silts of low to medium plasticity are interbedded with the coarse-grained material.

Individual soils within this stratigraphic unit are discontinuous both horizontally and vertically and commonly grade into one another. Lenses of silty clay, clayey silt, sand, clayey sand and sandy silt, designated as D_1, D_2, D_3, and D_4 on the as-graded geologic map (figure 2D-3), were mapped to clarify contact relationships. The fine-grained soils, D_1, D_3, and D_4, have a low to medium plasticity and are firm to very stiff. The coarse-grained soils (D_2) are loose to moderately dense, poorly sorted to well sorted, angular to subangular, fine- to coarse-grained sand containing 12 to 30% fines. Stratigraphic unit D can be distinguished from stratigraphic unit B by its darker brown to red color, higher percentage of clay and silt, numerous distinct soils, and by its much more dense nature.

The contact between stratigraphic unit D and the underlying silts and clays of unit E is erosional and very sharp.

2D.3.2.5 Stratigraphic Unit E

Stratigraphic unit E consists of brown to reddish brown, silty clays and clayey silts with occasional thin lenses of very fine-grained sand. Maximum thickness of this stratigraphic unit, exposed in the PVNGS Unit 2 excavation, is 23 feet. The silts and clays are very stiff to hard with low to high plasticity, dry to saturated, noncalcareous to moderately calcareous, with locally caliche nodules, and 12 to 20% sand. Contacts between the silts and clays are highly gradational and it was not practical to map these soils separately.

Four fine- and coarse-grained horizons, designated E_1, E_2, E_3, and E_4, are exposed in the PVNGS Unit 2 auxiliary building excavation. These horizons are continuous to discontinuous and the contacts are gradational. The fine-grained soils (E_1, E_2, and E_3) are red to dark reddish brown, mottled brown-white and brown, stiff to hard with low to high plasticity. Horizon E_2 is clay, caliche, and caliche nodules. The coarse-grained soil, E_4, is brown to black and sand and silty sand. The sands are loose to moderately dense and consist of poorly to moderately sorted, angular to subangular, very fine- to fine-grained quartz sand.

2D.4 PVNGS UNIT 3

2D.4.1 GENERAL

Stratigraphic units A through E are exposed in the walls and floor of this excavation as in PVNGS Units 1 and 2 excavations and demonstrate stratigraphic continuity throughout the excavation and the site. As in the other excavations, the most obvious stratigraphic horizon is the contact between stratigraphic units D and E which marks the change from light-colored sand and gravel (LZ-5) on top to the dark-colored silt and clay below (LZ-4). The contact is irregular due to erosion that accompanied deposition of stratigraphic unit D, but the contact is easily mapped because of the difference in color and grain size of the two stratigraphic units. The contact is continuous around the excavation and demonstrates a lack of faulting.

Stratigraphic unit C is discontinuous and commonly completely removed by erosion during deposition of the overlying unit B. This forms a complex relationship and thus stratigraphic units C and D are not differentiated on the geologic map of the PVNGS Unit 3 excavation (figure 2D-5). Distinctive soils are differentiated, however, within the combined C/D stratigraphic unit. It should be noted that the stratigraphic units are generally similar from excavation to excavation but that the subdivisions (for example, A_1, A_2, etc.) do not represent directly correlative units. Detailed descriptions of subunits are given on figure 2D-5.

2D.4.2 STRATIGRAPHY

2D.4.2.1 Stratigraphic Unit A

Stratigraphic unit A is the uppermost stratigraphic unit exposed in the PVNGS Unit 3 excavation. This stratigraphic unit is generally about 10 feet thick. The unit has been subdivided into four soil units (figure 2D-5). Subunits A and A_1 are the most extensive.

Unit A_2 is a reddish brown to grayish, quartz and lithic sand exposed in the east wall of map areas 7 and 8. Unit A_3 is a caliche and clay unit exposed as small, scattered lenses generally between units A and A_1. Unit A is a silty sand, clayey and sandy silt, and silty and sandy clay which is distinguished from stratigraphic unit A_1, which is comprised of sands and gravel, by its grain size and color.

2D.4.2.2 Stratigraphic Unit B

Stratigraphic unit B is a sand and gravel unit which is distinguished primarily by its coarse grain size. The stratigraphic unit is subdivided into six subunits based on varying proportions of sand and gravel. Subunits B_1, B_2, and B_3 are generally finer than subunits B, B_4 and B_5. Subunits B and B_1 are the most pervasive. The contact between them is gradational.

Stratigraphic unit B is about 18 feet thick. Its upper contact with unit A is generally quite regular and distinct. The lower contact with stratigraphic unit CD is highly irregular with numerous erosional channels cut into the underlying unit.

2D.4.2.3 Stratigraphic Unit CD

Stratigraphic unit CD is comprised of seven subunits (figure 2D-5). The cumulative thickness is about 15 feet with subunit CD comprising at least 75% of the total thickness. Subunit CD is a reddish brown to yellowish brown, clayey gravelly sand, clayey sand, and sand. Gravel clasts reach diameters up to about 6 inches. The other subunits are generally finer grained and are very discontinuous both vertically and laterally. The upper contact with stratigraphic unit B is highly irregular, and as in PVNGS Units 1 and 2, is a result of extensive erosion of stratigraphic unit C and D. The lower contact with stratigraphic unit E is irregular but quite obvious due to the difference in grain size between the two stratigraphic units.

2D.4.2.4 Stratigraphic Unit E

Stratigraphic unit E is distinctive because of its fine grain size compared to other stratigraphic units exposed in the PVNGS Unit 3 excavation. This stratigraphic unit is mostly clay with a few scattered silts and sands. Four subunits are identified; subunits E and E_1 are the most extensive with subunits E_2 and E_3 occurring only as scattered lenses and pockets. Subunit E is a dark reddish brown to brown, silty clay to sandy clay. It is medium stiff to very stiff and has low to medium plasticity. Subunit E_1 is a grayish brown to reddish brown silty sand to sandy silt and clay.

APPENDIX 2E

LABORATORY TESTS

APPENDIX 2E

LABORATORY TESTS

An extensive laboratory testing program was undertaken at PVNGS to classify soils and to determine subsurface engineering parameters for stability, settlement, and liquefaction analyses. A summary of the purpose and approximate number of tests presented in both the Units 1, 2, and 3 PSAR and the Units 4 and 5 PSAR is shown in table 2E-1.

Permeability test results are summarized in Appendix 2G.

X-ray diffraction tests are presented in Appendix 2R of the Units 1, 2, and 3 PSAR. Moisture-density test results are presented on the boring logs, Appendix 2K, of both the PVNGS 1, 2, and 3 PSAR and the PVNGS 4 and 5 PSAR. With a few minor exceptions, all other laboratory testing on soil samples is presented in Appendix 2T of the two PSARs.

In addition to the testing summarized in this appendix, a large number of in-place density tests, grain size analyses, compaction tests, and other index tests are being performed in conjunction with construction activities at the site.

APPENDIX 2E

Table 2E-1

LABORATORY TEST SUMMARY

Test	Primary Purpose	Total Number
Moisture-density	Physical properties and classification	7275
Atterberg limits	Physical properties and classification	1410
Grain-size analyses	Physical properties and classification	2224
Specific gravity	Physical properties and classification	601
X-ray diffraction	Chemical properties	30
Compaction	Compaction characteristics	35
Minimum/maximum density	Relative density	11
Static triaxial compression	Static strength and elastic parameters	198
Direct shear	Static strength	56
Cyclic triaxial	Modulus and damping parameters; liquefaction potential	237
Resonant column	Modulus and damping parameters	167
Consolidation	Compressibility	82
Permeability	Permeability	258
Unconfined compression (rock)	Static strength and elastic parameters	5
Disk tensile strength (rock)	Static strength	2

APPENDIX 2F

SUMMARY OF SUBSURFACE EXPLORATION

APPENDIX 2F

SUMMARY OF SUBSURFACE EXPLORATION

This appendix presents a summary of borings drilled and trenches excavated at the PVNGS site. A total of approximately 578 borings and 3 trenches were drilled and excavated, respectively, at locations shown in figure 2.5-70. A tabulation of detailed information for each boring and trench, such as coordinates, elevation, boring type, depth, drilling method, sample type, and remarks is presented in table 2F-1. Unless otherwise specified in table 2F-1, boring logs are presented in Appendix 2K of the PVNGS 1, 2, and 3 and PVNGS 4 and 5 PSARs. The borings included in the Units 1, 2, and 3 PSAR have the following prefixes: PV-, U1-, U2-, U3-, and borings E-18-1 through E-18-6. Included in the Units 4 and 5 PSAR are borings with a U4- or U5- prefix.

Table 2F-1

DETAILS OF SUBSURFACE EXPLORATION PROGRAM (Sheet 1 of 12)

Explanation of Symbols Used:		
Boring Type:	P =	Principal, S = Supplementary
Drilling Type:	R =	Rotary wash, A = Flight auger
	BA =	Bucket auger
	BH =	Backhoe
Sample Type:	P =	Pitcher tube, D = Drive sample, SPT = Standard penetration test, B = Bulk, C = Core, HB = Hand-carved block sample, SH = Shelby tube
Remarks:	1 =	Supplementary boring to evaluate effects of drill method on SPT blowcount.
	2 =	Limited interval boring.
	3 =	Groundwater observation well being monitored on a regular schedule as of March 1979.
	4 =	Crosshole seismic survey boring.
	5 =	Pump test well.
	6 =	Boring used to obtain block samples for liquefaction testing.
	7 =	Coordinates estimated using nearby surveyed boring locations for reference.
	8 =	Borings for which logs are not presented due to lack of sampling; typically in an area where logs are presented for nearby sampled borings.
	9 =	Inflow-type borehole permeability test.
	10 =	Logs presented in Appendix 21 of Units 4 and 5 PSAR.

APPENDIX 2G

SUMMARY OF PERMEABILITY TESTING

2G.1 INTRODUCTION

The permeability characteristics of the soils underlying PVNGS have been evaluated by field and laboratory tests. The tests were performed for various purposes during several phases of geotechnical investigations at the site, and results were presented in several reports. This appendix summarizes all permeability test data related to the site and provides references to the documents where more detailed discussions of tests can be found.

2G.2 FIELD TESTS

The permeability of the site soils was investigated by both inflow and outflow type field permeability tests. Inflow type tests were conducted in accordance with Bureau of Reclamation Procedures E-18 and E-19 on both coarse- and fine-grained soils encountered in the upper 80 feet of the subsurface profile. Outflow type pumping tests were conducted to determine the permeability of both shallow perched water zone and the deeper, regional aquifer. Test locations are shown in figure 2G-1.

Field permeability test data from the upper coarse-grained unit, the middle fine-grained unit, and the lower coarse-grained unit are presented in tables 2G-1, 2G-2, and 2G-3, respectively.

2G.3 LABORATORY TESTS

Laboratory permeability tests were performed on undisturbed samples of mostly fine-grained soils from the site.

During the early siting studies, permeability tests were performed on undisturbed samples of soils representative of the entire subsurface profile of the site. The test specimens were enclosed in brass rings 1.5 inches in diameter and 1 inch high, and were tested under constant head conditions. Results of these tests, that measured both horizontal and vertical permeabilities, were presented in Appendix 2J of the PVNGS 1, 2, and 3 PSAR, and are also summarized in table 2G-4. Similar tests were performed during the preliminary geotechnical investigations for siting of the water storage reservoir and the evaporation ponds. Results of these tests are summarized in table 2G-5.

During more recent studies, related to the seepage analysis, permeability tests were performed on undisturbed samples representative of the upper 20 to 30 feet of the aquitard soils at the site. The test specimens were trimmed to 2.5 inches in diameter and 4 to 6 inches high and were enclosed in rubber membranes. The tests were conducted in triaxial test cells under confining pressures representative of in situ conditions. Results of these tests are summarized in table 2G-6.

APPENDIX 2G

Table 2G-1
SUMMARY OF FIELD PERMEABILITY TEST DATA[a]
UPPER COARSE-GRAINED UNIT

Individual Test Data			Integrated Test Data[b]	
Test No.	Elevation of Tested Interval (ft)	Permeability (cm/sec)	Elevation Range (ft)	Effective Horizontal Permeability (cm/sec)
E-19-1	944-939	1.3×10^{-3}		
E-19-2	937-932	1.2×10^{-3}	944-925	9.9×10^{-4}
E-19-3	930-925	4.3×10^{-4}		
E-19-11	949-935	4.9×10^{-5}	949-935	4.9×10^{-5}
E-19-12	945-930	5.2×10^{-4}	949-930	5.2×10^{-4}
Unit 2 Pump Test	913-873	1.2×10^{-4}	913-873	1.2×10^{-4}
Unit 3 Pump Test	908-898	7.0×10^{-3}	908-898	7.0×10^{-3}
E-19-14	929-914	6.6×10^{-4}	929-914	6.6×10^{-4}
E-19-13	922-909	5.5×10^{-4}		
Unit 5 Pump Test	909-892	1.0×10^{2}	922-892	5.9×10^{-3}

a. Detailed descriptions of these tests are provided in the following PSAR sections:

E-19 tests: PVNGS 1, 2 and 3 PSAR, Appendix 2AE
Unit 2 and 3 pump tests: PVNGS 1, 2 and 3 PSAR, Appendix 2I
Unit 5 pump test: PVNGS 4 and 5 PSAR, Appendix 2I

b. Where two or more tests were performed over different intervals at the same general location, the effective horizontal permeability was calculated over the entire interval tested.

Table 2G-3

SUMMARY OF AQUIFER PUMPING TEST DATA

LOWER COARSE GRAINED UNIT (REGIONAL AQUIFER) Test Location:
Irrigation well (B-1-6)34abb, near the construction water storage reservoir

Depth of Well	=	1413 feet
Aquifer Thickness	=	Approximately 1000 feet
Transmissivity	=	100,000 gallons per day per foot
Permeability	=	100 gallons per day per square foot ($5x10^{-3}$ centimeters per second)
Storage Coefficient	=	0.005

A detailed description of the test is provided in Appendix 2I, PVNGS 1, 2, and 3 PSAR.

3. DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT AND SYSTEMS

3.1 CONFORMANCE WITH NRC GENERAL DESIGN CRITERIA

Brief discussions are presented in this section in response to the current General Design Criteria for Nuclear Power Plants, Appendix A to 10CFR50. These discussions summarize the manner in which the principal design features comply with the various individual criteria and include references to sections of CESSAR that provide additional specific information for the nuclear steam supply system. PVNGS design is in compliance with the NRC General Design Criteria, unless specifically stated otherwise under individual criteria.

3.1.1 CRITERION 1 -- QUALITY STANDARDS AND RECORDS

Structures, systems, and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. Where generally recognized codes and standards are used, they shall be identified and evaluated to determine their applicability, adequacy, and sufficiency and shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. A quality assurance program shall be established and implemented in order to provide adequate assurance that these structures, systems, and components will satisfactorily perform their safety functions. Appropriate records of the design, fabrication, erection, and testing of structures, systems, and components important to safety shall be maintained by or under the control of the nuclear power unit licensee throughout the life of the unit.

RESPONSE:

The structures, systems, and components of the PVNGS are classified according to their importance in the prevention and mitigation of accidents using the classification system described in ANSI N18.2. Each safety-related component is given a safety class designation. The codes, standards, and quality control applicable to each component and its safety class designation are identified in section 3.2. Where applicable, design and fabrication are in accordance with the codes required in 10CFR50.55a. The quality assurance program, including record retention, conforms with the requirements of 10CFR50, Appendix B, Quality Assurance Criteria for Nuclear Power Plants, and is presented in chapter 17. Chapter 14 describes initial tests and operation to assure performance of installed equipment commensurate with the importance of the safety function. The component safety classifications also are shown on P&IDs presented within their appropriate sections.

3.1.2 CRITERION 2 -- DESIGN BASES FOR PROTECTION AGAINST NATURAL PHENOMENA

Structures, systems, and components important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without loss of capability to perform their safety functions. The design bases for these structures, systems, and components shall reflect: (1) appropriate consideration of the most severe of the natural phenomena that have been

historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated, (2) appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena, and (3) the importance of the safety functions to be performed.

RESPONSE:

Structures, systems, and components important to safety are designed to withstand the effects of earthquakes and tornadoes without loss of the capability to perform their safety functions.

The effects of tsunami and seiches are not considered because of the remote and elevated position of the site relative to any large body of water.

Sections 2.3, 2.4, and 2.5 give historical data on tornadoes, floods, and earthquakes, respectively. Effects of hurricanes are less than those of tornadoes and, therefore, are not treated. The data in sections 2.3, 2.4, and 2.5, in conjunction with a detailed site investigation, are used to predict the effects of the most severe natural phenomena incorporated in the design bases. Combinations of the effects of natural phenomena are described in sections 3.8, 3.9, and 3.10. The importance of safety functions being performed is identified by the classification system provided in section 3.2.

The design of safety related structures, systems and components is consistent with conservative structural envelopes. These "envelopes" have been selected based on the design bases earthquakes at the majority of potential plant sites in the continental U.S., using current containment structure designs.

In the design stage, normal operating and accident loads are appropriately combined with the seismic loads and allowable stress limits and deformations are defined so that safety functions are not jeopardized. Discussion of this material is found in section 3.7.

3.1.3 CRITERION 3 -- FIRE PROTECTION

Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat-resistant materials shall be used wherever practical throughout the unit, particularly in locations such as the containment and control room. Fire detection and firefighting systems of appropriate capacity and capability shall be provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Firefighting systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

RESPONSE:

Structures, systems, and components important to safety are designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Equipment and facilities for fire protection, including detection, alarm, and extinguishment, are provided to protect plant equipment and personnel from fire, explosion, and the resultant release of toxic vapors. Wet and dry types of firefighting equipment are provided.

Normal fire protection is provided by deluge systems, sprinklers, carbon dioxide, halon, and portable extinguishers.

Rupture or inadvertent operation of the firefighting systems will not impair systems important to safety.

High grade noncombustible and fire-resistant materials are used in the containment, control room, components of safety features systems, and throughout each unit wherever practical. A description of the fire protection system is presented in subsection 9.5.1.

3.1.4 CRITERION 4 -- ENVIRONMENTAL AND MISSILE DESIGN BASES

Structures, systems, and components important to safety shall be designed to accommodate the effects of, and to be compatible with, the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including loss-of-coolant accidents. These structures, systems, and components shall be appropriately protected against dynamic effects, including the effects of

missiles, pipe whipping, and discharging fluids, that may result from equipment failures and from events and conditions outside the nuclear power unit. However, the dynamic effects associated with postulated pipe ruptures of primary coolant loop piping in pressurized water reactors may be excluded from the design basis when analyses demonstrate the probability of rupturing such piping is extremely low under design basis conditions.

RESPONSE:

Structures, systems, and components important to safety are capable of withstanding the effects of, and are compatible with, the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including loss-of-coolant accidents (LOCA).

Environmental conditions associated with postulated accidents are pressure, temperature, humidity, radiation, and chemical attack. Environmental design of electric equipment is discussed in section 3.11. The criteria for combining the effects of accident conditions with conditions associated with normal operation, maintenance, and testing are given in sections 3.8, 3.9, and 3.10.

Design criteria based upon the dynamic effects of missiles, pipe whipping, and discharging fluids are treated in sections 3.5 and 3.6. Due to analysis submitted on the CESSAR docket, APS has excluded the dynamic effects associated with postulated pipe ruptures of primary coolant loop piping from the design basis. Events and conditions outside the nuclear

power unit that are considered in the design of structures, systems, and components important to safety are tornadoes, floods, and earthquakes. The bases of the design criteria for these events are presented in sections 3.3, 3.4, and 3.7.

C-E supplied structures, systems and components important to safety are designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing and postulated accidents, including loss of coolant accidents, (see section 3.11). The Ansaldo supplied steam generators are also designed as stated above.

Interface requirements are invoked to ensure that these structures, systems and components will be appropriately protected against dynamic effects (including the effects of missiles, pipe whipping, and discharge of fluids) that may result from equipment failures, postulated accidents, and from events and conditions outside the nuclear power unit.

3.1.5 CRITERION 5 -- SHARING OF STRUCTURES, SYSTEMS, AND COMPONENTS

Structures, systems, and components important to safety shall not be shared among nuclear power units unless it can be shown that such sharing will not significantly impair their ability to perform their safety functions, including, in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units.

RESPONSE:

Separate systems important to safety are provided for each unit. The Station Blackout Gas Turbine Generation (SBOG) System is shared between units. The SBOG system provides AC electrical power of sufficient capacity and reliability to operate the systems required for coping with a station blackout in any one of the units for a period of 16 hours. Some nonsafety-related systems and components are directly shared by PVNGS Units 1, 2, and 3. These systems are as follows:

A. Water Treatment Systems

Various water treatment systems are shared. These systems include:

1. Domestic water system
2. Demineralized water system
3. Sanitary treatment system
4. Water reclamation plant
5. Secondary chemistry system

Details of these systems are presented in sections 9.2 and 10.4.

B. Switchyard

A common switchyard is provided for PVNGS Units 1, 2, and 3. This complies with General Design Criterion 17. Details of the offsite power system are discussed in section 8.2.

C. Fire Protection System

The fire protection water supply and pumping equipment is shared by Units 1, 2, and 3. The plant two-way radio system is one of the communications means available for coordinating fire response team activities and safe shutdown activities. The plant two-way radio system is shared among all three units. Other fire protection equipment is provided for each unit individually.

3.1.6 CRITERION 10 -- REACTOR DESIGN

The reactor core and associated coolant, control and protection systems shall be designed with appropriate margin to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.

RESPONSE:

Specified acceptable fuel design limits are stated in section 4.4.1. Operation within the operating limits (Limiting Conditions for Operations) specified by the Technical Specifications will keep the reactor fuel within the specified acceptable fuel design limits for normal operation and during any moderate frequency event. In accordance with Regulatory Guide 1.70, Revision 2 moderate frequency events have been selected and analysis of the most limiting of these is presented in Chapter 15. Section 15.0.1 presents all of the events considered and categorized by type and expected

frequency. Events were categorized as moderate or infrequent based on PWR operating history data.

The plant is designed such that operation within Limiting Conditions for Operation, with safety system settings not less conservative than the Limiting Safety System Settings prescribed in the Technical Specifications results in confidence that specified acceptable fuel design limits will not be exceeded as a result of any initiating event of moderate frequency. Operator action, aided by the control systems and monitored by plant instrumentation, maintains the plant within Limiting Conditions for Operation during normal operation.

For further discussion see the following sections: Classification of Transients and Accidents, section 15.0.1; Fuel System Design, section 4.2; Reactor Coolant Systems, Chapter 5; Residual Heat Removal, section 5.4.7; Reactor Protective System, section 7.2; and Technical Specifications.

3.1.7 CRITERION 11 -- REACTOR INHERENT PROTECTION

The reactor core and associated coolant systems shall be designed so that in the power operating range the net effect of the prompt inherent nuclear feedback characteristics tends to compensate for a rapid increase in reactivity.

RESPONSE:

In the power operating range, the combined response of the fuel temperature coefficient, the moderator temperature coefficient, the moderator void coefficient, and the moderator

pressure coefficient to an increase in reactor power in the power operating range will be a decrease in reactivity; i.e., the inherent nuclear feedback characteristics will not be positive.

The reactivity coefficients for this reactor are discussed in detail in section 4.3.

3.1.8 CRITERION 12 -- SUPPRESSION OF REACTOR POWER OSCILLATIONS

The reactor core and associated coolant, control, and protection system shall be designed to assure that power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

RESPONSE:

Power level oscillations do not occur. The effect of the negative power coefficient of reactivity (see Criterion 11), together with the coolant temperature program maintained by control of regulating rods and soluble boron, provides fundamental mode stability. Power level is continuously monitored by neutron flux detectors (Chapter 7).

Power distribution oscillations are detected by neutron flux detectors.

Axial mode oscillations are suppressed by means of part strength or full strength neutron absorber rods. All other modes of oscillation are expected to be convergent.

Monitoring and protective requirements imposed by Criteria 10 and 20 are discussed in those responses and in Chapter 4.

3.1.9 CRITERION 13 -- INSTRUMENTATION AND CONTROL

Instrumentation and control shall be provided to monitor variables and systems over their anticipated ranges for normal operation, for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety, including those variables and systems that can affect the fission process, the integrity of the reactor core, the reactor coolant pressure boundary, and the containment and its associated systems. Appropriate controls shall be provided to maintain these variables and systems within prescribed operating ranges.

RESPONSE:

Instrumentation and control systems are provided for the containment and its associated systems to ensure adequate safety under all conditions.

Instrumentation is provided to monitor significant process variables which can affect the fission process, the integrity of the reactor core, the Reactor Coolant Pressure Boundary (RCPB) and their associated systems. Controls are provided for the purpose of maintaining these variables within the limits prescribed for safe operation. The principal process variables to be monitored and controlled are: neutron flux level (reactor power); CEA positions; neutron flux distribution (at various axial positions); reactor coolant

temperature and pressure; reactor pump speed; pressurizer level; and steam generator level and pressure. In addition, Departure from Nucleate Boiling Ratio (DNBR) margin and Local Power Density (LPD) margin, in Kw/ft, are also monitored.

The Plant Protection System (PPS) consists of the Reactor Protective System (RPS) and the Engineered Safety Features Actuation System (ESFAS). The RPS is designed to monitor NSSS operating conditions and to initiate reliable and rapid reactor shutdown if monitored variables or combinations of monitored variables deviate from the permissible operating range to a degree that a safety limit may be reached.

The ESFAS is designed to monitor plant variables and to initiate Engineered Safety Feature (ESF) Systems during a design basis event.

The following are provided to monitor and maintain control over the fission process during transient and steady state periods over the lifetime of the core:

A. Eight independent channels of ex-core nuclear instrumentation, which constitutes the primary monitor of the fission process,

   1. Four safety channels for PPS input,

   2. Two control channels for the reactor control,

   3. Two startup channels for low power operation;

B. Three independent CEA Position Indicating Systems for each CEA,

1. Two independent Reed Switch Position Transmitter (RSPT) assemblies for PPS input,

2. A Pulse Counting System within the Plant Monitoring System;

C. Manual and automatic control of reactor power by means of CEAs;

D. Manual regulation of coolant boron concentration;

E. In-core instrumentation is provided to supplement information on core power distribution and to provide a means for calibration of ex-core flux detectors.

The non-nuclear instrumentation measures temperatures; pressures, flows and levels in the Reactor Coolant System and main steam and auxiliary systems and is used to maintain these variables within the prescribed limits. The instrumentation and control systems are described in detail in Chapter 7.0. The process radiation monitor is discussed in Chapter 9. When it is required that a variable be monitored during a Design Basis Event (DBE), in addition to normal operation, the results of analysis of the course of the event are used to ensure that the instruments provided will cover the range anticipated for the event conditions.

Instrumentation and control systems are described in detail in chapter 7.

3.1.10 CRITERION 14 -- REACTOR COOLANT PRESSURE BOUNDARY

The reactor coolant pressure boundary shall be designed, fabricated, erected, and tested so as to have an extremely low probability of abnormal leakage, of rapidly propagating failure, and of gross rupture.

RESPONSE:

The reactor coolant pressure boundary is defined in accordance with 10CFR50, Section 50.2(v) and ANSI N18.2, (see response to GDC-55).

Reactor Coolant System components are designed to meet the requirements of the ASME Code, Section III. To establish operating pressure and temperature limitations during startup and shutdown of the Reactor Coolant System, the fracture toughness rules defined in the ASME Code, Section III, are followed. Quality control, inspection, and testing are performed as required by ASME Section III and allowable reactor pressure-temperature operations are specified to ensure the integrity of the Reactor Coolant System.

The reactor coolant pressure boundary is designed to accommodate the system pressures and temperatures attained under all expected modes of unit operation including all anticipated transients, and maintain the stresses within applicable limits.

Piping and equipment pressure parts of the reactor coolant pressure boundary are assembled and erected by welding unless applicable codes permit flanged or screwed joints. Welding procedures are employed which produce welds of complete fusion

and free of unacceptable defects. All welding procedures, welders, and welding machine operators are qualified in accordance with the requirements of Section IX of the ASME Boiler and Pressure Vessel Code for the materials to be welded. Qualification records, including the results of the procedure and performance qualification tests and identification symbols assigned to each welder; are maintained.

The pressure boundary has provisions for inservice inspection in accordance with Section XI of the ASME Boiler and Pressure Vessel Code, to ensure continuance of the structural and leaktight integrity of the boundary (see response to GDC No. 32, also). For the reactor vessel, a material surveillance program conforming with the requirements of Appendix H to 10CFR Part 50 is provided.

3.1.11 CRITERION 15 -- REACTOR COOLANT SYSTEM DESIGN

The reactor coolant system and associated auxiliary, control, and protection systems shall be designed with sufficient margin to assure that the design conditions of the reactor coolant pressure boundary are not exceeded during any condition of normal operation, including anticipated operational occurrences.

RESPONSE:

The design criteria and bases for the reactor coolant pressure boundary are described in the response to Criterion 14.

The operating conditions for normal steady state and transient plant operations are established conservatively. Normal operating limits are selected so that an adequate margin exists between them and the design limits. The plant control systems are designed to ensure that plant variables are maintained well within the established operating limits. The plant transient response characteristics and pressure and temperature distributions during normal operations are considered in the design as well as the accuracy and response of the instruments and controls. These design techniques ensure that a satisfactory margin is maintained between the plant's normal operating conditions, including design transients, and the design limits for the reactor coolant pressure boundary.

Plant Control Systems function to minimize the deviations from normal operating limits in the event of most anticipated operational occurrences. Where control systems response would be inadequate or fail upon demand, the Plant Protection System functions to mitigate the consequences of such events.

The Plant Protection System functions to mitigate the consequences in the event of accidents. Analyses show that the design limits for the reactor coolant pressure boundary are not exceeded in the event of any ANSI N18.2 Conditions.

3.1.12 CRITERION 16 -- CONTAINMENT DESIGN

Reactor containment and associated systems shall be provided to establish an essentially leaktight barrier against the uncontrolled release of radioactivity to the environment and

to ensure the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

RESPONSE:

A steel-lined, prestressed, post-tensioned concrete containment encloses the entire RCPB. It is designed to sustain, without loss of required integrity, all effects of equipment failures up to and including the double-ended rupture of the largest pipe in the RCPB. In the event of a LOCA, the safety injection system (SIS) and containment spray system (CSS) are actuated, cool the reactor core, and return the containment to near atmospheric pressure. The containment, SIS, CSS, and containment isolation system ensure the functional capability of containing any uncontrolled release of radioactivity. Refer to sections 3.8 and 6.2 for details. Primary containment isolation is discussed in the response to General Design Criterion 56.

3.1.13 CRITERION 17 -- ELECTRICAL POWER SYSTEMS

An onsite electrical power system shall be provided to permit functioning of structures, systems, and components important to safety. The safety function for each system (assuming the other system is not functioning) shall be to provide sufficient capacity and capability to assure that: (1) specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences, and (2) the

core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

The onsite electrical power sources, including the batteries, and the onsite electric distribution system shall have sufficient independence, redundancy, and testability to perform their safety functions assuming a single failure.

Electric power from the transmission network to the onsite electric distribution system shall be supplied by two physically independent circuits (not necessarily on separate rights of way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions. A switchyard common to both circuits is acceptable. Each of these circuits shall be designed to be available in sufficient time following a loss of all onsite alternating current power supplies and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of these circuits shall be designed to be available within a few seconds following a LOCA to assure that core cooling, containment integrity, and other vital safety functions are maintained.

Provisions shall be included to minimize the probability of losing electric power from any of the remaining sources as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the

transmission network, or the loss of power from the onsite electric power sources.

RESPONSE:

For each nuclear power unit of PVNGS, an onsite electric power system and an offsite electric power system provide power for electric loads important to safety. Two completely independent and redundant electric load groups important to safety are provided for each unit. Each load group has sufficient capability, independent of the other load group for the same unit, to ensure that:

A. Specified acceptable fuel design limits and design conditions of the RCPB are not exceeded as a result of anticipated operational occurrences.

B. The core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

Each redundant load group is provided with two offsite (preferred) electric power supplies, an onsite diesel generator (standby) power supply, and two sets of batteries (subject to the limitations of power system development, paragraph 8.2.1.2.1). In addition, Station Blackout Generators (SBOGs) supply power to one of the safety related 4.16kV busses as discussed in section 8.3.1.1.10. These provide sufficient independence, redundancy, and testability to perform their safety functions, assuming a single failure.

Eight physically independent circuits on four separate rights-of-way provide electric power from the transmission network to

the Palo Verde 525kV switchyard which, in turn, supplies offsite (preferred) power to the onsite power system. Design of the offsite power system minimizes the possibility that failure of any one circuit will cause the failure of any other circuit. For each nuclear power unit, two physically independent, full-capacity electric power circuits supply offsite (preferred) power to the onsite power system. Each circuit is available following a postulated LOCA to ensure that core cooling, containment integrity, and other vital safety functions are maintained.

Provisions are included to minimize the probability of losing electric power from any of the remaining sources as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite diesel generator. Electric system stability studies indicate that major disturbances on one circuit of the transmission network will not cause loss of the transmission network circuits supplying off-site electric power to the units. Furthermore, separation of the transmission lines is such that physical failure of any transmission line or tower will not compromise the performance of adjacent transmission lines (a failure of the Mead-Perkins transmission line could affect both West-Wing transmission lines). A fault on any preferred power source circuit supplying offsite electric power to the units will be cleared automatically to prevent loss of other offsite preferred power sources.

In addition to its two offsite (preferred) electric power supplies, each redundant load group is supplied by an emergency diesel generator. The diesel generator is capable of providing the total load requirements for a safe shutdown of the unit, or for the engineered safety features, following a LOCA or other postulated accidents.

The inherent design of the onsite power system prevents automatic paralleling of the two redundant load groups for each unit, the paralleling of the two diesel generators for each unit, or the automatic paralleling of any diesel generator with any of the offsite (preferred) power supplies. The electric power system is described in chapter 8.

3.1.14 CRITERION 18 -- INSPECTION AND TESTING OF ELECTRICAL POWER SYSTEMS

Electric power systems important to safety shall be designed to permit appropriate periodic inspection and testing of important areas and features, such as wiring, insulation, connections, and switchboards, to assess the continuity of the systems and the condition of their components. The systems shall be designed with a capability to test periodically: (1) the operability and functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses; and (2) the operability of the systems as a whole and, under conditions as close to design as practical, the full operation sequence that brings the systems into operation, including operation of applicable portions of the protection system, and the transfer of power among the

nuclear power units, the offsite power system, and the onsite power system.

RESPONSE:

Inspection and testing of the station service transformers, high voltage switchyard circuit breakers, and transformer and transmission line protective relaying are done on a routine basis without removal of the transformers, circuit breakers, and transmission lines from service. The transformer insulating oil is sampled and tested for dielectric strength on a routine basis. Drawout type protective relays with built-in test switches facilitate testing of protective devices and circuits without removal from service of the protected transformers, circuit breakers, and transmission lines.

Functional performance and operability of the preferred ac power system and components are inspected and tested on a routine basis in conformance with requirements of General Design Criterion 18. The electric power system is discussed in chapter 8.

3.1.15 CRITERION 19 -- CONTROL ROOM

A control room shall be provided from which actions can be taken to operate the nuclear power unit safely under normal conditions and to maintain it in a safe condition under accident conditions, including LOCAs. Adequate radiation protection shall be provided to permit access and occupancy of the control room under accident conditions without personnel

receiving radiation exposures in excess of 5 rem whole body, or its equivalent to any part of the body, for the duration of the accident.

Equipment at appropriate locations outside the control room shall be provided: (1) with a design capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown, and (2) with a potential capability for subsequent cold shutdown of the reactor through the use of suitable procedures.

RESPONSE:

The units are designed to provide safe occupancy of the control room during abnormal conditions. The control room is in a Seismic Category I structure. Under accident conditions, sufficient shielding and ventilation are provided to permit occupancy of the control room continuously for 30 days without receiving more than 5 rem whole body, or its equivalent, to any part of the body. The shielding is described in subsections 12.1.2 and 12.3.2. Habitability and ventilation is discussed in section 6.4 and subsection 12.3.3.

In the unlikely event that the control room should become inaccessible, sufficient instrumentation and controls are provided outside the control room to:

- Achieve prompt hot shutdown of the reactor
- Maintain the unit in a safe condition during hot shutdown

- Achieve cold shutdown of the reactor through the use of suitable procedures

Refer to subsection 7.4.1 for details on the instrumentation and controls provided outside the control room.

3.1.16 CRITERION 20 -- PROTECTION SYSTEM FUNCTIONS

The protection system shall be designed (1) to initiate automatically the operation of appropriate systems including the reactivity control systems, to assure that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences and (2) to sense accident conditions and to initiate the operation of systems and components important to safety.

RESPONSE:

A Plant Protection System (PPS), consisting of a Reactor Protective System (RPS) and an Engineered Safety Features Actuation Systems (ESFAS) is provided. The RPS automatically initiates a reactor trip when the monitored variable or combination of variables reaches a trip function setpoint. The ESFAS automatically actuates Engineered Safety Features (ESF) and their support systems when the monitored variable or variables reach a predetermined setpoint.

