The main steam supply system delivers the steam from the steam generators to the high-pressure turbine for a range of flows and pressure varying from system warmup to maximum operating conditions. It also provides steam to the moisture separator reheater, the feedwater pump turbines, the auxiliary steam system, and the turbine gland steam seal system.

10.3.1.3 Environmental Design Bases

Refer to section 3.11 and CESSAR Section 3.11 for a discussion of environmental design bases.

10.3.1.4 Codes and Standards

The main steam supply is designed in accordance with the codes and standards identified in table 3.2-1.

10.3.1.5 CESSAR Interface Requirements

Refer to subsection 5.1.4.

10.3.2 DESCRIPTION

10.3.2.1 General Description

The main steam supply system, shown in engineering drawings 01, 02, 03-M-SGP-002 and -001, includes the following major components:

- Main steam piping from the steam generator nozzles to the main turbine stop valves
- One main steam isolation valve per main steam line
- Main steam safety valves, 5 per main steam line
- Atmospheric dump valves, 1 per main steam line

Table 10.3-1 lists the design data covering the major components of the main steam supply system.

10.3.2.2 Component Description

10.3.2.2.1 Main Steam Piping

The main steam lines deliver the required steam flow from the secondary side of the two steam generators to the high-pressure turbine; while brunch lines deliver steam to the moisture separator/reheater, feedwater pump turbines, steam seal system, and the auxiliary steam system. Each of the main steam lines from the steam generators is anchored at the containment wall and has sufficient flexibility to accommodate thermal expansion. Design of the attachment of the main steam piping to the steam generators includes design considerations that incorporate the allowable nozzle loading moments and stresses for both steam generators operating, or with one of them out of service. The design of all piping and supports considers all static and dynamic loadings, stresses, and moments arising from normal operation, pressure transients, or pipe rupture. The design of Seismic Category I piping and supports considers the loads discussed in subsection 3.9.3.

Each main steam line contains five spring-loaded safety valves, one atmospheric dump valve, and one isolation valve. All of these valves are located outside the containment and are installed as close as possible to the containment wall. Containment penetrations are discussed in subsection 6.2.4.

Turbine bypass valves are provided between the main steam isolation valves and turbine generator stop valves as discussed under the turbine bypass system (refer to subsection 10.4.4). Connections are provided for nitrogen pressurization of the steam generators. Also, sample connections are provided

downstream of the steam generator nozzles for determination of steam quality. Branch piping provides steam to moisture separator reheaters, main and feedwater pump turbine gland steam sealing systems, the feedwater pump turbines, the auxiliary feedwater pump turbine, and the bypass steam to the condenser and to atmosphere.

The main steam lines are designed to permit preoperational cleaning to remove foreign material and rust. The design is such as to prevent entry of foreign material into either the steam generators or turbine-generator. The main steam piping drops several feet immediately downstream of the steam generators prior to being routed to the turbine stop valves. The lines are sloped in the direction of the turbine, and drains are provided at all low points to provide for flushing and drainage.

Pertinent design parameters for the main steam piping out to the main steam isolation valve are presented in table 10.3-2.

The main steam piping out to the first isolation valve is inspected and tested in accordance with ASME Code, Sections III and XI. ANSI B31.1 piping is inspected and tested in accordance with Paragraphs 136 and 137 of ANSI B31.1.

10.3.2.2.2 Main Steam Isolation Valves

Each of the main steam lines is equipped with one quick acting main steam isolation valve (MSIV). Each valve has an actuation time of 4.6 seconds or less and operates automatically in the event of rupture in the main steam piping or associated components either upstream or downstream of the MSIV. They prevent blowdown of more than one steam generator (assuming a single active failure of an MSIV to close coincident with rupture) based on the MSIV's ability to close against maximum design differential pressure in either direction. The valves are designed to close upon loss of electric power. Once isolation is initiated, in response to a main steam isolation signal (MSIS), the valves continue to close and cannot be opened until the initiating MSIS is reset or overridden manually by the operator in the control room.

Table 10.3-2

MAIN STEAM ISOLATION VALVE EXPECTED LEAKAGE

Differential Pressure (psi)	Pressurized (Upstream/Downstream)	Seat Leakage
1400	Downstream (after steam line break)	0.1% VWO steam flow
1400	Upstream (after steam line break)	0.001% VWO steam flow

Each valve has two physically separate and electrically independent solenoid actuators in order to provide redundant means of valve operation. Refer to table 10.3-2 for valve leakage.

The main steam isolation valves are installed in the straight piping runs outside the containment. Table 10.3-3 tabulates all flow paths that branch off the main steam lines between the MSIVs and the turbine stop valves and provides information, including valve positions, to determine performance in the event of steam line break upstream of the MSIV. For those valves which remain open, the total steam flow through these valves is approximately 251,200 lbm/hr. The auxiliary feedwater pump (AFW) delivers at least 316,000 lbm/hr (650 gpm @ 180F.), to the intact steam generator at 1270 psia. Therefore, in the event of a postulated MSLB on one steam generator, and one MSIV failure to close on the intact steam generator, an auxiliary feedwater pump can provide sufficient make-up to the intact steam generator. The maximum stress level does not exceed the criteria specified in subsection 3.9.3. As noted in UFSAR Sections 15.1.5 and 15.1.6, however, the single failure of a HPSI pump to start on demand is more limiting for postulated MSLBs, than the single failure of an MSIV to close.

A mechanistic main steam line pipe rupture is not postulated to occur between the containment penetrations and the MSIVs nor between the MSIVs and the double concrete wall (designed as a pipe whip restraint) downstream from the MSIVs. However, the main steam support structure and safety-related equipment within are designed to withstand the temperature and pressure effects of a single area pipe break.

The bending moment resulting from a main steam line rupture downstream of the pipe whip restraint is absorbed by the pipe whip restraint and the MSIV nozzle has no bending moment transmitted to it.

The steady-state discharge thrust load from such a break does not cause nozzle bending or torsion. Axial thrust is resisted and balanced at the penetration.

The bending and axial loads resulting from a postulated main steam line break inside the containment are absorbed by the containment penetration which is designed to withstand pipe collapsing moments and axial thrust.

The operability of the MSIVs is thus unaffected by the above postulated main steam line breaks.

The MSIVs are designed, manufactured, inspected, tested, and certified in accordance with the requirements of the ASME Code, Section III.

The supplier of the MSIVs has designed the valve body to the specified design pressure and temperature and designed the disc, piston, cylinder, connecting shaft, and all other valve and operational components subject to the closing and opening loads within the specified operational time limits to the design differential pressure (in either direction). Disc load and disc assembly inertia load are safely transferred to the valve body.

Total load combinations and stress limits (including pressure load and disc assembly inertia load acting on the valve seat) meet the requirements of table 3.9-3.

The maximum disc stress due to differential pressure and the inertia load due to the moving disc assembly do not exceed 75% of the yield strength in bending and 50% of the yield strength in shear of the disc material at the operating temperature.

The MSIVs are qualified for operability in conformance to paragraph 3.9.3.2.1.2.

10.3.2.2.3 Main Steam Safety Valves

Each main steam line is provided with five ASME Code, spring loaded safety valves located upstream of the main steam isolation valves but outside the containment. The total relieving capacity of these valves is divided equally between the main steam lines and is sufficient to pass the steam flow equivalent to 105% of the plant's maximum steam flow. Design data for the main steam safety valves are included in table 10.3-1. The safety valve pressure accumulation does not exceed 3% and the maximum pressure while relieving is below the maximum allowable of 10% above the steam generator design pressure, in accordance with Article NC-7000 of ASME Section III, Nuclear Power Plant Components Code. The design pressure-temperature rating of the main steam piping is 1270 psia and 600F, which are more conservative than the design conditions for the steam generator secondary side.

10.3.2.2.4 Atmospheric Dump Valves

Atmospheric dump valves, one per main steam line, are provided to allow cooldown of the steam generators when the main steam isolation valves are closed, or when the main condenser is not available as a heat sink. Each atmospheric dump valve is sized to hold the plant at hot standby while dissipating core decay heat or to allow a flow of sufficient steam to maintain a controlled reactor cooldown rate. No automatic control capability is required or provided. Refer to section 7.4 for

discussion of the control of the atmospheric dump valves. A nitrogen accumulator is provided for each valve. The accumulator is designed to Seismic Category I standards and is sized for 4 hours at hot standby plus 9.3 hours of operation to reach cold shutdown[(1)] under natural circulation conditions in the event of failure of the normal control air system, with a minimum nitrogen accumulator pressure of 615 psig indicated. Refer to subsection 9.3.6 for a discussion of the nitrogen supply for the atmospheric dump valve accumulators.

10.3.2.3 Radiological Considerations

Because the steam from the steam generator is not normally radioactive, no radiation shielding is required for the main steam system and associated components. Thus, radiological considerations will not affect access to system components during normal conditions. In the event of a primary-to-secondary system leak caused by a steam generator tube leak, it is possible for the steam to become radioactively contaminated. Discussions of the radiological aspects of primary-to-secondary leakage are presented in chapters 11 and 12.

10.3.3 EVALUATION

Table 10.3-4 covers the failure mode and effects analysis of the main steam supply system.

10.3.3.1 Safety Evaluation

Safety evaluations are numbered to correspond to the safety design bases and are as follows:

A. Safety Evaluation One

Under the following conditions, with the steam generators in service, the power-operated atmospheric dump valves are used to dissipate reactor coolant system energy and core decay heat into the atmosphere:

1. When the turbine generator or main condenser is not in service
2. When the plant is being started up or shut down
3. During core physics testing
4. Following a turbine-generator trip on loss of main condenser vacuum
5. Loss of electric power to plant auxiliaries

Controlled cooldown can be accomplished by use of the dump valves.

B. Safety Evaluation Two

Isolation valves are included in the system design. These valves are described in paragraph 10.3.2.2.2 and their performance under the accident conditions is discussed in chapter 15.

C. Safety Evaluation Three

The main steam system is designed in accordance with seismic criteria set forth in chapter 3. The design of the main steam system with respect to natural phenomena is also discussed in chapter 3.

Table 10.3-4

MAIN STEAM SYSTEM FAILURE MODE AND EFFECTS ANALYSIS (Sheet 1 of 3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision
1	Main steam isolation valve	a) Fails open	Solenoid failure	None, redundant solenoid will close valve	Valve Position Indicator, S. G. Pressure and Level Indicators, and steam line flow recorders	Each MSIV has redundant trip circuits, solenoid valves, accumulators, and position indicators.
		b) Fails closed	Actuator failure	Decrease in steam flow to the turbine generators, about 25%	Valve Position Indicator and steam line flow recorders	None
2	MSIV bypass valve	a) Fails closed	Mechanical binding Pneumatic operator failure	Main steam isolation valves can't be opened if there is a pressure drop across them	Valve position indication in control room	Either of two valves can be used to equalize pressure in all four steam lines.
		b) Fails open	Mechanical binding	None, if MSIV is open. If MSIV is shut, then bleedoff of steam generator	Valve position indication in control room	Affects only one steam generator.

Table 10.3-4

MAIN STEAM SYSTEM FAILURE MODE AND EFFECTS ANALYSIS (Sheet 2 of 3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision
3	Valve, atm dump	a) Fails closed	Failure of seals or air supply	No effect unless coupled with some other failure	Valve position indication in control room	Backup nitrogen supply. Also, other steam generator atmospheric dump valves provide full capability for steam release
		b) Fails open	Mechanical binding	About 16% of one steam generator's steam output would be dumped to atmosphere. A stuck open ADV will result in both a reactor trip and a MSIS.	Noise level increase, and a decrease in steam generator pressure indicated in control room	Blowdown of only one steam generator
4	Main feedwater isolation valve	a) Fails open	Mechanical binding	No effect	Periodic tests	Two valves in series in each line are available for isolation. Auxiliary feed flow is available via alternate path
		b) Fails closed	Operator failure	Loss of 90% of flow to one section of the steam generator. Decrease in steam generator efficiency	Low flow indicated on flow indicator	Feed to steam generator still available to other sections

Table 10.3-4

MAIN STEAM SYSTEM FAILURE MODE AND EFFECTS ANALYSIS (Sheet 3 of 3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failure	Methods of Detection	Inherent Compensating provision
5	Main feedwater check valve	a) Fails closed	Mechanical binding	No flow to one portion of the economizer in one steam generator. Decrease in efficiency of the steam generator	Flow indicator in control room	Steam generator feed still available to other sections Feedwater control system will automatically compensate
		b) Fails open	Mechanical binding	No effect unless coupled with some other failure	Periodic test	Closing of containment isolation valve
6	Auxiliary feedwater check valve	a) Fails closed	Mechanical binding	Temporary low feedwater flow to one steam generator	Low flow indication in control room	Alternate flow paths available. Feedwater control system compensates automatically
		b) Fails open	Mechanical binding	No effect unless coupled with some other failure	Periodic test	None required

D. Safety Evaluation Four

All safety-related components in the main steam system are designed to perform their intended function in the normal and accident temperature, pressure, humidity, chemical, and radiation environment in which they will operate. Environmental design bases and qualifications are discussed in section 3.11.

E. Safety Evaluation Five

The main steam lines are routed from the containment to the turbine building with separations provided so that the failure of steam lines or components associated with one steam generator cannot damage the main steam lines, the isolation valves, and atmospheric dump valves associated with the other steam generator, or damage any component required to effect a safe reactor shutdown. Refer to sections 3.5 and 3.6 for the discussion of missile and pipe rupture effects.

F. Safety Evaluation Six

Removable insulation and access to welds, in accordance with ASME Section XI requirements, are provided in the main steam supply system.

G. Safety Evaluation Seven

Each steam generator steam outlet nozzle is equipped with a flow limiting device to limit steam flow in the event of a downstream pipe break. Refer to CESSAR Section 5.4.4 for a description of the flow limiting device.