The trip function setpoints of the RPS are selected to ensure that Design Basis Events which are expected to occur once or more during the life of the nuclear generating station, which credit the RPS, do not cause Specified Acceptable Fuel Design Limits (SAFDL), peak fuel centerline temperature and minimum

Departure from Nucleate Boiling Ratio (DNBR), to be violated. The reactor trips also help the ESF Systems in mitigating the consequences of Design Basis Events, which are expected to occur once during the life of several plants and arbitrary combinations of unplanned events and degraded systems that are never expected to occur, to within acceptable limits. Reactor trip is accomplished by de-energizing the Control Element Drive Mechanism (CEDM) coils through the interruption of the CEDM power supply either automatically or manually. The CEDM power supply is a pair of full capacity motor-generator sets. The path to the CEDMs is interrupted by opening the Reactor Trip Switchgear. With the CEDM coils de-energized, the CEAs are released to drop into the core by gravity, rapidly inserting negative reactivity to shutdown the reactor. The CEDMs are described in section 4.2, the specific reactor trips used are described in section 7.2.

The ESF Systems are actuated to minimize the effects of incidents which could occur. Controls are provided for manual actuation of the ESF System. The variables which automatically actuate the ESF System and the circuitry arrangements for the ESFAS are discussed in section 7.3, the ESF Systems are discussed in Chapter 6.0.

The SAFDL on peak fuel centerline temperature and DNBR are intended to enforce the principal thermal hydraulic design basis given in section 4.4.1 i.e., the avoidance of thermally induced fuel damage during normal steady state operation and during moderate frequency DBEs. The thermal hydraulic design limits are a minimum DNBR and a maximum fuel temperature as

described in Technical Specification Sections 2.1.1.1 and 2.1.1.2 and their associated Bases.

The SAFDL on fuel centerline temperature is specifically intended to prevent fuel melting.

3.1.17 CRITERION 21 -- PROTECTION SYSTEM RELIABILITY AND TESTABILITY

The protection system shall be designed for high functional reliability and inservice testability commensurate with the safety functions to be performed. Redundancy and independence designed into the protection system shall be sufficient to assure that (1) no single failure results in loss of the protection function and (2) removal from service of any component or channel does not result in loss of the required minimum redundancy unless the acceptable reliability of operation of the protection system can be otherwise demonstrated. The protection system shall be designed to permit periodic testing of its functioning when the reactor is in operation, including a capability to test channels independently to determine failures and losses of redundancy that may have occurred.

RESPONSE:

The PPS is designed to provide high functional reliability and inservice testability. The protection system is designed to comply with the requirements of IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations." No credible single failure will result in the loss of the

protection function. The protection channels are independent e.g., with respect to wire routing, sensor mounting and supply of power. Each channel of the protection system, including the sensors, up to the RTSS and ESFAS actuation devices, is capable of being checked during reactor operation. Measurement sensors of each channel used in the protection systems are checked by comparison of outputs of similar channels which are presented on indicators or recorders in the main control room, or which can be called up from the Remote Operators Modules of the DNBR/LPD Calculator Systems.

Trip channels and logic are tested by inserting a signal into the measurement channel ahead of the trip bistable and, upon application of a trip level input, observing that a signal is passed through the trip channels and the logic to the logic output relays. The logic output relays are tested individually for initiation of trip action. The parallel reactor trip circuit breakers which control power to the CEDM coils may be tested during reactor operation without effecting a reactor trip.

The ESFAS test circuitry in the PPS cabinet is identical to that of the RPS. This logic supplies initiation signals to the actuation logic contained in the ESFAS Auxiliary Relay Cabinets. The circuitry in the ESFAS Auxiliary Relay Cabinets operates the actuation relays for the various ESF Systems, these are tested so as not to actuate any components that could interfere with safe plant operation. ESFAS is discussed in detail in section 7.3.

To minimize inadvertent actuation of an ESF System or an inadvertent reactor trip, the protection systems require coincidence of two logic to operate. In addition, the channel being tested is bypassed so that the protection system converts to a two out of three logic while maintaining the coincidence of two. This allows periodic testing and operation of the various protective functions without reducing the availability of the protection systems.

3.1.18 CRITERION 22 -- PROTECTION SYSTEM INDEPENDENCE

The protection system shall be designed to assure that the effects of natural phenomena, and of normal operating, maintenance, testing and postulated accident conditions on redundant channels do not result in loss of the protection function or shall be demonstrated to be acceptable on some other defined basis. Design techniques, such as functional diversity or diversity in component design and principles of operation, shall be used to the extent practical to prevent loss of the protection function.

RESPONSE:

The protection systems conform to the independence requirements of IEEE 279-1971. Four independent measurement channels, complete with sensors, sensor power supplies, signal conditioning units, and bistable trip channels are provided for each protective parameter monitored by the protection systems except for the CEA position sensors which are two-fold redundant. The measurement channels are provided with a high degree of independence by separate connection of the channel

sensors to the process systems. Refer to Chapter 7.0 for a more detailed discussion of the protection systems.

Power to the protection systems' channels is provided by independent vital power supply busses. The power supply systems are discussed in Chapter 8.0. Interface requirements of the protection systems on the power supply systems are discussed in Chapter 8.0.

Functional diversity has been incorporated into the system design to the extent that is practical, to prevent the loss of the protective function. Whenever an RPS trip function is required, it is frequently backed up by other trip functions. The ESFAS actuation signals are used to actuate two independent ESF trains. Where it is practical, and ESFAS can be generated by more than one parameter.

The design goals are accomplished without excessive complexity by using only four channels for each parameter. This allows for testing and maintenance of a channel without reducing the system to a single channel for trip, which would make the system susceptible to spurious trip or actuation signals.

The protection systems are each functionally tested to ensure satisfactory operation prior to installation in the plant. Environmental and seismic qualifications are also performed utilizing type tests, specific equipment tests, appropriate analyses, or prior operating experience. For further information, refer to section 3.10 and 3.11.

3.1.19 CRITERION 23 -- PROTECTION SYSTEM FAILURE MODES

The protection system shall be designed to fail into a safe state or into a state demonstrated to be acceptable on some other defined basis if conditions such as disconnection of the system, loss of energy (e.g., electric power, instrument air) or postulated adverse environments (e.g., extreme heat or cold, fire, pressure, steam, water, and radiation) are experienced.

RESPONSE:

Protection system trip channels have been designed to fail into a safe state or into a state established as acceptable in the event of loss of power supply. A failure is assumed to occur in only one channel (i.e., a single failure). This channel can be placed into bypass which places the RPS and/or ESFAS into a two-out-of-three logic which retains the coincidence of two for trip. Refer to sections 7.2 and 7.3 for detailed Failure Modes and Effects Analysis information.

A loss of power to CEDM coils will cause the CEAs to insert into the core. Redundance, channel independence and separation are incorporated into the protection systems' design to minimize the possibility of the loss of a protective function. The loss of off-site power will cause the standby generators to start and energize the ESF trains which have actuation signals present.

3.1.20 CRITERION 24 -- SEPARATION OF PROTECTION AND CONTROL SYSTEMS

The protection system shall be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel which is common to the control and protection systems leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. Interconnection of the protection and control systems shall be limited so as to assure that safety is not significantly impaired.

RESPONSE:

Protection system components and control system components are electrically and functionally isolated from each other. See section 7.2 and 7.3 for details.

The protection systems are designed so that they can sustain one channel in a tripped condition and one channel bypassed indefinitely and still provide their safety actions.

3.1.21 CRITERION 25 -- PROTECTION SYSTEM REQUIREMENTS FOR REACTIVITY CONTROL MALFUNCTIONS

The protection system shall be designed to assure that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems such as accidental withdrawal (not ejection or dropout) of control rods.

RESPONSE:

Shutdown of the reactor is accomplished by the opening of the RTSS circuit breakers which interrupts power to the CEDM coils. Actuation of the circuit breakers is independent of any existing control signals.

The protection systems are designed such that SAFDL are not exceeded for any single malfunction of the reactivity control systems, including the withdrawal of a single full- or part-strength CEA. Analysis of possible reactivity control system malfunctions are discussed in Chapter 15.0. The various CEA related DBE's for which the protection systems are designed are discussed in section 7.2.

3.1.22 CRITERION 26 -- REACTIVITY CONTROL SYSTEM REDUNDANCY AND CAPABILITY

Two independent reactivity control systems of different design principles shall be provided. One of the systems shall use control rods, preferably including a positive means for inserting the rods, and shall be capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences, and with appropriate margin for malfunctions such as stuck rods, specified acceptable fuel design limits are not exceeded. The second reactivity control system shall be capable of reliably controlling the rate of reactivity changes resulting from planned, normal power changes (including xenon burnout) to assure acceptable fuel design limits are not exceeded. One of the systems shall be capable of holding the

reactor core subcritical under cold conditions. For further discussion, see section 7.4, Systems Required For Safe Shutdown and section 7.7, Control Systems Not Required for Safety.

RESPONSE:

Two independent reactivity control systems of different design principles are provided. The first system, using Control Element Assemblies (CEAs), includes a positive means (gravity) for inserting CEAs and is capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences, specified acceptable fuel design limits are not exceeded. The CEAs can be mechanically driven into the core. The appropriate margin for stuck rods is provided by assuming in the analyses of anticipated operational occurrences that the highest worth CEA does not fall into the core.

The second system, using neutron absorbing soluble boron, is capable of reliably compensating for the rate of reactivity changes resulting from planned normal power changes (including xenon burnout) such that acceptable fuel design limits are not exceeded. This system is capable of holding the reactor subcritical under cold conditions.

Either system is capable of making the core subcritical from a hot operating condition and holding it subcritical in the hot standby condition.

Either system is able to insert negative reactivity at a rate sufficient to prevent exceeding acceptable fuel design limits

as the result of a power change (i.e., the positive reactivity added by burnup of xenon).

3.1.23 CRITERION 27 -- COMBINED REACTIVITY CONTROL SYSTEMS CAPABILITY

The reactivity control systems shall be designed to have a combined capability, in conjunction with poison addition by the emergency core cooling system, of reliably controlling reactivity changes to assure that under postulated accident conditions and with appropriate margin for stuck rods the capability to cool the core is maintained.

RESPONSE:

Dissolved boron addition capability provided by the Safety Injection System (Chapter 6.0) in consideration with the control rod (CEA) system will be such that under postulated accident conditions (Chapter 15.0), even with the CEA of highest worth stuck out of the core, adequate reactivity control is available to maintain short and long term capability to cool the core.

3.1.24 CRITERION 28 -- REACTIVITY LIMITS

The reactivity control systems shall be designed with appropriate limits on the potential amount and rate of reactivity increase to assure that the effects of postulated reactivity accidents can neither (1) result in damage to the reactor coolant pressure boundary greater than limited local yielding nor (2) sufficiently disturb the core, its support

structures or other reactor pressure vessel internals to impair significantly the capability to cool the core. These postulated reactivity accidents shall include consideration of rod ejection (unless prevented by positive means) rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition.

RESPONSE:

The bases for control element assembly (CEA) design include ensuring that the reactivity worth of any one CEA is not greater than a preselected maximum value. The CEAs are divided into two sets, a shutdown set and a regulating set, further subdivided into groups as necessary. Administrative procedures and interlocks assure that only one group is withdrawn at a time, and that the regulating groups are withdrawn only after the shutdown groups are fully withdrawn. The regulating groups are programmed to move in sequence and within limits which prevent the rate of reactivity addition and the worth of individual CEAs from exceeding limiting values.

The maximum rate of reactivity addition which may be produced by the Chemical and Volume Control System is too low to induce any significant pressure forces which might rupture the reactor coolant pressure boundary or disturb the reactor vessel internals.

The reactor coolant pressure boundary (Chapter 5.0) and the reactor internals (Chapter 4.0) are designed to appropriate codes (refer for instance, to the response to Criterion 14)

and will accommodate the static and dynamic loads associated with an inadvertent, sudden release of energy, such as that resulting from a CEA ejection or steam line break (Chapter 15.0), without rupture and with limited deformation which will not impair the capability of cooling the core.

3.1.25 CRITERION 29 -- PROTECTION AGAINST ANTICIPATED OPERATIONAL OCCURRENCES

The protection and reactivity control systems shall be designed to assure an extremely high probability of accomplishing their safety functions in the event of anticipated operational occurrences.

RESPONSE:

Plant events, designated in ANSI N18.2, "Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants", have been carefully considered in the design of the protection systems and the reactivity control systems. Consideration of redundancy, independence and testability in the design, coupled with careful component selection, overall system testing, and adherence to detailed quality assurance, assure an extremely high probability that safety functions are accomplished in the event of Design Basis Events.

Detailed discussions of the protection systems are provided in Chapter 7.0. Design quality assurance is discussed in Combustion Engineering Topical Report CENPD 210A, "Discussion of the C-E Nuclear Steam Supply System Quality Assurance

Program" (Reference 1) and Chapter 17. The analysis of DBE is contained in Chapter 15.0.

3.1.26 CRITERION 30 -- QUALITY OF REACTOR COOLANT PRESSURE BOUNDARY

Components which are part of the reactor coolant pressure boundary shall be designed, fabricated, erected, and tested to the highest quality standards practical. Means shall be provided for detecting and, to the extent practicable, identifying the location of the source of reactor coolant leakage.

RESPONSE:

The reactor coolant pressure boundary components will be designed, fabricated, erected and tested in accordance with the ASME Code Section III. All components are classified Safety Class 1 or 2, in accordance with the ANSI N18.2, "Nuclear Safety Criteria for the Design of Stationary PWR Plants," definitions for Safety Classes and reactor coolant pressure boundary. Accordingly, they receive all of the quality measures appropriate to that classification.

Means are provided by C-E, or required to be provided by the applicant's, for the identification of the source of reactor coolant leakage. These include the detection of leakage to systems connected to the reactor coolant pressure boundary as well as leakage from the boundary into the containment.

C-E provides instrumentation to indicate and record makeup flow rate and integrated makeup flow to the primary water

system. This instrumentation permits detection of suddenly occurring leaks and those which are gradually increasing. Additional means for detecting leakage into the containment is required to be provided. Refer to section 5.2.5.

3.1.27 CRITERION 31 -- FRACTURE PREVENTION OF REACTOR COOLANT PRESSURE BOUNDARY

The reactor coolant pressure boundary shall be designed with sufficient margin to assure that when stressed under operating, maintenance, testing, and postulated accident conditions: (1) the boundary behaves in a nonbrittle manner; and (2) The probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the boundary material under operating, maintenance, testing, and postulated accident conditions and the uncertainties in determining: (1) Material properties; (2) The effects of irradiation on material properties: (3) Residual, steady state, and transient stresses; and (4) Size of flaws.

RESPONSE:

All the reactor coolant pressure boundary components are designed and constructed in accordance with ASME Section III and comply with the test and inspection requirements of these codes. The test and inspection requirements assure that flow sizes are limited so that the probability of failure by rapid propagation is extremely remote. Particular emphasis is placed on the quality control applied to the reactor vessel on which tests and inspections exceeding ASME code requirements

are performed. The tests and inspections performed on the reactor vessel are summarized in section 5.3.

Carbon and low alloy steel materials which form part of the pressure boundary are tested in accordance with the requirements of the fracture toughness requirements for materials, ASME Code Section III. Nonductile failure prevention will be ensured by utilizing the appropriate sections of the ASME Code.

Excessive embrittlement of the reactor vessel material due to neutron radiation is prevented by providing an annulus of coolant water between the reactor core and the vessel. In addition, to minimize the effects of irradiation on material toughness properties of core beltline materials, restrictions on upper limits for residual elements that directly influence the NDT shift are required by the design specification for the plates and deposited welds. Specifically, upper limits are placed on copper, phosphorous, sulfur, and vanadium.

The maximum integrated fast neutron flux exposure of the reactor vessel wall opposite the midplane of the reactor core is estimated to be less than 3.29E+19 neutrons per square centimeter for a 40-year lifetime. This estimate is confirmed periodically during plant lifetime by a material surveillance program. The maximum expected increase in transition temperature is about 140°F. The actual change in material toughness properties due to irradiation will be verified periodically during plant lifetime by a material surveillance

program. Based on the RT_{NDT}, operating restrictions will be applied as necessary to limit vessel stresses.

The thermal stresses induced by the injection of cold water into the vessel, following a LOCA, have been examined. The test results and analysis have shown that there is no gross yielding across the vessel wall when using the minimum specified yield strength in the ASME Boiler and Pressure Vessel Code, Section III.

3.1.28 CRITERION 32 -- INSPECTION OF REACTOR COOLANT PRESSURE BOUNDARY

Components which are part of the reactor coolant pressure boundary shall be designed to permit:

(1) Periodic inspection and testing of important areas and features to assess their structural and leak-tight integrity; and

(2) An appropriate material surveillance program for the reactor pressure vessel.

RESPONSE:

Provisions have been made in the design for inspection, testing, and surveillance of the Reactor Coolant System boundary as required by ASME Boiler and Pressure Vessel Code Section XI. The Applicant is required to install the system so that the required inservice inspections per Section XI can be performed. C-E recommends a reactor vessel surveillance program to the owner.

The reactor vessel surveillance program capability provided to the Applicant conforms with ASTM-E-185, "Standard Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels", as revised in 1979 for Unit 1 and 1982 for Unit 2 & 3. Sample pieces taken from the same shell plate material used in fabrication of the reactor vessel are installed between the core and the vessel inside wall. These samples will be removed and tested by the Applicant at intervals during vessel life to provide an indication of the extent of the neutron embrittlement of the vessel wall. Charpy tests will be performed on the samples to develop a Charpy transition curve. By comparison of this curve with the Charpy curve and drop weight tests for specimens taken at the beginning of the vessel life, the change of RT_{NDT} will be determined and operating procedures adjusted as required.

The surveillance program capability provided to the Applicant has provisions which comply with the AEC regulation, "Reactor Vessel Material Surveillance Program Requirements", 10CFR50, Appendix H, published in the Federal Register on July 17, 1973. The only exception between the recommended surveillance program and the requirements presented in Appendix H is the following:

A. Appendix H, Section II.C.2 - Attachments to the reactor vessel.

   In adhering to the requirement of placing the surveillance specimens as close as possible to the reactor vessel wall, the capsule holders are attached

to the cladding of the reactor vessel and are not major load-bearing components. By such placement, temperature, flux spectra, and fluence differences between the surveillance specimens and the reactor vessel are minimized, thereby permitting more accurate assessment of the changes in the reactor vessel properties.

3.1.29 CRITERION 33 -- REACTOR COOLANT MAKEUP

A system to supply reactor coolant makeup for protection against small breaks in the reactor coolant pressure boundary shall be provided. The system safety function shall be to assure that specified acceptable fuel design limits are not exceeded as a result of reactor coolant loss due to leakage from the reactor coolant pressure boundary and rupture of small piping or other small components which are part of the boundary. The system shall be designed to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished using the piping, pumps and valves used to maintain coolant inventory during normal reactor operation.

RESPONSE:

Reactor coolant makeup during normal operation is provided by the Chemical and Volume Control System (CVCS). Based on the analysis provided in UFSAR 9.3.4.4.11, it is concluded that this criterion is met.

3.1.30 CRITERION 34 -- RESIDUAL HEAT REMOVAL

A system to remove residual heat shall be provided. The system safety function shall be to transfer fission product decay heat and other residual heat from the reactor core at a rate such that specified acceptable fuel design limits and the design conditions of the reactor coolant pressure boundary are not exceeded.

Suitable redundancy in components and features, and suitable interconnections, leak detection and isolation and capabilities shall be provided to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

RESPONSE:

Residual heat removal capability is provided by the Shutdown Cooling System for reactor coolant temperatures less than 350°F. For temperatures greater than 350°F, this function is provided by the steam generators. The design incorporates sufficient redundancy, interconnections, leak detection, and isolation capability to ensure that the residual heat removal function can be accomplished, assuming a single active

failure[a]. Within appropriate design limits, either system will remove fission product decay heat at a rate such that specified acceptable fuel design limits and the design conditions of the reactor coolant pressure boundary will not be exceeded.

The Shutdown Cooling System and the steam generator auxiliaries are designed to operate either from offsite power or from onsite power sources.

Further discussion is included in Section 5.4.7 for the residual heat removal system and in Chapter 10.0 (see paragraph 10.3.2.2.4) for the Main Steam and Power Conversion System.

3.1.31 CRITERION 35 -- EMERGENCY CORE COOLING

A system to provide abundant emergency core cooling shall be provided. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate such that (1) fuel and clad damage that could interfere with continued effective core cooling is prevented and (2) clad metal-water reaction is limited to negligible amounts.

a. An active failure is a malfunction, excluding passive failure, of a component which relies on mechanical movement to complete its intended function upon demand. Check valves which receive regular exercise to ensure operability are treated as passive components. Examples of active failures include the failure of a valve to move to its correct position, or the failure of a pump, fan, or diesel generator to start. Spurious action of a powered component originating within the actuation system or its supporting systems shall be regarded as an active failure, unless specific design features or operating restrictions preclude such spurious action.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation and containment capabilities shall be provided to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

RESPONSE:

Emergency core cooling is provided by the Safety Injection System (described in Section 6.3). The system is designed to provide abundant cooling water to remove heat at a rate sufficient to maintain the fuel in a coolable geometry and to assure that zirconium-water reaction is limited to a negligible amount (less than one percent). Detailed analysis has been performed, utilizing models complying with 10CFR50, Appendix K, ECCS Evaluation Models, to verify that the system performance is adequate to meet the intent of the Acceptance Criteria for Emergency Core Cooling Systems for Light Water Power Reactors of 10CFR50, Paragraph 50.46(b).

The system design includes provisions to assure that the required safety functions are accomplished with either onsite or offsite electrical power system operation, assuming a single failure (qualified as described below) of any

component. The single failure may be an active failure[a] during the initial period following an accident (coolant injection phase of emergency core cooling) or an active or limited leakage passive failure[b] during the long term cooling (coolant recirculation) phase of emergency core cooling.

Though the ECCS is designed to accommodate a limited leakage passive failure during the recirculation phase, it does not accommodate arbitrary large leakage passive failures such as the complete double-ended severance of piping, which are extremely low probability events. Interface criteria require that the Applicant's layout and arrangement assure that the limited leakage passive failure does not preclude minimum acceptable recirculation capability. Where building design is not relied upon to mitigate and contain leakage from the ECCS passive failure, suitable automatic isolation and auxiliary equipment must be provided by the Applicant, as necessary, to comply with the interface criteria.

In lower Modes of plant operation (i.e., in Mode 3 with pressurizer pressure <1837 psia and RCS cold leg temperature <485°F, and in Mode 4), ECCS equipment operability

---

a. An active failure is a malfunction, excluding passive failure, of a component which relies on mechanical movement to complete its intended function upon demand. Check valves which receive regular exercise to ensure operability are treated as passive components. Examples of active failures include the failure of a valve to move to its correct position, or the failure of a pump, fan, or diesel generator to start. Spurious action of a powered component originating within the actuation system or its supporting systems shall be regarded as an active failure, unless specific design features or operating restrictions preclude such spurious action.

b. A passive failure is defined as the blockage of a process flow path or a breach in the integrity of a component or piping (for example, a piping failure).

requirements are reduced, and protection against single failures is not required, in accordance with plant technical specifications.

3.1.32 CRITERION 36 -- INSPECTION OF EMERGENCY CORE COOLING SYSTEM

The emergency core cooling system shall be designed to permit appropriate periodic inspection of important components, such as spray rings in the reactor pressure vessel, water injection nozzles, and piping to assure the integrity and capability of the system.

RESPONSE:

The Emergency Core Cooling System (Safety Injection System (SIS)) is designed to facilitate access to all critical components. All pumps, heat exchangers, valves and piping external to the containment structure are readily accessible for periodic inspection to ensure system leak-tight integrity.

Valves, piping and tanks inside the containment may be inspected for leak-tightness during plant shutdowns for refueling and maintenance.

Reactor vessel internal structures, reactor coolant piping and water injection nozzles are designed to permit visual inspection for wear due to erosion, corrosion or vibration, and nondestructive inspection techniques where these are applicable and desirable.

Details of the inspection program are described in Chapters 5.0 and 6.0, and Technical Specification and Technical Requirements Manual.

3.1.33 CRITERION 37 -- TESTING OF EMERGENCY CORE COOLING SYSTEM

The emergency core cooling system shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leak-tight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation, including operation of the applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

RESPONSE:

The Emergency Core Cooling System (Safety Injection System) is provided with testing capability to demonstrate system and component operability. Testing can be conducted during normal plant operation with the test facilities arranged not to interfere with the performance of the systems or with the initiation of control circuits, as described in section 6.3 and Chapter 14.

3.1.34 CRITERION 38 -- CONTAINMENT HEAT REMOVAL

A system to remove heat from the reactor containment shall be provided. The system function shall be to reduce rapidly, consistent with the functioning of other associated systems, the containment pressure and temperature following any LOCA and maintain them at acceptably low levels.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

RESPONSE:

The containment spray system consists of two completely independent subsystems. The heat removal capacity of the flow from either containment spray subsystem is adequate to keep the containment pressure and temperature below design conditions for any size break in the reactor coolant system piping up to and including a double-ended break of the largest reactor coolant pipe, with an unobstructed discharge from both ends.

Borated water is sprayed downward by the system from the upper regions of the containment to cool the atmosphere. Cooling reduces the containment pressure and temperature following a major LOCA.

Suitable redundancy in components and features is designed into the containment spray system to maintain the pressure and temperature conditions below containment design even in the event of a single failure, including the loss of onsite or offsite electrical power.

3.1.35 CRITERION 39 -- INSPECTION OF CONTAINMENT HEAT REMOVAL SYSTEM

The containment heat removal system shall be designed to permit appropriate periodic inspection of important components, such as the torus, sumps, spray nozzles, and piping to assure the integrity and capability of the system.

RESPONSE:

All essential equipment of the containment spray system is located outside the containment, except for spray headers, nozzles, containment sump, and associated piping. These components include the refueling water tank, two containment spray pumps, two shutdown cooling heat exchangers, and independent containment spray headers.

The detail arrangement and layout of system piping, pumps, heat exchangers, and valves will provide the separation, availability, and accessibility required for periodic inspection.

3.1.36 CRITERION 40 -- TESTING OF CONTAINMENT HEAT REMOVAL SYSTEM

The containment heat removal system shall be designed to permit appropriate periodic pressure and functional testing to assure: (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole, and, under conditions as close to the design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

RESPONSE:

System piping, valves, pumps, heat exchangers, and other components of the containment heat removal systems are arranged so that each component can be tested periodically for operability. Testing can be conducted during normal plant operation with the test facilities arranged not to interfere with the performance of the systems or with the initiation of control circuits, as described in section 6.2.

Performance testing of containment spray pumps is conducted in accordance with the Inservice Testing Program as described in Section 3.9.6.

Normal heat exchanger operation is verified during nominal plant cooldown. The low-pressure safety injection pumps

discharge into the safety injection header via the shutdown cooling heat exchangers and the low-pressure injection lines.

Actuator-operated valves can be cycled from the control room, and operation verified by observing control room indication of operation.

Check valves will be tested to ensure that the valves perform their safety functions. These valves include the refueling water storage tank check valves and the valves on the inlets and outlets of the containment spray pumps.

3.1.37 CRITERION 41 -- CONTAINMENT ATMOSPHERE CLEANUP

Systems to control fission products, hydrogen, oxygen, and other substances which may be released into the reactor containment shall be provided as necessary to reduce, consistent with the functioning of other associated systems, the concentration and quantity of fission products released to the environment following postulated accidents, and to control the concentration of hydrogen or oxygen and other substances in the containment atmosphere following postulated accidents to assure that containment integrity is maintained.

Each system shall have suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities to assure that, for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available), its safety function can be accomplished, assuming a single failure.

RESPONSE:

Two systems, namely the containment spray and hydrogen recombiner systems, are provided to control fission products, hydrogen, oxygen, and other substances that may be released into the reactor containment.

The post accident hydrogen recombiner system is designed with redundancy of vital components so that a single failure does not prevent operation of the system.

These systems are described in sections 6.2.2 and 6.2.5.

3.1.38 CRITERION 42 -- INSPECTION OF CONTAINMENT ATMOSPHERE CLEANUP SYSTEMS

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic inspection of important components, such as filter frames, ducts, and piping to assure the integrity and capability of the systems.

RESPONSE:

The containment atmosphere cleanup systems are designed and located so that they can be inspected periodically as required.

All major components of the hydrogen recombiner system are located outside containment and are readily accessible for periodic inspection. Purge piping and valves located inside containment may be inspected during plant shutdown.

See sections 6.2 and 6.5 for further information.

3.1.39 CRITERION 43 -- TESTING OF CONTAINMENT ATMOSPHERE CLEANUP SYSTEMS

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic pressure and functional testing to assure: (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the systems such as fans, filters, dampers, pumps, and valves, and (3) the operability of the systems as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the systems into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of associated systems.

RESPONSE:

Testing of the containment spray subsystem shall be conducted to assure structural and leaktight integrity, and operability and performance in accordance with Criterion 40.

The hydrogen recombiner system is designed to permit periodic testing for structural and leaktight integrity of components and for operability of the system. Testing may be conducted during normal plant operation or shutdown. See section 6.2 for details.

3.1.40 CRITERION 44 -- COOLING WATER

A system to transfer heat from structures, systems, and components important to safety, to an ultimate heat sink,

shall be provided. The system safety function shall be to transfer the combined heat load of these structures, systems, and components under normal operating and accident conditions.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

RESPONSE:

The cooling water systems for safety-related functions consist of the essential cooling water system (ECWS) and the essential spray pond system (ESPS). Each system consists of two redundant and independent trains. The ECWS and ESPS trains are used for safe plant shutdown under normal shutdown and accident conditions.

During and following a postulated LOCA or loss of normal fuel pool cooling, the ECWS and ESPS are designed to meet the single failure criterion and still carry the essential heat load derived from safety-related components and systems.

The ECWS and ESPS perform their functions assuming that either offsite or onsite electric power is available.

The ultimate heat sink for each unit consists of two essential spray ponds that meet the guidelines of Regulatory Guide 1.27. These ponds are described in detail in subsection 9.2.5.

The ECWS and ESPS are described in subsections 9.2.2 and 9.2.1, respectively.

3.1.41 CRITERION 45 -- INSPECTION OF COOLING WATER SYSTEM

The cooling water system shall be designed to permit appropriate periodic inspection of important components, such as heat exchangers and piping, to assure the integrity and capability of the system.

RESPONSE:

The important components of the ESPS and ECWS are located in accessible areas. These components have suitable manholes, handholes, inspection ports, or other appropriate design and layout features to allow periodic inspection. Refer to section 9.2 for details.

3.1.42 CRITERION 46 -- TESTING OF COOLING WATER SYSTEM

The cooling water system shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and the performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation for reactor shutdown and for LOCAs, including operation of applicable portions of the protection system and the transfer between normal and emergency power sources.

RESPONSE:

Active components of the ESPS and ECWS are tested periodically for operability and functional performance.

Preoperational performance tests of the components are made in the manufacturer's shop. An initial system flow test demonstrates proper functioning of the system. Thereafter, periodic tests ensure that components function properly.

Each active component of the ECWS and the ESPS may be individually connected to the preferred power source at any time during reactor operation to demonstrate operability.

Many active components function during normal plant operation, thereby demonstrating operability. The essential trains are tested to ensure proper system operation. Remotely operated valves are exercised and actuation circuits are tested. The automatic actuation circuitry, valves, and pump breakers also are checked when integrated system tests are performed during a planned cooldown of the RCS. Refer to section 9.2 for additional information.

3.1.43 CRITERION 50 -- CONTAINMENT DESIGN BASIS

The reactor containment structure, including access openings, penetrations, and the containment heat removal system shall be designed so that the containment structure and its internal compartments can accommodate, without exceeding the design leakage rate and, with sufficient margin, the calculated pressure and temperature conditions resulting from any LOCA. This margin shall reflect consideration of: (1) the effects of

potential energy sources which have not been included in the determination of the peak conditions, such as energy in steam generators and energy from metal-water and other chemical reactions that may result from degraded emergency core cooling functioning, (2) the limited experience and experimental data available for defining accident phenomena and containment responses, and (3) the conservatism of the calculational model and input parameters.

RESPONSE:

The reactor containment structure and its internal compartments, including access openings, penetrations, and the containment heat removal system, accommodate the calculated pressure and temperature conditions resulting from any LOCA, without exceeding the design leakage rate and with a sufficient margin. Subcompartment analyses and associated structural evaluations of containment internal structures consider the worst case line breaks that are not precluded by Leak Before Break Criteria. Refer to subsection 3.8.1 and section 6.2 for further details.

3.1.44 CRITERION 51 -- FRACTURE PREVENTION OF CONTAINMENT PRESSURE BOUNDARY

The reactor containment boundary shall be designed with sufficient margin to assure that under operating, maintenance, testing, and postulated accident conditions: (1) its ferritic materials behave in a nonbrittle manner, and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and

other conditions of the containment boundary material during operation, maintenance, testing, and postulated accident conditions, and the uncertainties in determining: (1) material properties, (2) residual, steady-state, and transient stresses, and (3) size of flaws.

RESPONSE:

The reactor containment boundary has sufficient margin to ensure that under operating, maintenance, testing, and postulated accident conditions its ferritic materials behave in a nonbrittle manner and the probability of rapidly propagating fracture is minimized. To be assured of this, the steel-lined, prestressed concrete reactor containment is designed so that the 1/4-inch steel liner plate is in compression or nominal tension under all conditions stated above. The steel plate around penetrations may be in significant tension because of stress concentration. These areas are reinforced with thickened plates with a nil ductility transition temperature at least 30F below the minimum service temperature.

Uncertainties in determining material properties and flaw sizes are mitigated through the use of ultrasonic inspection and other nondestructive tests. Sufficient margin is provided in the design to account for residual, steady-state, and transient stresses. Refer to subsection 3.8.1 for details.

3.1.45 CRITERION 52 -- CAPABILITY FOR CONTAINMENT LEAKAGE RATE TESTING

The reactor containment and other equipment which may be subjected to containment test conditions shall be designed so that periodic integrated leakage rate testing can be conducted at containment design pressure.

RESPONSE:

The reactor containment, and any equipment subject to containment test conditions, incorporates provisions for conducting periodic local and integrated leakage rate tests. Details concerning these provisions and the nature and scheduling of leakage rate tests are provided in paragraph 3.8.1.7 and subsection 6.2.6.

3.1.46 CRITERION 53 -- PROVISIONS FOR CONTAINMENT TESTING AND INSPECTION

The reactor containment shall be designed to permit:
(1) appropriate periodic inspection of all important areas, such as penetrations, (2) an appropriate surveillance program, and (3) periodic testing at containment design pressure of the leaktightness of penetrations which have resilient seals and expansion bellows.

RESPONSE:

The reactor containment design permits periodic inspection of all important areas. Provisions are included for preoperational and post-operational testing and surveillance to assess the structural and leaktight integrity of the

containment and its penetrations. The post-operational surveillance program includes inservice tendon and liner plate inspection. Provisions also are included for periodic leakage rate testing of penetrations with resilient seals and expansion bellows. Refer to paragraph 3.8.1.7 and subsection 6.2.6 for details.

3.1.47 CRITERION 54 -- PIPING SYSTEMS PENETRATING CONTAINMENT

Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation, and containment capabilities having redundancy, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus and to determine if valve leakage is within acceptable limits.

RESPONSE:

Piping systems penetrating primary reactor containment are provided with containment isolation valves.

Penetrations, except instrument lines, that are closed for containment isolation have redundant valving and associated apparatus. Valve testing during normal operation or during shutdown conditions is conducted as described in subsection 6.2.4 to ensure operability when needed.

Instrument lines are designed in accordance with the suggested requirements of Regulatory Guide 1.11, Instrument Lines Penetrating Primary Reactor Containment.

Fittings are provided to permit periodic leakage rate testing of isolation valves to ensure that leakage is within acceptable limits. Refer to subsection 6.2.4 for details.

3.1.48 CRITERION 55 -- REACTOR COOLANT PRESSURE BOUNDARY PENETRATING CONTAINMENT

Each line that is part of the reactor coolant pressure boundary and that penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

(1) One locked closed isolation valve inside and one locked closed isolation valve outside containment; or

(2) One automatic isolation valve inside and one locked closed isolation valve outside containment; or

(3) One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

(4) One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to containment as practical and upon loss of actuating power,

automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of an accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements, such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment, shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

RESPONSE:

The reactor coolant system pressure boundary is defined in accordance with ANSI N18.2 Section 5.4.3.2 and 10CFR50, Section 50.2(v). All reactor coolant pressure boundary lines penetrating containment meet the isolation criteria of GDC 55 using the following basis for specific lines in addition to those noted above.

1. Safety injection lines, as shown on engineering drawing 01-M-SIP-001 (penetration numbers 11 through 20) are used to mitigate the consequences of accidents and therefore do not receive an automatic closure signal and are not locked closed.

2. When in the shutdown cooling mode of operation the Shutdown Cooling System is an extension of the reactor coolant pressure boundary. In this mode the

system is isolated from the environment by two isolation valves in series.