H. Safety Evaluation Eight

A branch connection upstream of the MSIVs from each steam generator provides steam to operate the auxiliary feedwater pump turbine. Refer to subsection 10.4.9.

10.3.3.2 CESSAR Interface Evaluation

Refer to subsection 5.1.5.

10.3.4 INSPECTION AND TESTING REQUIREMENTS

Refer to section 14.2 for preoperational testing requirements. Refer to section 3.9 and to the Technical Specifications for inservice testing and inspection requirements.

10.3.5 WATER CHEMISTRY (PWR)

10.3.5.1 Chemistry Control Basis

Steam generator secondary side water chemistry control is accomplished by:

A. Close control of the feedwater to limit the amount of impurities which can be introduced into the steam generator;

B. Blowdown of the steam generator to reduce the concentrating effects of the steam generator;

C. Chemical addition to establish and maintain an environment which minimizes system corrosion;

D. Preoperational cleaning of the feedwater system;

E. Minimizing feedwater oxygen content prior to entry into the steam generator.

Chemistry limits for secondary steam generator water and feedwater are established in accordance with EPRI PWR Secondary Water Chemistry Guidelines as endorsed by NEI 97-06, Steam Generator Program Guidelines. The EPRI guidelines and their bases represent the industry best practice, as developed from evaluation of the most recent experimental data and plant operating experience. Exceptions are fully evaluated and documented prior to implementation.

Secondary water chemistry is based on all volatile treatment to maintain system pH, ensure a reducing environment, and to scavenge dissolved oxygen present in the feedwater. Boric acid may be added to minimize SCC of the steam generator tubes.

A neutralizing amine such as ammonia, ethanolamine (ETA) and/or dimethylamine (DMA) is added to establish and maintain alkaline conditions in the feed train.

A reducing agent/oxygen scavenger, such as hydrazine is added to establish a reducing environment and to scavenge dissolved oxygen present in the feedwater. The reducing agent/oxygen scavenger also tends to promote the formation of a protective oxide layer on metal surfaces by keeping these layers in a reduced chemical state (lower electrochemical potential).

Both the pH agent and the reducing agent/oxygen scavenger can be injected continuously downstream of the condensate polishing demineralizers or in the extraction steam lines. These chemicals are added for chemistry control, and can also be added to the upper steam generator feed line when necessary.

Molar Ratio chemistry is monitored and may be controlled to provide additional assurance that aggressive species are not

concentrated above their respective molar concentration ratio (anion to cation ratio). Ammonium chloride injection may be utilized as a method to control Molar Ratio within a prescribed band.

Implementation of Boric Acid Treatment per NSSS Vendor recommendations and EPRI BAT Application guidelines is site specific and is controlled by the station chemistry control program. Boron is maintained at very low concentrations in wet layup to minimize excessive use of pH control agent.

pH is dependent on the pH agent used, the implementation of Boric Acid Treatment (BAT), which may be used to mitigate IGA/SCC of steam generator tubes (alloy 690 tubes, and the use of condensate polishing demineralizes. Alternate amine pH agents can be utilized to provide better pH control at the normal operating temperature of PWR steam generators. Implementation of BAT will require adjustment in the pH and boron specifications.

The normal chemistry conditions can be maintained by any plant operating with little or no condenser leakage. The steam generator limits permit operations with minor system fault conditions until the affected component can be isolated and/or repaired.

Secondary water chemistry monitoring is described in section 9.3.2.

Procedures will require prompt corrective action for out of specification secondary water chemistry conditions.

If condenser leakage is indicated, leak isolation procedures are instituted.

The abnormal limits permit operation with minor system fault conditions until the affected component can be isolated and/or repaired. If the abnormal limits are exceeded, plant shutdown procedures are considered.

Sampling of the steam generator water is done on a continuous basis; parameters monitored include pH, conductivity and radiation.

Out of specification chemical conditions are alarmed in the auxiliary building chemistry laboratory, with a common system trouble alarm in the control room.

In addition, recording and management of secondary water chemistry data will be covered by administrative procedures. These procedures will include the following requirements:

A. The composition, quantities, and addition rates of additives shall be recorded initially and thereafter whenever a change is made;

B. The electrical conductivity and the pH of the bulk steam generator water and feedwater shall be measured continuously (with provision for alternate sampling methods in case of equipment failure);

C. The electrical conductivity and sodium ion concentration of the condensate is measured continuously. An administrative procedure will specify responsibilities for interpretation of secondary water chemistry data, initiation of corrective action, maintaining secondary water chemistry conditions within specifications, and taking such action as is needed to correct out of specification or off control point conditions. The

Shift Manager is responsible for initiating corrective action for out of specification chemical parameters. The Shift Manager is advised in these corrective actions by the senior chemistry technician. Chemistry data sheets and reports are reviewed on a routine basis by unit chemistry management. Procedures will provide guidance for correcting out of specification and off control point conditions and will require prompt action to correct out of specification conditions.

Procedures for secondary water chemistry control and monitoring were available onsite for NRC review 60 days prior to filling the secondary side of a steam generator.

10.3.5.2 Corrosion Control Effectiveness

Alkaline conditions in the feedtrain and the steam generator reduce general corrosion at elevated temperatures and tend to decrease the release of soluble corrosion products from metal surfaces. These conditions promote the formation of a protective metal oxide film and thus reduce the corrosion products released into the steam generator.

The reducing agent/oxygen scavenger also promotes the formation of a metal oxide film by the reduction of ferric oxide to magnetite. Ferric oxide may be loosened from the metal surfaces and be transported by the feedwater. Magnetite, however, provides an adherent protective layer on carbon steel surfaces. The reducing agent/oxygen scavenger also promotes the formation of protective metal oxide layers on copper surfaces.

The removal of oxygen from the secondary waters is also essential in reducing steam generator corrosion mechanisms. Low levels of oxygen dissolved in water causes general corrosion that can result in pitting of ferrous metals, particularly carbon steel. Oxygen is removed from the steam cycle condensate in the main condenser deaerating section. Additional oxygen protection is obtained by chemical injection of a reducing agent/oxygen scavenger into the condensate stream. Maintaining a residual level of the reducing agent/oxygen scavenger in the feedwater ensures that any dissolved oxygen not removed by the main condenser is scavenged before it can enter the steam generator.

The presence of free hydroxide (OH^-) can cause rapid corrosion (caustic stress corrosion) if it is allowed to concentrate in a local area. Free hydroxide is avoided by maintaining proper pH control, and by minimizing impurity ingress in the steam generator.

Zero solids treatment is a control technique whereby both soluble and insoluble solids are excluded from the steam generator. This is accomplished by maintaining strict surveillance over the possible sources of feed train contamination (e.g.,: Main Condenser cooling water leakage, air in leakage and subsequent corrosion product generation in the Low Pressure Drain System, etc.). Solids (with the exception of boric acid, if used) are also excluded, as discussed above, by injecting only volatile chemicals to establish conditions which reduce corrosion and, therefore, reduce the transport of corrosion products into the steam generator. Reduction of

solids in the steam generator can also be accomplished through the use of full flow condensate demineralization.

In addition to minimizing the sources of contaminants entering the steam generator, continuous blowdown of one and/or both steam generators is employed to minimize their concentration. These systems are discussed in Section 10.4.6. With the low solid levels which result from employing the above procedures, the accumulation of scale and deposits on steam generator heat transfer surfaces and internals is limited. Scale and deposit formations can alter the thermal hydraulic performance in local regions to such an extent that they create a mechanism which allows impurities to concentrate to high levels, and thus could possibly cause corrosion. Therefore, by limiting the ingress of solids into the steam generator, the effect of this type of corrosion is reduced.

Because they are volatile, the chemical additives will not concentrate in the steam generator, and do not represent chemical impurities which can themselves cause corrosion.

10.3.5.3 Chemistry Control Effects on Iodine Partitioning

The partition factor assumed for the condenser vacuum pump outlet is discussed in subsection 11.1.8.

10.3.6 STEAM AND FEEDWATER SYSTEM MATERIALS

10.3.6.1 Fracture Toughness

The materials are in compliance with the ASME Boiler and Pressure Vessel Code, Sections II and III, 1974 Edition through the Winter, 1975 Addenda. The fracture toughness properties

meet the requirements of the Code, Section III, Paragraphs NB-2300, NC-2300, and ND-2300.

10.3.6.2 Material Selection and Fabrication

All pipe, flanges, fittings, valves, and other piping material conform to the latest referenced ASME, ASTM, ANSI, or MSS-SP code, including addenda and supplements.

The following code requirements apply:

	Stainless Steel	Carbon Steel
sPipe	ANSI B36.19	ANSI B36.10
Fittings	ANSI B16.9, B16.11 or B16.28	ANSI B16.9, B16.11 or B16.28
Flanges	ANSI B16.5	ANSI B16.5

The following ASME material specifications apply specifically:

ASME SA-155 GR KCF 70 Class 1 (impact tested) (Discontinued in 1978)

ASME SA-672 GR C 70 Class 21 (impact tested)

ASME SA-106 GR C (impact tested)

ASME SA-106 GR B

ASME SA-234 GR WP-22

ASME SA-234 GR WPB

ASME SA-234 GR WPBW (manufactured from ASME SA-516 GR 70 plate)

ASME SA-234 GR WPC (impact tested)

ASME SA-105

ASME SA-182

ASME SA-193 GR B7

ASME SA-194 GR 2H

ASME SA-333 GR 6 (impact tested)

ASME SA-335 GR P22

ASME SA-420 GR WPL6 (impact tested)

ASME SA-420 WPL6-W (manufactured from ASME SA-516 GR 70 plate) (impact tested)

ASME SA-350 LF 2 (impact tested)

ASME SA-403

ASME SA-312

ASME SA-376

For austenitic stainless steel components, consistency with the recommendations of Regulatory Guide 1.44, Control of the Use of Sensitized Stainless Steel; Regulatory Guide 1.36, Nonmetallic Thermal Insulation for Austenitic Stainless Steel; and Regulatory Guide 1.31, Control of Ferrite Content in Metal, is discussed in section 1.8.

For cleaning and handling of Class 1, 2, and 3 components, the recommendations of Regulatory Guide 1.37, Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants, and ANSI-N45.2.1-73, Cleaning of Fluid Systems and Associated Components During Construction Phase of Nuclear Plants, are followed as discussed in section 1.8.

With regard to preheat temperatures used for welding of Class 1, 2, and 3 low-alloy steel, the recommendations of Regulatory Guide 1.50, Control of Preheat Temperatures for Welding of Low-Alloy Steel, were followed.

All piping of the main steam system with pipe sizes larger than 2-1/2 inches is grit blasted.

Materials for use in Class 1, 2, and 3 components have been specified to conform to Appendix I of Section III of the Code and to Parts A, B, and C of Section II of the Code. Regulatory Guide 1.85, Code Case Acceptability ASME Section III Materials, has been used in conjunction with the above specifications.

For a discussion of conformance to Regulatory Guide 1.71, Welder Qualification for Areas of Limited Accessibility, refer to section 1.8.

10.4 OTHER FEATURES OF STEAM AND POWER CONVERSION SYSTEM

10.4.1 MAIN CONDENSER

The main condenser is designed to condense and deaerate exhaust steam from the turbine generator and the feedwater pump turbines.

10.4.1.1 Design Bases

10.4.1.1.1 Safety Design Bases

The main condenser has no safety function.

10.4.1.1.2 Power Generation Design Bases

Power generation design bases are as follows:

A. Power Generation Design Basis One

   The main condenser provides a heat sink for the exhaust steam from the turbine-generator and the feedwater pump turbines, as well as for turbine bypass steam and other cycle flows.

B. Power Generation Design Basis Two

   The main condenser provides hotwell storage for surge capability and retention of condensate in the event of a condenser tube leak.

C. Power Generation Design Basis Three

   The main condenser provides required deaeration of the condensate.

D. Power Generation Design Basis Four

The main condenser is designed to minimize air inleakage into the steam thermal cycle.

E. Power Generation Design Basis Five

The chemistry of the condensate and feedwater is maintained by the secondary chemical system under all normal operating and allowable upset or abnormal conditions.

10.4.1.1.3 Codes and Standards

The main condenser is designed in accordance with the applicable codes and standards identified in table 3.2-1.

10.4.1.2 System Description

The main condenser is a multi-pressure, three-shell, single-pass, deaerating type of surface condenser with divided waterboxes. The condenser is floor supported and is located beneath the low-pressure turbines. Expansion joints are provided between each turbine exhaust opening and steam inlet connection of the condenser shells. Main condenser design data are given in table 10.4-1. During normal operation, exhaust steam from the low-pressure turbines is directed downward into the condenser shells through exhaust openings in the bottom of turbine casings and is condensed. The condenser also receives vents and drains from feedwater heaters, miscellaneous equipment, valves, and piping. During transient conditions, the main condenser serves as a heat sink for feedwater heater

and drain tank high-level dumps and for the turbine bypass steam. The main condenser is designed to accept up to 41% of the rated steam flow through the turbine bypass system described in subsection 10.4.4. The bypassed steam flow is distributed between the three condenser shells. These conditions are accommodated without increasing the condenser backpressure to the turbine trip setpoint or exceeding the allowable turbine exhaust temperature. Provision is made to reduce the bypass steam pressure before exhausting into the condenser distribution manifold. Special considerations were given to the design of the condenser to avoid steam impinging on the tubes. The condenser has titanium tubes conforming to ASTM B388 which eliminate corrosion/erosion problems.

The condenser is cooled by the circulating water system that removes the heat rejected to the condenser. The use of divided water boxes, lined with repairable protective coating to minimize corrosion/erosion, on each shell permits isolation of one-half of the total circulating water flow through each shell. This permits access to the isolated water box on each shell for repair and/or inspection while one-half of the circulating water flows through the other water box. The circulating water system is described in subsection 10.4.5. The condenser hotwells provide 100,000 gallons of water storage, equivalent to that required for 4 minutes of operation at valves wide open load. The hotwells of each of the condenser shells are interconnected. In addition to struts and braces, the first, second, third, and fourth point low-pressure

feedwater heaters are installed in the steam dome of each condenser shell.

In the event that a condenser hotwell ruptures, the flooding will not jeopardize the safe shutdown of the plant. At no time would the water enter the auxiliary building, control building, or diesel generator building. The only access to any of these buildings from the turbine building is sufficiently above the turbine building basemat elevation. Since there is no safety-related equipment in the turbine building, none could be affected.

Air and noncondensable gases contained in the turbine exhaust steam are collected in the condenser and passed through the air removal section. Here, the noncondensable gases are removed by the condenser air removal system described in subsection 10.4.2. The maximum total condenser air inleakage is 60 standard cubic feet per minute, as calculated in accordance with Heat Exchange Institute Standard. Buildup of noncondensable gases is precluded since the air removal system is in continuous operation. The condenser reduces oxygen concentration in the condensate to 5 ppm or less by deaeration while the final oxygen content is reduced to 0.01 ppm or less by hydrazine injection at the discharge side of the condensate polishing system. The hydrazine injection system is discussed in subsection 10.4.6.

The internal steam dump fittings for the turbine bypass steam consist of double pressure reduction critical flow orifices. The steam exits in a horizontal direction away from both the turbine and the condenser tubes. In addition, the condenser tubes are protected from high temperature drains by austenitic stainless steel baffles that direct the flow away from the condenser tubes.

Loss of main condenser vacuum, as evidenced by the condenser pressure reaching or exceeding the setpoint of 7.5 in.Hg abs, trips the turbine. However, a standby vacuum pump having 100% capacity for one condenser shell is provided to prevent loss of vacuum. The pump is on automatic control to assist or take over the service of the operating pump. If the turbine is tripped because of high backpressure, the steam bypass valves close to prevent additional steam from entering the condenser.

Two of the eight bypass valves are directed to atmosphere and open only on high condenser pressure.

Rupture diaphragms on the main turbine exhaust hood are provided to protect the condenser and turbine exhaust hoods against overpressure. Exhaust hood overheating protection is provided by an exhaust hood spray system that uses condensate from the condensate pumps.

In the event of primary-to-secondary tube leakage, radioactive contaminants are present in the steam generator. Radioactive concentrations in the hotwell are given in section 11.1. During normal operation, there is no gaseous hydrogen going to the main condenser. In the event of a steam generator tube

leak, minute quantities of gaseous hydrogen are carried over to the main condenser. As noted in subsection 10.4.2, the condenser air removal system removes the hydrogen.

The reactor coolant system (RCS) is independent of the condenser circulating water system and the condensate and feedwater systems; therefore, the influence of condenser control functions on RCS operation is negligible. Minute changes in reactor power level occur as a result of changes in main turbine cycle efficiency caused by variations in condenser vacuum. However, these reactor power level variations are slight and are limited by the reactor regulating system. Each occurrence that leads to a loss of function of the condenser is accompanied by a loss of condenser vacuum, which is analyzed in section 15.2.

The operating chemistry limits for condensate and feedwater are discussed in section 10.3.5. Excessive leakage of coolant from the circulating water system into the condensate causes the condensate demineralizer to be placed in service. This system is also used to maintain water chemistry during startup, shutdown, and other conditions requiring the polishing of the condensate to maintain the required chemistry. The secondary chemistry control system, which controls and monitors the condensate chemistry, is discussed in subsection 10.4.6.

10.4.1.3 Safety Evaluation

The main condenser serves no safety function and has no safety design bases.

10.4.1.4 Tests and Inspections

Acceptance testing of the main condenser will be performed in accordance with section 14.2.

The condenser shells, hotwells, and waterboxes are provided with access openings to permit inspection and/or repairs.

During unit outages, the condenser shells can be completely filled with water and tested by the fluorescent tracer method for leaks in accordance with ASME Power Test Code 19.21, before returning the condenser to operation.

10.4.1.5 Instrument Application

Hotwell level and pressure indications are provided locally and associated alarms are provided in the control room for each condenser shell. The condenser hotwell in each shell contains conductivity cells to provide a means of detecting and locating condenser tube leaks. Rejection of hotwell condensate to the condensate tank is blocked automatically upon an indication of high hotwell cation conductivity. This feature prevents transfer of impurities into the condensate tank in the event of a condenser tube leakage. The condensate level in the main condenser hotwell is maintained within proper limits by automatically transferring condensate to or from the condensate tank. Condensate temperature is measured in the suction lines of the condensate pumps. Turbine exhaust hood temperature is monitored and automatically controlled by use of the water sprays. A high condenser backpressure alarm also is provided.

Turbine trip is activated on loss of main condenser vacuum when condenser pressure reaches or exceeds the setpoint. Monitoring of circulating water temperature, pressure, and differential pressure from waterbox to waterbox is provided.

10.4.2 MAIN CONDENSER EVACUATION SYSTEM

The main condenser evacuation system for PVNGS is the condenser air removal system (CARS) which establishes and maintains vacuum in the shell side of the condenser and provides for continuous removal of air and noncondensable gases from the condenser during normal power operation and plant startup.

10.4.2.1 Design Bases

10.4.2.1.1 Safety Design Bases

The CARS has no safety function.

10.4.2.1.2 Power Generation Design Bases

Applicable power generation design bases are as follows:

A. Power Generation Design Basis One

   The CARS is designed to remove air and noncondensable gases from the condenser and turbine gland sealing system and exhaust them to the atmosphere via the plant vent or through the effluent filtration system to atmosphere via the plant vent when radioactivity is detected.

B. Power Generation Design Basis Two

The CARS establishes and maintains vacuum in the condenser during startup and normal operation.

10.4.2.1.3 Codes and Standards

The CARS is designed in accordance with the codes and standards identified in table 3.2-1.

10.4.2.2 System Description

The CARS, shown schematically in engineering drawings 01, 02, 03-M-ARP-001, consists of four two-stage mechanical vacuum pumps, a moisture separator, post-filter, charcoal bed adsorber, blower, and associated valves and piping. The design parameters of the system are shown in table 10.4-2.

Operation of the vacuum pumps is initiated from the main control room. These pumps establish a vacuum of approximately 5 inches Hg abs, prior to buildup of steam generator pressure during plant startup.

During normal plant operation, three mechanical vacuum pumps evacuate air and noncondensables from the condenser.

Noncondensable gases, air, and water vapor are drawn from the three condenser shells to the vacuum pumps. The air and noncondensables from the vacuum pumps are directed to the filtration system whenever radioactivity is detected and prior to discharge to the plant vent stack.

Table 10.4-2
CONDENSER AIR REMOVAL AND TREATMENT SYSTEM
DESIGN DATA

Design Factor	Value

Design Noncondensable gas flow, std ft^3/min[(a)]	1,664
Charcoal bed adsorber	
Number	1
Vessel material	Carbon Steel
Bed depth, in.	2
Design temperature, °F	165
Design Noncondensable gas flow, std ft^3/min[(a)]	1,664

a. Includes noncondensable gas flow from turbine gland steam seal exhausters.

b. All values shown in the table that have units of std ft^3/min are based on standard temperature and pressure conditions of 60°F and 14.7 psia, respectively.

If the steam generators develop a primary to secondary leak, the CARS effluents will contain radioactive nuclides. A radiological evaluation of the discharge from the CARS and the basis for this evaluation are discussed in section 11.3. The

average and maximum steam generator tube leaks are given in section 11.1. The CARS effluents, after passing through the moisture separators, are treated in the effluent treatment system. The post-filter removes particulate radioactivity.

The charcoal adsorber removes iodine. Effluents from the treatment system are monitored for radioactivity by plant vent monitors before being released to the atmosphere via the plant vent stack. The effluent treatment system also treats effluent from the turbine gland sealing system (TGSS).

As long as the CARS is functional, its operation does not affect the RCS. Should the CARS fail completely, a gradual reduction in condenser vacuum would result from the buildup of noncondensable gases. The reduction in vacuum would cause a lowering of turbine cycle efficiency that requires an increase in reactor power to maintain the demanded electric power generation level. The reactor power is limited by the reactor regulating system as described in section 7.7. If the CARS remains nonfunctional, condenser vacuum decreases to the turbine trip setpoint and a turbine trip is initiated. Loss of condenser vacuum is discussed in section 15.2.

10.4.2.3 Safety Evaluation

The CARS has no safety function.

10.4.2.4 Tests and Inspections

Tests and inspections of the equipment and piping are performed in accordance with applicable codes and standards prior to

operation. CARS standby equipment is cycled periodically to ensure availability. Periodic inservice tests and inspections of the CARS are performed in conjunction with the scheduled maintenance outages.

10.4.2.5 Instrumentation Applications

Radioactivity of the effluent from the CARS is indicated and monitored in the main control room. In addition, high activity levels are alarmed.

10.4.3 TURBINE GLAND SEALING SYSTEM

The TGSS prevents air leakage into and steam leakage out of the main turbine and feedwater pump turbines.

10.4.3.1 Design Bases

10.4.3.1.1 Safety Design Bases

The TGSS has no safety function.

10.4.3.1.2 Power Generation Design Bases

Power generation design bases applicable to this system are as follows:

A. Power Generation Design Basis One

   The TGSS prevents air leakage into, and steam leakage out of, the turbine through the turbine shaft glands and through various steam valve stems.

B. Power Generation Design Basis Two

The TGSS returns the air-steam mixture to the turbine gland steam packing exhauster (GSC), condenses the steam, returns the drains to the main condenser, and exhausts the noncondensable gases to the atmosphere, via the effluent filtration system whenever radioactivity is detected.

10.4.3.1.3 Codes and Standards

The TGSS is designed in accordance with the applicable codes and standards identified in table 3.2-1.

10.4.3.2 System Description

The TGSS, shown schematically in engineering drawings 01, 02, 03-M-GSP-001, consists of steam seal supply and exhaust headers, gland steam regulators (GSRs), gland steam packing exhauster, steam packing exhauster drain tank, and the associated piping and valves. For the system to function satisfactorily from startup to full load, a fixed positive pressure in the steam seal supply header and a fixed vacuum in the outer ends of all the turbine glands (refer to table 10.4-3) must be maintained at all loads.

The steam discharge ends of all glands are routed to the GSC that is maintained at a slight vacuum by the redundant motor-driven blowers. The GSC is a shell and tube heat exchanger. Water supplied from the turbine cooling water system is used to condense the steam from the mixture of air and steam drawn from

the shaft packings. Drains from the GSC are returned to the main condenser, and the noncondensables are discharged to the atmosphere via the effluent filtration system of the MCES.

PVNGS operates with Auxiliary Steam as the preferred source to provide added protection to the main condenser in case of a main steam isolation signal. As the turbine is brought up to load, steam leakage from the high-pressure packings enters the steam-seal header becoming a steam source to the gland steam header. At higher loads, when more steam is leaking from the HP packings than is required by vacuum packings, the excess steam is discharged to the main condenser.

Table 10.4-3
TURBINE GLAND SEALING SYSTEM

Design Data	Value
Pressure in steam-seal header, psig	3 to 5
Vacuum in gland steam packing exhauster, in.WG	10 to 20
Number of gland steam packing exhausters	1
Number of blowers mounted on gland steam packing exhausters	2

In case of a malfunction of the GSR, a motor-operated bypass valve is opened and manually controlled to maintain steam-seal header pressure. Vacuum in the GSC can be maintained with one or both blowers in operation. Loss of both blowers may cause sufficient steam to blow through the seals into the turbine area and thus necessitate shutdown of the turbine. The radiological evaluation for the turbine gland sealing system is included in section 11.3. Relief valves on the steam-seal

header prevent excessive steam seal pressure. The valves are vented to atmosphere. The potential effects of high-energy pipe breaks are covered in section 3.6.

10.4.3.3 Safety Evaluation

The TGSS has no safety function.

10.4.3.4 Tests and Inspection

Tests and inspection on the TGSS equipment are performed in accordance with applicable codes and standards.

10.4.3.5 Instrumentation Applications

Local and control room displays consist of indicating and alarm devices of steam seal header pressure, temperature, and flow.

10.4.4 TURBINE BYPASS SYSTEM

The turbine bypass system removes heat from the NSSS and transfers it to the condenser or atmosphere following load rejections and during plant cooldown, plant startup, and hot standby.

For a discussion of environmental conditions for equipment qualification, refer to section 3.11.

10.4.4.1 Design Bases

10.4.4.1.1 Safety Design Bases

The turbine bypass system has no safety function.

10.4.4.1.2 Power Generation Design Bases

Power generation design bases applicable to the turbine bypass system are as follows:

A. Power Generation Design Basis One

Operate in conjunction with the reactor power cutback system (refer to CESSAR Section 7.7.l.l.6) to prevent reactor trip or opening of the pressurizer or main steam safety valves following load rejections provided the condenser is available.

B. Power Generation Design Basis Two

Remove heat from the NSSS and reject it to the condenser or atmosphere during plant cooldown, plant startup, and hot standby conditions.

C. Power Generation Design Basis Three

Control NSSS thermal conditions to prevent the opening of safety valves following a unit trip.

D. Power Generation Design Basis Four

Control NSSS thermal conditions when it is desirable to have reactor power greater than turbine power, e.g., during turbine synchronization.

E. Power Generation Design Basis Five

Provide pressure-limiting control during the loss of one out of two feedwater pumps.

F. Power Generation Design Basis Six

Provide a CEA automatic motion inhibit (AMI) signal when turbine power and reactor power fall below selected thresholds; provide AMI signal below 15% reactor power to block automatic control of the reactor below this power level.

G. Power Generation Design Basis Seven

Provide a means for manual control of RCS temperature during NSSS heatup or cooldown.

H. Power Generation Design Basis Eight

Provide for operation of the turbine bypass valves in a manner that minimizes valve wear and maintains controllability.