3. The charging and seal injection lines shown on engineering drawings 01, 02, 03-M-CHP-001 through -005 (penetration numbers 41 and 57) have automatic valves outside the containment which do not receive a CIAS closure signal. This is because it is desirable to maintain charging and seal injection flow as long as the charging pumps are in operation.

Details are given in subsection 6.2.4.

3.1.49 CRITERION 56 -- PRIMARY CONTAINMENT ISOLATION

Each line that connects directly to the containment atmosphere and penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

(1) One locked closed isolation valve inside and one locked closed isolation valve outside containment; or

(2) One automatic isolation valve inside and one locked closed isolation valve outside containment; or

(3) One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

(4) One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

RESPONSE:

Each line that connects directly to the containment atmosphere and penetrates containment is provided with containment isolation valves inside and outside containment. Where it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable, the additional isolation valves are not provided. Details are given in subsection 6.2.4.

3.1.50 CRITERION 57 -- CLOSED SYSTEM ISOLATION VALVES

Each line that penetrates primary reactor containment and is neither part of the reactor coolant pressure boundary nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, or locked closed, or capable of remote manual operation. This valve shall be outside containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

RESPONSE:

Each line that penetrates containment and is not connected directly to the containment atmosphere and is not part of the RCPB has at least one isolation valve (not a check valve) located outside containment near the penetration. Details are given in subsection 6.2.4.

3.1.51 CRITERION 60 -- CONTROL OF RELEASES OF RADIOACTIVE MATERIALS TO THE ENVIRONMENT

The nuclear power unit design shall include means to control suitably the release of radioactive materials in gaseous and liquid effluents and to handle radioactive solid wastes produced during normal reactor operation, including anticipated operational occurrences. Sufficient holdup capacity shall be provided for retention of gaseous and liquid effluents containing radioactive materials, particularly where unfavorable site environmental conditions can be expected to impose unusual operational limitations upon the release of such effluents to the environment.

RESPONSE:

The liquid radwaste system, gaseous radwaste system, and the solid radwaste system safely control the radioactive liquid, gaseous, and solid wastes generated during normal operation, including anticipated operational occurrences. These systems limit the release of radioactivity so that exposure to persons in restricted and unrestricted areas are as low as reasonably achievable in conformance with 10CFR20.1-20.601 and 10CFR50.

The facility also is designed with provisions to prevent radioactivity release during accidents from exceeding limits of 10CFR100.

The radwaste systems, the design criteria, and amounts of estimated releases of radioactive effluents to the environments are described in chapter 11.

3.1.52 CRITERION 61 -- FUEL STORAGE AND HANDLING AND RADIOACTIVITY CONTROL

The fuel storage and handling, radioactive waste, and other systems which may contain radioactivity shall be designed to assure adequate safety under normal and postulated accident conditions. These systems shall be designed: (1) with a capability to permit appropriate periodic inspection and testing of components important to safety, (2) with suitable shielding for radiation protection, (3) with appropriate containment, confinement, and filtering systems, (4) with a residual heat removal capability having reliability and testability that reflects the importance to safety of decay heat and other residual heat removal, and (5) to prevent significant reduction in fuel storage coolant inventory under accident conditions.

<u>RESPONSE</u>:

Fuel storage and handling and fuel pool cooling are discussed in section 9.1. Most of the components and systems in this category are in frequent use and no special testing is required. Those systems and components important to safety

that are not normally operating are tested periodically; e.g., the fuel handling equipment (prior to each refueling).

The spent fuel storage racks are located to provide sufficient shielding water over stored fuel assemblies to limit radiation at the surface of the water to no more than 2.5 mrem/h during the storage period. The exposure time during refueling is limited so that the integrated dose to operating personnel does not exceed the limits of 10CFR20.1001-20.2401.

Analysis has indicated that the accidental release of the maximum activity content of a gas decay tank will not result in doses in excess of 500 mrem whole body. See chapter 15 for details.

Cooling for the spent fuel pools is designed to prevent damage to fuel in the storage facilities that could result in radioactivity release to the plant operating areas or the plant environs.

The fuel building can withstand seismic events without loss of the pool water or damage to stored fuel.

The PVNGS Independent Spent Fuel Storage Installation (ISFSI) has been designed and licensed under 10 CFR Part 72 requirements, as appropriate, and is not subject to 10 CFR Part 50, Appendix A, General Design Criteria.

3.1.53 CRITERION 62 -- PREVENTION OF CRITICALITY IN FUEL STORAGE AND HANDLING

Criticality in the fuel storage and handling system shall be prevented by physical systems or processes, preferably by use of geometrically safe configurations.

RESPONSE:

The new, intermediate and spent fuel racks are all designed in accordance with ANSI N18.2. Each type of rack is designed with rectangular arrays of storage cells spaced such that the minimum edge to edge distance of stored fuel assemblies precludes accidental criticality. The minimum edge spacing for each specific type of rack includes allowances for fabrication tolerances and predicted deflections due to postulated accidents.

The new fuel racks are designed for dry storage of new fuel only. The intermediate and spent fuel racks are designed for wet storage of either new or spent fuel. In addition to maintaining minimum edge to edge spacing, fuel stored in the spent fuel storage racks is controlled administratively, according to initial enrichment, burnup, and decay time.

Design of the new fuel racks assures a k_{eff} of less than .98. Design of the spent fuel racks assures a k_{eff} of less than .95 for all conditions given partial credit for soluble boron contained in the spent fuel pool water. Design of the dry fuel storage fuel basket assures a k_{eff} of less than .95 even with full moderator intrusion.

The fuel storage and handling system is described in Section 9.1.

The PVNGS Independent Spent Fuel Storage Installation (ISFSI) has been designed and licensed under 10 CFR Part 72 requirements, as appropriate, and is not subject to 10 CFR Part 50, Appendix A, General Design Criteria.

3.1.54 CRITERION 63 -- MONITORING FUEL AND WASTE STORAGE

Appropriate systems shall be provided in fuel storage and radioactive waste systems and associated handling areas: (1) to detect conditions that may result in loss of residual heat removal capability and excessive radiation levels, and (2) to initiate appropriate safety actions.

RESPONSE:

The spent fuel pool has monitoring equipment that alarms if the water level falls below a predetermined level or if high water temperatures are experienced. The fuel building has monitoring equipment that alarms if high radiation levels are experienced. The high radiation level instrumentation also actuates the fuel building essential ventilation system. See section 7.3 for details.

The radwaste equipment is located in the radwaste building. Local radiation monitors in the building alarm at a predetermined setpoint to indicate excessive radiation levels. Appropriate action is taken following a radiation alarm to verify the condition and isolate the cause. See section 12.3 for details.

The PVNGS Independent Spent Fuel Storage Installation (ISFSI) has been designed and licensed under 10 CFR Part 72 requirements, as appropriate, and is not subject to 10 CFR Part 50, Appendix A, General Design Criteria.

3.1.55 CRITERION 64 -- MONITORING RADIOACTIVITY RELEASES

Means shall be provided for monitoring the reactor containment atmosphere, spaces containing components for recirculation of LOCA fluids, effluent discharge paths, and the plant environs for radioactivity that may be released from normal operations, including anticipated operational occurrences, and from postulated accidents.

RESPONSE:

The reactor containment atmosphere is monitored as described in table 11.5-1. Local radiation monitors are located throughout the facility to detect excessive radiation levels. In particular, areas that contain potentially radioactive liquid or gas are continuously monitored. All discharge paths to the environment, which might be associated with potentially radioactive gas, are continuously monitored during discharge. Additionally, radiation monitors are located about the plant environs, and samples are collected and analyzed in accordance with the radiological-environmental monitoring program. See sections 11.5 and 12.3 for details.

3.2 CLASSIFICATION OF STRUCTURES, COMPONENTS, AND SYSTEMS

The classification of structures, components, and systems within the Combustion Engineering, Inc. (C-E) scope of supply as defined in section 1.9 does not deviate from the classifications designated in CESSAR Section 3.2, and is included in table 3.2-1 for completeness.

3.2.1 SEISMIC CLASSIFICATION

CE SCOPE

The seismic category and safety and quality classification of mechanical components within the CESSAR scope are listed in Table 3.2-1. The only process piping included in the CESSAR scope is the RCS main loop piping. The safety class boundaries of other process piping, (not included in CESSAR scope) is indicated on the P&ID's (Chapters 5.0, 6.0, and 9.0). Seismic Category I includes all mechanical components within the safety class boundaries and extends to the first seismic restraint beyond the boundary. Structures or supports essential to the performance of a safety function by a mechanical component or capable of disabling interaction with it are designed to Seismic Category I requirements for structural integrity only. Where structures or supports essential to the performance of a safety function are not provided by C-E, interface requirements are stated in the interface sections. This allows PVNGS to design in such a way that any structures, systems, or components that could potentially have a disabling interaction with C-E supplied Seismic Category I mechanical structures, systems, or components are either prevented from doing so or

are designed to meet Seismic Category I structural integrity requirements.

The listing of major electrical components, which are normally in the C-E scope of supply is listed in section 3.11, which also includes safety and quality classification. Electrical structures, systems, and components not classified as Seismic Category I, but whose failure could represent a hazard to the operator or could interfere with the performance of required safety functions of electrical structures, systems and components, are classified as Seismic Category II. Any electrical system or structure or component not in Seismic Category I or II is considered non-seismic; see section 3.10. The use of Seismic Category II is limited to non-safety control system components, which are designed and documented to maintain structural integrity during an SSE.

PVNGS Scope

Seismic Category I is applied to those structures, systems, and components that must remain functional during a safe shutdown earthquake (SSE). Regulatory Guide 1.29; 10CFR50, Appendix A, General Design Criterion 2; and 10CFR100, Appendix A, require that nuclear power plant structures, systems, and components important to safety be designed to withstand the effects of earthquakes. Specifically, 10CFR100, Appendix A, requires that all nuclear power plants be designed so that, if the SSE occurs, all structures, systems, and components important to safety remain functional. These plant features are those necessary to assure:

- The integrity of the reactor coolant pressure boundary (RCPB)
- The capability to shut down the reactor and maintain it in a safe condition.
- The capability to prevent or mitigate the consequences of accidents that could result in potential offsite exposures comparable to the guideline exposures of 10CFR100.

Regulatory Guide 1.29 describes an acceptable method of identifying those plant features that should be designed to remain functional if the SSE occurs and which should be designated Seismic Category I. Seismic Category I structures, systems, and components are listed in table 3.2-1.

All Seismic Category I items are designed to remain functional and within applicable stress and deformation limits when subjected to the effects of the vibratory motion of the operating basis earthquake in combination with normal operating loads.

Structures, systems, and components not listed as Seismic Category I items are designed to appropriate static loads or comply with applicable building codes regarding seismic effects. The interface between different seismic classifications is indicated by the code breaks shown on the piping and instrumentation diagrams of the appropriate systems. Seismic Category I design requirements extend to the first seismic anchor beyond the interface of the classification change. All ASME Section III components and piping are Seismic

Category I and all components and piping identified as nonnuclear safety (NNS) are non-Seismic Category I.

3.2.2 SYSTEM QUALITY GROUP CLASSIFICATION

CE supplied equipment has been included in Table 3.2-1 as stated in section 3.2 above. Fluid systems or portions of fluid systems and their pressure-retaining components important to safety are classified in accordance with ANSI N18.2. The safety classes defined in these criteria are used as guides in designating codes, standards, and quality requirements for the safety-related fluid systems and components. This classification system influences the design, material selection, manufacture or fabrication, inspection, assembly, erection, and construction of the safety-related fluid systems and components. Safety class designations per ANSI N18.2, Quality Group Classifications per Regulatory Guide 1.26 and 10CFR50.55a, and the appropriate codes and standards for all plant components are delineated in table 3.2-1 and are shown on the applicable piping and instrumentation diagrams. For operational phase activities, including preoperational, initial startup, and operational testing, system classification is in accordance with Regulatory Guide 1.26 and 10CFR50.55a as indicated in table 3.2-1 and footnote (ff).

3.2.3 DRY CASK STORAGE CLASSIFICATION

Systems, structures and components associated with dry storage of spent fuel are classified in accordance with 10CFR72 and the guidance provided in NUREG/CR-6407 and Regulatory Guide 7.10,

Appendix A. As such, they are designated as Important to Safety Category A, B or C, or Not Important to Safety.

The classification of systems, structures and components designed and licensed by the cask certificate holder is identified in the cask FSAR. The classification of dry cask storage systems, structures and components other than those designed and licensed by the cask certificate holder has been established by APS. Significant systems, structures and components that have been classified by APS as Important to Safety Category A, B, or C are listed in Table 3.2-1.

NOTES

1. <u>Location</u>

AB = Auxiliary building
CB = Control building
C = Containment building
FB = Fuel building
DG = Diesel generator building
OU = Outside
RW = Radwaste building
TG = Turbine building
SB = Service building
MS = Main steam support structure
WR = Water reclamation plant
TSC = Technical Support Center
EOF = Emergency Operations Facility
LL = Low Level Radioactive Material Storage Facility
OSF = Outage Support Facility

2. <u>Principal Construction Codes and Standards</u>

I	=	ASME Boiler and Pressure Vessel Code, Section I
III-1,2,3,MC	=	ASME Boiler and Pressure Vessel Code, Section III, Class 1, 2, 3, or MC
III-NF,NG	=	ASME Boiler and Pressure Vessel Code, Section III, Section NF or Section NG
VIII	=	ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 of Division 2
ACI 349-97	=	American Concrete institute, “Code Requirements for Nuclear Safety Related Concrete Structures”
ASTM A:	=	American Society for Testing and Materials: A242, Abrasion Resistant Steel; A447, Type 2, Castings, High Temperature
AWWA	=	American Water Works Association
B9.1	=	ANSI B9.1, Safety Code for Mechanical Refrigeration
B31.1	=	ANSI B31.1.0, Code for Pressure Piping
SMACNA	=	Sheet Metal and Air Conditioning Contractors National Association, Inc.
HEI	=	Heat Exchange Institute
TEMA C	=	Tubular Exchanger Manufacturers Association, Class C
TEMA R	=	Tubular Exchanger Manufacturers Association, Class R
ASTM C	=	American Society for Testing and Materials; C64, C106, Fire Brick; C155, Insulating Brick; C213, Castable Refractory (Regular); C401, Castable Refractory (Insulating), C612 Class 5, Insulating Block
ASTM D3299-74	=	Filament Wound Glass-Fiber Reinforced Polyester Chemical Resistant Tanks
PS 15-69	=	National Bureau of Standards - Voluntary Product Standard PS 15-69 - Custom Contact-Molded Reinforced-Polyester Chemical Resistant Process Equipment
HIS	=	Hydraulic Institute Standards
IEEE-279	=	Institute of Electric and Electronic Engineers, Criteria for Protection Systems for Nuclear Power Generating Stations, 1971
IEEE-308	=	Institute of Electric and Electronic Engineers, Standard Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations, 1971
IEEE-317	=	Institute of Electric and Electronic Engineers, Standard for Electrical Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations, September 1972
IEEE-323	=	Institute of Electric and Electronic Engineers, Standard for Qualifying Class 1 Electric Equipment for Nuclear Power Generating Stations, - 1974
IEEE-334	=	Standard for Type Tests of Continuous Duty Class 1E Motors for Nuclear Power Generating Stations - 1974
IEEE-338	=	Institute of Electric and Electronic Engineers, Trial-Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems, 1971
IEEE-344	=	Institute of Electric and Electronic Engineers, Guide for Seismic Qualification of Class 1 Electronic Equipment for Nuclear Power Generating Stations, 1975
IEEE-379	=	Institute of Electric and Electronic Engineers, Trial-Use Guide for the Application of the Single-Failure Criterion to Nuclear Power Generating Station Protection Systems
IEEE-383	=	Institute of Electric and Electronic Engineers, Standard for Type Test of Class 1E Electric Cables, Field Splices, and Connections for Nuclear Power Generation Stations
IEEE-384	=	Trial-Use Standard Criteria for Separation of Class 1E Equipment

Table 3.2-1
QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 37 of 42)

2. Principal Construction Codes and Standards (continued)

IEEE-387 = Institute of Electric and Electronic Engineers, Criteria for Diesel Generator Units Applied as Standby Power Supplies for Nuclear Power Generating Stations, 1972

IEEE-420 = Trial-Use Guide for Class 1E Control Switchboards for Nuclear Power Generating Stations - 1973

IEEE-450 = IEEE Recommended Practice for Maintenance Testing and Replacement of Large Lead Storage Batteries for Generating Stations and Substations

HSI-306 = Health and Safety Information, United States Atomic Energy Commission, Revised Minimal Specification for the High-Efficiency Particulate Air Filter, Issue No. 306

NEMA = National Electrical Manufacturers Association

NFPA = National Fire Protection Association

AP1-650 = American Petroleum Institute, Welded Steel Tanks for Oil Storage, Atmosphere Tanks

AP1-620 = American Petroleum Institute, Recommended Rules for Design and Construction of Large, Welded, Low-Pressure Storage Tanks

ARI = Air Conditioning and Refrigeration Institute

na = Design requirements specified by designer with appropriate consideration of the intended service and operating conditions

ANI = American Nuclear Insurers

DEMA = Diesel Engine Manufacturers Association, Test Code for the Measurement of Sound from Heavy-Duty Reciprocating Engines

3. Seismic Category

I = Design and construction in accordance with seismic requirements of Regulatory Guide 1.29 and Appendix A to 10CFR100

na = Seismic Category I requirements are not applicable

4. PVNGS Quality Assurance Class

Q = Quality Assurance Class requires compliance with the requirements of 10CFR50, Appendix B

na = The requirements of 10CFR50, Appendix B, are not applicable

5. Regulatory Guide 1.26, Quality Group Classification

PVNGS has used the American Nuclear Society (ANS) Safety Classes 1, 2, 3 and NNS designation as defined in ANSI N18.2 for classification in the design, material selection, manufacture or fabrication, inspection, assembly, erection and construction of the safety-related fluid systems and components. The "Regulatory Guide 1.26, Quality Group Classification" column provides a summary of the relationship between the ANSI N18.2 safety class and the NRC quality group.

A,B,C,D = Quality group classification as defined in Regulatory Guide 1.26 and 10CFR50.55a.

na = Not applicable to quality group classification

6. ANSI N18.2 Safety Class

1,2,3,NNS = Safety classification as defined in ANSI N18.2

na = Not applicable to safety classification

7. Letter in Parentheses

Applicable portion of codes as identified in the following:

(a) American Concrete Institute, Building Code Requirements for Reinforced Concrete (ACI 318-71, or later edition)
American Institute for Steel Construction, Specifications for the Design, Fabrication, and Erection of Structural Steel for Buildings, adopted February 12, 1969, including Supplement Nos. 1 and 2, or later edition

Table 3.2-1
QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 38 of 42)

7. Letter in Parentheses (continued)

American Welding Society, Welding in Building Construction (AWS D1.1-72), (with 1973 revision, or later edition)

Uniform Building Code, 1973 Edition
See paragraph 3.8.1.2.

(b) Not used.

(c) Designated in accordance with BC-TOP-1, Rev. 1.

(d) The pressure boundary housing for this component is a reactor vessel appurtenance and is Safety Class 1 and Seismic Category I.

(e) These components and associated supporting structures must be designed to retain structural integrity during and after a seismic event but do not have to retain operability for protection of public safety. The basic requirement is prevention of structural collapse and damage to equipment and structures required for protection of the public safety.

(f) Only those core support structures necessary to support and restraint the core and to maintain safe shutdown capability are classified as Seismic Category I.

(g) There is no established standard for commercial pumps. ASME Section VIII, Division 1, and ANSI B31.1.0, Power Piping, represent related, available standards which, while intended for other applications, are used for guidance and recommendations in determining Quality Group D pump allowable stresses, steel casting quality factors, wall thicknesses, materials compatibility and specifications, temperature-pressure environment restrictions, fittings, flanges, gaskets, and bolting, installation procedures, etc.

(h) Hangers and supports are designed to the same classification as the associated equipment or piping when the equipment is required for safety. Nonsafety portions of structures, systems, or components whose failure could reduce the functioning of any safety-related structure, system, or component are designed and constructed such that a safe shutdown earthquake (SSE) would not cause such failure.

(i) Additional components that are part of the reactor coolant pressure boundary as defined in 10CRF50.2(v.), but excluded from the requirements of 10CFR50.55a pursuant to 10CFR50.55a(c) are Quality Group B and Safety Class 2 and designed to ASME Section III, Class 2.

(j) Loss of cooling water and/or seal water service to the reactor coolant pumps may require stopping the pumps. However, continuous operation of the pumps is not required during or after an SSE. The auxiliaries are, therefore, not necessarily Safety Class 2 or Seismic Category 1.

(k) Only those structural portions of the reactor coolant pumps which are necessary to assure the integrity of the reactor coolant pressure boundary are Safety Class 1.

(l) Two safety classes are used for heat exchangers to distinguish primary and secondary sides when they are different.

(m) Penetration sleeve is designed in accordance with BC-TOP-1, Rev. 1. Penetration head meets ASME B&PV Code, Section III, Class 2.

(n) Applies to supports for ASME Section III, Class 1, 2, 3 and MC components. ASME Section III, Appendix F, shall be used for designing supports for Class 1 components for the faulted condition. ASME Section III, Article NF (Draft), shall be used for the design of Class 2 and 3 plate- and shell-type component supports under emergency and faulted conditions.

Table 3.2-1

QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 39 of 42)

7. Letter in Parentheses (continued)

(o) D (AUGM) signifies Quality Group D augmented as defined in Branch Technical Position - ETSB 11 - 1 (Rev. 1), titled Design Guidance for Radioactive Waste Management Systems Installed in Light-Water-Cooled Nuclear Reactor Power Plants. Quality assurance shall be in accordance with the regulatory position of Regulatory Guide 1.143.

(p) Materials used for pressure retaining components conform to the requirements of Branch Technical Position, ETSB No. 11- 1 (Rev. 1).

(q) To be designed in accordance with CESSAR Section 4.5.2.

(r) To be designed in accordance with CESSAR Section 5.4.14.

(s) The gas stripper was originally designed and constructed to Seismic Category I requirements; however, this portion of the CVCS is not required to be Seismic Category I by Regulatory Guide 1.29, and is no longer maintained as Seismic Category I.

(t) Process solenoid valves will be constructed in accordance with manufacturer's standards.

(u) Equipment designated Category 1 or 2 (and some equipment designated Category 3) on table 1.8-1 is subject to Operations quality assurance requirements consistent with the regulatory position of Regulatory Guide 1.97.

(v) Designed to appropriate industry standards.

(w) External to the diesel engine package.

(x) Not used

(y) The requirements of NRC Branch Technical Position APCSB 9.5-1, Appendix A, Section C, are applied to operational phase activities associated with fire protection features relied on to protect safety related structures, systems or components.

(z) Refer to chapter 7 for further delineation of the components which comprise this system.

(aa) Operational phase activities of administration, control, operation, maintenance, inspection, etc., are considered to be quality-related activities and are subject to the pertinent requirements of the operational quality assurance program.

(bb) Connectors and terminal blocks are seismically qualified as part of the equipment in which they are installed.

(cc) The equipment is not required to remain functional following an SSE. However, the equipment has the capability to reduce the functioning of safety-related equipment, as defined in Regulatory Guide 1.29. Therefore, the design and the specific components critical to restraining this equipment during an SSE meet the requirements of Regulatory Guide 1.29 and shall be subject to the pertinent requirements of 10CFR50, Appendix B, during the operations phase.

(dd) The control rod drive mechanisms are not required to remain functional for the safety of the public during and after an SSE. Therefore, they are Quality Class Q in all aspects except operability.

(ee) Failure of the equipment, due to an SSE, could reduce the functioning of safety related equipment, as defined in Regulatory Guide 1.29. The design of the equipment is analyzed to preclude such failure during and after an SSE. The pertinent requirements of 10CFR50, Appendix B, are applied to this analysis. In addition, QA audits, monitoring and reviews verify that maintenance and modification activities are conducted in a manner such that the original design is not degraded.

Table 3.2-1
QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 40 of 42)

7. Letter in parentheses (continued)

(ff) For operational phase activities, including preoperational initial startup, and operational testing, system classification is in accordance with Regulatory Guide 1.26 and 10CFR50.55a. The following is a list of clarifications to the Regulatory Guide 1.26 column that will be used during operation phase activities:

PRINCIPAL COMPONENT	REGULATORY GUIDE 1.26 QUALITY GROUP CLASSIFICATION
Chemical and Volume Control System	
Equipment drain tank	D
Reactor drain tank pumps	D
Reactor drain filter	D
Preholdup ion exchangers	D
Piping and valves:	
From refueling water tank to first isolation valve	B
Safety Injection and Shutdown Cooling System	
Piping and valves:	
Relief piping from relief valves in auxiliary bldg	D
Control Building HVAC System	
ESF switchgear and battery rooms HVAC system:	
Dampers	na
ESF equipment room (channel A and B):	
Dampers	na
Steam and Power Conversion System	
Main steam supply system:	
Piping - steam generator to outboard containment isolation valve	B
Steam generator blowdown system:	
Piping from steam generators to outboard containment isolation valve	B
Radiation Monitoring System	
Monitors:	
Control room ventilation intake	na
Fuel pool area	na
Fuel building ventilation exhaust	na
Refueling machine area	na
Containment building purge exhaust	na
Containment building atmosphere	na
Post-accident purge area	na
Auxiliary building vent exhaust filter inlet	na
Auxiliary building lower level ventilation exhaust	na
Auxiliary building upper level ventilation exhaust	na

Table 3.2-1

QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 41 of 42)

7. Letter in Parentheses (continued)

(gg) All design, fabrication, materials, examination, inspection, and construction of the equipment hatch and its attachments shall comply with the requirements of ASME Section III, Division 1, Subsection NE. An ASME code stamp is not required.

(hh) The new fuel racks are designed to store new fuel in a noncritical array in accordance with Regulatory Guide 1.13. To fulfill this function they are required only to exhibit no permanent deformation following a seismic event. A QA program modified from the requirements of 10CFR50, Appendix B, is,therefore, acceptable. The design, specific components, and fabrication processes necessary for the structural integrity of the fuel racks provide that they will withstand the effects of a safe shutdown earthquake and remain functional per Regulatory Guide 1.29.

(ii) Meteorological system calibration is considered to be a quality-related activity and is subject to the pertinent requirements of the operational quality assurance program. The meteorological equipment is classified as not quality-related. This is in accordance with the Regulatory Guide 1.97, Rev. 2 requirements which require that Category 3 instrumentation be "high quality commercial grade." Regulatory Guide 1.97 does not impose any quality assurance program controls on Category 3 instrumentation.

(jj) Certain valves within these subsystems are not ASME Section III; however, engineering evaluation determined their acceptability for continued operation and use.

(kk) Specific QA requirements may exist for some non-Class 1E electrical systems or components based on regulations or commitments. Examples are, but not limited to, the following:

- Fire Protection (10 CFR Part 50, Appendix R)
- Rad Waste Management (RG 1.143)
- Post Accident Monitoring (RG 1.97)
- New Fuel Handling Equipment (RG 1.13)
- Heavy Load Handling Equipment (NUREG 0612 & GL 81-07)
- Anticipated Transient Without SCRAM (10 CFR Part 50.62)
- Station Blackout (10 CFR 50.63 & RG 1.155)
- Seismic Category IX Components (RG 1.133)
- Radiation Monitoring
- Non-Safety Related Auxiliary Feedwater
- Seismic Monitoring (RG 1.12 & RG 1.133)
- Permanent Plant Equipment
- Preferred Power Circuits (10 CFR Part 50, Appendix A Criterion 1)
- Dry Cask and Independent Spent Fuel Storage Installation (ISFSI) SSC's (10 CFR Part 72)

(ll) The quality assurance requirements of RG 1.155, "Station Blackout," Appendix A, Quality Assurance Guidance for Non-Safety Systems and Equipment, apply to the alternate ac source (10 CFR 50.2) installed to meet the requirements of 10 CFR Part 50.63.

(mm) = NRC has granted approval for the application of alternate quality assurance requirements to the flow sensor CH-FE210Y located in the normal borated makeup flowpath. See Section 1.8 for further detail on the exceptions to Regulatory Guide 1.26.

(nn) The system, structure or component has been classified as Important to Safety, Category A, as a result of its functions associated with dry storage of spent fuel, as governed by 10 CFR Part 72.

(oo) The system, structure or component has been classified as Important to Safety, Category B, as a result of its functions associated with dry storage of spent fuel, as governed by 10 CFR Part 72.

(pp) The system, structure or component has been classified as Important to Safety, Category C, as a result of its functions associated with dry storage of spent fuel, as governed by 10 CFR Part 72

Table 3.2-1
QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 42 of 42)

8. Expendable and Consumable Items
Expendable and consumable items necessary for the functional performance of safety-related structures, systems, and components are classified as safety-related items, and as such are subject to the pertinent requirements of the operational quality assurance program.

9. Radiation Protection Equipment
Radiation protection and chemistry equipment and services, limited to calibration standards procured for subsequent calibration of radiation protection and chemistry equipment and outside services procured to provide calibration of radiation protection and chemistry equipment, are subject to applicable requirements of the operational phase quality assurance program. Additionally, paragraphs 12.5.2.1.1, 12.5.2.1.2, and 12.5.2.1.3 are not subject to applicable requirements of the operational quality assurance program. This note does not supercede any of the requirements for radiation protection and chemistry systems and components which are contained in the body of table 3.2.1.

10. Emergency Plan Equipment
Emergency plan implementing procedures dealing with emergency plan equipment (including emergency kits, protective equipment, and supplies) are subject to quality assurance monitoring as described in chapter 17.

11. Valve Operators
Valve operators that are associated with safety-related valves which must perform a mechanical motion in order to shut down the plant, maintain the plant in a safe shutdown condition, or mitigate the consequences of a postulated event are classified as safety-related and as such are subject to the pertinent requirements of the operational quality assurance program.

12. EW System Radiation Monitors
These monitors and some associated tubing/piping and valves were originally installed to R2D Class requirements. These components have been upgraded to the equivalent of Q1C (for pressure boundary integrity) i.e. safety-related, seismic category I and ASME Sec III, Class 3. Future activities will be completed commensurate with the Q1C classification. (DFWOs 713354, 713350, 713353).

13. Fuel Transfer Valve and Associated Components
These components were originally installed as Quality Class NQR, Seismic Category II. The valve was designed per ANSI B31.1. The bellows was designed per the Expansion Joint Manufacturers Association Standards. The Fuel Transfer Tube Housing was designed per AISC. These components have been reclassified as Quality Class Q, Seismic Category I, Regulatory Guide 1.26 Quality Group C, ANSI N18.2 Safety Class 3. The components remain designed per their original design standards and remain non-ASME Section III components. Future activities will be completed commensurate with the Q1 classification.

14. Essential Exhaust
Shared with HF System located in FB

15. Steam Generator Blowdown System
The blowdown system piping and components which are associated with the Radwaste system are designed in accordance with Regulatory Guide 1.143 as mentioned in Note 7(o) above. Refer to the SC system P&ID for each component classification.

Table 3.2-1
QUALITY CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS (Sheet 42 of 42)

8. Expendable and Consumable Items
Expendable and consumable items necessary for the functional performance of safety-related structures, systems, and components are classified as safety-related items, and as such are subject to the pertinent requirements of the operational quality assurance program.

9. Radiation Protection Equipment
Radiation protection and chemistry equipment and services, limited to calibration standards procured for subsequent calibration of radiation protection and chemistry equipment and outside services procured to provide calibration of radiation protection and chemistry equipment, are subject to applicable requirements of the operational phase quality assurance program. Additionally, paragraphs 12.5.2.1.1, 12.5.2.1.2, and 12.5.2.1.3 are not subject to applicable requirements of the operational quality assurance program. This note does not supercede any of the requirements for radiation protection and chemistry systems and components which are contained in the body of table 3.2.1.

10. Emergency Plan Equipment
Emergency plan implementing procedures dealing with emergency plan equipment (including emergency kits, protective equipment, and supplies) are subject to quality assurance monitoring as described in chapter 17.

11. Valve Operators
Valve operators that are associated with safety-related valves which must perform a mechanical motion in order to shut down the plant, maintain the plant in a safe shutdown condition, or mitigate the consequences of a postulated event are classified as safety-related and as such are subject to the pertinent requirements of the operational quality assurance program.

12. EW System Radiation Monitors
These monitors and some associated tubing/piping and valves were originally installed to R2D Class requirements. These components have been upgraded to the equivalent of Q1C (for pressure boundary integrity) i.e. safety-related, seismic category I and ASME Sec III, Class 3. Future activities will be completed commensurate with the Q1C classification. (DFWOs 713354, 713350, 713353).

13. Fuel Transfer Valve and Associated Components
These components were originally installed as Quality Class NQR, Seismic Category II. The valve was designed per ANSI B31.1. The bellows was designed per the Expansion Joint Manufacturers Association Standards. The Fuel Transfer Tube Housing was designed per AISC. These components have been reclassified as Quality Class Q, Seismic Category I, Regulatory Guide 1.26 Quality Group C, ANSI N18.2 Safety Class 3. The components remain designed per their original design standards and remain non-ASME Section III components. Future activities will be completed commensurate with the Q1 classification.

14. Essential Exhaust
Shared with HF System located in FB

15. Steam Generator Blowdown System
The blowdown system piping and components which are associated with the Radwaste system are designed in accordance with Regulatory Guide 1.143 as mentioned in Note 7(o) above. Refer to the SC system P&ID for each component classification.

3.3 WIND AND TORNADO LOADINGS

Seismic Category I structures are designed for the extreme wind phenomena which are defined in Section 2.1 of BC-TOP-3-A[1]. BC-TOP-3-A defines tornado and extreme wind loadings and criteria for structures. It furnishes data, formulae, and procedures for determining maximum wind loading on structures and parts of structures. Seismic Category I structures are identified in subsection 3.2.1. Seismic Category I structures are designed for tornado effects. Additionally, structures that contain equipment required for safe shutdown after a tornado are designed for tornado effects.

3.3.1 WIND LOADINGS

3.3.1.1 Design Wind Velocity

The design wind velocity for all Seismic Category I structures is 105 miles per hour at 30 feet above ground for a 100-year recurrence interval.

3.3.1.2 Basis for Wind Velocity Selection

The selected design wind velocity is equal to the operating basis wind speed (100-year recurrence fastest mile wind) discussed in paragraph 2.3.1.2.3.

3.3.1.3 Vertical Velocity Distribution and Gust Factors

The vertical velocity distribution used is in accordance with exposure C (flat, open country; flat, open coastal belts; and grassland) of Section 6 of American National Standards Institute (ANSI) A58.1-1972[2]. Table 5 of this standard

contains the specific effective velocity pressures (q_F) for overall structural response. Table 6 of the standard contains the specific effective velocity pressure (q_p) for parts and portions of structure. Table 12 of the standard contains the specific effective velocity pressures for calculating internal velocity pressures (q_M). Values given in the above tables include appropriate gust factors. As an example, the range of gust factor variation for a basic wind velocity above 90 miles per hour is from 1.3 to 1.1 for heights ranging from 30 to 500 feet.

3.3.1.4 Determination of Applied Forces

The procedures used to convert the wind velocity into applied forces for structures are contained in ANSI A58.1-1972 and Sections 3.0 and 4.0 of BC-TOP-3-A. The wind velocity on which the applied forces depend is given in paragraph 3.3.1.1 above. The design pressures or design loads are obtained by multiplying the effective velocity pressures by the appropriate pressure coefficients as specified in Section 6.4 of ANSI A58.1-1972. Pressure coefficients are given in Sections 6.5 through 6.9 of the ANSI standard.

For Seismic Category I structures, the applied forces due to wind are calculated to determine if they are less severe than the applied forces due to tornado loadings. The applied tornado force magnitude and distribution are determined as discussed in paragraph 3.3.2.2. Appropriate stress levels and load factors discussed in section 3.8 are considered in determination of the governing loads. There are no Seismic

Category I structures for which wind governs the design. The total wind applied force magnitude and distribution were determined by procedures outlined in BC-TOP-3-A.

3.3.2 TORNADO LOADINGS

For purposes of structural analysis, the effects of a tornado are described in Section 3.0 of BC-TOP-3-A.

3.3.2.1 Applicable Design Parameters

Tornado-resistant Seismic Category I structures are analyzed for tornado loadings (not coincident with any unrelated accident condition or earthquake) as outlined in Sections 3.3 and 3.4 of BC-TOP-3-A. The loadings are calculated on the basis of having a maximum velocity of 300 miles per hour corresponding to a rotational speed of 240 miles per hour and a maximum translational speed of 60 miles per hour. The minimum translational speed is 5 miles per hour. The maximum design pressure drop is 2.25 psi with a maximum rate of change of 1.2 pounds per square inch per second. The radius (R_m) from the center of the tornado to the point at which the maximum wind velocity occurs is 150 feet. These parameters conform to those given in Regulatory Guide 1.76 for Region II. Tornado wind pressure loads, differential atmospheric pressure changes, associated time intervals, and missile effects are combined in accordance with BC-TOP-3-A. The design basis tornado missiles are discussed in subsection 3.5.1.