I. Power Generation Design Basis Nine

Provide for the operation of the turbine bypass valves in a manner to maximize thermal efficiency of the condenser.

J. Power Generation Design Basis Ten

Include redundancy in the design so that neither a single component failure nor a single operator error result in excess steam releases.

K. Power Generation Design Basis Eleven

Provide a condenser interlock which will block turbine bypass flow when unit condenser pressure exceeds a preset limit.

10.4.4.1.3 Codes and Standards

All components of the turbine bypass system are designed and constructed in accordance with the applicable codes and standards identified in section 3.2.

10.4.4.2 System Description

The turbine bypass system is shown schematically in figure 10.4-1.

The turbine bypass system consists of eight air-operated globe valves and associated instruments and controls. These valves branch from each main steam line downstream of the main steam isolation valve.

Six of these valves direct steam to the condenser and the remaining two vent directly to the atmosphere.

The valves are designed to quick open within approximately 1 second and quick close within approximately 5 seconds or modulate full open or closed within approximately 15 seconds. The valves are equipped with remote-operated handwheels to permit manual operation at the valve location.

The two valves which exhaust to the atmosphere are the last to open and the first to close during load rejections, thus minimizing the quantity of steam discharged to the environment. The valves and piping for the system are located in the turbine building.

The valves in the turbine bypass system are designed to fail closed to prevent uncontrolled bypass of steam. Should the

bypass valves fail to open on command, the main steam safety valves provide main steam line overpressure protection, and the power-operated atmospheric dump valves provide a means for controlled cooldown of the reactor. The main steam safety valves and power-operated atmospheric dump valves are described in paragraph 10.3.2.2.

In the event of a turbine trip, the amounts of radioactivity released and the resultant offsite doses are those stated in section 15.2. The main steam safety valves and power-operated atmospheric dump valves are used to control the load transient, if the bypass valves are disabled. Because the ASME Code safety valves provide the ultimate overpressure protection for the steam generators, the turbine bypass system is defined as a control system and is designed without consideration for the special requirements applicable to protection systems. Failure of this system will have no detrimental effects on the RCS.

The turbine bypass system removes heat from the NSSS following load rejections and during startup, plant cooldowns, and hot standby. The system removes heat by modulating bypass steam flow. The modulation of the bypass steam is performed by the turbine bypass valves, which receive signals from the steam bypass control system. Refer to section 7.7 for a discussion of the steam bypass control system.

The turbine bypass system provides a design steam dump capacity of at least 55% of the rated main steam flow. This amount of bypass steam capacity in conjunction with the reactor power cutback feature of the steam bypass control system will

dissipate enough energy from the NSSS to permit load rejection of any magnitude without lifting the main steam or pressurizer safety valves or tripping the reactor provided the condenser remains available. The effects of postulated system piping failure on safety-related equipment are given in section 3.6.

10.4.4.3 Tests and Inspections

A. Prior to initial operation, the complete turbine bypass system receives a field hydrostatic test and inspection in accordance with ANSI B31.1.

B. The turbine bypass system is tested under the requirements of the preventative maintenance program on a minimum frequency of every 18 months.

10.4.4.4 Instrumentation Applications

The control system for the turbine bypass system is discussed in CESSAR Section 7.7.

10.4.4.5 CESSAR Interface Requirements

Refer to subsection 5.1.4.

10.4.4.6 CESSAR Interface Evaluation

Refer to subsection 5.1.5.

10.4.5 CIRCULATING WATER SYSTEM

The circulating water system (CWS) removes heat from the main condensers and rejects it to the atmosphere using the plant cooling towers.

10.4.5.1 Design Bases

10.4.5.1.1 Safety Design Bases

The CWS has no safety function.

10.4.5.1.2 Power Generation Design Bases

The power generation design bases are as follows:

A. Power Generation Design Basis One

The circulating water receives the heat rejected by the turbine cycle.

B. Power Generation Design Basis Two

The plant cooling towers in the CWS dissipate waste heat from the turbine thermal cycle and from the plant cooling water system. The plant cooling water system is discussed in subsection 9.2.10.

10.4.5.1.3 Codes and Standards

The CWS is designed in accordance with codes and standards specified in table 3.2-1.

10.4.5.2 System Description

The CWS consists of the main condenser, cooling towers, circulating water pumps, a chemical injection system, and a makeup and blowdown system. The CWS is shown schematically in engineering drawings 01, 02, 03-M-CWP-001. Table 10.4-4 lists design data of the major components in the system.

The circulating water pumps are motor-driven, vertical, wetpit type, each rated at 25% capacity. The total design flow rate is 560,000 gallons per minute. These pumps take suction from the intake structure of the CWS and pump the circulating water through the main condensers. The CWS cooling water is returned from the main condensers through a common line to the cooling towers. The system is designed with cross-connected discharge piping from the circulating water pumps. The pump discharge lines are equipped with butterfly valves that permit any circulating water pump to be isolated individually.

Each circulating water path is provided with a butterfly valve at the low-pressure shell inlet and at the high-pressure shell outlet. In case of a condenser tube leak in any water box, the system will remain functional at reduced capacity.

The main condenser is discussed in subsection 10.4.1.

The cooling towers are designed for an ambient wet bulb temperature that will not be exceeded more than 5% of the time during the year. The design cooling range, design approach to ambient wet bulb temperature, and the unit data of the towers are shown in table 10.4-4.

In the event of flooding due to a failure in the portion of the circulating water system in the yard area (such as cooling towers, intake structure, buried pipe), the yard is graded in a direction to provide drainage of the water away from the power block and spray ponds. Therefore, the safe shutdown capability will not be compromised by flooding of the yard area.

A postulated failure in the circulating water system in the turbine building would flood the turbine building floor. The water would flow out of the building doors and side panels. The condenser area sumps and the oily waste sump would be filled to overflowing, but they are not safety-related. The condensate demineralizer sump, which is a sealed sump, would not be affected.

Assuming that 684,000 gallons per minute are available at the riser butterfly valve and considering the closing characteristics of the valve, it has been determined that 520,200 gallons would escape through the rupture with a valve closing time of 60 seconds. This amount of water would tend to flood the turbine building floor; however, as previously stated, the water would flow out of and away from the building. There are no passageways, pipe chases, cableways, or any other flow paths joining the turbine building floor. There are no essential electrical systems in the turbine building floor. These conclusions are based on the following conditions:

A. Low-pressure alarms in the circulating pumps discharge line will alert the operators.

Table 10.4-4
CIRCULATING WATER SYSTEM DESIGN DATA
FOR ONE TURBINE UNIT

Design Factor	Values
Circulating water pumps	
Number	4
Type	Vertical, wet-pit
Capacity each, gal/min	140,000
Head, ft (TDH)	103
Cooling tower	
Number	3 Round, mechanical draft
Design ambient temperatures	
Wet bulb temperature, °F	75
Dry bulb temperature, °F	116
Design range, °F	31.5
Design approach, °F	12.3
Unit tower data, VWO	
Makeup flow, gal/min	19,651
Blowdown flow, gal/min	1,284
Evaporation, gal/min	18,341
Drift, gal/min	26
Cooling tower circulating water flow, gal/min	587,000
Total turbine plant heat load, Btu/h	9.1×10^9
Chlorination facilities	
Chlorine injection rate (yearly average), lb/d	3,490 average

B. Each pump is capable of delivering 171,000 gallons per minute at maximum runout conditions.

C. The circulating water line crosstie is initially open.

D. Valve closing time is 60 seconds.

It is estimated that the operator action time to shut the valves and stop the circulating water pumps would be 20 seconds based on multiple indications of low circulating water pump discharge pressure and high condenser pressure. At 80 seconds, 748,200 gallons of water would have escaped. If the operator should fail to act, then the water would continue to flow out of the turbine building through doors and sidings at grade level 100 feet.

In the event of a failure of the circulating water system in the turbine building, at no time would the water enter the auxiliary building, control building, main steam support structure, or diesel generator building. Finish grade of 0.5% is established to permit flood water from a break in the circulating water system to spread and flow away from safety-related structures (reference Bechtel drawings 01-C-ZVC-400 through 01-C-ZVC-407). This flow pattern occurs whether the break is in the yard area or within the turbine building. The at-grade door sills in the auxiliary building and main steam support structure (MSSS) are sufficiently above expected water levels resulting from any postulated flooding source. An opening in the MSSS at the 81-foot elevation (a stairwell from the roof of the condensate tunnel) will have a waterproof door installed.

A makeup system is provided to replace water losses due to evaporation, blowdown, and drift from the unit cooling towers. Makeup water for the CWS is pumped from the water storage reservoirs to the CWS pump intake structure as required. Plant water requirements are covered in paragraph 2.4.11.5.

Salinity buildup in the CWS is controlled by blowing down to the evaporation ponds. Blowdown is taken from the circulating water system condenser discharge. Periodic samples are analyzed for dissolved solids, pH, temperature, and radioactivity.

The CWS is designed to prevent any injection of radioactive material into the circulating water. Circulating water passing through the main condenser is at a higher pressure than the steam on the condensing side. Therefore, any leakage, such as from the main condenser tubes, will be from the circulating water into the shell side of the main condenser.

Chemical injection systems add chlorine as sodium hypochlorite, sulfuric acid, and dispersant. The hypochlorite is used to control biological growth and the sulfuric acid adjusts pH in order to minimize corrosion and scaling from calcium carbonate. A flow diagram of the chemical injection system is shown in engineering drawings 01, 02, 03-M-CWP-001.

Sodium hypochlorite is received into storage from a chemical production system for chlorination. Upon initiation of a timed cycle, hypochlorite is fed to each unit CWS for biological control. The hypochlorite system serves all units, and

includes, at each unit, adjustable program control with a residual chlorine analyzer.

In addition to chlorination, a non-oxidizing biocide is used for control of aerobic slime forming bacteria and anaerobic corrosive bacteria, which are relatively unaffected by chlorine alone. The biocide is one which will hydrolyze to less toxic components with time.

10.4.5.3 Tests and Inspections

All active components of the system are accessible for inspection during station operation. Performance, hydrostatic, and leakage tests are conducted on the CWS butterfly valves in accordance with applicable codes and standards.

10.4.5.4 Instrumentation Application

Temperature and pressure in the CWS lines are measured at the main condensers. In addition, level alarms are provided at the CWS pump intake structure and high discharge pressure is alarmed in the control room.

10.4.6 CONDENSATE CLEANUP SYSTEM

Condensate cleanup is performed by the secondary chemistry control system (SCCS) which is an integrated system comprised of the condensate demineralization and blowdown processing subsystem and the chemical monitoring and addition subsystem.

These two subsystems, operating concurrently, provide the capability to maintain the proper operating chemistry of the

condensate feedwater and steam generator secondary side water. The SCCS is shown schematically in engineering drawings 01, 02, 03-M-SCP-002, -003, -001 and -004.

An interconnection exists between Secondary Chemistry (SC) and Auxiliary Steam (AS) condensate piping which permits the condensate cross connection header (APASNL107) to transfer warm (212 °F or less) condensate drained from the steam generators of a unit in operational mode 5 (when the primary system pressure is less than or equal to the secondary system pressure), mode 6, or defueled, to either or both of the other unit's Chemical Waste Neutralization Tanks for disposal or processing. The following conditions and restrictions apply to the use of this interconnection.

1. The unit discharging secondary coolant is in either Mode 5 and the primary system pressure is less than or equal to the secondary system pressure, or Mode 6, or in a defueled operating condition.

2. The specific activity of the secondary coolant in both the discharging and the receiving units is less than or equal to PVNGS Technical Specification LCO 3.7.16.

3. Radiological surveys and controls of ASNL107 will be performed as directed by the Radiation Protection Program.

4. Prior to transferring water, radiological conditions in the secondary system will be evaluated to ensure the transfer will not have a significant impact on operations in the receiving unit.

5. ASNL107 should be flushed after the draining of the steam generators to minimize the potential build-up of non-soluble particulates in the line. The flush may be waived if an evaluation of the radiological conditions determines it is not required.

6. Administrative controls (such as procedures) shall be in place to isolated the flow in the event of a large leak or pipe rupture.

7. Since flow rate from this modification may approach TDS sump pump capacity, monitor the sump as needed to ensure that is does not overflow.

8. During Operational Modes 1 through 4, valves 13PSCNV955 and 13PSCNV956 are to be verified closed and locked if not in use.

9. After use of pipe 13PSCNL479 and closure of 13PSCNV955 and 13PSCNV956, 13PSCNL479 must be drained.

10.4.6.1 Design Bases

The condensate cleanup system has no safety function.

10.4.6.1.1 Condensate Demineralization and Blowdown Processing Design Bases

The following design bases apply to the condensate demineralization and blowdown processing subsystem:

A. Maintain the purity and chemistry of the condensate, feedwater, and steam generator secondary side water.

When feeding the steam generators, the chemistry of the main feed train shall be in accordance with subsection 10.3.5.

B. Be capable of continuously purifying the full condensate flow. Full flow condensate demineralization systems shall be capable of continuous operation with 1 ppm total dissolved solids in the influent.

C. Continuously purify and recycle the steam generator blowdown. Blowdown flow for each steam generator may be used to maintain the steam generator chemistry within the limits outlined in subsection 10.3.5.

D. In order to minimize the consequences of a blowdown line rupture, each steam generator shall be equipped with an independent blowdown line.

10.4.6.1.2 Chemical Monitoring and Addition Design Bases

The following design bases apply to the chemical monitoring and addition subsystem:

A. Continuously monitor significant secondary side chemical parameters and alarm any fault conditions.

B. Continuously add volatile chemicals to the secondary side water to maintain pH and oxygen levels within the specified limits.

C. Inject boric acid into the secondary system as needed to mitigate denting and intergrannular attack/stress corrosion cracking (IGA/SCC) in the SGs.