3.3.2.2 Determination of Forces on Structures

The methods employed to convert tornado loadings into forces and the distribution across the structures are outlined in Section 3.5 of BC-TOP-3-A. Loading combinations are listed in Section 3.4 of BC-TOP-3-A. A load factor of unity for a tornado is used for tornado effects.

3.3.2.3 Ability of Seismic Category I Structures to Perform Despite Failure of Structures Not Designed for Tornado Loads

The design of all permanent non-Seismic Category I structures, systems, and components was analytically checked to assure that no missiles will be generated which have more severe effects than those tornado-generated missiles listed in subsection 3.5.1. This is to ensure that Seismic Category I structures, systems, and components required for safe shutdown after a tornado will perform their intended functions.

Non-Seismic Category I structures whose collapse could result in loss of required function of Seismic Category I structures, equipment, or systems required for safe shutdown after a tornado were analytically checked to determine that they will not collapse when subjected to extreme environmental loads. The bases for analytical procedures that were used are discussed in paragraph 3.8.4.4.

3.4 WATER LEVEL (FLOOD) DESIGN

3.4.1 FLOOD PROTECTION

The relationship of all Category I structures to design flood levels is discussed in subsection 2.4.3. All Seismic Category I structures are located beyond the extent of probable maximum flooding. Therefore, no flood protection measures for Category I structures are required, as discussed in subsection 2.4.10.

3.4.2 ANALYSIS PROCEDURES

All safety-related structures, systems, and components are located beyond the extent of probable maximum flooding. Therefore, static and dynamic loadings due to the design basis flood conditions are not applied.

The design basis groundwater conditions and the design bases for subsurface hydrostatic loadings are described in paragraph 2.4.13.5. Procedures by which the dynamic effects of the design basis groundwater conditions are applied are described in Section 4.4 of BC-TOP-4-A.

Structures that penetrate the maximum groundwater level (given in paragraph 2.4.13.5) are limited to the containment building and portions of the auxiliary building.

The interior of these structures is made watertight by the 2-foot minimum concrete thickness of the walls and base mat and the use of waterstops in construction joints. Waterstops are provided to minimum levels of 927 feet, 924 feet, and 921 feet msl for Units 1, 2, and 3, respectively. These levels provide adequate margin above the maximum predicted groundwater

levels. Auxiliary waterproofing of horizontal and vertical surfaces is not deemed necessary.

The essential spray pond intake structures are designed to withstand loads imposed by wind-caused waves. The loads are computed according to the methods outlined in references 1 and 2.

3.5 MISSILE PROTECTION

Missile protection criteria for PVNGS conform to 10CFR50, General Design Criterion 4, Environmental and Missile Design Bases. Protection against the postulated missiles identified in subsection 3.5.1 is provided to fulfill the following design criteria:

A. Reactor Coolant Pressure Boundary Missiles

   1. A missile generated from a loop in the reactor coolant pressure boundary (RCPB) will not cause:

      a. Loss of integrity of another loop of the RCPB

      b. Loss of integrity of the main steam or feedwater system

   2. A missile generated from a loop in the RCPB will not cause loss of function to systems required to mitigate the consequences of the loss-of-coolant accident (LOCA) or required for safe shutdown, assuming the failure of a single active component. These systems are:

      a. Reactor protective system

      b. Engineered safety features actuation system

      c. Safety injection system (HPSI and LPSI, including hot leg injection lines and refueling water tank)

      d. Containment spray system

e. Auxiliary feedwater system (including safety-related condensate transfer and storage system and condensate storage tank)

f. Class 1E electrical systems, ac and dc (including switchgear, batteries, and distribution systems)

g. Diesel generator system, including diesel generator starting, lubrication, and combustion air intake and exhaust systems

h. Diesel fuel oil storage and transfer system

i. Hydrogen recombiner systems

j. Control building HVAC system

k. Essential cooling water system (portions required for operation of other listed systems)

l. Essential spray pond system

m. Fuel building HVAC system

n. Diesel generator building HVAC system

o. Main control board (see tables 7.3-2 and 7.3-14 for systems required)

p. Containment isolation systems:

    (1) Penetration assemblies

    (2) Isolation valves

    (3) Equipment hatch

    (4) Emergency personnel hatch

(5) Personnel lock

(6) Liner plate

(7) Test connections

(8) Piping between penetration assemblies and isolation valves.

q. Excore neutron monitoring system

r. Safety-related radiation monitors (refer to section 11.5)

s. Chemical and volume control systems (piping associated with sampling of the reactor coolant)

t. Shutdown cooling system

u. Essential chilled water system

B. Main Steam and Feedwater Missiles

1. A missile generated from the main steam or feedwater pump discharge pressure boundary will not cause:

a. Loss of integrity to the RCPB

b. Loss of integrity to nonisolatable main steam or feedwater piping in another loop

c. Loss of integrity of the spent fuel pool

2. A missile generated from the main steam or feedwater pump discharge pressure boundary will not cause loss of function to systems required to mitigate the consequences of a main steam or

feedwater line accident or required for safe shutdown, assuming the failure of a single active component. These systems are:

a. Reactor protective system

b. Engineered safety features actuation system

c. Auxiliary feedwater system (including safety-related condensate transfer and storage system and condensate storage tank)

d. Safety injection system (HPSI and LPSI, including refueling water tank)

e. Containment spray system (for breaks inside the containment only)

f. Chemical and volume control system (charging portion including boric acid makeup tanks and pumps, charging pumps, interconnecting piping, and reactor coolant sampling portion)

g. Main steam and feedwater system (from unaffected steam generator out to the containment isolation valves, including the atmospheric steam dump, steam supply to the turbine-driven auxiliary feedwater pump, and the steam generator blowdown line)

h. Shutdown cooling system

i. Class 1E electrical systems, ac and dc (including switchgear, batteries, and distribution systems)

j. Diesel generator system, including diesel generator starting, lubrication, and combustion air intake and exhaust systems

k. Diesel fuel oil storage and transfer system

l. Essential cooling water system (portions required for operation of other listed systems)

m. Essential spray pond system

n. Control building HVAC system

o. Main control board (see tables 7.3-2 and 7.3-14 for systems required)

p. Essential chilled water system

q. Containment isolation systems:

   (1) Penetration assemblies

   (2) Isolation valves

   (3) Equipment hatch

   (4) Emergency personnel hatch

   (5) Personnel lock

   (6) Liner plate

   (7) Test connections

   (8) Piping between penetration assemblies and isolation valves

r. Fuel building HVAC system

s. Diesel generator building HVAC system

C. Internal Missiles Generated from Systems Other Than Reactor Coolant, Main Steam, or Feedwater

A missile generated from a plant system, other than the reactor coolant system (RCS), the main steam system, or feedwater pressure boundary, shall not perforate the containment or control room or cause loss of integrity to the spent fuel pool. Criteria for missiles generated from the reactor coolant and main steam systems and feedwater pump discharge lines are discussed in section 3.5, listings A and B. In accordance with criteria listed in section 3.5, listing B, the missile shall not cause loss of function of any system required for safe shutdown. Since such missiles do not result in a LOCA or a steam generator steam/water release requiring protective action, a loss of redundancy for such systems is permitted, but a loss of function is not permitted.

D. Tornado Missiles

Missiles generated by a tornado shall not perforate the containment, the auxiliary building, the control building, the diesel generator building, the diesel generator fuel storage tanks, the condensate storage tank, the refueling water tank, or cause loss of integrity to the spent fuel pool. The missiles shall not cause loss of function to any system described in section 3.5, listing B, as required for safe shutdown.

MISSILE PROTECTION

3.5.1 MISSILE SELECTION AND DESCRIPTION

The sources of missiles which, if generated, could affect the safety of the plant are considered in this section. These are rotating component failure missiles, pressurized component failure missiles, and tornado generated missiles.

3.5.1.1 Internally-Generated Missiles (Outside Containment)

There are two general sources of postulated missiles outside containment:

- Rotating component failures
- Pressurized component failure

A tabulation of safety-related structures, systems, and components outside the containment, their locations, seismic categories, quality group classifications, and the applicable FSAR sections, which include system piping and instrumentation drawings describing safety design features, is given in table 3.2-1. General arrangement and section detail drawings are located in section 1.2.

3.5.1.1.1 Rotating Component Failure Missiles

A tabulation of missiles generated by postulated failures of rotating components, their sources and characteristics, and provided missile protection is given in table 3.5-1.

Missile selection was based on the following conditions:

A. Rotating components that are operated during normal operating plant conditions are capable of becoming missiles

B. The energy a rotating part associated with 120% overspeed is assumed sufficient for component failure

C. Determination of whether the energy of the missile is sufficient to perforate the protective housing.

3.5.1.1.2 Pressurized Component Failure Missiles

A tabulation of missiles generated by postulated failures of pressurized components, their sources and characteristics, and provided missile protection is given in table 3.5-2. The bases for selection were:

A. Pressurized components in systems whose service temperature exceeds 200F or whose design pressure exceeds 275 psig are evaluated as to their potential for becoming missiles.

B. Temperature or other detectors installed on piping or in wells are evaluated as potential missiles if failure of a single circumferential weld could cause their ejection.

C. Unrestrained sections of piping such as vents, drains, and test connections were evaluated as potential missiles if the failure of a single circumferential weld could cause their ejection.

D. Valves of ANSI rating 900 psig and above, constructed in accordance with Section III of the ASME Boiler and Pressure Vessel Code, are pressure seal bonnet-type valves. For pressure seal bonnet valves, valve bonnets are prevented from becoming missiles by the retaining ring, which would have to fail in shear, and by the yoke, which would capture the bonnet or reduce bonnet energy.

   Because of the highly conservative design of the retaining ring of these valves (safety factors in excess of 8 may be used), bonnet ejection is highly improbable, and hence bonnets are not considered credible missiles.

E. Most valves of ANSI rating 600 psig and below are valves with bolted bonnets. Valve bonnets are prevented from becoming missiles by limiting stresses in the bonnet-to-body bolting material by rules set forth in the ASME Boiler and Pressure Vessel Code, Section III, and by designing flanges in accordance with applicable code requirements. Even if bolt

failure were to occur, the likelihood of all bolts experiencing a simultaneous complete severance failure is very remote. The widespread use of valves with bolted bonnets, and the low historical incidence of complete severance valve bonnet failures confirm that bolted valve bonnets need not be considered as credible missiles.[1]

F. Valve stems were not considered as potential missiles if at least one feature, in addition to the stem threads, is included in their design to prevent ejection. Valves with backseats are prevented from becoming missiles by this feature. In addition, air- or motor-operated valve stems will be effectively restrained by the valve operators.

G. Nuts, bolts, nut and bolt combinations, and nut and stud combinations have only a small amount of stored energy and thus are of no concern as potential missiles.

3.5.1.2 Internally-Generated Missiles (Inside Containment)

There are two general sources of postulated missiles inside the containment:

- Rotating component failure
- Pressurized component failure

3.5.1.2.1 Rotating Component Failure Missiles

A tabulation of missiles generated by postulated failures of rotating components, their sources and characteristics, and provided missile protection is given in table 3.5-3.

Missile selection was based on the following conditions:

A. Rotating components that are operated during normal operating plant conditions are capable of becoming missiles

B. The energy in a rotating part associated with 120% overspeed is assumed to be sufficient for component failures

C. Determination of whether the energy of the missile is sufficient to perforate the protective housing

3.5.1.2.2 Pressurized Component Failure Missiles

A. Reactor Coolant System Pressure Boundary

The selection of potential missiles is based on the application of single failure criteria to the normal retention features of plant equipment for which there is a source of energy capable of creating a missile in the event of the postulated removal of the normal retention features. Where redundancy is provided by the normal retention features such that sufficient retention capability remains to prevent creation of a missile in the event of a postulated failure of a single retention feature, no potential missile is postulated. Table 3.5-4 presents the potential missiles postulated to originate from RCPB equipment, summarizes their characteristics, and lists provided missile protection (including missiles from equipment within the C-E scope of supply).

The effects of secondary missiles were evaluated during separation reviews of the PVNGS scale model. The effects fell into one of three categories:

1. No secondary missile

2. Secondary missile with insufficient energy to cause damage

3. Secondary missile but without safety impact

As noted in paragraph 3.6.1.2, separation reviews were conducted to ensure that nonseismically supported equipment could not impair the function of essential equipment or structures.

B. Non-RCPB Systems

A tabulation of missiles generated from failures of pressurized components, their sources and characteristics, and provided missile protection is given in table 3.5-4. The bases for selection are identical to those described in paragraph 3.5.1.1.2.

3.5.1.3 Turbine Missiles

3.5.1.3.1 Turbine Placement and Orientation

The placement and orientation of the turbine generators is shown in figure 3.5-1.

3.5.1.3.2 Missile Identification and Characteristics

Analysis has indicated that high-pressure turbine missiles and generator missiles would be retained by their respective casings. Accordingly, the missiles discussed in this paragraph are limited to postulated low-pressure turbine missiles.

3.5.1.3.2.1 Nature of Missiles Released by Low-Pressure Turbine. For the originally installed General Electric low-pressure turbines, it is postulated that any shrunk-on

wheel on the low-pressure rotor could be a source of missiles, the missiles being large sectors of the wheel released by multiple radial fractures. In the event of such disc fragments penetrating the surrounding turbine casings, the debris of internal collisions might also be ejected as comparatively minor missiles.

In the original turbine missile analysis, adjacent turbine wheels are categorized by General Electric into three groups (designated stage groups I, II, and III). The approximate expected number of missiles generated after a hypothetical wheel burst is postulated by General Electric (GE) as 16 fragments of four size classes. Appropriate information regarding missile nomenclature, size, shape, weight, energy, and velocity is presented in Table 1 and Figure 1 of GE Memo Report.(3)

The replacement General Electric Low Pressure Turbine Rotors are of monoblock construction and do not have shrunk on wheels. Therefore, the formerly dominant brittle fracture failure mechanism is not applicable to the new rotors. The probability of ductile failure for a rotor of any type is considered to be a function of speed, temperature and material tensile strength. With stress below ultimate strength, the probability of a ductile failure is negligible. The brittle and ductile failure modes are statistically independent. The GE probabilistic analysis of turbine overspeed was also documented in the 1984 NRC report, and is applicable to units with LP monoblock rotors. For the Palo Verde #1, 2 and 3 rotors, the probability of attaining an overspeed of 120% is at or below 1.7×10^{-6} and there is a negligible probability of ductile failure at 120%.

Therefore, the probability of turbine missile generation caused by ductile failure is well below the NRC acceptance criterion of $1x10^{-4}$ for a favorably oriented turbine.

In addition, GE has analyzed the potential for L-1 to L-6 stage bucket missiles applying the methodology used to study wheel missiles. At up to 120% speed no postulated missiles from an L-1 through L-6 bucket would penetrate the inner casing. As discussed above, the probability of turbine speed exceeding 120% is below the NRC missile probability threshold; therefore the probability of an L-1 through L-6 bucket missile is below the NRC threshold. Potential L-0 bucket missiles have been reviewed as discussed in Attachment (1) of GE Letter Report, Dated March 25, 2002.[(6)]

The probability of failure of the L-0 bucket is bounded by the probability of failure of the L-0 wheel reported in Memo Report Hypothetical Turbine Missile Data, 43-Inch Last Stage Bucket Units, J.E. Downs, 3/15/73.[(3)] This probability is below the NRC threshold. Therefore, the historical background of the remaining sub-sections of the UFSAR, under turbine missiles, that discuss in detail the original wheel turbine missiles analysis are left in place since they provide the bounding case for the Potential L-0 bucket missiles.

3.5.1.3.3 Turbine Failure Missiles - Probability Analysis

Turbine missiles are ejected fragments of the turbine wheels or surrounding casing which originate due to brittle fracture at normal rated speed (low speed burst) or due to ductile fracture during turbine runaway (high speed burst).

Missiles may be ejected at any angle of the 360° arc about the turbine axis. The ejection path will not always be perfectly normal to the turbine axis, but may vary from -5° to +5° from the normal for the interior turbine wheels, according to GE data. For the two outer turbine wheels, GE postulates a range of missile ejection angles from -25° to +25° from the normal to the turbine axis.

The missile ejection angles are illustrated in figure 3.5-2. The vertical angle Φ is measured about the turbine axis from the horizontal plane; ψ is the angle measured from the normal to the turbine axis; and θ is the projection of ψ on the horizontal plane. The horizontal angle θ is related to ϕ and ψ by the formula:

$$\theta = \tan^{-1}\left(\frac{\tan \psi}{\cos \phi}\right) \qquad (1)$$

From equation 1, it is seen that the angular range of missile ejection measured on the horizontal plane increases with increasing ϕ, the vertical angle of ejection. For example, for a missile ejected in the horizontal plane, at $\phi = 0°$, the horizontal range of ejection angles varies from -5° to 5° for interior turbine wheels. At $\phi = 45°$, the angular range measured at the horizontal plane varies from -7° to +7°, and at $\phi = 90°$, it ranges from -90° to +90°. It is at least theoretically possible, therefore, for a missile to strike a target located in line with the turbine axis, although the probability of strike is, of course, much higher for targets located near the normal to the axis.

Due to plant layout, all missiles are high trajectory missiles as defined in figure 3.5-3.

3.5.1.3.3.1 Probabilities Considered. The following probabilities are considered in the determination of the likelihood of a turbine missile accident leading to damage of structures, systems, or components required for safe plant shutdown:

P_1 = the probability of missile genesis due to turbine failure which causes fragment ejection through the turbine casing.

P_2 = the probability that a fragment strikes a specified target given its generation and ejection.

P_3 = the probability that the fragment strike damages its target in a manner leading to unacceptable consequences.

The probability analysis is performed for a layout of the generating units with turbine buildings in a peninsular arrangement (figure 3.5-1).

3.5.1.3.3.2 Probability of Missile Genesis (P_1). The probability of missile genesis (P_1) has been determined by GE for turbine rotor failures at or near running speed (a low speed burst due to brittle fracture) and at high overspeed or runaway conditions (a high speed burst due to ductile yielding).

In this analysis, adjacent turbine wheels (or stages) are categorized by GE into three groups (designated stage groups I, II, III) rather than considering seven individual stages for each turbine flow. This approach reduces the complexity of calculations and is justified on the basis that hypothetical missiles of significant similarity are produced by adjacent stages. The approximate expected number of missiles generated after a hypothetical nuclear wheel burst is postulated by GE as 16 fragments of four size classes. Each size class (designated fragment group a, b, c, or d) contains a specified number of fragments with characteristic shape, size, mass, and velocity range.

For the low-speed burst condition, GE considers the last stage to be two orders of magnitude more likely to fail than the next more likely stage. Therefore, stage groups I and II do not make a statistically significant contribution to missiles occurring from low-speed failure and are eliminated from further consideration. For the high-speed burst case, all seven stages are designed to about the same general stress level and, therefore, are about equally likely to fail by general ductile yielding in the event of runaway.

The following annual failure probabilities have been considered as given in Regulatory Guide 1.115:

A. Probability of missile genesis: $P_1 = 1 \times 10^{-4}$/yr.

B. Annual low-speed burst:[a] (below 120% speed), Stage III 6×10^{-5}/yr.

C. Annual high speed bursts:[a] 4×10^{-5}/yr
(from 120 to 180% speed)

1. Stage Group I: 1.71×10^{-5}/yr
(Stages 1-3)

2. Stage Group II: 1.71×10^{-5}/yr
(Stages 4-6)

3. Stage Group III: 0.58×10^{-5}/yr
(Stage 7)

Appropriate information regarding missile nomenclature, size, shape, weight, energy, and velocity is presented in Table 1 and Figure 1 of a GE Memo Report.[3]

3.5.1.3.3.3 Probability of Missile Strike (P_2).

Calculation of P_2: Neglecting the effect of air resistance, a missile trajectory is determined by the initial ejection vector from the turbine casing. The direction of the ejection vector is defined by two angles: ϕ, which is measured about the turbine axis, and ψ, which is measured from the plane normal to the turbine axis. The magnitude of the ejection vector is V, the ejection velocity from the casing. Functions must be specified, $P(\phi)$, $P(\psi)$, and $P(V)$, which determine the distribution of the missile ejection probability over the range of the three variables.

The ejection probability distribution $P(\phi)$ is assumed to be uniform over the 360° arc about the turbine axis:

$$P(\phi)\ d\phi = \frac{d\phi}{2\pi} \tag{2}$$

The probability distribution for $P(\psi)$ is considered to be uniform within some specified angular limits:

$$P(\psi)\ d\psi = \frac{d\psi}{\psi_{max} - \psi_{min}},\ \psi_{min} < \psi < \psi_{max} \tag{3}$$

The limits ψ_{min} to ψ_{max} are typically -5° to +5° for missiles ejected from interior turbine wheels, and -25° to +25° for missiles ejected from the end turbine wheel.

---

a. Calculated from information contained in GE Memo Report.[2]

The ejection probability distribution P(V) is normally assumed to be uniform over the specified range of ejection velocities V_{min} to V_{max}:

$$P(V)dV = \frac{dV}{V_{max} - V_{min}}, V_{min} < V < V_{max} \tag{4}$$

The principle of the P_2 calculation is to determine, using the basic equations of missile ballistics, the ranges of the variables ϕ, ψ, and V which determine trajectories intersecting the specified target structure. The strike probability is determined by integrating the product of the three ejection probability distributions over the ranges of the variables corresponding to target strike:

$$P_2 = \int_{\phi_1}^{\phi_2} \int_{\psi_1(\phi)}^{\psi_2(\phi)} \int_{V_1(\phi,\psi)}^{V_2(\phi,\psi)} P(\phi)\, P(\psi)\, P(V)\, dV\, d\psi\, d\phi \tag{5}$$

The integral is evaluated by the computer code "TURMIS," (turbine missile). Discrete ejection directions are evaluated by first specifying a ϕ_i, for which the limits ψ_1 (ϕ_i) and $\psi_2(\phi_i)$ may be computed corresponding to target strike. Discrete values ψ_j within the range $\psi_1(\phi_i)$ to $\psi_2(\phi_i)$ are then specified. Given the values ϕ_i and ψ_j, the limits $V_1(\phi_i, \psi_j)$ and $V_2(\phi_i, \psi_j)$ corresponding to target strike are then computed, and the integral over V may be evaluated analytically. The subrange of velocities V_{min} to V_{max} is illustrated in figure 3.5-3.

3.5.1.3.3.4 Probability of Damage to Missile Targets (P_3). Calculation of P_3: The calculation of P_3 requires the

definition of a sufficient missile impact on a target structure to assume damage to safety-related systems contained inside. A missile of sufficient kinetic energy to penetrate the concrete structure surrounding a safety-related system will essentially ensure damage to the system. Damage may be incurred without missile penetration, however. A sufficient impact to generate spallation of concrete fragments from the interior surface will also constitute a hazard to unprotected equipment. Thus, a missile impact which initiates spallation in the concrete wall or roof slab immediately surrounding a safety-related system is conservatively defined as the threshold of target damage. Modified National Defense Research Council (NDRC) equations with a safety factor of 1.2 have been adapted to determine whether or not spallation (perforation for containment) will occur upon missile impact of a specified concrete slab.[(4)]

3.5.1.3.3.5 Analytical Results. Calculation of P_4: The value of P_4 for a particular target structure and a particular turbine failure mode is taken as $P_1xP_2xP_3$ for the worst missile.

The P_4 value for the plant is determined by summation of P_4 values corresponding to the critical failure mode for safety-related targets on the plant site. Table 3.5-5 lists missile targets, strike probabilities, and turbine missile damage probabilities, in case the turbine in Unit 1 fails. Similar numbers are listed in tables 3.5-6 and 3.5-7 for the cases when the turbine fails in Units 2 and 3, respectively.
Tables 3.5-5, 3.5-6, and 3.5-7 show the P_4 values for both the

high- and low-trajectory missiles. Figures 3.5-4 through 3.5-7 are provided to show physical locations and barriers of targets considered in this analysis. Since the targets in all units are similarly oriented within a unit relative to a functional operating axis, these figures are applicable to all units.

3.5.1.3.4 Turbine Overspeed Protection

A description of the turbine overspeed protection system, in terms of redundancy, diversity, component reliability, and testing procedures, is provided in subsection 10.2.2.

3.5.1.3.5 Turbine Valve Testing

Since the annual probability of attaining an overspeed of 120% or greater is 1.7×10^{-6} which is below the NRC threshold for probability of missile generation, protection against missile generation for the turbines can be shown by avoiding the potential for ductile failure at any operating speed below 120%. GE, in the course of designing the turbines, has evaluated tensile stresses in rotating components. All of the rotating components have sufficient margin to tensile strength at design component temperatures to support operating speeds well in excess of 120% of normal.

To keep the probability of a significant overspeed event very low, periodic maintenance and inspection of valves and other overspeed protection components are required. The intervals are established to maintain system reliability.

The 1.7 x 10^{-6} probability number assumes the longest permissible interval between valve inspections and would be lower with more frequent inspections. Assumed inspection intervals are:

Component	Inspection Interval
Main stop valve	Quarterly
Control valve	Quarterly
Intercept valve	Quarterly
Mechanical trip valve	Weekly
Electrical trip valve	Weekly
On-line overspeed trip	Weekly

The above inspection intervals are met by PVNGS Operations Department Repetitive Task program.

3.5.1.3.6 Turbine Characteristics

Turbine data pertinent to the evaluation of its failure characteristics, including a description of its overall configuration, major components (e.g., steam valves, reheaters, etc.), rotor materials and their properties, steam environment (e.g., pressure, temperature, quality, chemistry), and other appropriate properties, are provided in section 10.2.

Turbine operational and transient characteristics, including turbine startup and trip environments, as well as its overspeed parameters, also are provided in section 10.2.

3.5.1.3.7 Turbine Missile Barriers

In accordance with Regulatory Guide 1.115, no turbine missile barriers have been provided since the probability of damaging an essential system, summed over all such systems, is less than 0.001.

3.5.1.4 Missiles Generated by Natural Phenomena (Tornado)

Tornado-generated missiles were considered in design of structures which are required for safe shutdown. The missiles considered in design and their characteristics are listed in table 3.5-8.

Missiles generated by any other natural phenomena were not considered credible.

	Total			0.839 x 10^{-3}	0.839 x 10^{-7}

The missiles were considered as striking in all directions. Missiles A, B, C, D, and E were considered at all elevations and missiles F and G at elevations less than 30 feet above all grade levels within 1/2 mile of the facility structures.

A tabulation of structures and missile barriers used for missile protection is provided in subsection 3.5.2.

Tornado missile protection is not provided for the essential spray pond spray nozzles because the probability of loss of the ultimate heat sink safety function has been demonstrated by probabilistic risk assessment (PRA) to be less than a median value of 10^{-7} per reactor year or a mean value of 10^{-6} per reactor year without missile protection (Ref. 5). This PRA utilized the tornado missile spectrum in Standard Review Plan (SRP) Section 3.5.1.4 when considering potential missile sources. Class A through F missiles were averaged into a "standard missile." Class G missiles (automobiles) are excluded from explicit consideration because of the conservatism used in the number of “standard missiles” and the low probability of automobile injection compared to “standard missile” injection.

3.5.1.5 Missiles Generated by Events Near the Site

The potential for accidents in the vicinity of the site was discussed in section 2.2. Considering the distances from potential accident sites to the plant, missiles pose no credible hazard.

Table 3.5-8
TORNADO-GENERATED MISSILES CONSIDERED IN DESIGN OF SAFE SHUTDOWN STRUCTURES

Description	Weight (lbs)	Impact Area (ft^2)	Maximum Velocity (ft/s)	Kinetic Energy (ft-lbs)
(A) A 12-foot wood plank, 4 x 12 inches in cross-section, traveling end on at a speed of 240 mi/h.	200	0.333	352	3.85×10^5
(B) A steel pipe, Schedule 40, 3 inches in diameter by 10 feet long, traveling end on at 120 mi/h.	78	0.063	176	3.75×10^4
(C) A steel rod, 1 inch in diameter, 3 feet long, traveling end on at 180 mi/h.	8	0.005	264	8.66×10^3
(D) A steel pipe, Schedule 40, 6 inches in diameter by 15 feet long, traveling end on at 120 mi/h.	285	0.24	176	1.37×10^5
(E) A steel pipe, Schedule 40, 12 inches in diameter by 15 feet long, traveling end on at 120 mi/h.	743	0.886	176	3.57×10^5
(F) A utility pole, 13-1/2 inches in diameter, 35 feet long, traveling end on at 120 mi/h.	1490	0.994	176	7.17×10^5
(G) An automobile of 4,000 pounds weight, striking the structure at 60 mi/h.	4000	20.0	88	4.81×10^5

3.5.1.6 Aircraft Hazards

Aircraft hazards are discussed in paragraph 2.2.3.1.4.

3.5.2 STRUCTURES, SYSTEMS, AND COMPONENTS TO BE PROTECTED FROM EXTERNALLY-GENERATED MISSILES

3.5.2.1 General

The sources of missiles which, if generated, could affect the safety of the plant are considered in subsection 3.5.1. Safety-related structures and equipment that are protected from these postulated missiles are included in table 3.2-1.

Refer to sections 3A.13, 3A.14, and 3A.18 for additional discussions of missile barriers.

3.5.2.2 Missile Barriers Within Containment

The secondary shield, the primary shield, the refueling cavity walls, the reactor vessel and pressurizer missile shields, the various structural beams, and the operating floor act as missile barriers separating each reactor coolant loop from other protected components and missile sources (engineering drawings 13-P-OOB-002 through -011). These barriers also protect the RCPB in each loop from those identified missiles generated elsewhere in the containment. The containment protects the RCPB from externally generated missiles.

Except for short piping runs in the SIS, which must supply cooling water to the core after a LOCA, and SDC suction line and isolation valve, SI-651, the engineered safety features (ESFs) are located outside the secondary shield. The SIS and

SDC lines which penetrate the secondary shield do so in the vicinity of the loop segment to which they are attached.

A missile shield structure is provided over the control element drive mechanisms to block any identified missiles generated in that location. A barrier, or restraints, is provided to protect against identified missiles that originate in the region where the pressurizer extends above the operating deck.

Barriers or retainers are provided, as required, to prevent missiles generated by the failure of main steam or feedwater components inside the containment from causing loss of integrity to the containment liner, isolation system, or steam system associated with another steam generator, or from causing loss of function to other required systems or components inside the containment in accordance with the missile protection design criteria previously listed in this section.

3.5.2.3 Barriers for Missiles Generated Outside of Plant Structures

The protective structures, shields, components, and barriers designed to provide protection against identified missiles generated outside these structures, shields, and barriers are listed in table 3.5-9. The missile barriers listed were designed for the tornado and accident missiles described in subsection 3.5.1 utilizing the procedures stated in subsection 3.5.3.

3.5.2.4 Missile Barriers Within Plant Structures Other than Containment

Missile barriers or restraints are provided within plant structures outside containment in conformance with the missile protection design criteria discussed in section 3.5. For the pressurized and rotating component failure missiles that originate outside the containment, identified in subsection 3.5.1, the following steps are taken to assure that the missile protection design criteria are met:

A. Missiles were categorized according to the system in which they originate.

B. The components that must be protected from a missile were identified in accordance with the missile protection design criteria given in section 3.5.

C. The following methods were used as required to prevent a missile from causing loss of function to a protected component:

1. The missile characteristics are determined using the procedures given in subsection 3.5.1.

2. A determination is made as to whether the missile characteristics cause loss of function to protected components utilizing the procedures given in Section 2.0 of BC-TOP-9-A and Section 2.0 of Appendix 3C. Credit is taken for existing structures or components that are positioned between the point of missile origin and the protected component.

3. The trajectory is altered by changing the orientation or position of the missile and/or the position of the protected component if this is feasible.

4. If loss of function of the protected component can occur due to missile damage, either suitable restraints are provided to prevent the missile from leaving its point of origin, or barriers are installed to intercept the missile trajectory.

3.5.2.5 Missile Barrier Features

The layout and principal design features of structures serving primarily as missile-resistant barriers are shown in figures 3.5-4 through 3.5-7. Areas housing equipment, systems, and components that are required for a safe shutdown of the plant are considered targets. The target barrier is a slab (roof) over the target area that must be perforated before the target area can be struck.

3.5.3 BARRIER DESIGN PROCEDURES

Missile-resistant barriers and structures were designed to withstand and absorb missile impact loads without being perforated in order to prevent damage to protected components. The procedures employed in design of missile-resistant barriers are described in BC-TOP-9-A and appendix 3C.

3.5.4 NSSS INTERFACE

3.5.4.1 CESSAR Missile Barrier Design Interface Requirements

The following interface requirements are repeated from CESSAR Section 3.5.3.1:

1. For systems and parts of systems located inside containment (reactor coolant system and connecting systems, engineered safety features systems), appropriate missile barrier design procedures shall be used to insure that the impact of any potential missile shall not lead to a loss of coolant accident or preclude systems from carrying out their specified safety functions.

2. For systems and equipment outside containment, listed in Section 3.5.1, appropriate design procedures (for example, proper turbine orientation, natural separation, or missile barriers) shall be used to ensure that the impact of any potential missile does not prevent the system or equipment from carrying out its specified safety functions.

3. For all systems and equipment, appropriate design procedures shall be used to ensure that the impact of any potential missile does not prevent the conduct of a safe plant shutdown, or prevent the plant from remaining in a safe shutdown condition.

3.5.4.2 CESSAR Interface Evaluation

The CESSAR interface requirements set forth in paragraph 3.5.4.1 are satisfied in the FSAR sections and paragraphs indicated below for the corresponding requirements:

A. Paragraphs 3.5.1.1 and 3.5.1.2

B. Paragraphs 3.5.1.2 and 3.5.1.3

C. Section 3.5, listings A, B, C, and D.

3.6 PROTECTION AGAINST DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

This section describes the design bases and protective measures that are used to ensure that the containment, essential equipment, and other essential structures are adequately protected from dynamic effects associated with the postulated rupture of high and moderate energy piping. The pipe failure protection criteria conform to 10CFR50, Appendix A, General Design Criterion 4, Environmental and Missile Design Bases. Protection against pipe failure effects is provided to fulfill the following system protection criteria:

A. Preserve the ability to safely shut down the reactor and maintain it in a safe shutdown condition.

B. Maintain the containment fission product barrier in the event of a loss-of-coolant accident (LOCA) or main steam line break within the containment.

C. A pipe break occurring in lines other than the reactor coolant system, main steam, or main feedwater lines must not cause a consequential pipe break in a reactor coolant, main steam, or main feedwater line.

D. A pipe break in the reactor coolant system hot leg must not cause a consequential pipe break in the cold leg, or vice versa, excluding the loss of an instrument line.

E. A steam or feedwater line break in one steam generator system must not cause a steam or feedwater line break in the other steam generator system.

F. Resultant offsite radiological doses must be below the limits of 10CFR100.

Structures, systems, and components, which provide protection of essential equipment and structures from the dynamic effects associated with the postulated rupture of high and moderate energy piping, shall be classified as quality related and applicable quality assurance requirements shall be applied.

3.6.1 POSTULATED PIPING FAILURES IN FLUID SYSTEMS

This section sets forth the design bases, description, and safety evaluation for determining the effects of postulated piping failures in fluid systems both inside and outside containment.

3.6.1.1 Design Bases

Systems or components important to plant safety or shutdown (hereinafter called essential systems) are listed in paragraph 3.6.1.2. The criteria for determining the location of the break are given in paragraph 3.6.2.1 and the general design features used to protect essential systems are discussed in paragraph 3.6.1.3. For additional discussion, refer to sections 3A.19 and 3A.20.

3.6.1.2 Description

A listing of the high energy lines inside the containment is given in table 3.6-1. A listing of high energy lines outside the containment is given in table 3.6-2. Since the turbine and

radwaste buildings contain no safety-related equipment, high energy line breaks in those buildings are generally excluded from this table.

Essential systems are those systems that are needed to safely shut down the reactor or mitigate the consequences of pipe break for a given postulated piping failure. However, depending upon the type and location of a postulated pipe break, certain safety equipment may not be classified as essential for that particular event (e.g., the containment spray chemical addition system is not required to mitigate the consequences of a break in high energy, secondary side, pressure boundary piping).

The essential systems which are to be protected from the effects of postulated piping failures are identified below. These essential systems were selected for each postulated break to satisfy the protection criteria given in the introduction to section 3.6.

A. The following systems, or portions of these systems, are required to mitigate the consequences of postulated breaks of high energy reactor coolant pressure boundary piping that will result in a LOCA assuming a loss of offsite power:

   1. Reactor protective system

   2. Engineered safety features actuation system

   3. Safety injection system (HPSI and LPSI, including hot leg injection lines and refueling water tank)

(f) Conservatively evaluated for breaks even though the lines are exempt per UFSAR 3.6.2.1.1.1.

4. Containment spray system
5. Auxiliary feedwater system (including safety-related condensate transfer and storage system and condensate storage tank)
6. Class 1E electrical systems, ac and dc (including switchgear, batteries, and distribution systems)
7. Diesel generator system, including diesel generator starting, lubrication, and combustion air intake and exhaust systems
8. Diesel fuel oil storage and transfer system
9. Hydrogen recombiner systems
10. Control building HVAC system
11. Essential cooling water system (portions required for operation of other listed systems)
12. Essential spray pond system
13. Fuel building HVAC system
14. Diesel generator building HVAC system
15. Main control board (see tables 7.3-2 and 7.3-14 for systems required)
16. Containment isolation systems:
    a. Penetration assemblies
    b. Isolation valves
    c. Equipment hatch

d. Emergency personnel hatch

e. Personnel lock

f. Liner plate

g. Test connections

h. Piping between penetration assemblies and isolation valves

17. Excore neutron monitoring system

18. Safety-related radiation monitors (refer to section 11.5)

19. Chemical and volume control systems (piping associated with sampling of the reactor coolant)

20. Shutdown cooling system

21. Essential chilled water system.

B. The following systems, or portions of these systems, are required to mitigate the consequences of postulated breaks in high energy secondary pressure boundary piping (main steam, main feedwater, blowdown, or auxiliary feedwater) assuming a loss of offsite power:

1. Reactor protective system

2. Engineered safety features actuation system

3. Auxiliary feedwater system (including safety-related condensate transfer and storage system and condensate storage tank)

4. Safety injection system (HPSI and LPSI, including refueling water tank)

5. Containment spray system (for breaks inside the containment only)

6. Chemical and volume control system (charging portion including boric acid makeup pumps, charging pumps, interconnecting piping, and reactor coolant sampling portion)

7. Main steam and feedwater system (from unaffected steam generator out to the containment isolation valves, including the atmospheric steam dump, steam supply to the turbine-driven auxiliary feedwater pump, and the steam generator blowdown line)

8. Shutdown cooling system

9. Class 1E electrical systems, ac and dc (including switchgear, batteries, and distribution systems)

10. Diesel generator system, including diesel generator starting, lubrication, and combustion air intake and exhaust systems

11. Diesel fuel oil storage and transfer system

12. Essential cooling water system (portions required for operation of other listed systems)

13. Essential spray pond system

14. Control building HVAC system

15. Main control board (see tables 7.3-2 and 7.3-14 for systems required)

16. Essential chilled water system

17. Containment isolation systems:

    a. Penetration assemblies

    b. Isolation valves

    c. Equipment hatch

    d. Emergency personnel hatch

    e. Personnel lock

    f. Liner plate

    g. Test connections

    h. Piping between penetration assemblies and isolation valves

18. Fuel building HVAC system

19. Diesel generator building HVAC system.

C. For other postulated breaks not included in items A. and B. above, systems must not be affected such that any break, evaluated on a case-by-case basis, violates the following criteria:

1. The pipe break must not cause a reactor coolant, steam, or feedwater line break.

2. The function of safety systems required to perform protective actions to mitigate the consequences of the postulated break must be maintained.

3. The ability to place the plant in a safe shutdown condition must be maintained.

PVNGS utilized a three-dimensional scale model for design and layout of equipment. A systematic approach of multidiscipline analyses of safety-related and associated systems was initiated to verify compliance with design criteria, interface requirements, and safety design bases. Ongoing reviews of the model identified potential hazards and highlighted susceptibility of essential equipment from common mode failure, as well as provided an independent method of verification of the availability of essential equipment required to mitigate the consequences of postulated accident scenarios. The resolution of comments raised during these reviews resulted in changes to equipment layout, design of pipe whip and jet impingement restraints, upgrading some non-seismic supports to seismic, and the addition of curbs, drains, and other flood mitigation measures. Figures 3.6-2 through 3.6-31 depict the resulting pipe routing.

The potential effects of flooding as a consequence of a pipe break or critical crack were analyzed on a case-by-case basis to ensure that the operability of safety-related equipment would not be impaired.

For areas outside the containment, flooding calculations utilizing the worst case flow from high or moderate energy piping systems provided the basis for sizing the floor drains. Compartmentation as shown in Engineering drawings 13-P-OOB-002 through -006 was utilized to minimize the potential for common safety features to be affected by a hazard-producing event. A table identifying means of protection of safety-related systems from effects of high and moderate energy pipe breaks is provided as table 3.6-3.

An analysis of the potential effects of missiles is discussed in section 3.5.

The design bases for the protection of individual safety-related equipment follows the guidance of BTP ASB 3-1. One of the following methods is utilized (listed in decreasing order of preference):

- Separation of fluid piping systems from essential systems and components
- Enclosure of essential components such that they can withstand effects of postulated piping failure
- Addition of pipe whip restraints and/or jet impingement restraints and barriers
- Addition of active features for automatic isolation of the blowdown from the ruptured pipe

Internal flooding due to high energy pipe breaks and moderate energy pipe cracks was considered (on a room-by-room basis) to

result from a postulated break of the worst case fluid piping within a room, discharging for one-half hour at normal operating temperature and pressure. Only passive means for allowing water to leave the room (i.e., drains whose check valves are inspected under the Pump and Valve Inservice Testing Program and whose valves and piping are covered by the Maintenance Rule, doorways) were considered to mitigate the break effects during that time interval. The maximum flood levels were then calculated. Safety-related equipment was located so as to be unaffected.

Jet impingement due to high energy line break (HELB) was postulated using the Moody expansion model. Where impingement on safety-related equipment was found, operability was assured by damage assessment analysis (e.g., stress analysis of impinged piping systems) or addition of jet impingement restraints/barriers.

The potential environmental effects of steam on essential systems are discussed in section 3.11. In general, because of the protective measures of redundancy and separation between systems and trains, the consequential effect of the transport of steam will not be sufficient to impair the ability of the essential system to shut down the plant and/or mitigate the consequences of the given accident of interest. Environmental parameters due to postulated high and moderate energy breaks are addressed in Appendix A of the Equipment Qualification Program Manual.

Table 3.6-3

METHODS OF PROTECTION OF SAFETY-RELATED SYSTEMS

FROM HIGH AND MODERATE ENERGY LINE BREAKS (Sheet 6 of 6)

Notes:

a. Separation from high or moderate energy break effects is accomplished by the following methods in decreasing order of preference:

   - Layout (L)
   - Enclosure (E)
   - Redundancy (R)

b. Protection is provided from break effects originating in system listed in parentheses.

c. CVCS (charging) is required for nonaccident forced shutdown only. (SI provides reactor inventory for MS line break and LOCA.)

d. Monitors are separated from LOCA-induced jet impingement or pipe whip effects. Not required for any other design basis pipe break scenario.

e. Liner plate is separated from LOCA-induced jet impingement or pipe whip effects and is protected from MSLD whip and impingement effects by restraints or barriers. Not required for any other HELB scenario.

f. Except as noted, the jet impingement and pipe whip restraints constructed to alleviate the effects of an RCS pipe break are no longer required. However, the restraints are not removed.

g. Jet impingement barrier and pipe whip restraint protection are provided for valve SI-656.

The auxiliary steam system contains two redundant air operated isolation valves. These valves will fail closed upon the loss of either instrument air or a site loss of offsite power (LOOP).

The consequences of an unlimited auxiliary steam line HELB located in the auxiliary building, which continues until steady state conditions are reached, have been evaluated. This evaluation is predicated upon the existence of an atmospheric vent path for the steam through the building's HVAC exhaust duct.

It was determined that the resultant auxiliary building pressures from an unlimited HELB accident would not exceed the design pressure loading for the walls. Additionally, the environmental conditions were acceptable from an Equipment Qualification perspective. Therefore, no safe shutdown equipment is subject to failure due to the effects of an auxiliary steam HELB.

Pressure-temperature analyses of the chemical and volume control system (CVCS) letdown line indicated the worst case break resulted in pressure and temperatures that were within the allowable range for structural loading and for safe shutdown equipment environmental qualification, respectively.

No other safety-related structures, outside of the containment and the main steam support structure, enclose high energy lines. Therefore, pressure-temperature analyses of additional structures are not required.

There are no high energy lines in the vicinity of the control room. As such, there are no effects upon the habitability of the control room by pipe break either from pipe whip, jet impingement, or transport of steam. Further discussion on control room habitability systems is provided in section 6.4.

3.6.1.3 Safety Evaluation

By means of design features such as separation, barriers, and pipe whip and jet impingement restraints, all of which are discussed below, the effects of pipe break will not damage essential systems to an extent that would impair their design function nor affect necessary component operability.

Specific design features used for protecting the essential systems listed in paragraph 3.6.1.2 are identified in figures 3.6-1 through 3.6-30.

The ability of specific safety-related systems to withstand a single active failure concurrent with a postulated event is discussed in the failure modes and effects analyses provided in sections 6.2, 6.5, 7.2, 7.3, 8.3, 9.2, and 10.4.

A. Separation

The plant arrangement provides separation to the extent practical between redundant safety systems in order to prevent loss of safety function as a result of hazards different from those for which the system is required to function, as well as for the specific event for which the system is required to be functional.

Separation between redundant safety systems with their related auxiliary supporting features is the basic protective measure.

In general, layout of the facility followed a multistep process to ensure adequate separation.

1. Safety-related systems are located away from most high energy piping.
2. Redundant (e.g., A and B trains) safety systems and subsystems are located in separate compartments.
3. As necessary, specific components are enclosed to maintain the redundancy required for those systems that must function as a consequence of specific piping failure events.

B. Barriers-Shields and Enclosures

In many cases, protection requirements are met through the protection afforded by the walls, floors, columns, abutments, and foundations. Where adequate protection does not already exist due to separation, additional barriers, deflectors, or shields are provided as necessary to meet the functional protection requirements. Where compartments, barriers, and structures are required to provide the necessary protection, they are designed to withstand the combined effects of the postulated failure plus normal operating loads plus operating basis earthquake (OBE) loadings.

C. Piping Restraint Protection

Where adequate protection does not already exist due to separation, barriers, or shields, piping restraints are provided as necessary to meet the functional protection requirements. Restraints are not provided when it can be shown that the pipe break would not cause unacceptable damage to essential systems or components.

Typical pipe whip and jet impingement restraints are shown in figure 3.6-1.

The design criteria for pipe whip restraints are given in paragraph 3.6.2.3.2.

D. Facility Response Analyses

An analysis of postulated pipe break events was performed to identify those safety-related systems and components that provide protective actions required to mitigate, to acceptable limits, the consequences of the postulated pipe break event.

Whenever the separation inherent in the plant design is shown to assure the functional capability of the safety systems required following a postulated pipe break event, no additional protective measures are required for that event, and additional considerations of break type, location, orientation, restraints, and other protective measures are not required. When necessary, additional protective measures are incorporated into the design, as required, to assure the functional

capability of safety systems required following the postulated pipe break event.

In conducting the facility response analyses, the following criteria are utilized to establish the integrity of systems and components necessary for safe reactor shutdown and maintenance of the shutdown condition:

1. Offsite power is assumed to be unavailable if an automatic turbine generator trip or automatic reactor trip is a direct consequence of a postulated piping failure.

2. In addition to the postulated pipe failure and its accompanying effects, a single active component failure is assumed in the systems required to mitigate the consequences of the postulated piping failure.

   The single active component failure is assumed, except as noted in paragraph 3.6.1.3.D.4.

3. Each high or moderate energy fluid system pipe failure is considered separately as a single postulated initial event occurring during normal plant conditions.

4. Where a postulated piping failure is assumed in one of two redundant trains of a dual purpose system that is required to operate during normal plant conditions as well as to shut down the

reactor, single failures that prevent the functioning of the other train or trains of that system are not assumed, provided the system is designed to Seismic Category I standards, is powered from offsite and onsite sources, and is designed, constructed, operated, and inspected to quality assurance, testing, and inservice inspection standards appropriate for nuclear safety class systems.

5. All available systems and components, including non-Seismic Category I and those actuated by operator actions, may be employed to mitigate the consequences of a postulated piping failure. In judging the availability of such systems and components, account is taken of the postulated failure and its direct consequences, such as unit trip and loss of offsite power, and of the assumed single active component failure and its direct consequences. The feasibility of carrying out operator actions is based on a minimum of 30 minutes delay responding to alarm indication and adequate access to equipment being available for the proposed actions. (Access to the containment post-LOCA is not assumed.)

6. Piping systems containing high energy fluids are designed so that the effects of a single postulated pipe break cannot, in turn, cause

failures of other pipes or components with unacceptable consequences.

7. For a postulated pipe failure, the escape of steam, water, and heat from structures enclosing the high energy fluid containing piping does not preclude:

   a. Accessibility to surrounding areas important to the safe control of reactor operations.

   b. Habitability of the control room.

   c. Ability of instrumentation, electric power supplies, and components and controls to initiate, actuate, and complete a safety action. (A loss of redundancy is permissible, but not the loss of function.)

The design criteria define acceptable types of isolation for safety-related elements and for high energy lines from similar elements of the redundant train. Separation is accomplished by:

- Routing the two groups through separate compartments, or
- Physically separating the two groups by a specified minimum distance, or
- Separating the two groups by structural barriers.

The design criteria assure that a postulated failure of a high energy line or a safety-related element cannot take more than one safety-related train out of service. The failure of a component or subsystem of one train may cause failure of another of the same train; for example, a B train high energy pipe may cause failure of a B train electrical tray, but not failure of an A train electrical tray. The capability of shutting the plant down safely under such a failure will, therefore, remain intact.

Given the separation criteria above and the pipe break criteria in paragraph 3.6.2.1.1, the effects of high energy pipe breaks are not analyzed where it is determined that all essential systems, components, and structures are sufficiently physically remote from a postulated break in that piping run.

3.6.2 DETERMINATION OF BREAK LOCATIONS AND DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

This section describes the design bases for locating postulated breaks in high energy piping inside and outside of containment, the procedures used to define the jet thrust reaction at the break location, and the procedures used to define the jet impingement loading on adjacent essential structures, systems, and components.

3.6.2.1 Criteria Used to Define Break and Crack Locations and Configuration

The criteria for postulating break locations in high energy piping are described below.

3.6.2.1.1 High Energy Piping Other Than RCS Main Loop

3.6.2.1.1.1 High Energy Piping. Piping is considered high energy if, during normal plant conditions, it is either in operation or is maintained pressurized under conditions where either (or both) of the following conditions are met:

- Maximum operating temperature exceeds 200F, or
- Maximum operating pressure exceeds 275 psig.

Piping is not considered to be high energy if the piping run or branch run operates for less than 2% of the time that the system qualifies as a moderate energy system (as defined in paragraph 3.6.2.1.2). Also, auxiliary feedwater system leakages, from boundary SG system isolation valves between high and low/moderate energy lines located in rooms C-A09 and C-A10, is allowed as long as the maximum surface temperature of downsteam process piping would not exceed 212 degrees fahrenheit at atmospheric conditions.

3.6.2.1.1.2 Break Locations. In any given piping system, there are a limited number of locations which are more susceptible to failure by virtue of stress or fatigue than the remainder of the system. In determining the rupture locations,

system parameters are based on those associated with specified seismic events and operational plant conditions. The specified seismic event is the OBE; the operational plant conditions include normal reactor operation, upset conditions, and testing conditions. Where required, postulated pipe breaks are selected as described below and are analyzed to demonstrate the capability to place the plant in a safe shutdown condition.

A. ASME Section III, Code Class 1 Piping Within Containment (NRC Generic Letter 87-11 has been implemented)

For ASME Section III, Code Class 1 piping, breaks are postulated to occur at the following locations (i.e., at weld joints where the piping incorporates a fitting, valve, or welded attachment) in each piping run or branch run:

1. The terminal ends

2. At intermediate locations where the following are met:

   a. the stress range S_n exceeds 2.4 S_m, where S_m is the design stress intensity as defined in Section III of the ASME Code, or

   b. the stress range S_n as calculated by Equation 10 of Paragraph NB-3653 exceeds 2.4 S_m and the stresses computed by

Equations 12 and 13 of Paragraph NB-3653 are greater than 2.4 S_m, or

c. If fatigue analysis is performed, any intermediate location between terminal ends where the cumulative usage factor under loading associated with operational plant conditions and an OBE exceed 0.1 of the Code allowable.

In the absence of a Class 1 stress analysis, breaks are conservatively postulated at terminal ends and at all fittings, valves, or welded attachments.

B. ASME Section III, Code Class 2 and 3 Piping Within Containment (NRC Generic Letter 87-11 has been implemented)

For ASME Section III, Code Class 2 and 3 piping, breaks are postulated to occur at the following locations (i.e., at weld joints where the piping incorporates a fitting, valve, or welded attachment) in each piping run or branch run:

1. The terminal ends

2. The maximum stress as calculated by the sum of Equations 9 and 10 in Paragraph NC-3652 of the ASME Code, Section III, considering normal and upset plant conditions (i.e., sustained loads, occasional loads and thermal expansion) including

an OBE event are less than 0.8 (1.2 S_h + S_A), where S_h and S_A are the allowable stress at maximum (hot) temperature and the allowable stress for thermal expansion, respectively, as defined in Article NC-3600 of ASME Code, Section III.

3. If fatigue analysis is performed, any intermediate location between terminal ends where the cumulative usage factor exceeds 0.1 under loading associated with the normal and upset plant condition and an OBE

C. Fluid System Piping Penetrating Containment

Pipe breaks are not postulated in portions of ASME Code, Section III, Class 2 high energy fluid system piping between containment isolation valves or, where no isolation valve is used inside containment, between the first rigid pipe connection to the containment penetration or the first pipe whip restraint inside containment and the outside isolation valve, provided that the piping meets the following requirements:

1. The piping is designed to meet the requirements of NE-1120 of ASME Code, Section III.

2. The maximum stress as calculated by the sum of Equations (9) and (10) in subarticle NC-3600, ASME Code, Section III, considering those loads and conditions thereof for which level A and level B stress limits have been specified in the system’s

Design Specification (i.e., sustained loads, occasional loads, and thermal expansion) including an OBE event should not exceed 0.8 (1.8 S_h + S_A). The S_h and S_A are allowable stresses at maximum (hot) temperature and allowable stress range for thermal expansion, respectively, as defined in subarticle NC-3600 of the ASME Code, Section III.

3. The maximum stress as calculated by Equation (9) in NC-3600 under the loadings resulting from a postulated piping failure of fluid system piping beyond these portions of piping should not exceed the lesser of 2.25 S_h and 1.8 S_y except that following a failure outside containment, the pipe between the outboard isolation valve and the first restraint may be permitted higher stresses provided a plastic hinge is not formed and operability of the valves with such stresses is assured in accordance with the requirements specified in SRP section 3.9.3. This exception may be applied provided that when the piping between the outboard isolation valve and the restraint is constructed in accordance with the Power Piping Code ANSI B31.1 (see ASB 3-1 B.2.c(4)), the piping shall either be of seamless construction with full radiography of all circumferential welds, or all longitudinal and circumferential welds shall be fully radiographed.

Primary loads include those which are deflection limited by whip restraints.

4. Welded attachments to portions of piping or direct welding to the outer surface of the piping for pipe supports or pipe restraint are avoided, except where detailed stress analyses or tests are performed.

5. The number of circumferential or longitudinal welds in piping and branch connections is minimized.

6. The length of the piping run is minimized.

7. The augmented inservice inspection of the circumferential and longitudinal welds will be performed in accordance with section 6.6.

8. Geometric discontinuities such as pipe-to-valve section transitions, branch connections, and changes in pipe wall thicknesses are designed to minimize discontinuity stresses.

9. The piping run beyond the isolation valve outside the containment is restrained such that excessive pipe loads following a postulated pipe break are no transmitted to the isolation valve, which would impair the ability of the valve to perform its required function; or the piping run can be shown to have insufficient energy to cause damage to the isolation valve; or the break can be shown not to

result in unacceptable consequences, as described in the protection criteria of section 3.6.

10. Penetration is designed to withstand loadings resulting from a postulated piping failure inside the containment so that neither isolation valve operability nor, in the case of a main steam line break, the leaktight integrity of the containment is impaired.

Pressure-temperature analyses, assuming a one square foot nonmechanistic break of the main steam and feedwater lines in the MSSS, were performed to establish both the structural and the environmental design parameters for components installed in the MSSS. The original design analysis was performed using the COPDA(2) code and an eleven node model. Updates to this analysis have been performed using the PCFLUD[3] code. Evaluations have been conducted for a core power level of 3990 MWt.

Flow formulations between compartments included ideal gas, incompressible liquid, and Moody two-phase blowdowns. The pressure and temperature profiles obtained were used to establish or evaluate design loadings and environmental parameters for the main steam support structure above ground level.

A revision to the computer code used to calculate MSLB blowdown in the MSSS has been made to better represent

the secondary side. This improved model was applied for the current evaluation of the units. The revised code provides a more detailed modeling of the four main steam lines versus the original analysis which modeled only two main steam lines, the closing of the MSIVs and the steam flow through the main steam line cross header path following the closure of MSIVs. The improved secondary model provides a better representation of the post – MSIS M&E release.

A reduction in some conservative input values selected in the analysis of the original plant configuration and a revised reactor trip methodology have also been implemented. The current analysis evaluates all reasonable reactor trips and identifies the most conservative trip.

A main steam line pipe rupture is neither postulated to occur between the containment penetration and the MSSS wall nor between the double wall (designed as a pipe whip restraint) downstream from the MSIVs.

Inservice inspection requirements of Code Class 2 and 3 components are discussed in section 6.6.

D. High Energy Fluid Systems Outside Containment

1. ASME Code, Section III, Class 2 and 3 Piping

Design basis breaks in ASME Code, Section III, Class 2 and 3 high energy fluid system piping are postulated at the following locations in each

piping and branch run, except those portions of fluid system piping identified in paragraph 3.6.2.1.1.2, listing C:

a. At terminal ends

b. At intermediate locations where combined stresses associated with normal and upset plant conditions and an OBE event calculated by Equations 9 and 10, Paragraph NC-3652 or Paragraph ND-3652 of the ASME Code, Section III, exceed 0.8 (1.2 S_h + S_A) but at not less than two separate locations chosen on the basis of highest stress. In the case of a straight run without any pipe fittings or welded attachments and all stresses below 0.8 (1.2 S_h + S_A), a minimum of one location will be chosen on the basis of highest stress.

   In the absence of a Class 2 or 3 stress analysis, breaks are conservatively postulated at terminal ends and at all fittings, valves, or welded attachments.

2. Nonnuclear Class Piping

   Breaks in nonnuclear class high energy piping are postulated at the following locations in each piping and branch run:

a. At terminal ends of the pressurized portions of the run

b. At each intermediate location where combined stresses, as calculated by Equations 12 and 13, Paragraph 104.8 of ANSI B31.1, Power Piping Code, exceed 0.8 (1.2 S_h + S_A), or at each intermediate pipe fitting and welded attachment if detailed stress analyses are not performed.

Pressure-temperature analyses, assuming a single area break of the auxiliary steam (AS) line, were performed to evaluate the design of the internal structure of the auxiliary building under pipe break.

Version 3.7 of computer program PCFLUD(4) was used with the individual sub-compartments containing AS line considered as nodes.

The pressure and temperature profiles obtained were used for comparison against design loadings and environmental parameters for the auxiliary building both above and below ground level.

For the purpose of the analysis, the AS line rupture was postulated to occur at any single location along the pipe routing.

3.6.2.1.1.3 Type of Breaks in Fluid High Energy System Piping. At locations where breaks are postulated to occur, the following breaks are considered:

A. Full cross-sectional area circumferential breaks with at least one pipe diameter displacement, in piping greater than 1 inch, unless the separation is physically limited by piping restraint, structural members, or piping stiffness, as may be demonstrated by inelastic limit analysis. Circumferential breaks are not postulated at locations where circumferential stress range is at least 1.5 times the axial stress range.

   Circumferential breaks are perpendicular to the pipe axis and the break area is equivalent to the pipe flow area exposed by the separation of the two sections of pipe. Dynamic forces resulting from such breaks are assumed to separate the piping axially and cause the pipe to move in the direction of the thrust force. Pipe whipping is assumed to occur in the plane defined by the piping geometry and configuration, and to cause pipe movement in the direction of the jet reaction.

B. Single cross-sectional area longitudinal breaks in piping 4 inches and greater except at locations where axial stress range is at least 1.5 times the circumferential stress range. Longitudinal breaks are not postulated at:

1. The terminal ends, or

2. Intermediate locations where break locations are selected only to satisfy the minimum number criterion.

Longitudinal breaks are assumed to result in an axial split without pipe severance, causing piping deflections to occur in the direction of the jet reaction unless limited by structural members, piping restraints, or piping stiffness, as demonstrated by inelastic limit analysis. The break area is based on a circular break area equal to the effective cross-sectional flow area of the pipe.

3.6.2.1.2 Moderate Energy Piping

A fluid system is considered moderate energy if, during normal plant conditions, it is either in operation or maintained pressurized under conditions where both of the following are met:

- Maximum operating temperature is 200F or less, and
- Maximum operating pressure is 275 psig or less.

3.6.2.1.2.1 Postulating Criteria. The criteria for postulating break locations in moderate energy piping are described below:

A. Moderate energy fluid system pipe leakage cracks are only postulated if all of the following conditions are met:

   1. The moderate energy fluid system is not adequately separated from essential system active components such that the effects of a postulated leakage crack could impair the operability of such components.

   2. The system or portion of a system sustaining the leakage crack operates during normal plant operational modes 1, 2, and 3 defined in Table 1.1-1 of the Technical Specifications.

   3. The failed line is greater than 1 inch in diameter.

B. Where a postulated leakage crack occurs in one train of a Seismic Category I, dual-purpose, moderate energy piping system, single active component failures are not assumed in the other train (refer to Branch Technical Position APCSB 3-1, B.3.b.3). The postulated leakage crack must not adversely affect active components of both trains.

C. Through-wall leakage cracks are not postulated in portions of ASME Code, Section III, Class 2 moderate energy fluid system piping passing through the containment penetrations and extending to the first outside isolation valves if they meet the requirements

of NE-1120 of ASME Code, Section III, and the combined stresses, as calculated by Equations 9 and 10, Paragraph NC-3652 of the ASME Code, Section III, do not exceed 0.4 (1.2 S_h + S_A).

D. In portions of ASME Code, Section III, Class 2 and 3 piping and nonnuclear piping located within, or outside, and adjacent to protective structures containing safety-related systems or components, through-wall leakage cracks are postulated where combined stresses, as defined previously, exceed 0.4 (1.2 S_h + S_A) except as exempted in paragraph 3.6.2.1.2.1, listings C and E. The cracks are postulated to occur individually at locations that result in the maximum effects from fluid spraying and flooding, and the consequent hazards or environmental conditions developed.

E. Cracks are not postulated in moderate energy fluid system piping located in an area in which a break in high energy fluid system piping is postulated, provided such cracks do not result in more limiting environmental conditions than the high energy piping break. Where a postulated piping leakage crack in the moderate energy fluid system piping results in more limiting environmental conditions than the break in the proximate high energy fluid system piping, the

provisions of paragraph 3.6.2.1.2.1, listing D will be applied.

F. Through-wall leakage cracks instead of breaks are postulated in the piping of those fluid systems that qualify as high energy fluid systems for only short operational periods but qualify as moderate energy fluid systems for the major operational period. An operational period will be considered "short" if the fraction of time that the system operates within the pressure-temperature conditions specified for high energy fluid systems is less than 2% of the time that the system operates as a moderate energy fluid system.

3.6.2.1.2.2 Type of Break in Moderate Energy Piping. Moderate energy leakage cracks are based on an area equal to that of a rectangle one-half pipe diameter in length and one half pipe wall thickness in width.

3.6.2.1.3 Protection Requirements

Measures for protection against pipe whipping as a result of the breaks postulated by the above criteria are not provided for piping where any one of the following applies:

A. The piping is physically separated (or isolated) by protective barriers from any essential safety-related structure, system, or component required to place the plant in a safe shutdown condition following the

postulated rupture or is restrained from whipping by plant design features such as concrete encasement.

B. Following a single break, the unrestrained pipe movement of either end of the ruptured pipe cannot damage, to an unacceptable level, any essential safety-related structure, system, or component required to place the plant in a safe shutdown condition following the postulated rupture.

C. The energy associated with the whipping pipe can be demonstrated to be insufficient to impair, to an unacceptable level, the safety function of any essential structure, system, or component required to place the plant in a safe shutdown condition following the postulated rupture (a whipping pipe is considered insufficient to rupture an impacted pipe of equal or larger nominal pipe size and equal or heavier wall thickness).

For moderate energy systems, design measures are included that provide protection from the effects of the resulting water spray and flooding for each postulated leakage.

3.6.2.1.4 Definition of Operating Plant Conditions

For the purpose of calculating the pipe stresses, the following definitions apply:

A. Normal Plant Conditions are defined in the ASME Boiler and Pressure Vessel Code, Section III, and include

reactor startup, operation at power, hot standby, and reactor cool down to cold shutdown. The operational plant conditions do not include hydrostatic testing (however, the hydrostatic testing condition will be considered in calculating the cumulative usage factor).

B. Upset Plant Conditions are defined in the ASME Boiler and Pressure Vessel Code, Section III, and include transients of moderate frequency, which are anticipated operational occurrences caused by equipment failures, operator errors, and similar occurrences, including the OBE, but not testing conditions.

3.6.2.2 Analytical Methods to Define Forcing Functions and Response Models

The analytical methods used to define forcing functions and the response models used in paragraph 3.6.1.3 are described in the following sections.

3.6.2.2.1 High Energy Piping Other Than RCS Main Loop

Analytical methods for calculation of jet thrust forces, pipe and single restraint motion under jet force, restraint characteristics, and jet impingement forces are described in reference 1.

Jet thrust force is based on the pressure and momentum differences, inside and outside the break, for single or two-phase flow from the break. Methods for calculation of pipe and

restraint dynamic behavior include the effects of pipe-to-restraint gap and elastic and plastic deformation properties, using a simplified conservative model.

3.6.2.3 Dynamic Analysis Methods to Verify Integrity and Operability

3.6.2.3.1 High Energy Piping Other Than RCS Main Loop

The criteria for performing the dynamic analyses in paragraph 3.6.1.3 are:

A. An analysis of the pipe run or branch is performed for each longitudinal and circumferential postulated rupture at the break locations determined in accordance with the criteria of paragraph 3.6.2.1.

B. The loading condition of a pipe run or branch prior to postulated rupture in terms of internal pressure, temperature, and stress state is that condition associated with the normal and upset plant conditions and an OBE.

C. For a circumferential rupture, pipe whip dynamic analyses are only performed for that end (or ends) of the pipe or branch that is connected to a contained fluid energy reservoir having sufficient capacity to develop a jet stream.

D. Dynamic analytical methods used for calculating the piping and piping/restraint system response to the jet

thrust developed after a postulated rupture adequately account for the effects of the following:

1. Elastic and inelastic deformation of piping and/or restraint.

2. Nozzle movement where applicable.

3. On specific systems where plastic analysis is performed:

   a. Translational masses (and rotational masses for major components) and stiffness properties of the piping system, restraint system, major components, and support walls.

   b. Transient forcing function(s) acting on the piping system and jet thrusts on affected structures.

E. An allowable design strain limit of 50% of ultimate uniform strain of the materials of the restraints is used.

F. A 10% increase of minimum specified design yield strength (S_y) is used to account for strain rate effects in inelastic nonlinear analyses.

3.6.2.3.2 Pipe Whip Restraint Design Criteria

3.6.2.3.2.1 High Energy Piping Restraints Other Than RCS Main Loop Piping.

A. Design Bases

The pipe break locations and orientation are determined in accordance with paragraph 3.6.2.1. For each postulated pipe break, the possible effects of the break are investigated and, if necessary (per paragraph 3.6.1.3), restraints are provided to prevent pipe whip. Two types of restraints have been used:

1. Stainless steel U-bar type restraints where energy is absorbed by elasto-plastic elongation of the bars, and

2. Rigid frames with honeycomb material which will absorb energy through crushing.

In addition, there are steel or concrete bumpers which will resist the pipe break reactions in compression. Functional requirements are discussed in listing B below.

B. Functional Requirements

High energy pipe whip restraints are designed to ensure that the pipe whip will be eliminated or minimized. The restraints are designed to permit the predicted thermal and seismic movements of the pipes.

C. Design Parameters

After the pipe restraint locations are identified, the following design parameters are determined:

1. Jet thrust force
2. Pipe seismic displacements
3. Pipe thermal displacements
4. Pipe insulation thickness
5. Maximum allowable pipe travel (if any).

The jet thrust force and maximum allowable pipe travel are used in the analysis process.

Insulation and seismic and thermal movements are used in determining the minimum gap between the restraint and pipe surfaces.

D. Analysis and Design

Analysis of, and design for, postulated pipe break effects are in accordance with reference 1. Specifically, the following criteria are adopted in analysis and design:

1. Restraints are designed based on energy absorption principles by considering the elastic-plastic, strain hardening behavior of the materials used.
2. A rebound factor of 1.1 is applied to the jet thrust force.

3. Except in cases where plastic hinge calculations are performed, the energy absorbed by the ruptured pipe is conservatively assumed to be zero (i.e., the thrust force developed goes directly into moving the broken pipe, and is not reduced by the force required to bend the pipe).

4. In elastic-plastic design, limits for strains are as follows:

   ε = Allowable strain used in design

   a. Stainless steel U bars

      $\varepsilon = 0.5\varepsilon_u$

      where:

      ε_u = ultimate uniform strain of stainless steel (strain at ultimate stress)

   b. Crushable material (honeycomb)

      $\varepsilon = 0.8\ \varepsilon_u$

      where:

      ε_u = maximum crushable height at uniform crushable strength

5. A dynamic increase factor (DIF) of 1.1 is used for steel which is designed to remain elastic.

6. Only one structural element of a restraint has been designed to yield (U-bar or honeycomb). The

remainder of the restraint is designed elastically.

7. In the design of cantilevered compression restraints, lateral supports are provided in two orthogonal directions. These lateral supports are designed for a minimum of 5% of axial load, if the compression member is intended to yield.

E. Materials

The materials used in restraint design are selected to ensure ductile behavior. The components of the restraint which are intended to yield are made of ASTM A479 type 304 or 304L stainless steel or ASTM A36 or ASTM A992 steel. Other components, such as pins, bolts, and anchors, are designed to remain within their elastic limit. The material used for pins is ASTM A193-GR. B7; other components are made of ASTM A516 GR. 70, A36 and A500 GR.B.

3.6.2.4 Guard Pipe Assembly Design Criteria

No guard pipes are used. Any possible pipe whipping is prevented by restraints. Refer to paragraph 3.6.1.3.

3.6.2.5 Material Submitted for the Operating License Review

3.6.2.5.1 RCS Main Loop Piping

Although a summary of the dynamic analyses applicable to the RCS main loop piping and component supports that determine the

loading resulting from postulated RCS pipe breaks is covered in paragraph 3.9.1.4, these analyses are no longer required by 10CFR50, Appendix A, Criterion 4.

3.6.2.5.2 High Energy Piping Other Than RCS Main Loop

This section summarizes the dynamic analyses applicable to high energy piping systems and associated supports that determine the loading resulting from postulated pipe breaks.

A. The implementation of the stress criteria in paragraph 3.6.2.1.1 is shown in figures 3.6-2 through 3.6-30 which provide the location and number of postulated breaks on which the dynamic analyses are based. Analyses performed provide the postulated break orientation, such as the circumferential and/or longitudinal breaks, for each postulated break.

B. The implementation of criteria for inservice inspection is shown in section 6.6. The design of pipe whip restraints is described in paragraph 3.6.2.3.2. Figures 3.6-2 through 3.6-30 provide the location and number of pipe whip restraints required to protect essential systems.

C. The jet thrust and impingement functions and the pipe break analysis are derived from reference 1. The resulting whip and impingement restraints are presented in figures 3.6-2 through 3.6-30.

D. To ensure that their design-intended functions will not be impaired to an unacceptable level of integrity or operability as the result of high energy pipe breaks, essential systems and components are protected by:

   1. Physical separation from high energy systems, or

   2. Enclosing either the high energy systems or the safety-related features in protective structures, or

   3. Where neither 1. nor 2. above is practical, providing pipe restraints or protective barriers to ensure the operability of the safety-related features.

E. Protective assembly design and locations are shown in figures 3.6-2 through 3.6-30. Examination of all process piping welds required by the inservice inspection program can be accomplished without additional access openings.

3.6.2.5.2.1 Elimination of RCS Guillotine Breaks

Based upon the elimination of the double ended guillotine breaks on the RCS main loop piping (refer to GDC 4 response section 3.1.4 as approved under CESSAR SER 3, section 3.6.2), the dynamic effects of these breaks may be removed from the analyses of mechanical components and supports.

3.7 SEISMIC DESIGN

Structures, systems, equipment, and components related to plant safety feature systems are required to have the ability to withstand potential earthquakes.

Structures, systems, and components are placed in the applicable seismic category, depending on their function. A two-level system is used for the seismic classification of structures, systems, and components:

- Seismic Category I structures, systems, and components
- Non-Category I structures, systems, and components

A definition of the seismic categories and a listing of those structures, systems, and components included in each category are given in subsection 3.2.1.

The design basis safe shutdown earthquake (SSE) and the operating basis earthquake (OBE) peak ground acceleration values are 0.25g and 0.13g, respectively. These values were chosen to provide additional conservatism beyond the 10CFR100, Appendix A, required values determined in section 2.5

Non-Category I structures and equipment are designed in such a manner that failure would not cause loss of function of Category I structures, systems, or components under SSE conditions.