D. Add chemicals to the feed train and steam generators prior to wet layup to minimize corrosion during long outages.

10.4.6.2 System Description and Operation

10.4.6.2.1 Condensate Demineralization

A full flow condensate demineralization subsystem capable of continuous service maintains feedwater purity during startup and periods of condenser leakage. In the condensate demineralizers, dissolved solids are removed by ion exchange, and suspended solids are removed by filtration.

The Condensate demineralization subsystem is comprised of six mixed bed ion exchangers in the hydrogen-hydroxide form. The demineralizers are normally in standby unless condenser leakage dictates that they be in service. If full flow service is needed, five of the demineralizers are required to be in service to support full power (approximately 26,000 gallons per minute), leaving one vessel in standby where it is available when one of the other beds becomes exhausted. This extra vessel allows the system to remain in continuous operation without reducing the process capability. The effluent from each condensate demineralizer is continuously monitored for conductivity and specific ions. This will assure that the

quality of the effluent is within the specified limits for feedwater (subsection 10.3.5).

The condensate demineralizer subsystem is designed to have sufficient capacity to continuously process condensate contaminated by small condenser leaks, and will permit an orderly shutdown if a larger leak occurs. The size of the leak that is able to be tolerated will depend partly on the pH at which the secondary system is being maintained. It takes approximately 24 hours to perform a regeneration of both the cation and anion resin. The secondary pH may be lowered slightly to allow sufficient time to perform full regenerations if the condenser leakrate exceeds the capacity of the resin to maintain acceptable effluent chemistry.

The operation of the CDS during plant startup is described in paragraph 10.4.6.2.5.

In order to ensure that a condensate demineralizer is always on standby, and to minimize the possibility of introducing regenerant chemicals into the feed train, the exhausted resin from the condensate demineralizers is externally regenerated.

Resin regeneration is performed in one of the two modes:

- Full regeneration, including backwash, anion resin chemical regeneration, and cation resin chemical regeneration
- Partial regeneration, including backwash and cation resin chemical regeneration.

Wastes produced by resin regeneration are minimized by reusing those which are acceptably low in TDS. Low TDS rinse water is

recycled to the condenser hotwell. Low TDS regenerant waste is recycled to the circulating water system for use in condenser cooling. Condensate polisher Pre-Service Rinse water can be diverted directly to the Retention Tank for ultimate onsite disposal. High TDS regenerant waste is unacceptable for reuse and is processed through the chemical waste system. From here the waste is sent either to the retention tank for ultimate onsite disposal or, if radioactivity exceeds the release limits stated in the Offsite Dose Calculation Manual (ODCM), to the liquid radwaste system for further processing and eventual recycle.

10.4.6.2.2 Steam Generator Blowdown Processing

Steam generator blowdown controls the concentration of impurities in the steam generator secondary side water. Each steam generator will be equipped with its own blowdown processing line with the capability of blowing down either the primary inlet or primary outlet regions of the steam generator. In addition to a hot leg blowdown line, the steam generators are also equipped with a blowdown line that allows blowdown from the downcomer region, and an additional downcomber blowdown line.

The blowdown will be directed into a flash tank operating at 225 psig where the flashed steam is returned to the cycle via the heater drain tanks. The liquid portion then flows to a heat exchanger where it is cooled by condensate to 140F (Blowdown Demineralizer in use) or 165F (Blowdown Demineralizer bypassed). It is then directed through a blowdown filter where

the major portion of the suspended solids are removed. It can also be directed to the retention tank for ultimate onsite disposal. After filtration, the blowdown fluid is processed by the blowdown demineralizer or directed straight to the condenser hotwell (Blowdown Demineralizer bypassed).

In the event of malfunction of the blowdown processing equipment, the flow can be directed to the condenser, thus maintaining the steam generator chemistry. During this mode of operation, the condensate polishing demineralizers would be placed in service.

10.4.6.2.3 Chemical Monitoring

The chemical monitoring subsystem is designed to provide continuous indication of significant chemical parameters in the secondary system and to alert the operator of faulty chemistry or equipment malfunction. Continuous online samples are taken from each section of the main condenser, the condensate demineralizer system inlet and outlet, the main feed lines, and the steam generator blowdown lines or downcomer sample, feedwater lines, and circulating water lines.
Samples taken from each section of the main condenser are analyzed for sodium ion concentration and intensified conductivity. Besides providing indications of condenser tube leakage, these monitors can be used in locating the section of the condenser that is leaking.

Upon indication of a condenser tube leak by the sampling system, the condensate polishing demineralizer may be placed

into service and the polishing demineralizer bypass valve closed. The condensate polishers will handle a maximum circulating water inleakage of 1 gallon per minute on a continuous basis. If this leakage is exceeded, the affected condenser hotwell half may be isolated by motor-operated valves in the condensate pump suction and discharge lines. The remaining condenser hotwell storage and the makeup rate will provide enough condensate for reduction to 50% power by utilizing a 10% step and then a 5% per minute ramp down to a 50% power level. The respective circulating water path is isolated and the condenser half is drained. The leaking tubes can be plugged and the contaminated hotwell can be pumped out by one condensate pump to the condenser circulating water outlet.

Leakage from the condensate demineralizers will allow contaminants to enter the steam generators (SGs). To detect for this possibility, the condensate demineralizers' influent and effluent will be monitored. Sodium, specific conductivity, cation conductivity, sulfates, and chlorides will be measured on the demineralizer effluent.

Hydrazine monitors are used to measure the hydrazine content in the main feed lines.

The main feed lines will be analyzed for pH, and samples taken from the steam generator blowdown lines are monitored for pH, conductivity, and radiation. Continuous pH measurements will ensure that the specified alkaline conditions exist in the system. This will ensure an alkaline environment which

minimizes corrosion. Conductivity measurements on the steam generator blowdown will verify that dissolved solids are not concentrating in the steam generators. A steam generator sample is measured for radioactivity in order to detect primary to secondary leakage.

10.4.6.2.4 Chemical Addition

The function of the chemical addition subsystem is to establish and maintain the proper chemistry within the condensate, feedwater, and steam generator secondary side water. During normal operation, volatile chemicals are added to the feed train downstream of the condensate demineralizers. These additives serve to control the pH, establish a reducing environment, and to scavenge any dissolved oxygen. In addition, the chemical addition subsystem is also used to provide the proper chemical environment during wet layup.

Since these additives are volatile, they will not concentrate in the steam generators. This characteristic is desirable for several reasons. First, the concentration of solids in the steam generators will be minimized. This will lessen the dangers associated with solids attack of Inconel 690. In addition, the volatile nature of these additives will allow for some corrosion protection throughout the steam system. This is especially important in protecting the large metal surface areas of the feedwater heater shells.

A pH controlling additive, usually ammonia, is used to raise the feedwater pH to within normal limits. This pH range is effective in slowing the corrosion rate of carbon steel.

Continuous ammonia additions are required during operations because the volatile ammonia will be scrubbed from the condensing steam in the air removal section of the main condenser or be removed by the condensate demineralizers if it redissolves in the condensate.

An inventory of a reducing agent/oxygen scavenger, usually hydrazine, is maintained in the feed train as a means of scavenging dissolved oxygen and to ensure a reducing environment is maintained in the steam generators. Hydrazine also contributes to the formation of an adherent metal oxide film on system surfaces that reduces corrosion product release. Ammonia is a by-product of Hydrazine once it volatilizes.

Boric acid, a non-volatile chemical, may be injected into the secondary system for mitigating denting and Intergranular Attack/Stress Corrosion Cracking (IGA/SCC) in the steam generator. Boric acid reduces pH in the steam generator crevices by reacting with sodium hydroxide (NaOH) to form a borate complex. Also, boric acid dilutes the hydroxide (OH^-) concentration, thereby lowering the chemical activity and reducing the probability that OH^- is present at the actively corroding grain boundary of the steam generator crevices. The small affect that boric acid has on lowering the secondary plant pH can be offset by increasing the pH controlling chemical additive.

Chemical additions necessary for wet layup will be accomplished through the use of the auxiliary feedwater system. The chemical additions will be made at the suction of the non-Seismic Category I auxiliary feed pump. This will ensure that each steam generator receives adequate protection during long outages.

Chemical additions are typically made by metering pumps. The ammonia addition subsystem consists of three positive displacement pumps which inject into the steam generator main feedwater, demineralized condensate, blowdown condensate, or auxiliary feedwater. All three can be aligned to take ammonia from two ammonia tanks.

The hydrazine addition subsystem consists of three positive displacement pumps. Any of the three pumps can be aligned to pump from two hydrazine tanks to any of the hydrazine injection points. The hydrazine pumps inject into the steam generator main feedwater, extraction steam lines to high-pressure feedwater heaters, demineralized condensate, blowdown condensate, or auxiliary feedwater. Hydrazine can be transferred into the ammonia tanks for injection via the ammonia addition system.

10.4.6.2.5 System Operation During Plant Startup

While the secondary plant is in a cold shutdown condition, it is possible for air to enter the system. Use of nitrogen blankets and a reducing agent/oxygen scavenger, such as hydrazine will minimize, but not eliminate, the corrosion of

metal surfaces. This corrosion results in loose oxide layers being formed on the surfaces of the feed train. Before returning to power, it is necessary to reduce the concentration of the reducing agent/oxygen scavenger in the secondary system, remove the corrosion products generated during layup, and reduce the dissolved oxygen concentration to within the normal operating specifications.

Reduction in the reducing agent/oxygen scavenger concentration is accomplished by draining the steam generators and refilling them with auxiliary feedwater containing the correct hydrazine concentration. In addition, the draining of the steam generators serves to remove any suspended solids which might be present in the generators.

Once the steam generators have been refilled with water, the primary plant temperature will be raised and the steam generators warmed up.

Next, feed train recirculation is started by initiating flow through the presteam generator cleanup line.

The concentration of suspended solids is reduced by draining a portion of the circulating flow prior to entering the hotwell or by circulating through the condensate demineralizers. Make-up at a rate of approximately 500 gallons per minute is supplied from the condensate storage tank.

Oxygen will be removed from the recirculating feedwater by using the vacuum that has been established in the main condenser. Since the feedwater has been heated to 175F, a

condenser vacuum to 6 inches of Hg (abs) is sufficient to remove dissolved oxygen from the feedwater.

Once main feed has been initiated, the reactor power can be increased.

10.4.6.3 Safety Evaluation

The secondary chemistry control system serves no safety-related functions. Therefore, no safety evaluation is performed. Each of the steam generator blowdown lines is equipped with two remotely operated containment isolation valves that automatically close on a main steam isolation signal (MSIS), auxiliary feedwater actuation signal (AFAS), or safety injection actuation signal (SIAS).

The sample lines from the steam generator blowdown lines are each equipped with two remotely operated containment isolation valves which automatically close on an AFAS, MSIS, or SIAS.

10.4.6.4 Tests and Inspections

Preoperational testing will include a test of the system instrumentation. Automatic control features will be tested to ensure proper operation. Piping, valves, and components will be checked for proper installation. Pumps will be tested for head and capacity. Valves will be operated and checked for function. The system will be operated automatically to ensure that the system will function as designed. Heat exchangers will be checked for proper performance and flow rates adjusted where necessary to establish proper conditions.

During normal plant operations, testing, inspection, and calibration will be conducted on a regular schedule to ensure proper system operation. Data taken during operating periods will be used to evaluate the performance of the secondary chemistry control system.

10.4.6.5 Instrumentation Requirements

Flow and conductivity of the demineralized condensate are continuously recorded.

Local instrumentation is provided for the demineralizer regeneration system including temperature control of the dilute caustic and level control of acid and rinse tanks.

Conductivity of the demineralized condensate is recorded continuously. Local conductivity indication is provided for the resin regenerant solutions and rinses.

Local instrumentation is provided for the chemical addition and monitoring subsystem. The sampling instruments are protected from a high temperature sample by a bypass valve operated by a temperature controller.

10.4.7 CONDENSATE AND FEEDWATER SYSTEM

The condensate and feedwater system provides heated feedwater to the steam generators. The system has the capability of maintaining the proper feedwater inventory in the steam generator during startup and normal operation.

10.4.7.1 Design Bases

10.4.7.1.1 Safety Design Bases

Pertinent safety design bases are as follows:

A. Safety Design Basis One

   The feedwater lines are designed so that failure in this piping will have minimal effects on the reactor coolant pressure boundary (RCPB).

B. Safety Design Basis Two

   The feedwater lines are designed so that the failure of any feedwater supply piping will not prevent safe shutdown of the reactor.

C. Safety Design Basis Three

   The containment feedwater isolation valves and piping from the valves to the steam generator nozzles are designed to withstand the effects of a safe shutdown earthquake (SSE).

D. Safety Design Basis Four

   Components and piping shall be designed, protected from, or located to protect against the effects of high and moderate energy pipe rupture, whip, and jet impingement.

E. Safety Design Basis Five

   This system will be designed such that adverse environmental conditions such as tornados, floods, and earthquakes will not impair its safety function.

F. Safety Design Basis Six

The loss of offsite power to the system will not prevent the safe shutdown of the reactor.

10.4.7.1.2 Power Generation Design Bases

Power generation design bases applicable to this system are as follows:

A. Power Generation Design Basis One

The condensate and feedwater system is designed to provide feedwater to the steam generator at the required temperature and pressure during all phases of operation.

B. Power Generation Design Basis Two

Extraction lines and feedwater heaters are designed to minimize the possibility of water slug induction to the main turbine and to limit main turbine overspeed due to entrained energy in the extraction system.

10.4.7.1.3 Codes and Standards

Components of the condensate and feedwater systems are designed and constructed in accordance with the applicable codes and standards identified in table 3.2-1.

10.4.7.2 System Description

The condensate and feedwater system is shown schematically on engineering drawings 01, 02, 03-M-CDP-001, -002, -003, -004 and 01, 02, 03-M-FWP-001. The condensate and feedwater system

supplies the steam generators with heated feedwater in a closed steam cycle using regenerative feedwater heating. The main turbine cycle heat balance at guaranteed load is given in section 10.1. Extraction steam is covered in subsection 10.2.2.