A complete dynamic analysis for Seismic Category I structures is accomplished by developing mathematical models using a multilumped mass system. Dynamic soil properties and damping

coefficients are determined, and models representing the structures are used to obtain natural frequencies, mode shapes, internal forces, and floor equipment response spectra. The design spectrum or the free-field, time-history motion is used as the input for the models.

The time-history response analysis is used to obtain the in-structure response spectra. These floor response spectra provide the earthquake environment for the design of internal equipment, systems, and components.

3.7.1 SEISMIC INPUT

3.7.1.1 Design Response Spectra

The site design response spectra are provided in figures 3.7-1 and 3.7-2 for the horizontal and vertical components of the SSE and in figures 3.7-3 and 3.7-4 for horizontal and vertical components of the OBE.

The shape of the design spectra is in accordance with Regulatory Guide 1.60 and is discussed in Section 2.5.1(b) of BC-TOP-4-A. Discussion of the effects of earthquake duration, epicentral distance, and amplification is provided in paragraph 2.5.2.6.

3.7.1.2 Design Time-History

A synthetic earthquake time-history is generated because the response spectra of a recorded earthquake motion does not necessarily envelop the site design spectra. A 24-second earthquake duration is used which is comparable to the strong motion duration of the earthquake records used, and is, therefore, considered to be adequate for the time-history type

of analysis of structures and equipment. Comparison between the free-field, time-history response spectra and the design spectra for both horizontal and vertical motions, and the basis for the generation of the synthetic time-history are discussed in Section 2.5 of BC-TOP-4-A. The time-history of the design earthquake is assumed to be the free-field motion at the base of the foundation for each Category I structure.

3.7.1.3 Critical Damping Values

The damping values (percent of critical damping) used for seismic design of Category I structures are listed in table 3.7-1, and are the same as those specified in Regulatory Guide 1.61. Alternative damping values, allowed by ASME Code Case-N-411, may be used for reconciliation of as-built design, for support optimization, and for design of plant systems in accordance with conditions outlined in Regulatory Guide 1.84. Strain-corrected damping values for the foundation materials were developed using the computer program SHAKE[1] and soil properties from field and laboratory test results. The average strain-dependent damping ratios for clay and sand are shown in figures 3.7-5 and 3.7-6, respectively.

Frequency-dependent soil damping values were obtained using the LUCON computer program[2] and the strain-dependent relationships for use in the time-history analysis of lumped-mass models of structure-foundation systems. For the design response spectrum method of analysis, soil damping values for the structure-foundation system were computed using the expressions given in Table 3-2 of BC-TOP-4-A.

Refer to appendix 3A, Question 3A.4, for additional discussion. The applicable allowable design levels are given in section 3.8 for the various loading combinations which include seismic loadings.

Table 3.7-1
DAMPING VALUES (PERCENT OF CRITICAL DAMPING)

Structure or Component	Operating Basis Earthquake	Safe Shutdown Earthquake
Equipment and large-diameter piping system, pipe diameter greater than 12 inches	2	3
Small-diameter piping system, diameter equal to or less than 12 inches	1	2
Welded steel structures	2	4
Bolted steel structures	4	7
Prestressed concrete structures	2	5
Reinforced concrete structures	4	7

3.7.1.4 Supporting Media for Seismic Category I Structures

For purposes of the seismic analysis, the site is assumed to be a multilayer system consisting of soil over bedrock. The approximate depth of soil deposit over bedrock for each unit at the site is as follows:

	Unit 1	Unit 2	Unit 3
Depth of Soil, feet	400	360	310

The upper layers (soil) are relatively uniform, both at each unit and between units. A composite soil profile is formed by

averaging the thickness and properties of each layer in the soil profile at the three units. This composite design soil profile is shown in figure 3.7-7. The strain-dependent relationships for shear moduli for clay and sand are shown in figures 3.7-8 and 3.7-9, respectively.

The foundation embedment depth, width of structural foundation, and total structural height for each Category I structure are provided in table 3.7-2.

3.7.2 SEISMIC SYSTEM ANALYSIS

3.7.2.1 Seismic Analysis Methods

3.7.2.1.1 NSSS Seismic Systems

The major components of the reactor coolant system (reactor vessel, steam generators, reactor coolant pumps, pressurizer, and reactor coolant piping) are designed to the appropriate stress and deformation criteria of the ASME Code, Section III, for the loading criteria included in the component design specification. The adequacy of seismic loadings used for the design of the major components are confirmed by dynamic analysis methods, employing time-history modal analysis techniques.

A composite three-dimensional, lumped-mass model of the reactor vessel, the two steam generators, the four reactor coolant pumps, and the interconnecting piping is coupled with a three-dimensional, lumped-mass model of the containment building and foundation springs for performing the analysis of these dynamically coupled components of the reactor coolant system. In addition, the representation of the reactor vessel assembly used in this coupled model includes sufficient detail

of the reactor internals to account for possible dynamic interaction between the reactor coolant system and internals. The seismic input excitation is the free-field acceleration time-history.

The results of this analysis include appropriate time-history forcing functions for use in separate analyses of the pressurizer and of a more detailed model of the reactor internals.

A model of the coupled components of the reactor coolant system is shown in Figure 3.7-9, and is similar to CESSAR Figure 3.7.2-1 except that the model representation of the original steam generators (OSG) was replaced by the model representation of the current steam generators. The three-dimensional, beam-stick containment building model with foundation springs and connecting members, which is coupled with the reactor coolant system model, is developed from the planar models used for analysis of the containment building as discussed in paragraph 3.7.2.3.2. The separate pressurizer model is shown in CESSAR Figure 3.7.2-2.

The analytical methods used, the selection of significant modes, and the selection of adequate number of masses and dynamic degrees of freedom is in accordance with CESSAR Section 3.7.2.1.

Table 3.7-2
EMBEDMENT DEPTHS OF CATEGORY I STRUCTURES

Structure	Foundation[(a)] Embedment Depth (ft)	Least Foundation Width (ft)	Structure Height (ft)
Containment	33	161	223
Main steam support	25	40	81
Auxiliary	35	144	123
Control	30	86	111
Fuel	7	86	95
Diesel generator	6.3	68	52
Condensate storage tank	4.5	50	56.5
Refueling water tank	13.8	50	72.5

a. Effective embedment based on a weighted average of contact conditions around the perimeter of the foundation.

3.7.2.1.2 Seismic Systems Other Than NSSS

Category I structures, systems, and components are classified in accordance with NRC Regulatory Guide 1.29 (refer to section 3.2). These structures, systems, and components are analyzed for two earthquake conditions -- the SSE and OBE.

The analysis methods utilized are based upon linear dynamic analysis techniques. In general, two separate analytical procedures are employed to perform the dynamic analysis. A time-history analysis is used to develop in-structure response spectra, and a response spectrum analysis is used to obtain force distributions within the various structures. The

mathematical idealization of the structural characteristics of the various Seismic Category I structures is accomplished by a lumped-parameter, beam stick model. Modeling techniques, such as the selection of the minimum number of mass points and the number of degrees of freedom per mass point, are described in Section 3.2 of BC-TOP-4-A. The seismic input is defined in terms of the OBE and SSE design response spectra (paragraph 3.7.1.1), the free-field acceleration time-history (paragraph 3.7.1.2), and the soil-structure interaction parameters (paragraph 3.7.2.4). Structural damping values are defined in table 3.7-1 and soil-damping characteristics are in accordance with figures 3.7-5 and 3.7-6.

The lumped-mass models used for analysis of the containment, auxiliary, control, and fuel buildings are shown in figures 3.7-10 through 3.7-13, respectively. Mathematical models developed include both horizontal and vertical planar models. The analytical methods used are in accordance with BC-TOP-4-A, and the general procedure for seismic analysis is indicated in figure 3.7-14. Following this procedure, fixed-base structural mode shapes and frequencies are calculated for the purpose of computing composite modal damping. Whenever appropriate, soil-structural interaction analyses are performed by coupling the fixed-base structure models with the foundation springs and dampers. Structural mode shapes, frequencies, and modal damping values are computed for the soil-structure models. The results of the analysis include accelerations, displacements, shears, moments, and other parameters for structural design, as well as floor response spectra for design of equipment. Section 3.8 describes design allowable stresses and loading combinations which include seismic loadings.

Consideration of maximum relative support displacements for Seismic Category I structures is in accordance with Section 5.3 of BC-TOP-4-A and Section 4.0 of BP-TOP-1.

Significant effects such as components and piping interaction, external structural restraints, and hydrodynamic effects are included in the analysis.

The lateral seismic earth pressures acting upon embedded walls consist of active and passive pressures. The active and passive pressures are calculated separately and each wall is designed for the most severe of the two conditions.

3.7.2.2 Natural Frequencies and Response Loads

3.7.2.2.1 NSSS Seismic Systems

Natural frequencies and dominant degrees of freedom for the fixed support coupled components of the 3800 MWt reactor coolant system and pressurizer are provided in Tables 3.7-3A and 3.7-3B, respectively. Natural frequencies, participation factors and effective mass value for the reactor coolant system coupled building models are provided in Tables 3.7-4.

The reactions (forces and moments) at all design points in the reactor coolant system, obtained from the dynamic seismic analysis, are compared with seismic loads in each component design specification. The results of this comparison are summarized in tabular form for the points of maximum calculated load in Tables 3.7-5 and 3.7-6 for the reactor coolant system.

The maximum seismic loads calculated by the time-history techniques are the result of a search and comparison over the entire time domain of each individual component of load. The maximum calculated components of load for each design location do not in general occur at the same time and therefore use of these results constitute a conservative worst case.

3.7.2.2.2 Seismic Systems Other Than NSSS

A summary of significant natural frequencies for the major Category I structures is provided in tables 3.7-7 through 3.7-10 and includes the effects of soil-structure interaction. Since the soil impedance functions utilized in the analyses of the Category I structures are strain-dependent, they are different for the OBE and SSE. This change in soil impedance functions accounts for the difference in frequencies for the Category I structures for the OBE and SSE. Mode shapes and participation factors are provided in figures 3.7-21 through 3.7-23. The solution of the equations of motion for the containment structure was carried out by the method ascribed to Foss[3]. A detailed discussion of the method is given by Hurty and Rubinstein[4]. This method is adopted so that proper consideration can be given to the radiation damping effects during soil-structure interaction analysis. Because of the relatively different energy dissipation characteristics of the structure and the soil, the resulting damping matrix is nonproportional and, hence, a solution as given by Foss properly takes this into account.

The solution of the eigenvalue problem with nonproportional damping results in complex eigenvectors (mode shapes). Thus,

in the strict sense, classical normal modes do not exist and no direct account can be taken of the classical participation factor associated with proportional damping. The interpretation of complex eigenvectors is not simple since the components of the vectors differ in phase as well as in amplitude. The vectors could be plotted in the complex plane showing amplitude and phase (see, for example, Meirovitch,[5] pp. 415-419); however, a direct interpretation of such a plot would not be practical. The solution is analogous to the direct integration technique that does not explicitly consider mode shapes.

The mode shapes and participation factors for the auxiliary building corresponding to the natural frequencies listed in table 3.7-8 are shown in amended figure 3.7-21.

The mode shapes and participation factors for the control building corresponding to the natural frequencies listed in table 3.7-9 are shown in amended figure 3.7-22.

The mode shapes and participation factors for the fuel building corresponding to the natural frequencies listed in table 3.7-10 are shown in amended figure 3.7-23.

Response loads for major Category I structures, including accelerations, shears, moments, and displacements are provided in figures 3.7-15 through 3.7-19. Horizontal and vertical response spectra are calculated at major Seismic Category I structure elevations and equipment support points for the OBE and SSE earthquakes. The response spectra at selected plant elevations with major equipment and equipment support points for each structure are given in appendix 3D.

3.7.2.3 Procedure Used for Modeling

3.7.2.3.1 General

The lumped-mass modeling technique is used for the seismic analysis of Seismic Category I structures and equipment. A description of the procedures used to locate lumped masses and for decoupling of systems and subsystems is provided in Section 3.2 of BC-TOP-4-A.

3.7.2.3.2 Containment Building Model

Four, two-dimensional, lumped-parameter coupled models (E-W horizontal and vertical, N-S horizontal and vertical) of the containment structure and the NSSS were used for the time-history analyses. Response characteristics and in-structure response spectra along the two principal axes of the containment structure and the NSSS were obtained using these models. Each model consists of four separate subsystems: soil, containment shell, internal structure, and the NSSS.

Simplified models of the NSSS were developed and provided by the NSSS supplier. The NSSS models consist of 72 nodal points with six mass points for horizontal analyses and three mass points for the vertical analyses. This model development is an adequate representation of the mass and stiffness of the subsystem. The containment beam-stick model is coupled with the simplified NSSS model as shown in figure 3.7-10. For horizontal motion analysis, each nodal point of the containment interior and exterior structure is assigned translational as well as rotational degrees of freedom. However, for vertical analysis, only a translational degree of freedom is assigned. The local stiffness characteristics of each interface between

the NSSS and the interior structure are obtained and then incorporated into the coupled model with appropriate member properties and member end releases. An example of this is the steam generator snubber support. This support is located on a wall panel that has local deflection characteristics. A horizontal spring is used to include this effect. The spring constant is determined from a static analysis of a three-dimensional, fixed-base, finite-element model of the interior structure.

Kinematic condensation is used to eliminate the dependent coordinates and the Householder-Ortega-Wilkinson method(6) is used to effectively extract eigenvalues and eigenvectors for the fixed-base cases. Structural damping values of the superstructure are incorporated into the analysis by observing the predominate individual fixed-base response characteristics of a given mode. For example, if the predominate response in a given mode is due to the containment shell, the modal damping ratio is closely related to the damping value for pre-stressed concrete. Modal damping values given in table 3.7-1 along with the fixed-base frequency and mode shapes are used to evaluate the damping matrix for the superstructure.

The effects of soil-structure interaction are investigated by coupling the fixed-base model to foundation springs and dampers. Since the soil impedance is a function of frequency for a layered site(7), the governing equations of motion for a soil-structure interaction system are relatively complex. The FOSIN computer program(8) which is an extension of the Foss

method[9] is used to perform the time-history analyses. The FOSIN computer program has the capability of generating relative displacement, relative velocity, and relative and absolute acceleration time-histories.

The relative response displacement time-histories are used as input for the STICK program[10] to obtain the seismic shear force and bending moment for each lumped mass point in the containment structure. The absolute response acceleration time histories are used to generate in-structure response spectra. Due to geometric coupling within the structure, rocking and horizontal motion will create a vertical response component. Therefore, the vertical response spectra are obtained from the square-root-of-the-sum-of-the-squares (SRSS) combination of the responses produced by the vertical excitation and two horizontal rocking components. Response spectra for representative mass points of the containment and other Category I structures are presented in appendix 3D.

3.7.2.3.3 Other Category I Structure Models

Structures are modeled as systems of lumped masses located at floor elevations and other mass concentrations. The mathematical models used for seismic analysis of the auxiliary, control, and fuel buildings are shown in figures 3.7-11, 3.7-12, and 3.7-13, respectively. The basemat has both translational and rotational degrees of freedom. For excitation in the horizontal direction each mass point of the superstructure is assigned both translational as well as rotational degrees of freedom. For the vertical excitation however, only a

translational degree of freedom is assigned in the direction of motion.

A time history analysis is used to develop in-structure response spectra, and a response spectrum analysis is used to obtain force distributions within the various structures except for the auxiliary building. Force distributions for the auxiliary building are obtained using an equivalent static method employing zero period accelerations (ZPAs) from the response spectra.

The effect of the foundation medium is considered by providing springs at the base of the model. The spring values are evaluated using the provisions of BC-TOP-4-A. Strain-corrected soil properties were developed using the computer program SHAKE with the soil properties and strain correction factors shown in figures 3.7-7 through 3.7-9.

Essential spray pond walls and their connection to the slab are designed to withstand the loading combinations of static soil pressure, surcharge, and dynamic forces under OBE and SSE conditions. The analysis conservatively assumed that the spray ponds were empty of water. A separate analysis was performed to demonstrate that the spray pond walls can withstand the effects of the static water pressure, plus the hydrodynamic forces under OBE and SSE conditions. In this analysis, the presence of a soil embankment was conservatively ignored.

A dynamic analysis of the essential spray pond pump house was performed by using a stick model with lumped masses at each floor and by performing a spectral response analysis using, as input, the PVNGS free-field response spectra.

3.7.2.3.4 Reactor Coolant System

The major components of the reactor coolant system are analyzed using a coupled model of the reactor coolant system and containment building with foundation springs which accounts for dynamic interaction effects with the internal building support structure. The 3800 MWt Unit coupled model was developed and analyzed in the STRUDL environment. For the 3990 MWt Unit reactor coolant system analysis, the 3800 MWt Unit STRUDL coupled model was converted to ANSYS, the coupled ANSYS model was benchmarked against the STRUDL model, and then the OSG representation was replaced with the RSG representation in the ANSYS coupled model. Procedures used for modeling the major components of the reactor coolant system are given CESSAR. Procedures used for modeling the major components of the reactor coolant system are given in CESSAR Section 3.7.2.1.2. All other NSSS vendor supplied systems and components are analyzed as decoupled "seismic subsystems".

3.7.2.4 Soil-Structure Interaction

The effect of soil-structure interaction is taken into account by coupling the structural model with the foundation media. The lumped parameter representation, which uses impedances to represent the dynamic effects of the soil, was employed in the formation of analytical models. The impedance functions are represented by equivalent spring stiffnesses and radiation damping coefficients. In general, the foundation impedances are complex functions of basemat configuration, embedment depth, elastic properties of the foundation medium, and forcing frequencies. Whether or not frequency dependent, they can always be represented by a mechanical analog composed of

equivalent springs and dampers. The equivalent dampers represent the radiation effect of the seismic wave energy away from the structural base. The material damping of the foundation medium is neglected in the lumped-parameter representation since it is small compared with radiation damping.

Figure 3.7-20 shows a schematic lumped-parameter model of the soil-structure system with the equivalent translational and rotation foundation springs, k_x and k_ψ, and radiation dampers, c_x and c_ψ, representing the foundation impedances for horizontal seismic excitation. The foundation is represented by translational springs and dampers, k_z and c_z, respectively, for vertical motion, and k_t and c_t respectively, for torsion. These impedance functions are the superposition of the effect due to the foundation medium below the base slab elevation and the effect due to the structural embedment. Various tests indicate that embedment has the effect of increasing both the equivalent spring stiffnesses and the radiation damping[11][12]. For simplicity of analysis, only the additional spring stiffnesses due to the embedment are considered and the additional damping due to embedment is conservatively neglected.

Accordingly,

$$k_x = k_x^{'} = k_x^{''}$$
$$k_\psi = k_\psi^{'} + k_\psi^{''}$$
$$k_z = k_z^{'} + k_z^{''}$$
$$c_x = c_x^{'}$$
$$c_\psi = c_\psi^{'}$$
$$c_z = c_z^{'}$$

in which $k'_x \ldots, c'_z$ are due to the material below the base slab elevation and k''_x, k''_ψ, and k'_z are due to structural embedment. The embedment effects are based on the embedment depths and minimum foundation dimensions given in table 3.7-2. If the material below the base slab elevation is uniform, the impedance functions are independent of frequency(13)(14). Table 3-2 of BC-TOP-4-A gives the expressions for equivalent stiffnesses and radiation damping coefficients,. $k'_x, \ldots, C'_z$ for circular and rectangular bases. If the material below the base slab consists of a layered media resting on an elastic half-space, the appropriate frequency-dependent foundation impedances are obtained using the LUCON computer program(2)(15) which considers not only radiation damping, but also the additional damping due to energy dissipation in the soil material. Since the site consists of alternating layers of sand and clay over bedrock as shown in figure 3.7-7, the latter approach for a layered media is used in the seismic analysis of Seismic Category I structures.

With the foundation impedances specified, the soil-structure system is formulated by coupling the fixed-base structure with the foundation medium through the basemat. The method of coupling, in terms of the equations of motion, is described in Appendix D of BC-TOP-4-A, with the structure represented by its fixed-base normal modes. The equations of motion for the interaction system are a mathematically coupled system. However, when frequency-independent impedances are used, it is usually sufficient to represent this coupled system by normal modes. Appendix D of BC-TOP-4-A shows one technique to determine the composite modal damping of the interaction system

in this case. This is accomplished by requiring that, at predetermined locations of the structural model, the dynamic amplification functions of both the coupled and uncoupled systems match each other at the natural frequencies of interest[16]. For structures supported on a layered medium resting on an elastic half-space, the frequency-dependent impedances are obtained using the LUCON computer program. The response of the soil-structure interaction system is obtained using the computer program FOSIN[8] which is an extension of the Foss method[9]. The complex eigenvalues and eigenvectors corresponding to the frequency-dependent interaction stiffness and damping must be obtained by an iterative process since the Foss method is applicable only to equations with constant coefficients[17].

A comparative study was made for the structural responses by two different approaches of soil modeling. A finite-element soil-structure interaction analysis was performed for SSE and OBE using the computer program LUSH[a]. In-structure response spectra for Category I structures were calculated.

These spectra were then compared to those spectra generated by the impedance method at corresponding locations. Figures 3.7-24 through 3.7-39 show the comparison of these spectra for the selected structures and locations.

---

a. Lysmer, J., Udaka, T., Seed, H. B., and Huang, R., "LUSH-A Computer Program for Complex Response Analysis at Soil-Structure System," Earthquake Engineering Research Center, University of California, Berkeley, California, Report No. 74-4, April 1974.

It can be seen that response spectra from LUSH analysis are, in general, lower than those spectra generated by the analysis using the impedance method. The impedance method is thus the more conservative method for generation spectra. Based on the commitment in the PSAR to use the more conservative method to generate spectra (paragraph 3.7.1.6), the spectra from the impedance method were used for the design of the plant.

Input motions used in the LUSH analysis were applied at the "fixed boundary" of the soil medium. The fixed boundary can be the surface of bedrock or an arbitrary boundary at a great depth. The PVNGS LUSH models had a fixed boundary at 334 feet below grade level. To obtain these input motions, the computer program SHAKE was used to deconvolve the surface motions that were defined in paragraphs 3.7.1.1 and 3.7.1.2. The resulting motions at the structure foundation level, in general, meet the requirement of the Standard Review Plan, Section 3.7.1, Seismic Input, Paragraph II.2.

3.7.2.5 Development of Floor Response Spectra

A modal time-history analysis of the structural model established for each of the two horizontal and vertical directions is performed. Time-history motion is obtained at each floor for each independent direction considered and then used to compute the response spectra for that direction. The method is described in detail in Sections 4.2 and 5.2 of BC-TOP-4-A.

3.7.2.6 Three Components of Earthquake Motion

3.7.2.6.1 NSSS Seismic Systems

Procedures for considering the effects of three components of earthquake motion in determining the seismic response of NSSS vendor-supplied systems, components, and supports are in accordance with Regulatory Guide 1.92. Detailed procedures used for the reactor coolant system are described in CESSAR Section 3.7.2.1.

3.7.2.6.2 Seismic Systems Other Than NSSS

Procedures for considering the three components of earthquake motion in determining the seismic response of structures, systems, and components follow the recommendations of Regulatory Guide 1.92 and are described in Section 4.3 of BC-TOP-4-A for structures and in Section 5.1 of BP-TOP-1 for piping systems.

In addition to the SRSS method for combining responses of three components of earthquake motion as recommended in Regulatory Guide 1.92, the component factor method[15] has also been used as discussed in paragraph 3.7.3.6.

3.7.2.7 Combination of Modal Responses

The square root of the sum of the squares method is the procedure normally used to combine the modal responses when the modal analysis response spectrum method of analysis is employed. The procedure is modified only in two cases:

A. In the analysis of simple system where three or less dynamic degrees-of-freedom are involved, the modal

responses are combined by the summation of the absolute values method;

B. In the analysis of complex systems where closely spaced modal frequencies are encountered, the responses of the closely spaced modes are combined by the summation of the absolute values method and, in turn, combined with the responses of the remaining significant modes by the square root of the sum of the squares method. Modal frequencies are considered closely spaced when their difference is less than ±10 percent of the lower frequency.

Sections 4.2 and 5.3 of BC-TOP-4-A describe the techniques used to combine modal responses for structures and equipment. Sections 5.1 and 5.2 of BP-TOP-1 describe the criteria used for piping systems.

Individual modal responses are combined by the SRSS summation method. However, when modal frequencies are closely spaced (within 10% of each other), the contribution from these modes are first summed using the sum of their absolute values. Then the results from each group of closely spaced frequencies are considered in the SRSS modal summation. This is the grouping method using Equation 4 of Regulatory Guide 1.92.

3.7.2.8 Interaction of Non-Category I Structures With Seismic Category I Structures

The failure of any non-Category I structure will not impair the safety function of Seismic Category I structures or components.

Section 3.4 of BP-TOP-1 describes the techniques used to consider the interaction of Seismic Category I piping with non-Category I piping.

3.7.2.9 Effects of Parameter Variations on Floor Response Spectra

The procedures used to transform calculated floor response spectra into design floor response spectra are specified in Section 5.2 of BC-TOP-4-A. The floor response spectra computed from the floor time-history are smoothed and the peaks broadened to account for variations in the structural frequencies owing to uncertainties in such parameters as the material properties of the structure and soil, damping values, soil-structure interaction techniques, and the approximations in the modeling techniques used in seismic analysis. The peaks associated with each of the structural frequencies are broadened by a frequency $\pm 0.15\ f_j$ where f_j is the jth modal structural frequency.

3.7.2.10 Use of Constant Vertical Static Factors

Constant vertical load factors are not used for Seismic Category I structures, equipment, and piping. The methodology for vertical seismic analysis of structures is discussed in Sections 3.0, 4.0, and 5.0 of BC-TOP-4-A, and for piping in Section 2.3.2 and Appendix D of BP-TOP-1. The methodology for vertical seismic considerations for equipment is in accordance with IEEE 344, as stated in section 3.10.

3.7.2.11 Method Used to Account for Torsional Effects

The mathematical models used in seismic analysis of Category I systems, components, and piping systems include sufficient mass points and corresponding dynamic degrees-of-freedom to provide a three-dimensional representation of the dynamic characteristics of the system. The distribution of mass and the selected location of mass points account for torsional effects of valves and other eccentric masses.

Torsional effects were found insignificant, and therefore were excluded from the horizontal models at locations of mass and/or structure eccentricity. Section 3.2 and Appendix C of BC-TOP-4-A describe the techniques used to account for torsional effects.

3.7.2.12 Comparison of Responses

A comparison of maximum structural response accelerations for the control building calculated using the time-history analysis and the response spectrum method is presented in tables 3.7-11 and 3.7-12. These results indicate that both methods gave essentially the same response in terms of total lateral force and overturning moment.

3.7.2.13 Methods of Seismic Analysis of Seismic Category I Dams

There are no Seismic Category I dams at PVNGS.

3.7.2.14 Determination of Seismic Category I Structure Overturning Moments

The method used to compute structural overturning is given in Section 4.4.1 of BC-TOP-4-A. The effects of embedment, groundwater, and buoyancy are considered in the overturning analysis. Maximum soil pressure underneath structural basemats is computed as described in Section 4.4.2 of BC-TOP-4-A.

3.7.2.15 Analysis Procedure for Damping

Refer to CESSAR Section 3.7.2.1.1 for NSSS seismic systems.

The analysis procedure employed to account for damping in different elements of the model of a coupled system and the criteria used to account for composite damping in a coupled system with different elements are described in Sections 3.2 and 3.3 of BC-TOP-4-A. The analysis is based on the use of Category I structural models which include a simplified version of the NSSS model provided by the NSSS supplier.

3.7.3 SEISMIC SUBSYSTEM ANALYSIS

3.7.3.1 Seismic Analysis Methods

Seismic Category I subsystems other than piping are analyzed by use of the response spectrum method as discussed in Sections 1.0 through 6.0 of BC-TOP-4-A.

3.7.3.2 Determination of Number of Earthquake Cycles

For the NSSS Seismic Subsystems, the procedure used to account for the fatigue effect of cyclic motion associated with the OBE recognizes that the actual motion experienced during a seismic event consists of a single maximum or peak motion, and some

number of cycles of lesser magnitude. The total or cumulative fatigue effect of all cycles of different magnitude will result in an equivalent cumulative usage factor. The equivalent cumulative usage factor can also be specified in terms of a finite number of cycles of the maximum or peak motion. Based on this consideration, NSSS Seismic Category I subsystems, components, and equipment are designed for total of 200 full-load cycles about a mean value of zero and with an amplitude equal to the maximum response produced during the entire OBE event.

Procedures to determine the number of earthquake cycles for piping during seismic events are discussed in Section 6.2 of BP-TOP-1. Structures and equipment are designed on the basis of analytical results. In general, the design of structures and the majority of the equipment is not fatigue controlled since most stress and strain reversals occur only a small number of times. The occurrence of earthquake and design basis accident full-design strains occurs too infrequently and with too few cycles to generally require fatigue design of structures.

The number of earthquake cycles to be used in the design of subsystems is dependent upon three parameters:

- The significant frequency characteristics of the subsystem and/or supporting media
- The duration of the postulated seismic event
- The number of seismic events to which the plant might be subjected

Table 3.7-12

COMPARISON OF RESPONSES CONTROL BUILDING (SSE)

	Elevation (ft)	Time-History Analysis (g)	Response Spectrum Analysis (g)
Horizontal (E-W)	180	0.67	0.82
	160	0.63	0.73
	140	0.57	0.60
	120	0.54	0.49
	100	0.41	0.38
	74	0.33	0.27
Horizontal (N-S)	180	0.81	0.87
	160	0.75	0.75
	140	0.61	0.63
	120	0.53	0.49
	100	0.41	0.38
	74	0.36	0.26
Vertical[a]	180	1.50	1.48
	160	0.90	1.05
	140	0.79	0.90
	120	0.76	0.87
	100	0.56	0.67
	74	0.37	0.29

a. Maximum vertical acceleration at floor beams.

The number of earthquake cycles used in the fatigue design for ASME, Section III, Class 1 piping is 960 cycles, obtained from the product of these three parameters:

$$N = n \times f \times d$$

where:

N = number of earthquake cycles

n = number of seismic events to be considered (= 2)

f = significant frequency characteristic of the subsystem and/or supporting media (= 20 Hz)

d = duration of the postulated seismic event (= 24 seconds)

Further conservatism is introduced by applying the resulting number of design cycles to the maximum stress range even though most of the actual stress cycles are well below the maximum stress range. In the application of this relation, two occurrences of the OBE are assumed to occur during the life of the plant.

3.7.3.3 Procedure Used for Modeling

Modeling of reactor internals, core, and control element drive mechanisms is described in section 3.7.3.14. Modeling procedures used for analysis of NSSS vendor supplied auxiliary components are given in section 3.9.3.

General modeling techniques used are in accordance with the criteria specified in Section 3 of BC-TOP-4-A. The modeling incorporates either a multidegree of freedom lumped-parameter technique or a finite-element approach. The degree of

complexity of the individual models is sufficient to define the dynamic behavior characteristics of the specific subsystem. Modeling of the attachment interface is consistent with the method of mounting the subsystem in its installed condition. Sections 2.0 and 3.0 of BP-TOP-1 discuss the techniques and procedures used to model Seismic Category I piping other than buried piping.

3.7.3.4 Basis for Selection of Frequencies

The basis for acceptability of the seismic design of equipment and subsystems is that the stresses and deformations produced by vibratory motion of the postulated seismic events, in combination with other coincident loadings, be within the limits established by applicable codes and standards in section 3.9.3.

Within practical limitations, the seismic design is accomplished in a manner to maintain the resonant frequencies well above the range which is significantly excited by the forcing frequencies. If the stresses and deformations resulting from analysis of the preliminary design exceed the established acceptable limits the stiffness of the restraint and supports system is modified as required to maintain the fundamental frequencies of equipment and subsystems sufficiently removed from the resonant range and, thereby, maintain the seismic response within the loads given in the component design specifications. The subsystem supports design is sufficiently adaptable that, dependent on the quantitative change in frequency required and the subsystem involved, modifications can be made either by changing the stiffness of existing support assembly components or by adding additional

support system restraints to the subsystems or components whose response otherwise exceeds the established limits.

If, during the analysis of the preliminary design, frequencies of the reactor coolant system were found to be in the range of resonance with those of the building, the supports for each of the components could be modified to increase their natural frequencies.

Specifically, the fundamental frequencies of the reactor vessel can be increased in both horizontal directions by the welding of a set of keys to the RV to further restrain lateral motion or rotation of the vessel. The keys would be laterally restrained by a structure supported by the primary shield wall.

The RCP moves in all three directions when seismically excited in any one direction. The fundamental frequency of the RCP can be raised by relocating the snubber from the top of the motor mount to the top of the motor. The orientation of the snubber would remain unchanged.

The SG frequency can be raised in the direction parallel to the axis of the RV outlet piping by the addition of a second set of snubbers and levers and in the direction perpendicular to the axis of the RV outlet piping by an additional set of keys above the original set.

See section 3.9.3 for auxiliary components.

Wherever practicable, Seismic Category I subsystems are designed to have fundamental frequencies well above the range of the forcing frequencies included within the response peak of the support spectra. When natural frequencies are not well separated from the critical forcing frequencies or are not

known, a dynamic analysis is made and subsystems designed for calculated response loads.

3.7.3.5 Use of Equivalent Static Load Method of Analysis

The equivalent static load method involves the multiplication of the total weight of the equipment or component member by the specified seismic acceleration coefficient. The magnitude of the seismic acceleration coefficient is established on the basis of the expected dynamic response characteristics of the component. Components that can be adequately characterized as a single degree of freedom system are considered to have a modal participation factor of one. Seismic acceleration coefficients for multidegree of freedom systems, which may be in the resonance region of the amplified response spectra curves, are increased by 50% to account conservatively for the increased modal participation. When increases of less than 50% are used for specific multidegree of freedom systems they are individually justified by comparative analysis or parametric evaluations.

For piping, refer to BP-TOP-1.

3.7.3.6 Three Components of Earthquake Motion

Procedures for considering the three components of earthquake motion in determining the seismic response of structures, subsystems, and components follow the recommendations of Regulatory Guide 1.92 and are described in BC-TOP-4-A for structures and equipment, and in BP-TOP-1 for piping systems.

Section 3.7.3.14 discusses the procedures used in the analysis of reactor internals, fuel assemblies, and control element

drive mechanisms. Procedures for considering the effects of three components of earthquake motion for auxiliary components are provided in section 3.9.3.

In addition to the SRSS method, the component factor method[15] has also been used for combining the three components of earthquake motion. The component factor method is discussed in the appendix 3A response to Question 3A.9.

3.7.3.7 Combination of Modal Responses

Refer to section 3.7.2.7 for NSSS seismic subsystems.

For structures, equipment, and piping systems, modal responses are combined using one of the methods recommended in Regulatory Guide 1.92.

3.7.3.8 Analytical Procedures for Piping

The design criteria and analytical techniques applicable to piping systems are discussed in BP-TOP-1. The effects of relative displacements between piping supports are considered.

3.7.3.9 Multiple-Supported Equipment Components with Distinct Inputs

The criteria and procedures used for seismic analysis of the multiply supported major components of the reactor coolant system are described in section 3.7.2; analysis methods used for the reactor internals and fuel assemblies are given in section 3.7.3.14.

Other seismic subsystems supported at two or more locations are analyzed using an upper bound envelope of all individual

support response spectra to calculate maximum inertial responses. Responses due to relative support displacements, imposed on the supported subsystem in the most unfavorable combination, are then combined with the responses due to inertial effects by the absolute sum method.

Section 5.3 of BC-TOP-4-A describes the approaches used for multiple-supported systems. Section 4.0 of BP-TOP-1 discusses the methods for piping systems.

3.7.3.10 Use of Constant Vertical Static Factors

A constant seismic vertical load factor is not used for the seismic design of Seismic Category I structures, components, and equipment. (Refer to paragraph 3.7.2.10. Also refer to Section 2.3.2 and Appendix D of BP-TOP-1).

3.7.3.11 Torsional Effects of Eccentric Masses

Refer to section 3.7.2.11 for NSSS seismic subsystems.

The significant torsional effects of valves and other eccentric masses are taken into account in the seismic piping analysis by the techniques discussed in BP-TOP-1.

Torsional effects are accounted for directly in the modeling for other subsystem analysis similar to the approach discussed in subsection 3.7.2 and in Appendix C of BC-TOP-4-A.

3.7.3.12 Buried Seismic Category I Piping Systems and Tunnels

Appendix 3G discusses the techniques used to calculate the stresses from seismic loadings for buried seismic piping. The buried Seismic Category I piping is designed to remain

functional when subjected to seismic loads. This is accomplished by limiting the calculated stresses in the pipe material under loading combinations, including earthquake.

3.7.3.13 Interaction of Other Piping with Seismic Category I Piping

The techniques used to consider the interaction of Seismic Category I piping with non-Category I piping are described in BP-TOP-1.