The main condenser hotwells receive condensate makeup from the condensate tank. Refer to subsection 9.2.6 for a discussion of the condensate storage system.

The main portion of the feedwater flow is deaerated condensate pumped from the main condenser hotwells by the condensate pumps.

This stream passes in sequence through the condensate cleanup system; the three trains of low-pressure heaters, each train consisting of No. 1, No. 2, No. 3, and No. 4 low-pressure heaters; the steam generator feedwater pumps; the two trains of high-pressure heaters, each train consisting of No. 5, No. 6, and No. 7 high-pressure heaters; control and isolation valves; and on into the two steam generators of the NSSS. The balance of the feedwater flow is provided by the drains from the moisture separator reheaters and No. 7, No. 6, and No. 5 heaters that are collected into a drain tank and pumped into the feedwater pump suction stream by the heater drain pumps.

To allow feedwater and condensate system startup recirculation, a cleanup system called "long path recirculation" is provided. This system allows condensate from the hotwell to be pumped by a condensate pump through all major feedwater/condensate piping and components up to the economizer crosstie line. From this

point the recirculation flow is returned to the hotwell. The system is sized to allow a flow velocity of up to 2 ft/sec in the largest portion of the main flow path, thereby ensuring shearing and entrainment of pipe scale and other system impurities. A drain connection is provided upstream of the return nozzle to the hotwell.

Transients within the condensate and feedwater system that affect the final feedwater temperature or flow have a direct effect on the RCS. Occurrences that produce an increase in feedwater flow or a decrease in feedwater temperature result in excessive heat removal from the RCS, which is compensated for by control system action as described in section 7.7. These occurrences are considered in section 15.1 in conjunction with the failure of compensatory control actions, and are shown to be safely terminated by the reactor protective system. Events that produce the opposite effect; i.e., decreased feedwater flow or increased feedwater temperature, result in reduced heat transfer in the steam generators. Normally, automatic control system action is available to adjust feedwater flow and reactor power to prevent excess energy accumulation in the RCS, and the increasing reactor coolant temperature provides a negative reactivity feedback that tends to reduce reactor power. In the absence of control action, the high outlet temperature and high-pressure trips of the reactor protective system are available to assure reactor safety. Loss of all feedwater, the most severe transient of this type, is examined in section 15.2.

Nitrogen accumulators are provided on the feedwater control and isolation valves in the feedwater line to the steam generator downcomer nozzle. These accumulators allow the operator to remotely operate these valves without normal instrument air. In conjunction with the non-Seismic Category I auxiliary feedwater pump described in subsection 10.4.9, this provides a third flow path for auxiliary feedwater to the steam generators. This use of the non-essential AFS train is provided to improve the overall availability of the AFS system and is not required for Chapters 6 and 15 accident mitigation.

10.4.7.2.1 Component Description

Refer to table 10.4-5 for design data.

10.4.7.2.1.1 Condensate Pumps. The condensate pumps are motor-driven, of the vertical mixed-flow type, and operate in parallel. Valving is provided to allow removal of individual pumps and maintain system functionality.

10.4.7.2.1.2 Condensate Cleanup System. Refer to subsection 10.4.6 for a discussion of the condensate cleanup system.

Table 10.4-5
MAIN FEEDWATER/CONDENSATE SYSTEM REQUIREMENTS
FOR MAJOR COMPONENTS DESIGN DATA

Equipment	Number	Capacity
Condensate pumps	3	50%[b]
No. 1 to No. 4 feedwater heaters	4/train 3 trains	33%/train
Steam generator feedwater pumps	2	65%
No. 5, No. 6, and No. 7 HP feedwater heaters	3/train 2 trains	50%/train [a]
Heater drain tank	1/train 2 trains	50%/train
Heater drain pumps	1/train 2 trains	50%/train

a. Approximately 40%/train and 20% bypass in feedwater temperature reduction mode of full power operation.

b. Capacity listed is a nominal initial sizing value. Three Condensate pumps may be required to support plant operation at 100% power as described in site procedures.

10.4.7.2.1.3 Low-Pressure Feedwater Heaters. The low-pressure heaters are of the closed type and are installed in the main condenser necks. Low-pressure feedwater heaters have integral drain coolers. The No. 4 drains to No. 3 heater, No. 3 drains to No. 2, and No. 2 drains to No. 1 and from there to the main condenser. The condensate, after passing from the main condenser through the low-pressure heaters (three trains), is routed to a header and fed to the steam generator feedwater pumps.

Low-pressure feedwater heaters have main condenser drain lines to allow direct discharge to the main condenser.

10.4.7.2.1.4 Feedwater Pumps. The feedwater pumps operate in parallel and discharge to the high-pressure feedwater

heaters. The pumps take suction from the No. 4 low-pressure feedwater heaters of the three parallel low-pressure heater trains and discharge through the two parallel trains of high-pressure feedwater heaters. Each pump is turbine-driven with independent variable speed control units. Steam for the turbines is supplied from the main steam header at low loads, and from the hot reheat line during normal operation.

Isolation valves are provided to allow each steam generator feedwater pump to be individually removed from service, while continuing operations at reduced capacity with the parallel pump.

10.4.7.2.1.5 High-Pressure Feedwater Heaters. The feedwater system contains two parallel trains of high-pressure feedwater heaters. High-pressure feedwater heaters Nos. 6 and 7 are provided with integral drain coolers. High-pressure heater No. 7 drains to high-pressure heater No. 6. High-pressure heaters Nos. 6 and 5 drain to the high-pressure heater train drain tank.

Isolation valves and bypasses are provided to allow each train of high-pressure heaters to be removed from service. System functionality is maintained with the remaining train. The bypass line may also be used in conjunction with flow through both heater trains when operating the plant in the feedwater temperature reduction mode of full power operation.

Provisions are made in heater drain lines to allow direct discharge to the main condenser.

10.4.7.2.1.6 Heater Drain Tank. A single heater drain tank for each high-pressure heater train receives the drains from the shells of high-pressure feedwater heater Nos. 5 and 6 and moisture separator reheater drain tank and provides reservoir capacity for drain pumping into the feed pump suction header. Each high-pressure heater train drain tank is installed beneath the No. 5 feedwater heater so that high-pressure heaters drain freely. The drain level is maintained within the train drain tank by a level controller in conjunction with the heater drain pump discharge flow control valve.

The high-pressure heater train drain tank is provided with an alternate drain line to the main condenser for automatic dumping upon high level. The alternate drain line also is used during startup and shutdown when it is desirable to bypass the drain pumping for feedwater quality purposes.

10.4.7.2.1.7 Heater Drain Pumps. The high-pressure heater drain pumps operate in parallel, each taking suction from its high-pressure heater train drain tank and discharging to the suction header of the feedwater pumps. Each high-pressure heater drain tank pump is a motor-driven, multistage, centrifugal pump located below the heater drain tank and is designed for the available suction conditions.

10.4.7.2.1.8 Pump Recirculation Systems. Minimum flow control systems are provided to allow all pumps in the main condensate and feedwater trains to operate at a sufficient rate to prevent damage.

10.4.7.2.1.9 Containment Feedwater Line Isolation Valves. The containment feedwater isolation valves discussed in subsection 6.2.4 are designed to isolate the feedwater system from the steam generator in the event of a steam line break, feedwater line break, or loss-of-coolant accident (LOCA). This isolation precludes any possibility of radioactivity release from the containment due to a condensate or feedwater pipe break. The isolation valves in the feedwater line to the steam generator downcomer nozzle are provided with nitrogen accumulator to allow manual remote control with a loss of offsite power to supply auxiliary feedwater to the steam generators from the non-Seismic Category I auxiliary feedwater pump described in subsection 10.4.9. Note that the backup nitrogen accumulator for the feedwater control and isolation valves was not credited during a normal loss of offsite power event.

10.4.7.2.2 System Operation

10.4.7.2.2.1 Prestartup Feedwater Cleanup Procedure. The condensate pumps circulate condensate from the condenser hot-wells, through the condensate cleanup system, through all feedwater heater trains through the recirculation valve, and back to the hotwell. This procedure is repeated until the condensate cleanup system has yielded feedwater quality equivalent to that specified in section 10.3.5.

10.4.7.2.2.2 Power Generation Operation. Feedwater is supplied to the steam generator from the steam generator

feedwater pumps. Feedwater flow is controlled through the main feedwater control valves that establish steam generator feedwater balancing in conjunction with the variable speed feedwater pump turbine drives. The feedwater system may be operated either with the high pressure feedwater bypass valve open or closed in conjunction with both feedwater heater trains being in service. When the plant is operated at the licensed reactor power with the bypass valve closed, additional plant thermal efficiencies are achieved. When the plant is operated at the licensed reactor power with the bypass valve open in the feedwater temperature reduction mode, both plant thermal efficiencies and steam generator thermal stresses are reduced. Extended operation in either configuration is within the system and plant design and licensing basis.

10.4.7.3 Safety Evaluation

Safety evaluations, numbered to correspond to the safety design bases, are as follows:

A. Safety Evaluation One

The main feedwater lines are restrained or are separated to the extent necessary to prevent damage to the RCPB in the event of a feedwater pipe rupture. Refer to section 3.6 for additional discussion on this subject.

B. Safety Evaluation Two

Main feedwater lines are designed and routed so that a failure will not prevent a safe shutdown of the

reactor. Refer to section 3.6 for information on this subject.

C. Safety Evaluation Three

The containment feedwater isolation valves and piping between them and the steam generators are designed to meet Seismic Category I criteria in accordance with requirements given in sections 3.7 and 3.9.

D. Safety Evaluation Four

Components and piping are designed to protect against the effects of high and moderate energy pipe rupture as discussed in section 3.6.

E. Safety Evaluation Five

Adverse environmental conditions do not impair the safety function of this system. Wind and tornado loadings are discussed in section 3.3. Flood design is covered in section 3.4. Seismic design is discussed in section 3.7.

F. Safety Evaluation Six

The loss of offsite power does not prevent the safe shutdown of the reactor as discussed in sections 7.4 and 8.3.

10.4.7.4 Tests and Inspections

ASME Code, Section III, Class 2, piping is inspected and tested in accordance with ASME Code, Sections III and XI and the ASME OM Code. ANSI B31.1.0 piping is inspected and tested in

accordance with Paragraphs 136 and 137. ASME Code, Section III, Class 2, valves are periodically inservice-tested for exercising and leakage in accordance with ASME OM Code. Isolation valves, vent and drain valves, and test connections required in the system to effect these tests are included in engineering drawings 01, 02, 03-M-CDP-001, -002, -003, -004 and 01, 02, 03-M-FWP-001.

Each feedwater heater, heater drain tank, pump, and valve is shop-tested by hydrostatic pressure tests performed in accordance with applicable codes. Tube joints of feedwater heaters are shop leak-tested. Prior to initial operation, the completed condensate and feedwater system receives a field hydrostatic test and inspection in accordance with the applicable code. Periodic tests and inspections of the system are performed in conjunction with scheduled maintenance outages. In addition, PVNGS agrees to perform a steam generated feedwater water hammer test in accordance with NUREG/CR-1606. PVNGS will perform the test according to a standard operating procedure (SOP). PVNGS will run the plant at approximately 15% of full power by using feedwater through the downcomer nozzle. The feedwater will then be switched from the downcomer nozzle to the economizer nozzle and the following transient will be observed and recorded. Inservice inspections are not required unless there is an indication of malfunction somewhere in the system.

10.4.7.5 Instrumentation Applications

Feedwater flow control instrumentation measures the feedwater flowrate from the condensate and feedwater system. This flow measurement, transmitted to the feedwater control system, regulates the feedwater flow to the steam generators to meet system demands. Refer to section 7.7 for a description of the feedwater control system.

Instrumentation and controls are provided for regulating minimum pump flowrates for the condensate pumps, high-pressure heater drain pumps, and steam generator feedwater pumps.

Sampling means are provided for monitoring the quality of the final feedwater, as described in subsection 10.4.6.

In the feedwater heating portion of the system, temperature measurements are provided for each stage of heating. These measurements include the temperature into and out of each feedwater heater for the water side and out of each heater for the steam side of the system except that steam temperature is determined by its saturation pressure in feedwater heater Nos. 1, 2, 3, and 4. Steam pressure measurements are provided at each feedwater heater. Liquid pressure measurements are provided at appropriate locations throughout the system.

Instrumentation and controls are provided to maintain the proper condensate level in the feedwater heater or heater drain tank. High level alarm and automatic dump action on high level also are provided.

Appropriate instrumentation displays and alarms are provided in the control room.

10.4.8 STEAM GENERATOR BLOWDOWN SYSTEM

The steam generator blowdown system is an integral part of the secondary chemistry control system of the condensate cleanup system, and is discussed in subsection 10.4.6.

10.4.8.1 CESSAR Interface Requirements

Refer to subsection 5.1.4.

10.4.8.2 CESSAR Interface Evaluations

Refer to subsection 5.1.5.

10.4.9 AUXILIARY FEEDWATER SYSTEM

The auxiliary feedwater system (AFS) is designed to provide steam generator feedwater during startup, hot standby, normal shutdown, and emergency conditions.

The AFS reliability analysis (formally appendix 10B) has been archived as historical information only in PVNGS engineering calculation 13-NC-AF-200, "Auxiliary Feedwater System (AFS) Reliability Analysis." Refer to appendix 5A, Question 5A.17, for additional discussion.

10.4.9.1 Design Bases

10.4.9.1.1 Safety Design Bases

The following safety design bases are applicable to the essential portions of the AFS only:

A. Safety Design Basis One

The AFS shall provide feedwater for the removal of decay heat from the RCS following reactor shutdown from any power level until such time as cooling by the shutdown cooling system may be initiated.