3.7.3.14 Seismic Analyses for Reactor Internals

The seismic analysis of the reactor internals and core was performed on a plant-specific basis. For Palo Verde, the seismic response necessitated the use of the vertical nonlinear analytical method and the results of the analysis are acceptable. The methodology is described below:

3.7.3.14.1 Reactor Internals and Core

The seismic analyses of the reactor internals and core consists of two phases. In the first phase, linear lumped-parameter models are formulated, natural frequencies and mode shapes for the models are determined, and the response is obtained utilizing the modal analysis response spectrum method. The response spectra used are based upon the acceleration of the reactor vessel flange. The response spectrum analysis is used to obtain preliminary design seismic loads and displacements in the vertical and horizontal directions.

In the second phase, because the relative displacements between the core and core shroud and between the core-support barrel

and pressure-vessel snubbers are sufficiently large to close the gaps that exist between these components, a nonlinear horizontal time history analysis is performed. The horizontal nonlinear analysis is divided into two parts. In the first part, the internals and core are analyzed to obtain the internals response and the proper dynamic input for the reactor core model. In the second part, the core plate motion from the first part is applied to a more detailed nonlinear model of the reactor core.

The input excitation to the internals model is the response time-history of the reactor vessel at the ledge and snubber elevations determined from the RCS analysis. Coupling effects between the internals and reactor vessel are accounted for by including a simplified representation of the internals within the RCS model. This is discussed in subsection 3.7.2. Since the linear vertical analysis indicates that the response of the core may be sufficiently large to cause it to lift off the core plate, a vertical nonlinear analysis of the internals was also performed. If this method is used a statement will be provided that a nonlinear analysis was performed and that the results were acceptable.

In these analyses, two horizontal components and one vertical component of the seismic excitation are considered and the maximum responses for the three components are combined by the method of square root of the sum of the squares.

Closely spaced modes are considered in accordance with Regulatory Guide 1.92.

3.7.3.14.1.1 Mathematical Models

Equivalent multimass mathematical models are developed to represent the reactor internals and core. The linear mathematical models of the internals are constructed in terms of lumped masses and elastic-beam elements. At appropriate locations within the internals and core, points (nodes) are chosen to lump the weights of the structure. A sketch of the internals and core showing the relative node locations for the horizontal model is presented in Figure 3.7.40-1. Figures 3.7.40-2 and 3.7.40-3 show the idealized linear horizontal and linear vertical models. The criterion for choosing the number and location of mass concentration is to provide for accurate representation of the dynamically significant modes of vibration of each of the internals components. Between the nodes properties are calculated for moments of inertia, cross-section areas, effective shear areas, and lengths. Separate horizontal and vertical models of the internals and core are formulated to more efficiently account for structural differences in these directions. In the horizontal nonlinear lumped mass representation of the internals and core, shown in Figure 3.7.40-4, gap and spring fuel assemblies and the peripheral row assemblies with the adjacent core shroud. Lumped-mass nodes in the core are positioned to coincide with fuel-spacer grid locations. To simulate the nonlinear motion of the fuel, nonlinear spring couplings are used to connect corresponding nodes to the fuel assemblies and core shroud. Incorporated into these nonlinear springs is the spacer grid impact stiffness derived from test results. The core is modeled by subdividing it into fuel assembly groupings and choosing stiffness values to adequately

characterize its beam response and contacting under dynamic loading.

The horizontal nonlinear reactor core model consisting of one row of 17 individual fuel assemblies is depicted in Figure 3.7.40-5A. In this model each fuel assembly is represented with mass points located at spacer grid locations. To simulate the gaps in the core, nonlinear spring couplings are used to connect corresponding nodes on adjacent fuel assemblies and core shroud. The impact stiffness and impact damping (coefficient of restitution) parameters for the gap elements are derived from the impact tests which are described in section 4.2. The spacer grid impact representation used for the analysis is capable of representing two types of fuel assembly impact situations. In the first type, only one side of the spacer grid is loaded. This type of impact occurs when the peripheral fuel assembly hits the core shroud, or when two fuel assemblies strike one another. The second type of impact loading occurs typically when the fuel assemblies pile up on one side of the core. In this case, the spacer grids are subjected to a through-grid compressive loading.

The fuel assemblies in the coupled core/internals model and the detailed core model are modeled with beam elements to represent the horizontal stiffness between mass points and rotational springs at each end to simulate the end fixity existing at the top and bottom of the core. The value used for fuel horizontal stiffness and end fixity are based upon a parametric study in which analytic predictions are correlated with fuel assembly static and dynamic test data. Fuel assembly structural damping as a function of vibrational amplitude was derived from fuel

assembly forced vibration and pluck tests defined in section 4.2. The damping values used in the seismic analysis of the reactor internals are in accordance with the values in Table 3.7-1.

The vertical nonlinear model incorporates nonlinear spring couplings to account for the nonlinear behavior of the internals in the vertical direction. The vertical nonlinear model is shown in Figure 3.7.40-8A.

Additional salient details of the internals and core models are discussed in the following paragraphs.

A. Hydrodynamic Effects

It has been shown both analytically and experimentally[9] that immersion of a body in a dense-fluid medium lowers its natural frequency and significantly alters its vibratory response as compared to that in air. The effect is more pronounced where the confining boundaries of the fluid are in close proximity to the vibrating body as in the case for the reactor internals. The method of accounting for the effects of a surrounding fluid on a vibrating system has been to ascribe to the system additional or "hydrodynamic mass".

The hydrodynamic mass of an immersed system is a function of the dimensions of the real mass and the space between the real mass and confining boundary.

Hydrodynamic mass effects for moving cylinders in a water annulus are discussed in Reference 22 and 23. The results of these references are applied to the

internals structures to obtain the total (structural plus hydrodynamic) mass matrix that is then used in the evaluation of the natural frequencies and mode shapes.

B. Core Support Barrel

The core support barrel is modeled as a beam with shear deformation. It has been shown that the use of beam theory for cylindrical shells gives sufficiently accurate results when shear deformation is included.(11)(12)

C. Fuel Assemblies

The fuel assemblies are modeled as uniform beams with rotational springs at each end to represent the proper end condition. The member properties for the beam elements representing the fuel assemblies are derived from the results of experimental tests of the fuel-assembly load deflection characteristics and fundamental natural frequency.

D. Support-Barrel Flanges

To obtain accurate lateral and vertical stiffness of the upper and lower core-support barrel flanges and the upper guide structure support barrel upper flange, finite-element analyses of these regions are performed. As shown in Figure 3.7.40-6 these areas are modeled with quadrilateral and triangular ring elements. Unit deflections and rotations are applied in the lateral and axial directions, and the resulting reaction forces are calculated. These

results are then used to derive the equivalent member properties for the flanges.

E. Upper Guide Structure

For the horizontal model, the upper guide structure including CEA shrouds, connecting plates and tie rods are modeled as contilever beams. A separate member is modeled to account for the connection between the tie rods and the upper guide structure support plate.

F. Lower Support Structure

To obtain vertical stiffnesses for the lower support structure grid beams and cylinder, a finite element analysis is performed. A top view of the finite element model is shown in Figure 3.7.40-7. Displacements due to vertical (out-of-plane) loads applied at the beam junctions are calculated through the use of a computer program[(13)]. Average stiffness values based on these results yield an equivalent member cross-section area for the vertical model.

3.7.3.14.1.1.1 Mathematical Models applicable to the 3990 MWt

The reactor internals horizontal direction internals and fuel model used in the 3990 MWt Unit seismic evaluations is shown in Figure 3.7.40-4A, and the vertical direction model is shown in Figure 3.7.40-8A. These models are the same as used for the structural evaluations of the 3800 MWt Units except that the fuel assembly weights and rotary inertias were increased to account for the weight of the value added fuel. The vertical direction model was used to obtain the fuel response loads.

Detailed horizontal direction core models of the longest row with 17 assemblies (3.7.40-5A) and the shortest row with 7 assemblies were to obtain the fuel assembly deflected shapes at times of maximum response loadings and the maximum one-sided and through-grid response loads.

3.7.3.14.1.2 Analytical Techniques

A. Natural Frequencies and Mode Shapes

The mass- and beam-element properties of the models are utilized in a computer program to obtain the natural frequencies and mode shapes. This computer code is described in section 3.9.1.2.3.7. The program utilizes the stiffness-matrix method of structural analysis. The natural frequencies and mode shapes are extracted from the system of equations:

$$(\underline{K} - W_n^2 \underline{M}) \phi_n = 0 \qquad (12)$$

where:

$\underline{K}$ = model stiffness matrix

$\underline{M}$ = model mass matrix

W_n = natural circular frequency for the n^{th} mode

ϕ_n = normal mode shape matrix for n^{th} mode

The mass matrix, $\underline{M}$, includes the hydrodynamic and structural masses.

B. Response Calculations Methods

1. Response Spectra Method

The response spectrum analysis is performed using the modal extraction data and the following relationships for each mode:

a. Nodal Accelerations

$$\ddot{X}_{in} = \gamma_n A_n \phi_{in} \qquad (13)$$

where:

$\ddot{X}_{in}$ = absolute acceleration at node "i" for node "n"

γ_n = modal participation factor

A_n = modal acceleration from response spectrum

ϕ_{in} = mode shape factor at node "i" for node "n"

b. Nodal Displacement

$$Y_{in} = \frac{\ddot{X}_{in}}{W_n{}^2} \qquad (14)$$

where:

Y_{in} = displacement at node "i" for mode "n" relative to base

W_n = natural circular frequency for n^{th} mode

c. Member Forces and Moments

$$F_n = \frac{(\gamma_n A_n)}{W_n^2} \bar{F}_n \qquad (15)$$

where:

F_n = actual member force for mode "n"

$\bar{F}_n$ = modal member force for mode "n"

The effect of the fluid environment is accounted for by defining the modal participation as follows:

$$\gamma_n = \frac{\sum_{j=1}^{M} W_{si} \phi_{in}}{\sum_{i=1}^{M} \sum_{j=1}^{M} \phi_{in} W_{ij} \phi_{jn}} \qquad (16)$$

where:

W_{si} = structural weight of node "i"

W_{ij} = structural + hydrodynamic weight terms

M = number of masses

The SRSS method is normally used to combine the modal responses. Where modal frequencies are closely spaced, the responses of these modes are combined by the sum of their absolute values. The modal damping factors are obtained by the method of "mass mode weighting", which gives:

$$B_n = \frac{\sum M_i\ \phi_{in}\ B_i}{\sum M_i\ \phi_{in}} \tag{17}$$

where:

B_n = modal damping factor

M_i = structural mass of mass node "i"

ϕ_{in} = absolute value of the mode shape at mass node "i"

B_i = damping associated with mass point "i"

C. Nonlinear Analysis

The nonlinear seismic response and impact forces for the internals and fuel are determined using the CESHOCK computer program (refer section 3.9.1.2.3-5). The computer program provides the numerical solution to transient dynamic problems by step-by-step integration of the differential equations of motion. The input excitation for the model is the time-history accelogram of the reactor vessel.

Input to the CESHOCK computer program consists of lumped masses, linear-spring stiffnesses, mass moments of inertia, nonlinear spring loads vs. deflection curves, and the acceleration time-histories. The output from the CESHOCK computer program consists of displacements, translational and angular accelerations, impact forces, shears, and moments.

D. Non-linear Analysis Applicable to Units with Core Power of 3990 MWt.

The methodology provided in Section 3.7.3.14.1.2C is also applicable to the 3990 MWt Unit.

3.7.3.14.1.3 Results

The nonlinear response loads for the internals, including impacting if any exist, are determined for the vertical and horizontal directions. Loads for the fuel are determined in a separate reactor core nonlinear analysis. The results are determined for the Safe Shutdown Earthquake (SSE) and the Operational Basis Earthquake (OBE).

Section 3.7.3.14.1.3 results applicable to the 3990 MWt Unit.

The above results also apply to the 3990 MWt Unit.

3.7.3.14.2 Control Element Drive Mechanisms (CEDM)

The pressure-retaining components of the CEDM are designed to the appropriate stress criteria of ASME Code Section III for all loadings specified. The structural integrity of the CEDM when subjected to seismic loadings is verified by combination of test and analysis. Methods of modal dynamic analysis

employing response spectrum techniques or time history analysis are supported with experimentally obtained information.

3.7.3.14.2.1 Input Excitation Data

For the dynamic analyses, a response spectra or time history definition of the excitation at the base of the CEDM nozzle is obtained from the seismic analysis of the RCS. The excitation is applied simultaneously in three mutually perpendicular directions (2 horizontal and 1 vertical).

3.7.3.14.2.2 Analysis

A dynamic analysis of the mathematical structural model is performed utilizing one or more of the computer programs discussed in section 3.9.1.2.

3.7.3.14.2.3 Tests

A functional test utilizing a minimum drop weight is performed to verify that drop characteristics meet the input design requirements. Results from this test are compared to the calculated CEDM deflections under seismic loading for the individual site. Verification of the proper function is thus established based on both analytical and test results.

3.7.3.15 Analysis Procedure for Damping

3.7.3.15.1 NSSS Seismic Systems

Composite modal damping values are used in analyzing the major components of the reactor coolant system using a reactor coolant system model coupled with a model of the containment building with foundation springs.

The composite modal damping values are obtained in three steps. In the first step, the equivalent modal damping values for the fixed-base model that consists of containment building and reactor coolant system are calculated by the mass weighting technique as described in Section 3.2 of BC-TOP-4A. In the second step, the complete coupled system damping matrix is formed by coupling the fixed-base damping matrix and the soil impedances.(16) Finally, the composite modal damping values for the coupled system are then calculated by assuming that normal modes exist in the classical sense, which is equivalent to retaining the diagonal terms in the coupled system damping matrix in generalized coordinates.(17)(18) The actual damping values used are contained in table 3.7-13.

3.7.3.15.2 Systems Other Than NSSS

The analysis procedure for damping of Seismic Category I subsystems is given in Section 3.2.1 of BC-TOP-4-A. The damping used in the analysis of piping systems is described in BP-TOP-1.

3.7.4 SEISMIC INSTRUMENTATION

3.7.4.1 Comparison with Regulatory Guide 1.12, Revision 2

Seismic instrumentation is provided on the basis of architect-engineer experience with seismic instrumentation used on other nuclear power plants and on the basis of currently available technology of equipment testing and qualification. In conformance with Regulatory Guide 1.12, Revision 2, Section B, only one complete set of seismic instrumentation as described below is provided for the site. Since the expected seismic

response is the same for all units, one set of seismic instrumentation installed on Unit 1 meets the requirements of Regulatory Guide 1.12, Revision 2, except as noted in section 1.8. The instrumentation program complies with Regulatory Guide 1.12, Revision 2, except as noted in section 1.8.

3.7.4.2 Location and Description of Instrumentation

The following instrumentation and associated equipment are used to measure plant response to earthquake motion:

- Six (6) – Force Balance Accelerometer (FBA) Units
- Six (6) – Recorders
- Alarm Panel
- Central Controller
- UPS (uninterruptible power supply)
- Control Panel

a. Composite modal damping values are expressed as a percentage of critical modal damping.

3.7.4.2.1 Force Balance Accelerometer (FBA) Unit

The FBA unit is used to measure the time varying acceleration input from an earthquake, and relaying the information to its corresponding recorder for information storing. Each FBA unit houses three (3) orthogonally mounted force balance accelerometers. Each force balance accelerometer measures a different axial acceleration (longitudinal, transverse, and vertical) of an earthquake. The measured data of an earthquake is used to produce a response spectrum, which is used for analysis and comparison with that of the plant's design. The FBA unit is positioned with its main horizontal axis in parallel with the major horizontal axis assumed in the seismic analysis. The location of each FBA unit is provided in Table 3.7.4.2.1-1.

Table 3.7.4.2.1-1
ACCELEROMETER UNIT LOCATION:

Motion Sensor Accelerometer Units (6)	**Location**
1	55' (Containment Bldg. – Tendon Gallery)
1	80' (Containment Bldg. – Floor)
1	140' (Containment Bldg. – Floor)
1	74' (Control Bldg. – Base Slab)
1	160' (Control Bldg. – Floor)
1	Free Field (South side of OSB Bldg., referencing Plant North)

3.7.4.2.2 Recorder

The recorders are housed in the control panel, which is located at the 140' level of the Control building in Unit 1. The main

function of the recorder is to record the acceleration input of an earthquake sent from its corresponding FBA unit.

The recorder consists basically of an ADC (analog to digital converter), MCU (main control unit), PCMCIA (Personal Computer Memory Card International Association) flash memory card, power supply charger, and an internal battery backup.

The analog acceleration data of an earthquake, sent from the FBA unit to its corresponding recorder, is converted to digital form by the ADC. The digital data is processed and sent to the MCU for examination. The MCU examines the digital data and determines if the acceleration exceeds the set trigger threshold. If the trigger threshold is exceeded, the recorder initiates and starts recording the digitized acceleration of the earthquake on the PCMCIA flash memory card. All the recorders will automatically activate and start recording when the set trigger threshold for a recorder is exceeded.

The recorder operates on direct current (DC) power provided by the power supply charger, which converts the local AC power to DC power. The power supply charger also keeps the internal battery fully charged. The internal battery provides DC power to the recorder during a loss of local AC power for up to 30 hours.

3.7.4.2.3 Central Controller

The central controller is a standard personal computer (motherboard, central processing unit, and hard drive). The central controller takes the recorded digital data stored on the PCMCIA flash memory cards, and through application software computes the response spectrum of an earthquake. The computed

response spectrum is stored on the local hard drive. A hard copy of the response spectrum can be printed out on the printer at the control panel.

3.7.4.2.4 UPS (Uninterruptible Power Supply)

The main function of the UPS is to provide backup power to the central controller, visual display, and printer during the loss of local AC power. The UPS provides 1 hour of battery backup power. If the loss of AC power should occur during an earthquake, the response spectrum can still be computed, stored on the hard drive, and retrieved for analysis.

3.7.4.2.5 Alarm Panel

The alarm panel is linked to the plant’s annunciator system in Unit 1. The audible and visual annunciation in the control room is activated if an anomaly has occurred. The anomaly can be a seismic event (exceedance of a trigger threshold setpoint), an OBE exceedance, or a health problem with the seismic monitoring system. The exact cause of the annunciation is displayed at the control panel.

3.7.4.2.6 System Control Panel

The control panel is located on the 140' level of Control building in Unit 1. The control panel houses the alarm panel, recorders, display screen, keyboard terminal, central controller, printer, and the UPS. The seismic instrumentation is controlled and monitored through the use of a custom graphical user interfSace software, along with the display screen for viewing, and the keyboard terminal/mouse for input.

The central controller in conjunction with recorders, and FBA units produce a time-history record of an earthquake. The time-history of an earthquake is stored on the local hard drive and printed in hard copy form by the printer. Each recorder has an internal trigger which can be set to activate the recorder for recording. The trigger threshold for the recorder is set at the control panel through the graphical user interface software, and the keyboard terminal/mouse.

3.7.4.3 Control Room Operator Notification

The activation of the audible and visual alarm in the Unit 1 control room will signify an anomaly has occurred. The anomaly can be a seismic event (exceedance of a trigger threshold setpoint), an OBE exceedance, or a health problem with the seismic monitoring system. The exact cause of the annunciation is displayed at the control panel. If a seismic event has occurred, notification to the control rooms of Unit 2 and Unit 3 will be done administratively by the control room of Unit 1.

Exceeding the trigger threshold setpoint causes an audible and visual annunciation in the control room, alerting the plant operator that an earthquake has occurred. The annunciation of a seismic event is initially set to occur at 0.01g horizontal and/or vertical acceleration for the free-field, Containment tendon gallery (55'), Control building foundation (74'). Annunciation is also set to occur at 0.02g horizontal and/or vertical acceleration for the Containment floor (80'), for the Containment operating floor (140') and the upper cable spreading room of the Control building (160'). These levels cause initiation of the recording system at horizontal or vertical acceleration levels slightly higher than the expected

background level; including induced vibrations from sources such as traffic, elevators, people, and machinery. These setpoints are based on experience at PVNGS and in existing plants and may be changed once significant plant operating data have been obtained which indicate that a different setpoint would provide better FBA system operation.

The peak acceleration level experienced at the free-field is available immediately following the earthquake. The information is obtained by retrieving the stored data from the free-field location, using the graphical user interface software and the keyboard terminal/mouse. The peak value is displayed on the visual display screen for viewing. A hardcopy of the peak value is produced by the printer.

3.7.4.4 Comparison of Measured and Predicted Responses

Initial determination of the earthquake level is performed immediately after the earthquake by performing a OBE (operating basis earthquake) response spectrum check and a cumulative absolute velocity (CAV) check for the free field. (Reg. Guide 1.166, (4.1), (4.2), March '97).

If the OBE response spectrum check and the CAV check were exceeded, the OBE was exceeded and plant shutdown is required. (Reg. Guide 1.166, (5.1), March '97).

After the earthquake, the acceleration data from the recorders are retrieved for each location of the FBA units. The acceleration data is used to compute the response spectra. The response spectra are compared with those used in the plant design, to determine whether the containment structure, or other Seismic Category I structures, system, and components is

still adequate for future use. The structure, system, or components is considered adequate for future operations if the measured responses are less that the values used in the design and qualification of the Seismic Category I structures, systems, and components; otherwise a new analysis is made to check the adequacy of these items for future use.

3.8 DESIGN OF CATEGORY I STRUCTURES

This section provides information on the containment building, its internal structure, other Category I structures, and their foundations and supports. Refer to section 3A.12 for additional discussion.

3.8.1 CONCRETE CONTAINMENT

The containment structure is designed to house the reactor coolant system (RCS) and is referred to as the containment. The containment is part of the containment system whose functional requirements are summarized by the following criteria:

A. The containment must withstand the peak pressure and time-varying thermal gradient resulting from a hypothetical failure of the RCS or main steam system as discussed in subsection 6.2.1.

B. The containment must provide biological shielding during normal operation and following a postulated loss-of-coolant accident (LOCA) to minimize radiation exposure.

C. The containment must be leaktight in order to minimize leakage of airborne radioactive materials.

D. The containment must provide approximately 150 penetrations for piping and electrical cabling, as well as personnel and equipment access, and provides rigid anchor points for piping entering or leaving the containment.

This section describes the structural design considerations for the containment. Further information relative to the containment is covered in Topical Report BC-TOP-5A which provides the bases for design, construction, testing, and surveillance for the prestressed concrete containment.

3.8.1.1 Description of the Containment

3.8.1.1.1 Containment Basic Configuration

The containment consists of three basic parts:

- Flat base slab with a central cavity and an instrumentation tunnel
- Right circular cylinder
- Hemispherical dome

Principal nominal dimensions of the containment are as follows:

Interior diameter	146 feet
Interior height (above filler slab)	206 feet 6 inches
Cylindrical wall thickness	4 feet 0 inch
Dome thickness	3 feet 6 inches at dome apex 4 feet 0 inch at wall springline
Basemat thickness	10 feet 6 inches
Liner plate thickness	1/4 inch
Internal free volume	2,600,000 cubic feet net

Typical sections and details are shown in engineering drawings 13-P-OOB-002 through –011.

The containment is constructed of reinforced concrete pre-stressed by post-tensioned tendons in the cylinder and the dome. The basemat is designed and constructed of conventionally reinforced concrete (engineering drawings 13-C-ZCS-102 and -104). Special reinforcing details are provided at discontinuities and at openings in the shell. Typical shell wall and dome reinforcing steel details are shown in engineering drawings 13-C-ZCS-108, -111, -114, -115, -123 and –124.

A welded steel liner attached to the inside face of the concrete limits the release of radioactivity from the containment. The base liner is installed on the top of the basemat and is covered by a 2-foot 9-inch-thick concrete slab. The containment building provides biological shielding during normal operation and following a LOCA. It also functions as a leak-tight barrier following an accident inside the containment.

3.8.1.1.2 Post-Tensioning System

The tendon system is shown in figures 3.8-1, 3.8-2 and engineering drawings 13-C-ZCS-175, -177 and -181. High strength wires are used with buttonhead anchorage techniques. There are 186 1/4-inch diameter wires per tendon.

Each tendon assembly consists of wires together with end anchor heads and ring nuts. The tendons transfer load to the structure through shims and a bearing plate.

Tendons are installed in sheaths that form ducts through the concrete between anchorage points. Trumpets, which are enlarged ducts attached to the bearing plate, allow the wires to spread out at the anchorage to suit buttonhead spacing requirements. Further, trumpets facilitate field buttonheading of wires.

Tendon sheathing provides an enclosed space surrounding each tendon. A valved vent at the highest points of curvature permits release of entrapped air during greasing operations. Drains are provided at the lowest points of curvature to remove accumulated water prior to installing tendons. After the greasing operation, the vents and drains are closed and sealed.

The prestressing tendons are protected against atmospheric corrosion during shipment and installation, and during the life of the containment. Prior to shipment, the tendons are coated with a thin film of petrolatum containing rust inhibitors. The sheathing filler material used for permanent corrosion protection is a modified, refined petroleum-base product. The material is pumped into the sheathing after stressing.

Prestressing of the cylindrical wall is achieved by a post-tensioning system consisting of both vertical inverted U-shaped and circumferential (hoop) tendons. Vertical tendons are anchored at the base slab and extend up and over the dome to form an inverted U-shape. Three buttresses are equally spaced

at 120° around the cylinder and extend over the dome, joining together at the crown. The hoop tendons are anchored at buttresses located at 240° apart. The successive hoop tendons are anchored at alternate buttresses so that two complete horizontal loops are achieved by three consecutive horizontal tendons. Refer to figure 3.8-2 for buttress arrangement and schematic arrangement of hoop tendons.

Prestressing of the hemispherical dome is achieved by a two-way pattern of tendons, which are an extension of the continuous vertical tendons and are anchored at the base slab. They are arranged to produce two families of tendons mutually intersecting each other at 90° on the horizontal projected plane. Hoop tendons extend into the hemispherical region to provide a two-way pattern up to the 90° solid angle of the dome. Refer to engineering drawing 13-C-ZCS-177 for schematic arrangement of dome tendons.

3.8.1.1.3 Liner Plate System

3.8.1.1.3.1 Liner Plate and Anchors. A welded steel liner plate covers the entire inside surface of the containment (excluding penetrations) to satisfy the leaktight criteria. The liner is typically 1/4 inch thick and is thickened locally around penetration sleeves, large brackets, and attachments to the basemat and shell wall. The stability of the liner plate, including the thickened plate, is controlled by anchoring it to the concrete structure. The shell wall and dome liner plate system is also used as a form for construction. Typical details of the liner plate system and anchors are shown in

engineering drawings 13-C-ZCS-200, -201, -205, -206, -207, -211, -212, -213, -215 and -217.

3.8.1.1.3.2 Equipment and Personnel Penetration Assemblies. A circular equipment hatch and two personnel airlock assemblies penetrate the concrete cylinder walls. Penetration assemblies consist of steel sleeves or nozzles, reinforcing plates, and anchors. They are anchored to the concrete walls and are welded to the steel liner. Hatch and air lock doors are provided with double-gasketed flanges with provisions for leak testing the flange-gasket combinations.

One of the two personnel air locks is for emergency access. Each personnel air lock has a door at each end and is an ASME Code-stamped pressure vessel. A quick-acting equalizing valve connects the personnel air lock with the interior or exterior of the containment to equalize pressure in the two systems.

During plant operation, the two doors of each personnel air lock are interlocked to prevent both being opened simultaneously.

Provision is made to bypass the interlock system during plant cold shutdown. Equipment hatch and personnel airlock liner plate penetration details are shown in engineering drawings 13-C-ZCS-206, -207 and –212.

3.8.1.1.3.3 Process Pipe Penetration Assemblies. Single barrier piping penetrations are provided for all piping passing through the containment walls. The closure for process piping

to the liner plate is accomplished with a special flued head welded into the piping system and to the penetration sleeve which is, in turn, welded to a reinforced section of the liner plate. In the case of piping carrying hot fluid, the pipe is insulated to prevent excessive concrete temperatures and to prevent excessive heat loss from the fluid. Closures to these penetration assemblies are provided by the piping systems that are served by the penetrations. For typical details of the pipe penetration assemblies used in the shell wall, refer to engineering drawings 13-C-ZCS-205, -206 and –213.

3.8.1.1.3.4 Electrical Penetration Assemblies. Electrical penetration assemblies provide means for carrying one or more electric circuits through a single aperture (nozzle) in the containment pressure barrier while maintaining the integrity of the pressure barrier.

Medium voltage power penetrations are configured in the form of a tubular canister slightly shorter than the containment structure nozzle into which it will be installed. The penetration assemblies are installed in 24-inch diameter nozzles. The canister is used as a pressure chamber to monitor penetration leakage rate by pressurizing the interior space with nitrogen and measuring the leak rate with a pressure gauge. The medium voltage power penetration is flange-mounted to the outside containment wall with nuts, bolts, washers, and lock-washers. The aperture seal is formed between the header plate and the flange with two concentric Viton O-rings.

The low voltage power, control, and instrumentation penetrations are also flange-mounted to the outside containment wall in the manner described for the medium voltage power penetrations. Each penetration in this category has a stainless steel header plate at the outside containment end. Stainless steel feed-through subassemblies, containing electrical conductors, pass through the header plate and are secured and sealed with special stainless steel compression fittings. The interstices between the seals and feed-through subassemblies provide a pressure chamber which is used to monitor the leakage rate. These penetrations are installed in 12- or 18-inch diameter nozzles.

For locations of electrical penetration sleeves, refer to engineering drawings 13-C-ZCS-205 and -206.

3.8.1.1.3.5 Fuel Transfer Tube. A fuel transfer tube penetration is provided for refueling. An inner pipe acts as the refueling tube with an outer pipe as the housing. The tube is fitted with a double-gasketed blind flange in the refueling canal and a standard gate valve in the spent fuel pool. This arrangement prevents leakage through the refueling tube. Outer sleeves permit the transfer tube to penetrate the refueling canal wall, the containment shell, and the exterior wall of the fuel handling building, while maintaining a pressure-tight boundary at each wall. The sleeves are anchored into each wall respectively and welded to each wall's liner plate. The housing is supported by the sleeves in the vertical and horizontal directions. Bellows at both the interior and

exterior faces of the containment shell and of the fuel handling building permit thermal expansion of the transfer tube and of the housing. The same expansion bellows permit differential movement between structures. Details are shown in engineering drawings 13-C-ZCS-206 and -211.

3.8.1.1.3.6 Attachments and Brackets. Attachments to the shell wall are brackets for support of the polar crane, electrical conduit and cable tray, spray piping, lighting and ventilation. The polar crane support brackets consist of built-up steel plate, the top flange penetrating the thickened liner plate, and are anchored in the concrete of the shell wall. For details, see engineering drawings 13-C-ZCS-205, -206, -207 and -215.

Attachments to the basemat include anchor bolts for columns that support floors and reinforcing steel for internal structures support. Attachment of the reinforcing steel is accomplished by B-series cadweld connectors welded to the top and bottom of the thickened liner plate.

3.8.1.1.4 Shell Discontinuities

Significant discontinuities in the shell structure are at the wall-to-basemat connection, the buttresses, and the large penetration openings.

3.8.1.1.4.1 Wall-to-Basemat Connection. The shell wall interface at the basemat is designed to accommodate axial

forces, moments, and shears. Refer to engineering drawing 13-C-ZCS-104 for details.

3.8.1.1.4.2 Buttresses. Buttresses project out from the shell wall and dome surface to provide adequate space for hoop tendon anchorage and tendon stressing equipment. The anchorage surfaces of the buttress are normal to the tangent line of hoop tendons anchored. Details are shown in engineering drawings 13-C-ZCS-114 and -115.

3.8.1.1.4.3 Large Penetration Openings. The concrete shell around the equipment hatch opening and around the penetrations for the main steam and feedwater pipes is thickened as shown in engineering drawing 13-C-ZCS-117.

3.8.1.2 Applicable Codes, Standards, and Specifications

The following codes, standards, regulations, specifications, design criteria, and NRC Regulatory Guides constitute the basis for the design, fabrication, construction, testing, and inservice inspection of the containment structures. Modifications to these codes, standards, etc., are made when necessary to meet the specific requirements of the structure. These modifications are indicated in the sections where references to the codes and standards are made. Later editions of certain baseline standards as noted in subsequent sections are acceptable provided they are identified in applicable design calculations or specifications for fabrication, construction, testing, or inspection.

3.8.1.2.1 Regulations

The following regulations apply to containment design:

- Code of Federal Regulations, Title 10-Atomic Energy, Part 50, Domestic Licensing of Production and Utilization Facilities, 1972
- Code of Federal Regulations, Title 29-Labor, Part 1910, Occupational Safety and Health Standards, 1972

3.8.1.2.2 Codes and Standard Specifications

The following codes and standards are applicable to containment design:

- American Concrete Institute, Building Code Requirements for Reinforced Concrete (ACI 318-71).
  - In the containment design, portions of this Code, particularly Chapters 18, 19, and Appendix A, are superseded by the other provisions described in subsection 3.8.1.
- American Institute for Steel Construction (AISC), Specification for the Design, Fabrication and Erection of Structural Steel for Buildings, adopted February 12, 1969 and Supplement Nos. 1, 2, and 3, or later edition.
- American Institute of Steel Construction (AISC), Specification for Structural Joints Using ASTM A325 or A490 Bolts Approved by the Research Council on Riveted

and Bolted Structural Joints of the Engineering Foundation, May 8, 1974, or later.

- American Society of Mechanical Engineers (ASME), Boiler and Pressure Vessel (B&PV) Code, Section II, 1974 Edition and Addenda through Winter 1974; Section III, Division 1, 1974 Edition and Addenda through Winter 1974; Section III, Division 2, Article CC-3000, 1975 Edition and Addenda through Winter 1975; Section V, 1974 Edition and Addenda through Summer 1974; Section VIII, Division 1, 1974 Edition and Addenda through Winter 1975; Section IX, 1974 Edition and Addenda through Winter 1974; Section XI, Subsections IWE and IWL, 1992 Edition with the 1992 Addenda.

- American Welding Society (AWS), Structural Welding Code (AWS D1.1-72, Rev. 1-1973 or later version) except as noted in paragraph 3.8.1.6.6.1, listing A.

- Crane Manufacturers Association of America Inc., CMAA Specification No. 70, 1971.

- American National Standards Institute (ANSI), Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel during the Construction Phase of Nuclear Power Plants (ANSI N45.2.5-1974) except as noted in paragraph 3.8.1.6.1.2, listings A and H, and paragraph 3.8.1.6.6.1, listing D.

3.8.1.2.3 General Design Criteria, Industry Standards, and Topical Reports

The following general design criteria, industry standards, and topical reports apply to containment design:

- NRC Regulatory Guides (applicable revisions and dates are provided in section 1.8)
  - Regulatory Guide 1.10, Mechanical (Cadweld) Splices in Reinforcing Bars of Category I Concrete Structures
  - Regulatory Guide 1.15, Testing of Reinforcing Bars for Category I Concrete Structures
  - Regulatory Guide 1.18, Structural Acceptance Test for Concrete Primary Reactor Containments
  - Regulatory Guide 1.19, Nondestructive Examination of Primary Containment Liner Welds
  - Regulatory Guide 1.29, Seismic Design Classification
  - Regulatory Guide 1.35, Inservice Inspection of Ungrouted Tendons in Prestressed Concrete Containment Structures
  - Regulatory Guide 1.46, Protection Against Pipe Whip Inside Containment

- Regulatory Guide 1.54, Quality Assurance Requirements for Protective Coatings Applied to Water-Cooled Nuclear Power Plants
- Regulatory Guide 1.55, Concrete Placement in Category I Structures
- Regulatory Guide 1.59, Design Basis Floods for Nuclear Power Plants
- Regulatory Guide 1.60, Design Response Spectra for Seismic Design of Nuclear Power Plants
- Regulatory Guide 1.61, Damping Values for Seismic Design of Nuclear Power Plants
- Regulatory Guide 1.63, Electrical Penetration Assemblies in Containment Structures for Light-Water-Cooled Nuclear Power Plants
- Regulatory Guide 1.64, Quality Assurance Requirements for the Design of Nuclear Power Plants
- Regulatory Guide 1.69, Concrete Radiation Shields for Nuclear Power Plants
- Regulatory Guide 1.76, Design Basis Tornado for Nuclear Power Plants
- Regulatory Guide 1.94, Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural

Steel During the Construction Phase of Nuclear Power Plants.

Exceptions to and interpretations of these regulatory guides are given in section 1.8. In addition, inservice inspection of the containment liner plate, exterior concrete surface, and tendon post-tensioned system shall be per the requirements of ASME Section XI, Subsections IWE and IWL, 1992 Edition with the 1992 Addenda, as modified and supplemented by 10 CFR 50.55a.

- NRC (AEC) Publication TID 25021, Nuclear Reactors and Earthquakes, is used for computing hydrodynamic loads imposed on the refueling canal walls.

- Industry Standards

  Nationally recognized industry standards, such as those published by American Society for Testing and Materials (ASTM), are used whenever possible to describe material properties, testing procedures, fabrication, and construction methods.

- Bechtel Power Corporation Topical Reports (applicable titles, dates, and revisions are provided in section 1.6.

  - BC-TOP-1
  - BC-TOP-3-A
  - BC-TOP-4-A
  - BC-TOP-5-A

- BC-TOP-7
- BC-TOP-8
- BC-TOP-9-A

3.8.1.2.4 Project Design and Construction Specifications

Project design and construction specifications are prepared to cover the areas related to design and construction of the containments. These specifications, prepared specifically for PVNGS, emphasize important points of the industry standards for the design and construction of the containment, and reduce options that otherwise would be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards. They cover the following subject areas:

- Excavation and backfill
- Concrete placement
- Inspection of concrete production
- Reinforcement steel placement
- Structural steel erection
- Miscellaneous metalwork installation
- Stainless steel liner plate system installation
- Post-tensioning system embedded items installation
- Concrete and concrete products

- Reinforcing steel and associated products
- Prestressing steel and related accessories
- Structural steel
- Miscellaneous steel and embedded materials
- Stainless steel liner plate
- Containment polar cranes
- Containment liner plate system including locks and hatches
- Fuel transfer tube

3.8.1.3 Loads and Load Combinations

Applicable loads and load combinations used and the load factors selected for each load component are listed in ASME B&PV Code, Section III, Division 2, Article CC-3000 (Subarticle CC-3200). These loads and load combinations are used in the design and analysis of the overall structure, as well as in the design and analysis of components and localized areas. Wind and tornado loads, flood design bases, and the seismic loads are given in sections 3.3, 3.4, and 3.7, respectively. Pressure transients resulting from the LOCA and MSLB serve as the design basis for the containment design pressure of 60 psig. The prestressing forces (F) are related to P_a as discussed in Section 6.2.1 of BC-TOP-5-A. Missile effects and postulated pipe rupture effects are discussed in sections 3.5 and 3.6, respectively.

Upon completion of construction, the containment and its penetrations are tested at 115% of the design pressure as discussed in paragraph 3.8.1.7.

The design pressure will not be exceeded during any subsequent long-term pressure transient caused by the combined effects of heat sources. These effects are overcome by the combination of safety features and heat sinks.

The temperature gradient through a typical PWR containment wall during operating conditions and during LOCA is shown in Figure 7-5 of BC-TOP-5-A. The variation of temperature with time and the expansion of the liner plate with temperature are considered in determining the thermal stresses.

3.8.1.4 Design and Analyses Procedures

3.8.1.4.1 Analytical Methods

The analysis of the containment structure complies with the requirements of ASME Section III, Division 2, Article CC-3000. Classical theory, empirical equations, and numerical methods were applied as necessary for the analysis of structural elements. They are described in BC-TOP-5-A.

3.8.1.4.2 Design Methods

The design of the containment structure complies with the requirements of ASME Section III, Division 2, Article CC-3000, supplemented by the design methods described in BC-TOP-5-A, Sections 6.2 and 6.3. They involved the initial proportioning of structures using the results of preliminary analyses.

Experience based on complete design, as well as parametric studies of other structures of a similar nature, was used.

The final design phase incorporated and refined information gained in earlier phases. It also incorporated closer approximations of the equipment and piping and related loads based on completion of detailed engineering design.

The containment is considered an axisymmetric structure for the overall analysis (BC-TOP-5-A, Section 7.2.1). Although there are deviations from this ideal shape (such as major penetrations), these deviations are localized and are handled by special analyses; hence, axisymmetric analyses are considered acceptable.

The overall analysis of the containment, given the application of axisymmetric loads, is performed by Bechtel's nonlinear FINEL finite-element computer program (BC-TOP-5-A, Section 7.1.2). A detailed description of this program is provided in appendix 3B, section 3B.13. The entire containment is modeled with one finite-element mesh consisting of the shellwall, basemat, internal structure, and soil.

The entire concrete structure is modeled by continuously interconnected elements. The geometry of the mesh allows the representation of reinforcing steel superimposed on the corresponding concrete elements.

The finite-element mesh of the structure is extended into the soil to account for the elastic nature of the soil material and its effect on the behavior of the basemat. The tendon access gallery is analyzed as a separate structure.

The use of the nonlinear finite-element analysis permits accurate determination of the stress pattern at any location of the structure.

Analysis and design of tendon anchorage zones and reinforcement in buttresses are discussed in BC-TOP-7, BC-TOP-8, and BC-TOP-5-A, Section 6.6. The method of analyzing the effect of the penetrations, the thickening, the reinforcements, and the embedments, is discussed in BC-TOP-5-A, Section 7.3. The design of the liner and its anchorage system are covered in BC-TOP-1 and BC-TOP-5-A, Section 7.5.

Information on analyses for computation of seismic loads is provided in section 3.7. The overall analysis of the containment for the application of nonaxisymmetric loads is performed by Bechtel's linear elastic ASHSD finite-element computer program. A detailed description of this program is provided in appendix 3B, section 3B.2. Comparisons of predictions were made, as appropriate, within allowable values of stresses, strains, deformations, and capacities. This procedure was used for both preliminary and final phases of design.

3.8.1.4.3 Computer Programs

The programs used in the computer analyses and design of the containment for static and dynamic loads are discussed in appendix 3B. The verification of these programs is also provided in appendix 3B.

3.8.1.4.4 Tendon Anchorage Zones

The design of tendon anchorage zones is based on results of tests presented in BC-TOP-7 and BC-TOP-8 and conforms to the requirements of ASME Section III, Division 2, Paragraph CC-3543.

For a discussion on the design method, refer to BC-TOP-5-A, Section 6. Refer to figures 3.8-1 and 3.8-2 for details of tendon anchorage.

3.8.1.4.5 Reinforcing Steel Design Requirements

The reinforcing steel requirements in the critical areas of the containment shell dome and basemat are described in BC-TOP-5-A.

3.8.1.4.6 Liner Plate Leaktight Barrier

The details which depict the typical liner plate system and stiffeners are shown in BC-TOP-5-A, Figure 6-24.

The design of the liner and its anchorage system is covered in BC-TOP-1 and conforms to the requirements of ASME Section III, Division 2, Article CC-3000.

The relative strength of the liner plate against buckling as compared with its anchor and anchor welds is discussed in BC-TOP-1. BC-TOP-1 provides sample calculations that demonstrate that the strength of the anchor and the anchor welds is sufficient to preclude any possibility of overall buckling failure as a result of anchor pullout.

The elastic and plastic solutions are used to analyze the stresses in the anchors and concrete resulting from a buckled panel of the liner. The panel and anchors are modeled as a series of springs. Using the strains from all loads being considered, equilibrium of forces and compatibility of deformations, the stresses in the anchor and concrete are obtained. BC-TOP-1 provides details and further discussions.

The containment structure has a 1/4-inch liner plate in accordance with the requirements of table 3.8-1.

The liner plate above the spring line of the containment has the shape of a hemispherical dome that is self-supporting during placement of the dome concrete. It is stiffened in two directions. Details of the dome are shown in BC-TOP-5-A, Figure 6-24.

3.8.1.4.7 Brackets and Attachments

For details of the polar crane bracket and thickened liner plate assembly, refer to engineering drawings 13-C-ZCS-115 and -215. The crane bracket is completely shop-fabricated, including the thickened liner plate portion. The crane bracket top flange penetrates the thickened liner plate and is welded to the plate using full penetration welds.

The entire bracket and plate assembly is attached to the 1/4-inch thick liner plate with full penetration welds. In following established procedures, 2% of thickened liner plate perimeter welds are radiographed and 100% vacuum box-tested for

Table 3.8-1

b. Penetration sleeve assemblies are post-weld heat-treated in accordance with ASME Section III.

c. The energy requirements shall be 15 and 20 for SA-333, Grades 1 and 6, respectively.

leaktightness. The thickened plate to 1/4-inch plate weld does not carry the crane loads (refer to paragraph 3.8.3.4.7).

The polar crane box beam bracket is cantilevered from the containment shell. The bracket is designed to resist vertical, radial, tangential loads, torque, and bending moments in vertical and tangential (to the radius) directions. Vertical shear is transferred from the webs of the box beam bracket to the liner reinforcing plate ribs, which, in turn, transfer it to the embedded baseplate and into the concrete. Anchored bearing plates are provided at ends of the top and bottom flange. The top flange is a tension member, embedded in the concrete to develop the shear strength of concrete to prevent trapezoidal type pullout failure.

The bottom flange, in compression, is embedded in the concrete so that it can resist punchout shear due to pyramid type failure on the exterior shell face. Vertical and horizontal reinforcing bars in the vicinity of brackets are provided to resist moments induced by the critical crane loads including earthquake, dead load, live load, and impact loads.

The crane support bracket supports a circumferential crane girder which provides the support for the crane rails. The top of the rail elevation is 207 feet 6 inches and the radius to the centerline of the 171 pounds per yard crane rail is 70 feet 0 inch plus or minus 1/4 inch. The rated capacity of the polar crane is 225 tons.

3.8.1.5 Structural Acceptance Criteria

The structural acceptance criteria complies with ASME Section III, Division 2, Article CC-3000. The fundamental acceptance criteria for the complete containment are successful completion of the structural integrity test with measured responses within the limits predicted by analyses. Prediction of limits are based on test load combinations and code values for stress, strain, or gross deformation for the range of material properties and construction tolerances specified.

The structural integrity test is planned to yield information on both the overall response of the containment and the response of localized areas, such as major penetrations or buttresses, which are important to its design functions. This information, together with the test information documented in BC-TOP-7 and BC-TOP-8, makes possible the assessment of the margins of safety available locally.

The design and analysis methods, as well as the type of construction and construction materials, are chosen to allow assessment of the structure's capability throughout its service life. Additionally, surveillance testing, and inservice inspections provides further assurances of the structure's continuing ability to meet its design functions.

Table 3.8-2 lists the loading combinations used for the design and final analysis of the containment structure.

Table 3.8-3 shows the calculated stresses and strains, as well as the allowables, taken from critical sections of the containment structure as indicated in figure 3.8-3.

Table 3.8-2

LOADING COMBINATION FOR DESIGN AND FINAL ANALYSIS OF CONTAINMENT SHELL (Sheet 1 of 2)

Reference Loading (RLC)	PVNGS Project Criteria: Category	PVNGS Project Criteria: Loading Combination	ASME Sect III, Div. 2	BC-TOP-5A R-3	Final Analysis Performed	Remarks
1	Test	$D + L + F_i + P_t + T_t$	Same	Same	Yes	T_t is considered same as T_o; initial prestress is more critical

7	Severe Environment	$D + 1.3L + F + T_o + 1.5E_o + R_o$	None	Same	No	Less severe than loading Combination No. 11
8	Severe Environment	$D + 1.3L + F + T_o + 1.5W + R_o$	None	Same	No	Less Severe than loading Combination No. 7
9	Severe Environment	$D + 1.3L + F + T_o + 1.5E_o + R_o + P_v$	Same	None	No	Less severe than loading Combination No. 7
10	Severe Environment	$D + 1.3L + F + T_o + 1.5W + R_o + P_v$	Same	None	No	Less severe than loading Combination No. 8
11	Extreme Environment	$D + L + F + T_o + E_{ss} + R_o + P_v$	None	Same	Yes	R_o is a local load; P_v is omitted conservatively
12	Extreme Environment	$D + L + F + T_o + W_t + R_o + P_v$	None	Same	No	Less severe than loading Combination No. 11

Notation

D = Dead load

L = Live Load

F_i = Initial prestress

F = Final prestress

T_o = Normal operating temperature

P_a = Design accident pressure

W = Wind Load

R_o = Pipe reactions during normal operating or shutdown conditions

R_a = Pipe reactions due to postulated break (including R_o)

T_a = Design accident temperature

P_t = Test pressure(=1.15 P_a)

T_t = Test temperature (assumed equal to T_o)

P_v = Design external pressure (vacuum)

E_o = Operating basis earthquake

E_{ss} = Safe shutdown earthquake

W_t = Tornado Loads (including differential pressure and tornado missiles)

R_r = Local effects of containment due to postulated pipe breaks

Table 3.8-2

LOADING COMBINATION FOR DESIGN ANAD FINAL ANALYSIS

OF CONTAINMENT SHELL (Sheet 2 of 2)

Reference Loading (RLC)	PVNGS Project Criteria		ASME Sect III, Div. 2	BC-TOP-5A R-3	Final Analysis Performed	Remarks
	Category	Loading Combination				
13	Extreme Environment	$D + L + F + T_o + E_{ss} + P_v$	Same	None	No	Less severe than loading Combination No. 11
14	Extreme Environment	$D + L + F + T_o + W_t + P_v$	Same	None	No	Less Severe than loading Combination No. 12
15	Abnormal	$D + L + F + 1.5P_a + T_a + R_a$	Same	Same	Yes	R_a is a local load
16	Abnormal	$D + L + F + P_a + 1.25R_a$	None	Same	No	Less critical than loading Combination No. 17 in local analysis
17	Abnormal	$D + L + F + P_a + T_a + 1.25R_a$	Same	None	No	R_a is a local load, less severe than loading Combination No. 15
18	Abnormal with Severe Environment	$D + L + F + 1.25P_a + T_a + 1.25E_o + R_a + R_r$	None	Same	Yes	R_a and R_r are local loads
19	Abnormal with Severe Environment	$D + L + F + 1.25P_a + T_a + 1.25W + R_a + R_r$	None	Same	No	Less severe than loading Combination No. 18
20	Abnormal with Severe Environment	$D + L + F + 1.25P_a + T_a + 1.25E_o + R_a$	Same	None	No	Same as loading Combination No. 18 without local loads
21	Abnormal with Severe Environment	$D + L + F + 1.25P_a + T_a + 1.25W + R_a$	Same	None	No	Less severe than loading Combination No. 19
22	Abnormal with Severe Environment	$D + L + F + T_o + E_o$	Same	None	No	Less severe than loading Combination No. 13
23	Abnormal with Severe Environment	$D + L + F + T_o + W$	Same	None	No	Less severe than loading Combination No. 14
24	Abnormal with Extreme Environment	$D + L + F + P_a + T_a + E_{ss} + R_a + R_r$	Same	Same	Yes	R_a and R_r are local loads

Notation

D = Dead load

L = Live Load

F_i = Initial prestress

F = Final prestress

T_o = Normal operating temperature

P_a = Design accident pressure

W = Wind Load

R_o = Pipe reactions during normal operating or shutdown conditions

R_a = Pipe reactions due to postulated break (including [illegible])

T_a = Design accident temperature

P_t = Test pressure(=1.15 P_a)

T_t = Test temperature (assumed equal to T_o)

P_v = Design external pressure (vacuum)

E_o = Operating basis earthquake

E_{ss} = Safe shutdown earthquake

W_t = Tornado Loads (including differential pressure and tornado missiles)

R_r = Local effects of containment due to postulated pipe breaks

Note: Local loads are not considered in the overall analysis but are taken into account in local design. Also the live load has a negligible effect on the pressure boundary and thus is not included in the final analysis.

Table 3.8-3

STRESS ANALYSIS RESULTS (Sheet 2 of 9)

Footnotes:

a. Sign Conventions are:

Stresses and strains . . . . (+) tensile . . . . (-) compressive

Deflections . . . . (+) outward . . . . (-) inward

b. Allowable liner strains shown are based on the lowest values from the ASME Code, Section III, division 2.

c. All deflections shown are normal to the given surface.

d. Completely cracked sections; partially cracked sections are not indicated.

e. The stresses for section 22 were determined from a more detailed analysis, in addition to the FINEL analysis.

f. The stresses were obtained from OPTCON computer output.

g. Membrane stress is greater than 200 psi and thus the section is assumed cracked.

h. Reinforcement is assumed to yield at 54 ksi, the calculated strain is 0.00200 in/in.

3.8.1.5.1 Factors of Safety and Margin of Safety

The concrete portions of the containment are designed according to the requirements specified in this section. The structure is designed for the factored loads and load combinations given in ASME B&PV Code, Section III, Division 2, Article CC-3000 (Subarticle CC-3200) supplemented by additional load combinations and load factors which are included in BC-TOP-5-A, Appendix C, Table CC-32001. The load factors used to compute ultimate loads provide factors of safety against variation in loads, assumptions in structural analysis, simplifications in calculations, and effects of construction sequence and methods. The load factors are the ratio by which loads are multiplied for design purposes to assure that the load/deformation behavior of the structure is one of elastic, low-strain behavior. The load factor approach is used to make a rational evaluation of the isolated factors that must be considered to assure an adequate safety margin for the structure. This approach places the greatest conservatism on those loads most subject to variation and which most directly control the overall safety of the structure. It also places minimum emphasis on the fixed gravity loads and maximum emphasis on accident and earthquake or wind loads.

Load factors for the abnormal category demonstrate that the containment has the capacity to withstand pressure loadings at least 50% greater than those calculated for the postulated LOCA or MSLB (refer to subsection 6.2.1). The abnormal/severe environmental category demonstrates that the containment has

the capacity to withstand loadings at least 25% greater than those calculated for the postulated LOCA or MSLB with a coincident OBE; the abnormal/extreme environmental category demonstrates that the containment has the capacity to withstand the rupture of any attached piping coincident with the safe shutdown earthquake; and the extreme environmental category demonstrates that the containment has the capacity to withstand a tornado loading.

Tendon anchorage zones and buttresses are designed in accordance with BC-TOP-5-A, Section 6. The reinforcing steel is designed based on BC-TOP-7 and BC-TOP-8. These reports conclude that there is adequate margin of safety of the tendon anchorage and buttress design when subjected to the maximum condition of loading.

3.8.1.5.2 Allowable Stresses

The allowable stresses for factored loads and service loads in concrete, reinforcing steel, and the tendon system are as specified in ASME Section III, Division 2, Article CC-3000 (Subarticle CC-3400). The liner plate allowables are as specified in ASME Section III, Division 2, Article CC-3000 (Subarticle CC-3700).

3.8.1.5.3 Design of Shear Reinforcement

Methods used for radial shear design are as specified in ASME B&PV Code, Section III, Division 2, Article CC-3000. Methods

used for tangential shear design are as specified in appendix 3F.

3.8.1.5.4 Liner Plate System

The steel liner plate and anchorage are designed in accordance with ASME B&PV Code, Section III, Division 2, Article CC-3000, supplemented by the design methods and criteria of BC-TOP-1 and BC-TOP-5-A.

The basic information is described as follows:

A. Design Criteria

The design criteria applied to the containment liner to meet the specified leak rate under operating and accident conditions are as follows:

1. The liner plate is protected against damage by missiles generated from a LOCA.

2. The liner plate strains are limited to those values that have been shown by past experience to result in leaktight pressure vessels and are in conformance with the requirements of ASME Section III, Division 2, Article CC-3000 (Subarticle CC-3700).

3. The liner plate is prevented from developing distortions sufficient to impair leak tightness.

4. Criteria for protection against dynamic effects associated with the postulated rupture of piping are included in section 3.6.

B. Loads

The loads and load combinations required in paragraph 3.8.1.3 are considered in the analysis.

The following loads are considered in liner design:

1. Thermal cycling due to annual outdoor temperature variations where:

    a. Daily temperature variations do not penetrate a significant distance into the concrete shell to appreciably change the average temperature of the shell relative to the liner plate

    b. The number of cycles for this loading was 40 cycles for plant life of 40 years and was increased to 60 cycles for extended plant life of 60 years.

2. Thermal cycling due to variation in the interior temperature of the containment during the heatup and cooldown of the reactor system in which the number of cycles was assumed to be 500* cycles for plant life of 40 years. Five hundred (500) “assumed” interior operational heatup/cooldown cycles corresponds to an average of 8-1/3 cycles/year for a 60-year plant life (reactor system operational cooldown/heatup approximately every 6 weeks) which

* The reactor vessel studs shall be limited to 250 cycles

is adequately conservative to accommodate 60-year extended plant life.

3. Thermal cycling due to the LOCA is assumed to be one cycle, in which:

   a. Thermal load cycles in the piping systems are somewhat isolated from the penetration sleeve by the concentric sleeves between the pipe and the liner plate

   b. Attachments are designed in accordance with ASME B&PV Code, Section III, Division 2, Article CC-3000 fatigue considerations

   c. All penetration sleeves are reviewed for a conservative number of cycles expected during plant life

   d. Typical containment temperatures as a function of time are shown in Figure 7-5 of BC-TOP-5-A.

4. Other loads considered are the following:

   a. Local thermal loads, i.e., at hot process penetrations

   b. Construction loads, particularly those applied to the liner before the concrete is placed and after concrete has been placed but prior to time concrete has attained design strength

   c. Local loads, such as those due to restraint of support of equipment

C. Stresses and Permissible Strains

Due to the nature of the loads and other effects together with the types of components, the allowable capacities of the components are specified in terms of stress, strain, force, or displacement, whichever is applicable.

1. Liner plate

   a. The load combinations shown in ASME B&PV Code, Section III, Division 2, Article CC-3000 (Table CC-3230-1) are applicable to the liner plate except that load factors for all load cases may be taken equal to 1.0.

   b. The calculated strains and stresses for the liner plate are not to exceed the values given in ASME B&PV Code, Section III, Division 2, Article CC-3000 (Table CC-3720-1).

2. Liner plate anchors

   a. The liner plate is anchored to the concrete containment so that the liner strains do not exceed the strain allowables listed in the ASME B&PV Code, Section III, Division 2, (Subsubarticle CC-3720). The anchor size and spacing is chosen so that the response of the liner is predictable for all loads and load combinations given in paragraph 3.8.1.3. The anchorage system is designed so that it can

accommodate the design in-plane (shear) loads or deformations exerted by the liner plate and loads applied normal to the liner surface.

b. The allowable force and displacement capacity is given in ASME B&PV Code, Section III, Division 2, Article CC-3000 (Table 3730-1). Mechanical loads are those which are not self-limiting or self-relieving with load application. Displacement limited loads are those resulting from constraint of the structure or constraint of adjacent material and are self-limiting or self-relieving.

c. A nil ductility transition temperature requirement is not specified for liner plate material less than 5/8 inch thick (refer to paragraph 3.8.1.6.4). Failure by brittle fracture or cleavage mode of failure is precluded by the absence of significant tensile stresses.

3. Weld design

ASME Code, Section VIII, Subsection B, Paragraphs UW-8 to UW-19 are used as a guide in design of welds. Particular attention is given in the design of welds to the anticipated behavior of the structure under accident conditions.

3.8.1.6 Materials, Quality Control, and Special Construction Techniques

Materials used in the construction of the containment conform to the requirements of ACI 301, 318, and 211.1 for concrete and to ASTM 615 for reinforcing steel.

The containment is constructed of concrete and steel using proven methods common to heavy, industrial construction. The typical range of properties assumed in design is listed in tables 3.8-1, 3.8-4, and 3.8-5.

In instances where a particular property is not defined in tables 3.8-1 and 3.8-5, the range assumed for design is identified by standard industry specifications (paragraph 3.8.1.2.3).

3.8.1.6.1 Concrete

The compressive strength of concrete used for the containment is as follows:

- Basemat and gallery - f_c' = 5000 psi
- Cylinder and dome - f_c' = 6000 psi at 91 days

Table 3.8-4

TYPICAL RANGE OF PROPERTIES FOR CONCRETE CONTAINMENT STRUCTURES

Maximum aggregate size, in.	3/4 to 1-1/2
Unit weight, lb/ft^3	141 to 155
Predicted creep + autogenous length change at 40 years, millionths[(a)]	113 to 375
Predicted creep + autogenous + elastic length change at 40 years, millionths[(a)]	283 to 735
Modulus of elasticity at 28 days, 73F, psi x 10^6	3.6 to 7.3
Poisson's ratio at 28 d, 73F	0.16 to 0.28
Diffusivity at 28 days, 73F, ft^2/h	0.029 to 0.067
Coefficient of thermal expansion, millionths/F at 28 d, 73F	5.1 to 7.4

a. Loaded at age 180 days, 73F, 1530 psi

Table 3.8-5

LINER PLATE MATERIAL PROPERTIES AND CHARACTERISTICS

AS USED IN CONSTRUCTION

Material and Specification	Properties and Characteristics Used									
	Ultimate Strength (fu, ksi) Nominal	Ultimate Strength (fu, ksi) Range	Defined Yield (fy, ksi) Nominal	Ultimate Strain (ult, %) Nominal	E ($x10^3$ ksi) Range	Poisson's Ratio Range	Thermal Conductivity Btu / ft^3 ^oF hr Nominal	Coefficient of Linear expansion ($10^{-6}/^oF$) Nominal	Heat Capacity (Btu lb/^oF) Range	Unit Weight (lb/ft^3) Range
Liner Plate										
ASME SA-285 grade A	45	45-65	24	30	29-30	0.27-0.30	27	6.5	0.10-0.11	485-490

ASME SA-240 type 304	75		30	40	29-30	0.25-0.30	27	6.5	0.10-0.11	485-490

The test age of concrete using pozzolan in the concrete mix is designated as 91 days. The test age of concrete without pozzolan in the concrete mix is designated as the normal 28 days. These strength designations are in accordance with ACI 301.

Structural concrete is batched and placed in accordance with Specifications for Structural Concrete for Buildings (ACI 301-72) and Building Code Requirements for Reinforced Concrete (ACI 318-71) with additional specific information and exceptions as noted in paragraph 3.8.1.6.1.2.

A. Cement

Cement is type II conforming to Specification for Portland Cement (ASTM C150-74). The cement does not contain more than 0.60% by weight of alkalies calculated as Na_20 plus 0.658 K_20 nor more than 58% by weight of tricalcium silicate and tricalcium aluminate. Certified copies of mill test reports showing the chemical composition and physical properties are obtained for each load of cement delivered.

In addition, the in-process tests are performed on cement used, in accordance with ANSI N45.2.5.

The purpose of these in process tests is to ascertain conformance to ASTM C150. An additional test, STM C109-73, is repeated periodically during construction to check storage environmental effects on cement

characteristics. The tests supplement visual inspection and material storage procedures.

B. Aggregates

All aggregates conform to Standard Specifications for Concrete Aggregate (ASTM C33-74). In addition to the specified gradation, the fine aggregate (sand) has a fineness modulus of not less than 2.5 nor more than 3.1 during normal operations. At least four of five successive test samples should not vary in fineness modulus more than 0.20 from the average.

Coarse aggregate may be rejected if the loss, when subjected to the Los Angeles abrasion test, ASTM C131-69, using grading A, exceeds 40% by weight at 500 revolutions.

Source acceptance of aggregates is based on the following tests:

ASTM No.	Name
D75-71	Sampling
C131-69	Los Angeles Abrasion
C142-71	Clay Lumps and Friable Particles
C117-69	Material Finer than No. 200 Sieve
C123-69	Lightweight Pieces
C40-73	Organic Impurities
C235-68	Soft Particles
C289-71	Potential Reactivity (Chemical)
C136-71	Sieve Analysis
C88-73	Soundness
C295-65	Petrographic Examination (Reapproved 1973)

In addition to the foregoing initial source tests, in-process tests are performed on the aggregate in accordance with Table B of ANSI N45.2.5.

C. Water

Water used in mixing concrete is free of injurious amounts of oil, acid, alkali, organic matter, or other deleterious substances as determined by the following tests:

C109-73	Standard Method of Test for Compressive Strength of Hydraulic Cement Mortars (using 2-inch, 50 mm, cube specimen)
C151	Standard Method of Test for Autoclave Expansion of Portland Cement
C191-74	Standard Method of Test for Time of Setting of Hydraulic Cement by Vicat Needle

Water shall not contain impurities in amounts that will cause either:

- A change in the time of setting of cement by more than 25%
- A reduction in the compressive strength of mortar by more than 5% compared with results obtained with distilled water

- A change in the results of soundness by more than 0.10%

The pH range shall be 6.0 to 8.5.

When ice is used in the concrete and it is made from a water source different from concrete mixing water, the source is tested in the same manner as the source for the concrete mixing water.

D. Admixtures

The concrete may also contain an air entraining admixture and/or a water reducing admixture. The air entraining admixture is in accordance with Specification of Air Entraining Admixtures for Concrete (ASTM C260). It is capable of entraining 3 to 6% air, is completely water soluble, and is completely dissolved when it enters the batch. The water reducing and retarding admixture conforms to Standard Specification for Chemical Admixtures for Concrete (ASTM C494-71), Types A and D. Type A is used when average ambient temperature for the daylight period is below 70F. Type D is used when average ambient air temperature for the daylight period is 70F and above. Pozzolans, if used, conform to Specifications for Fly Ash and Raw or Calcined Natural Pozzolans for use in Portland Cement Concrete (ASTM C618-73). Admixtures containing chloride ions added in the manufacturing process are not used. In-process tests for admixtures are according to Table B of ANSI N45.2.5.

E. Concrete Mix Design and Testing

Concrete mixes are designed in accordance with ACI 211.1-74, Recommended Practice for Selection Proportions for Normal and Heavy Weight Concrete, using materials qualified and accepted for this work. Only mixes meeting the design requirements specified for concrete are used.

An independent testing laboratory at the site designs and tests the concrete mixes. To maintain the quality of the concrete, workability and other characteristics of the concrete mixes are ascertained by the testing laboratory before placement.

Bechtel's concrete technologist participates in the preparation of concrete specifications, mix design, placement procedures, field quality control, and testing programs and visits the site periodically during construction.

For the concrete used in the post-tensioned containment, uniaxial creep, modulus of elasticity and Poisson's ratio, autogenous shrinkage, thermal diffusivity, thermal coefficient of expansion, and compressive strength are determined.

3.8.1.6.1.1 Construction Joints. Where horizontal shear keys are not used, the concrete surface of construction joint is prepared by a sandblasting, chipping, or airwater cutting to remove laitance and other foreign materials. The surface of

the concrete is then washed thoroughly to remove loose material. Concrete surfaces to receive new concrete shall be in a saturated condition but essentially free of standing water. Small puddles of water covering less than 10% of the area are acceptable.

In cases where shear of significant magnitude exists, in horizontal and vertical joints, shear keys are provided to transfer the shear. The same surface preparation described above applies to the keyed construction joint as well.

3.8.1.6.1.2 Concrete Construction. Standards applied to concrete construction include the following:

A. Specifications for Structural Concrete for Buildings ACI 301-72, Revised 1973) -- Used except as noted below:

   1. Chapter 3, Proportioning, Section 3.2, Strength -- The compressive strength test age of concrete using pozzolan in the concrete mix is designated as 91 days. The compressive strength test age of concrete not using pozzolan in the concrete mix is designated as the normal 28 days.

   2. Chapter 4, Formwork, Section 4.5, Removal of Forms -- The following requirements apply in place of requirements specified in Section 4.5.4:

      a. Forms for columns, walls, sides of beams, slabs and girders, and other parts not supporting the weight of the concrete are

removed as soon as practicable in order to avoid delay in curing and repairing surface imperfections.

b. Wood forms or insulated steel forms for members 2-1/2 feet or greater in thickness are stripped within 24 hours or the forms are kept in place for a minimum of 7 days. If forms are stripped within 24 hours, the surface is cured by moist curing or membrane curing as specified in Chapter 12.

3. Section 4.3, Tolerances for Formed Surfaces -- Changed to the following:

a. Variation from plumb:

(1) In the lines and surfaces of columns, piers, and walls:

- In any 10 feet of length, 1/2 inch
- Maximum for the entire length, 1-1/2 inches

(2) For exposed corner columns, control-joint grooves, and other conspicuous lines:

- In any 20 feet of length, 1/2 inch
- Maximum for the entire length, 1 inch

b. Variation from the level or from the grades specified in the contract documents:

(1) In slab soffits, ceilings, beam soffits, and arrises, measured before removal of supporting shores:

- In any 10 feet of length, 1/2 inch
- In any bay or any 20 feet of length, 5/8 inch
- Maximum for the entire length, 1 inch

(2) In exposed lintels, sills, parapets, horizontal grooves, and other conspicuous lines:

- In any bay or any 20 feet of length, 3/8 inch
- Maximum for the entire length, 1 inch

c. Variation of the linear building lines from established position in plan and related position of columns, walls, and partitions:

- In any bay, 1/2 inch
- In any 20 feet of length, 1/2 inch
- Maximum for the entire length, 1 inch

- Jump form of containment shell, horizontal deviation of ±2 inches from design radius in 120° arc
- Jump form of containment shell, ±1 inch vertical deviation in 80 feet
- Jump form of containment shell, ±1/4 inch for local deviation in 5 feet in any direction
- For each 30° section of containment shell form, with the midpoint held to the erection tolerance, each end may deviate plus 1 inch from the design radius, in addition to other tolerances allowed for containment forms
- Minimum thickness of containment wall shall be 3 feet 8 inches regardless of tolerance allowance

d. Variation in size of sleeves, floor, and wall openings:

- -1/4 inch, +1/2 inch

Variation in location of sleeves, floor and wall openings:

- ±1/2 inch

e. Variation in cross-sectional dimensions of columns and beams and in the thickness of slabs and walls:

- -1/2 inch
- +1 inch
- For containment shell wall, the variation of thickness shall not exceed -4 inches, or +5 inches

f. Footings:

(1) Variations in dimensions in the plan:

- -1/2 inch
- +6 inches

(2) Misplacement or eccentricity:

- 2% of the footing width in direction of misplacement, but not more than 2 inches

(3) Thickness:

- Decrease in specified thickness, 5%
- Increase in specified thickness, no limit

4. Section 12.3.1, Cold Weather -- The requirements of ACI 306-66 were used subject to the exceptions given elsewhere in this section.

5. Chapter 14, Massive Concrete, Section 14.4, Placing -- The following requirements apply:

   a. Section 14.4.1:

      (1) The average slump of the concrete at the point of transport discharge is 4 inches or less. Slump is specified in the construction specification for the particular location and degree of congestion.

      (2) An inadvertency margin for maximum slump of +1 inch is used.

   b. Section 14.4.3 -- The permissible placing depth of individual layers within a concrete placement is 24 inches. Placing depth may exceed 24 inches when required to obtain sufficient hydrostatic pressure to force concrete around penetrations.

6. Chapter 14, Massive Concrete, Section 14.5, Curing and Protection -- The following requirements apply:

   a. If moist curing is used, the minimum curing period is 7 days or the time necessary to attain 70% of the specified design strength, whichever time is less. For other curing methods, the minimum curing period is 7 days.

b. Liquid membrane curing of concrete may be used during the first 48 hours under winter conditions in lieu of moist curing.

7. Chapter 15, Prestressed Concrete, Section 15.4.4 -- Tendon sheathing and trumpet extensions shall be fabricated in a manner which ensures the final specified function and load capacity of the complete tendon system. Tolerances shall ensure consistent installation to $\pm 3/4$ inch. Tendon sheathing and trumpet extensions will be accurately installed at the location shown on the plans to a tolerance of $\pm 3/4$ inch.

8. Chapter 16, Testing, Section 16.3.4.3

   a. Concrete strengths for the containment cylinder and dome are specified as 91-day strengths.

   b. For large structural concrete placements (placements greater than 1000 cubic yards), where placing of concrete is a continuous operation, cylinders are made for each 100 cubic yards for the first 500 cubic yards placed and for each 250 cubic yards for the remaining concrete placed (applicable to FSAR subsections 3.8.4 and 3.8.5 only).

   c. For the containment building, cylinders are taken for each 100 cubic yards placed.

B. Recommended Practice for Cold-Weather Concreting (ACI 306-66) -- Used with the following exceptions:

1. In heating the water and aggregate, the resulting temperature of the mixed concrete will not be more than 10F higher than the temperatures indicated in the following table. The temperature of the concrete, when delivered to the forms, will not be more than 5F below the temperatures indicated in the following table:

Air Temp. (°F)	Concrete Sections Less than 2-1/2 ft in Least Dimension (°F)	Concrete Sections 2-1/2 ft or more in Least Dimension (°F)
30 to 45	55	45
0 to 30	60	50
Below 0	65	55

C. Building Code Requirements for Reinforced Concrete (ACI 318-71) -- Used with the following exceptions:

1. Section 5.5, Curing -- The following requirements apply:

a. During summer conditions the concrete is moist cured for 7 days or the time necessary to attain 70% of the design strength, whichever time is less. Liquid membrane curing of concrete may be used during the first 48 hours under winter conditions in lieu of moist curing. If liquid membrane

curing is used, the minimum curing period is 7 days.

b. The methods used in liquid membrane curing will be in accordance with ACI 306-66 and the manufacturer's instructions.

2. Section 6.3.2.4, Conduits and Pipes Embedded in Concrete -- ASME Boiler and Pressure Vessel Code, Section III, Division 1, provisions apply to nuclear piping and ANSI B31.1 apply to nonnuclear power piping. Test provisions of state and local plumbing codes apply in all cases. The following provisions of this section apply only where the above are inapplicable:

   a. Magnitude of test pressure

   b. Duration of test

   c. Timing of test

3. Section 7.3.2, Tolerances -- Tolerances for placing reinforcing, pre-stressing steel, and prestressing steel ducts are determined by the engineer based upon the structure geometry, bar size, and degree of congestion and are as follows:

   a. For containment portions other than walls and dome and for other Seismic Category I structures, the following tolerances are used for clear concrete protection and for depth (d) in flexural members, walls, and

compression members, but the cover is not reduced by more than one-third of the specified cover:

- 8 inches or less, +1/2 inch
- More than 8 inches but less than 24 inches, ±1/2 inch
- 24 inches or more, +1 inch

For floors with drains, reinforcing is placed the proper distance measured from the drain, and installed to the drain elevation throughout the floor.

b. For containment exterior walls and dome reinforcement, the concrete cover over any point on the outer curtain of reinforcing steel shall be:

- 4 ±1-1/2 inches for No. 14 and No. 18 bars
- 3 ±1 inch for all other bars