B. Safety Design Basis Two

One motor-driven AFS pump and one steam turbine-driven AFS pump and associated valves and piping shall be designed to Seismic Category I requirements. In addition, the isolation valves and piping connections to this Seismic Category I piping shall be designed to Seismic Category I requirements.

C. Safety Design Basis Three

The turbine-driven Seismic Category I AFS pump shall be available in the event of a loss of all ac power.

D. Safety Design Basis Four

The Seismic Category I motor-driven AFS pump and its associated power-operated valves shall be connected to one onsite (diesel generator) power bus as discussed in subsection 8.3.1. In addition, the turbine-driven AFS pump's turbine control system and its associated

power-driven valves are connected to the dc power system as discussed in subsection 8.3.2.

E. Safety Design Basis Five

Redundancy shall be provided throughout the AFS and supporting systems to ensure the supply of feedwater to either or both steam generators in the event of an accident plus one active failure.

F. Safety Design Basis Six

The AFS shall be designed to maintain water level in the steam generators under the following operating modes and accident conditions:

1. Reactor coolant system cooldown at a maximum rate of 75F per hour from hot standby to a temperature of 350F with a loss of offsite power and normal onsite power.
2. Hot standby for 8 hours with a loss of offsite power and normal onsite power.
3. Reactor coolant system cooldown using the intact steam generator following a main steam line break or main feedwater line break inside the containment with a loss of offsite power and normal onsite power.

G. Safety Design Basis Seven

Each of the two Seismic Category I AFS pumps shall be designed to provide 100% of the required flow (see Table 10.4-6) for decay heat removal. The head

generated by each pump is sufficient to deliver feedwater into the steam generators at 1270 psia or equivalent at the entrance of the steam generators.

H. Safety Design Basis Eight

In the unlikely event that the control room must be evacuated, the AFS shall be capable of being operated for shutdown from a remote shutdown station.

I. Safety Design Basis Nine

The Seismic Category I, motor-driven AFS pump shall be located in a separate room designed to Seismic Category I requirements in the main steam support structure. The Seismic Category I, steam turbine-driven AFS pump shall also be located in a separate room designed to Seismic Category I requirements in the main steam support structure.

J. Safety Design Basis Ten

The components, including piping for each AFS pump safety train, shall be separated from each other and are either enclosed by a Seismic Category I structure or installed underground.

K. Safety Design Basis Eleven

The combination of motor-driven and steam turbine-driven pumps shall provide diversity of power sources to assure delivery of feedwater under an emergency condition.

L. Safety Design Basis Twelve

All components and piping shall be designed, protected from, or located to protect against the effects of high and moderate energy pipe rupture, pipe whip, and jet impingement.

M. Safety Design Basis Thirteen

This system shall be designed such that adverse environmental conditions such as tornados, floods, and earthquakes will not impair its safety function.

10.4.9.1.2 Power Generation Design Basis

The non-Seismic Category I, motor-driven AFS pump is used as the feedwater pump during startup, hot standby, and normal shutdown conditions.

10.4.9.1.3 CESSAR Interface Requirements

Refer to subsection 5.1.4.

10.4.9.1.4 CESSAR Interface Evaluation

Refer to subsection 5.1.5.

10.4.9.1.5 Codes and Standards

The AFS is designed to codes and standards identified in table 3.2-1.

10.4.9.1.6 Reliability/Availability Bases

The bases contained within this section represent the major design features of the non-essential AFS train which were added to improve the original AFS design from a reliability/availability perspective or are major assumptions which have been credited in performing risk related analyses for PVNGS. These bases reflect the most relevant features of the non-essential AFS train design from a reliability/availability perspective and are not intended to be all encompassing. The PVNGS Individual Plant Examination (IPE) provides a complete description of the reliability/availability assessments that were completed for the AFS. The following bases are only applicable to the non-essential AFS trains:

A. Reliability/Availability Bases One

The non-essential AFS train is not required to perform a safety function for the mitigation of the design basis accidents presented in Chapters 6 and 15. The emergency operating procedures provide instructions for using the non-essential AFS train, if available, in addition to the essential AFS trains as a defense-in-depth measure that assists in mitigating plant events. The non-essential AFS train is not required to mitigate accidents, but provides additional reliability/availability to the AFS. Risk related analyses shall consider operator actions (including human errors) in assessing the reliability or availability of the AFS.

B. Reliability/Availability Bases Two

The following bases have been credited in the risk assessments performed on the non-essential portion of the AFS as part of the IPE:

1. The non-Seismic Category I AFS pump minimum flow recirculation path back to the condensate storage tank does not need to be isolated to meet the IPE performance as described in Table 10.4-6, note c. In addition, the IPE does not require the flow path to remain open in situations where the minimum flow requirements for the pump are met with the minimum flow path isolated.

2. Periodic full-flow testing of the non-Seismic Category I AFS pump is not required.

3. The downcomer feedwater isolation valves are designed to fail open on a loss of power.

4. The backup nitrogen accumulator for the downcomer feedwater control and isolation valves was not credited during a normal loss of offsite power event.

5. The AFS flow to the steam generators is controlled in accordance with the standard post trip actions as defined in the emergency operating procedures (see Table 10.4-6, note c, for IPE credited performance for the AFS pumps).

C. Reliability/Availability Bases Three

The AFS overall reliability is enhanced by including the non-essential AFS pump in each unit's Technical Specifications.

D. Reliability/Availability Bases Four

The non-Seismic Category I motor driven AFS pump and associated power-operated valves shall have the capability to be powered by the Train A diesel generator when connected by manual action to the load group 1 bus as described in Section 8.3.1. The non-Seismic Category I motor driven AFS pump may be controlled from the main control room.

E. Reliability/Availability Bases Five

The non-Seismic Category I motor driven AFS pump is located within the Turbine Building. This structure and the non-essential AFS train components contained within this structure are not designed to withstand adverse environmental conditions resulting from earthquakes, tornadoes, floods or hazards for which the essential AFS trains are required to be designed to withstand.

Should a seismic even occur when the nonseismic auxiliary feedwater pump is in service, the operator can take the necessary action to locally close one of the suction line valves should the line fail. This action will be taken with sufficient time to prevent a significant loss of water from the condensate storage tank.

F. Reliability/Availability Bases Six

The design and performance requirements for the non-Seismic Category I motor driven AFS pump are provided in Table 10.4-6.

10.4.9.2 System Description

10.4.9.2.1 General Description

The AFS consists of one Seismic Category I, motor-driven AFS pump; one Seismic Category I, steam turbine-driven AFS pump; and one non-Seismic Category I, motor-driven AFS pump, associated piping, controls, and instrumentation. Engineering drawings 01, 02, 03-M-AFP-001 show the piping and instrumentation diagram of the system.

The primary source of auxiliary feedwater is the condensate storage tank. The condensate storage tank provides a reserve capacity (see Table 9.2-21) for the AFS during emergency shutdown conditions. This provides an orderly RCS cooldown to shutdown cooling initiation conditions as addressed in safety design basis six of paragraph 10.4.9.1.1 and provides sufficient feedwater to maintain the plant as hot standby for 8 hours.

Both motor-driven auxiliary feedwater pumps and their motor-operated valves can receive power from both onsite and offsite power sources. In the event of a loss of offsite power, power is supplied to these motor-driven pumps by their standby diesel generators. The Seismic Category I, motor-driven pump and its motor-operated valves are connected to the train B power source by automatic initiation or by operator action. The non-Seismic

Category I pump and its valves can be connected to the train A power source by operator action only. The two Seismic Category I auxiliary feedwater pumps are separated by a physical barrier. Piping and components for the Seismic Category I pumps are located, separated, or protected to preclude damage from any missile effects.

The turbine-driven AFS pump is supplied with steam from the main steam lines of either steam generator upstream of the main steam isolation valves. The turbine controls and associated valves are powered from the dc bus.

10.4.9.2.2 Component Description

Principal components are listed in table 10.4-6.

10.4.9.2.3 System Operation

For emergency operation, normal flow is from the condensate tank to either the Seismic Category I, motor-driven AFS pump or to the steam turbine-driven, Seismic Category I AFS pump which are located in the main steam support structure. An alternate supply of water is provided by cross-connections to the reactor makeup tank.

A minimum flow recirculation system is provided on each pump discharge with recirculation to the condensate tank and supports pump testing. Each pump can supply either steam generator with feedwater.

One auxiliary feedwater path to the steam generators is provided for the non-Seismic Category I, motor-driven auxiliary

feedwater pump through the feedwater header, with manual operation of feedwater valves possible during emergency operation. This feature of the non-essential AFS train is provided to improve the overall availability of the AFS system and is not required for Chapters 6 and 15 accident mitigation.

The two Seismic Category I auxiliary feedwater pumps only provide flow to the downcomer feedwater nozzles on each steam generator. Either Seismic Category I auxiliary feedwater pump

Table 10.4-6
AUXILIARY FEEDWATER SYSTEM DESIGN DATA

Design Factor	Value	Notes
Auxiliary feedwater pumps		
Quantity		
Motor-driven, non-Seismic Category I	1	
Motor-driven, Seismic Category I	1	
Steam turbine-driven, Seismic Category I	1	
Flow, Seismic Category I, gal/min, net	750	a, b
Miniflow, Seismic Category I, gal/min, maximum	260	b
Flow, non-Seismic Category I, gal/min, net	710	a, c
Miniflow, non-Seismic Category I, gal/min, maximum	300	c
Head, ft - Seismic Category I at 750 gal/min plus 260 gal/min miniflow	3,280	b
Head, ft - non-Seismic Category I at 710 gal/min plus 300 gal/min miniflow	2,960	c

a. Net flow delivered to steam generators.

b. The values shown are for the design performance specifications of the auxiliary feedwater pumps. The safety analysis credits delivery of 650 gpm at a steam generator pressure of 1270 psia or equivalent at the steam generator entrance for design basis accidents.

c. The values shown in this Table are based on the design performance specifications for the non-Seismic Category I AFS pump. The power generation design bases for this pump assumes a minimum performance of 650 gpm delivered to the steam generator(s) at a design no load pressure of 1170 psia. The IPE credits a AFS flow of approximately 500 gpm to the steam generator(s) when steam generator conditions are maintained in accordance with the standard post trip actions as defined in the emergency operating procedures.

can supply the necessary feedwater for reactor decay heat removal and reactor cooldown to 350F.

At a reactor coolant temperature of 350F, the shutdown cooling system is placed in operation.

A minimum flow path is provided for each pump. Approximately 26% of the Seismic Category I pump capacity and 30% of the non-Seismic Category I pump capacity is recirculated back to the condensate tank whenever a pump is operating. The minimum flow line is provided to prevent pump overheating in the event the pump discharge line is isolated.

The Seismic Category I pump motor driver is powered from a separate engineered safety features (ESF) bus which is powered by the load group 2 diesel generator. The Seismic Category I, steam turbine-driven pump's associated valving is powered from the dc bus as discussed in subsection 8.3.2. The turbine for this pump is supplied with steam from either of the steam generators. The turbine controls are powered from the dc bus.

Auxiliary feedwater control for the essential trains is normally from the control room, but instrumentation is provided for operation from the remote shutdown panel in the unlikely event that the control room must be evacuated.

Signals from the auxiliary feedwater actuation signal (AFAS) start the Seismic Category I, motor-driven auxiliary feedwater pump and the Seismic Category I, steam turbine-driven auxiliary feedwater pump, shut all steam generators' blowdown and blowdown sample isolation valves, and open the associated isolation valves to the downcomer nozzles of the intact steam

generator(s). The non-Seismic Category I, motor-driven pump is started manually and its associated valves are opened manually from the control room.

Assuming a pipe break in either steam generator lower feedwater supply line in the containment, a single electrical failure will not prevent the system from accomplishing its function. Either Seismic Category I pump can supply the flow required for safe shutdown. Table 10.4-7 lists the Seismic Category I valves in the AFS.

10.4.9.3 Safety Evaluation

Safety evaluations, numbered to correspond to the safety design bases, are as follows:

A. Safety Evaluation One

The AFS, in conjunction with the condensate tank described in subsection 9.2.6, provides a means of pumping feedwater to maintain the plant at hot standby for 8 hours, with a subsequent cooldown at a maximum rate of 75F per hour to a reactor coolant temperature of 350F.

B. Safety Evaluation Two

The two Seismic Category I AFS pumps and their associated valves and piping are designed to Seismic Category I requirements. The isolation valves and piping connections to the Seismic Category I piping are also designed to Seismic Category I requirements.

C. Safety Evaluation Three

During normal operation, the two Seismic Category I AFS pumps are each available in the event of loss of off-site power and normal onsite power.

D. Safety Evaluation Four

The Seismic Category I, motor-driven AFS pump and its associated line valves are connected to the load group 2 onsite power bus as discussed in subsection 8.3.1. The turbine-driven AFS pump control system and the associated line valves are connected to the dc power system as discussed in subsection 8.3.2.

E. Safety Evaluation Five

Redundancy is provided throughout the AFS and associated systems to ensure the supply of feedwater to either or both steam generators in the event of an accident plus one active failure. Table 10.4-8 presents a single failure analysis for the AFS.

F. Safety Evaluation Six

The AFS is designed to maintain an adequate water level in the steam generators under the following operating modes and accident conditions:

1. Reactor cooldown at a maximum administratively controlled rate of 75F per hour from hot standby to 350F with a loss of offsite power and normal onsite power.

a. Seismic Category I valves listed below are omitted from the list:

- Instrument isolation valves
- Vent valves
- Drain valves
- AFW PP turbine cooling subsystem valves
- AFW PP bearing cooling and gland seal injection subsystem valves
- Makeup (primary, alternate and suction) Isolation Valves. Effective for Units where DMWO 4345882 has been implemented.

b. A = active; N = nonactive; Note that "A" and "N" are related to the component's movement during performance of its safety function and not to the application of single failure criteria.

c. Valves in AFW system shown in condensate transfer and storage system (CT)

d. Valves in AFW system shown in main steam system (SG)

e. Valves isolate downcomer feedwater (an AFW flow path) from recirculation lines.

f. Valve size in Unit 2 is 1½ inches

Table 10.4-8

SINGLE FAILURE MODE ANALYSIS--AUXILIARY FEEDWATER SYSTEM (Sheet 1 of 3)

Component	Failure Mode/Cause	Effects on System	Method of Detection	Inherent Compensating Provision	Remarks
Isolation valve to reactor makeup water tank	Fails closed/ mechanical failure or inadvertent misposition	Loss of secondary source of water for the auxiliary feedwater pumps	Valve stem position	Redundant lines from condensate tank	
	Fails open/ mechanical failure or inadvertent misposition	None	Valve stem position		Valve is normally closed.
Check valves from reactor makeup water tank	Fails closed/corrosion	None	None	Redundant lines available to condensate tank	Only used in case condensate tank not available.
	Fails open/ contamination	None	None		
Isolation valves to condensate tank	Fails closed/ mechanical binding	None	Handle position	Redundant line available from condensate tank	Valve is normally locked open.
	Fails open/locking mechanism jams	None	Handle position	None	Valve is locked open.
Check valves from condensate tank	Fails closed/corrosion	None	None	Redundant line available from condensate tank	
	Fails open/ contamination	None	None		
Auxiliary feedwater pump (Seismic Category I)	Fails to pump/ mechanical electrical failure	No effect on system performance	Low pressure indication from pump	Redundant 100% capacity Seismic Category I auxiliary feedwater pump available. A 100% capacity non-Seismic Category I pump is also available	

Table 10.4-8

SINGLE FAILURE MODE ANALYSIS--AUXILIARY FEEDWATER SYSTEM (Sheet 2 of 3)

Component	Failure Mode/Cause	Effects on System	Method of Detection	Inherent Compensating Provision	Remarks
Pump discharge check valves	Fails closed/ corrosion	Loss of one auxiliary feedwater pump	High-pressure indication from pump	Redundant 100% capacity auxiliary feedwater pump available.	
	Fails open/ contamination	No effect other than causing trouble if maintenance of valve is required while system is operating.	None		
Discharge valves, auxiliary feedwater pumps	Fails open/ mechanical or electrical failure	None	Handle position		Valve is normally locked open
	Fails closed/ mechanical binding	Effective loss of one auxiliary feedwater pump	Handle position	Redundant 100% capacity auxiliary feedwater pump	Valve is normally locked open
Isolation valves to feedwater header	Fails open/ mechanical or electrical failure	Loss of double isolation between the main feedwater supply and auxiliary feedwater supply to one steam generator	Valve position indicator in control room	Redundant valves	
	Fails closed/ mechanical or electrical failure	Slight decrease in flexibility of feedwater system	Valve position indicator in control room	None required	
Check valves to feedwater header	Fails open/ contamination	No serious effect	Periodic test	None required	
	Fails closed/ corrosion	Slight decrease in flexibility of feedwater system	Periodic test	None requried	
Overpressure Relief Valves for Outboard AF Containment Isolation Valves	Fails open/ mechanical failure	Slight decrease in amount of water delivered to Steam Generator(s)	Periodic test	Both auxiliary feedwater pumps remain available such that their total combined Technical Specification required flow is met.	
	Fails closed/ mechanical failure or corrosion	Effective loss of one auxiliary feedwater pump	Periodic test	Redundant 100% capacity auxiliary feedwater pump	
FW recirculation isolation valve[(a)]	Fails open/inadvertent position	None	Handle position	Redundant valve	Valves are locked closed and administratively controlled

a. Valves isolate downcomer feedwater (an AFW flow path) from recirculation lines.

Table 10.4-8

SINGLE FAILURE MODE ANALYSIS--AUXILIARY FEEDWATER SYSTEM (Sheet 3 of 3)

Component	Failure Mode/Cause	Effects on System	Method of Detection	Inherent Compensating Provision	Remarks
SG Primary and Alternate Makeup Valves	Fails closed/ corrosion	No effect on system	Operator	None Required	Redundant isolation valves provided. Inboard valve is locked closed.
(Effective for Units where DMWO 4345882 has been implemented.)	Fails open/operator error	No effect on system	Operator	None Required	
SG Alternate Suction Isolation Valve	Fails closed	No effect on system	Operator	None Required	Multiple failures required to affect B Train Auxiliary Feedwater Pump
(Effective for Units where DMWO 4345882 has been implemented.)	Fails open	Effective loss of one Auxiliary Feedwater Pump	Periodic Test	Valve is locked closed	

2. Hot standby for 8 hours with a loss of offsite power and normal onsite power.

3. Reactor coolant system cooldown using the intact steam generator following a main steam line break or main feedwater line break inside the containment with a loss of offsite power and normal onsite power.

Only the Seismic Category I pumps are started on an AFAS. The Seismic Category I AFS pumps are not routinely used for normal plant operations. The non-Seismic Category I AFS pump is utilized for startup, hot standby and normal shutdown of the plant.

G. Safety Evaluation Seven

Each of the essential AFS pumps is capable of delivering 650 net gallons per minute at 1270 psia or equivalent at the entrance of the steam generator.

H. Safety Evaluation Eight

The AFS can be operated from either the control room or from a remote shutdown station.

I. Safety Evaluation Nine

Each Seismic Category I AFS pump is installed in a separate room designed to Seismic Category I requirements. These rooms are in the main steam support structure.

J. Safety Evaluation Ten

The components and piping for each Seismic Category I AFS pump train are separated from each other in that no credible hazard within either train pump room can affect both trains. Where complete physical separation is not met as a result of design constraints, separation criteria are satisfied because sufficient protection is provided to assure an inherently reliable and safe design configuration which ensures essential AFS train redundancy. The components and piping of both Seismic Category I AFS trains are either enclosed by a Seismic Category I structure or are installed underground.

K. Safety Evaluation Eleven

The combination of the one Seismic Category I, motor-driven pump and the one Seismic Category I, steam turbine-driven pump utilizes a diversity of power sources to assure delivery of feedwater under emergency conditions.

L. Safety Evaluation Twelve

All components and piping are designed to protect against the effects of high and moderate energy pipe ruptures as discussed in section 3.6.

M. Safety Evaluation Thirteen

Adverse environmental conditions will not impair the safety function of this system. Wind and tornado loadings are discussed in section 3.3. Flood design is

covered in section 3.4. Seismic design is discussed in section 3.7.

10.4.9.4 Inspection and Testing Requirements

The system is capable of being tested while the plant is in normal operation. Each of the essential and non-essential AFS pumps is provided with a minimum flow recirculation line back to the condensate storage tank. This line ensures that the minimum flow requirements for each pump are met and allows for periodic testing required by the applicable codes that are identified in Section 3.9.6. This design allows the AFS to be operationally tested up to the steam generator auxiliary feedwater isolation valves. Full flow testing of the essential AFS pumps is performed in accordance with the Technical Specifications. These tests ensure the operability of the essential AFS by taking a supply from the condensate storage tank and injecting auxiliary feedwater into the steam generators. Successful performance of these full flow tests ensure that the essential AFS meets the minimum performance requirements credited in the safety analyses (Table 10.4-6, note b) for Chapter 6 and 15 events. Full flow testing of the non-essential AFS pump is not required to be performed since this pump is not credited in the safety analyses for Chapter 6 and 15 events.

Power Operated Containment isolation valves can be tested by either remote or local operation during normal plant operation.

The system is inspected as required by the applicable codes as identified in table 3.2-1.

Temperature monitoring of both the Seismic Category I and Non-Seismic Category I Auxiliary Feedwater pump is conducted in accordance with the recommendations of Generic Letter 88-03, Steam Binding of Auxiliary Feedwater Pumps.

10.4.9.5 Instrumentation Requirements

Instrumentation and controls are provided as described in paragraph 10.4.9.3. Control room instrumentation includes auxiliary feedwater flow and pump discharge pressure, steam generator level, control hand switches, and position indication for all power-operated valves, and auxiliary feedwater pump, turbine speed control, and indication.

Control logic for the AFS is addressed in section 7.3.

This page intentionally left blank

APPENDIX 10A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

CONTENTS (cont)

APPENDIX 10A

QUESTION 10A.1 (NRC Question 430.37) (10.1)

Provide a general discussion of the criteria and bases of the various steam and condensate instrumentation systems in section 10.1 of the FSAR. The FSAR should differentiate between normal operation instrumentation and required safety instrumentation.

RESPONSE: The response is given in subsection 10.1.3 and amended paragraph 10.4.9.5.

QUESTION 10A.2 (NRC Question 430.38) (10.2)

Expand your discussion of the turbine speed control and over-speed protection system. Provide additional explanation of the turbine and generator electrical load following capability for the turbine speed control system with the aid of system schematics (including turbine control and extraction steam valves to the heaters). Tabulate the individual speed control protection devices (normal emergency and backup), the design speed (or range of speed) at which each device begins operation to perform its protective function (in terms of percent of normal turbine operating speed). In order to evaluate the adequacy of the control and overspeed protection system provide schematics and include identifying numbers to valves and mechanisms (mechanical and electrical) on the schematics. Describe in detail, with references to the identifying numbers, and sequence of events in the turbine trip including response times, and show that the turbine stabilizes. Provide the results of a failure mode and effects analysis for the overspeed protection systems. Show that a single steam

valve failure cannot disable the turbine overspeed trip from functioning. (SRP 10.2, Part III, Items 1, 2, 3, and 4).

RESPONSE: Expanded discussion of turbine speed control and overspeed protection system is given in amended subsection 10.2.2 and table 10.2-3.

QUESTION 10A.3 (NRC Question 430.39) (10.2)

The FSAR discusses the main steam stop and control, and reheat stop and intercept valves. Show that a single failure of any of the above valves cannot disable the turbine overspeed trip functions. (SRP 10.2, Part III, Item 3).

RESPONSE: The turbine overspeed protection system is an equipment protection system and is not required for plant safety.

Nevertheless, as described below and in section 10.2, the turbine overspeed protection system provides a highly reliable system to trip the turbine in the event of a turbine overspeed condition.

The function of the turbine overspeed trip sensors is to provide signals to the turbine trip system which, in turn, actuates the solenoid valves in the emergency trip systems. The emergency trip actuates the disk dump valve for each stop, control, reheat stop, and intercept valve to depressurize hydraulic fluid in trip system. This allows spring to close the valves to terminate the flow of steam to the turbine.

Each of the main steam and reheat lines supplying steam to the high-pressure and low-pressure cylinders of the turbine has two valves (stop and control) in series. Failure of one valve to close will not prevent tripping the turbine since the second valve in the same line will close, thus terminating the flow of steam to the turbine.

(Figure 10.1-1, sheet 1, indicates the approximate location of the turbine main steam stop, control, reheat stop, and intercept valves.)

QUESTION 10A.4 (NRC Question 430.40) (10.2)

Expand your discussion of the inservice inspection program for throttle-stop, control, reheat stop, and interceptor steam valves to include inspection times and the capability for testing essential components during turbine generator system operation. (SRP 10.2, Part III, Items 5 and 6).

RESPONSE: The response is given in amended paragraph 10.2.3.6.

QUESTION 10A.5 (NRC Question 430.41) (10.2)

Discuss the effects of a high and moderate energy piping failure or failure of the connection from the low pressure turbine to condenser on nearby safety-related equipment or systems. Discuss what protection will be provided the turbine overspeed control system equipment, electrical wiring, and hydraulic lines from the effects of a high or moderate energy pipe failure so that the turbine overspeed protection system

will not be damaged to preclude its safety function. (SRP 10.2 Part III, Item 8).

RESPONSE: High and moderate energy piping failure within the turbine building, or failure of the connection between the low-pressure turbine to the condenser will not adversely affect plant safety since there is no safety-related equipment located within the turbine building. Further response is given in paragraph 3.6.1.2. The turbine overspeed protection system is for equipment protection only.

Nevertheless, the turbine overspeed protection system provides a highly reliable system to trip the turbine in event of a turbine overspeed condition. Aside from providing two redundant channels of speed control, two additional means of overspeed protection are provided as discussed in paragraph 10.2.2.3.1.5. Because of the redundancy in the mode of operation and the physical separation of components, a high or moderate energy pipe failure will not preclude protective function of the turbine overspeed control system.

<u>QUESTION 10A.6</u> (NRC Question 430.42) (10.2)

In paragraph 10.2.3.6 you discuss inservice inspection and exercising of the main steam turbine stop and control and reheater stop and intercept valves. You do not discuss the inservice inspection, testing and exercising of the extraction steam valves. Provide a detail description of: 1) the extraction steam valves, and 2) your inservice inspection and testing program for these valves. Also provide the time

interval between periodic valve exercising to assure the extraction steam valves will close on turbine trip.

RESPONSE: The extraction steam valves are described in amended paragraph 10.2.2.5.

<u>QUESTION 10A.7</u> (NRC Question 430.43) (10.2)

Describe with the aid of drawings, the bulk hydrogen storage facility including its location and distribution system. Include the protective measures considered in the design to prevent fires and explosions during operations such as filling and purging the generator, as well as during normal operations.

RESPONSE: The following drawings (sent under separate cover) show the location of the bulk hydrogen storage facilities and the hydrogen distribution system:

- 13-P-ZYA-958, Rev. 0
- 01-C-ZVC-305, Rev. 7
- 01-C-CVC-306, Rev. 7
- 13-P-GAF-201, Rev. 4
- 13-P-GAF-401, Rev. 2
- 13-P-ZYA-015, Rev. 6
- 13-M-GAP-001, Rev. 4
- 13-M-GAP-002, Rev. 2
- 13-M-GHP-001, Rev. 4
- 13-M-CHP-002, Rev. 6
- 13-P-CHF-218, Rev. 5

Further response is given in paragraph 9.3.6.2.2.

APPENDIX 10A

<u>QUESTION 10A.8</u> (NRC Question 430.44) (10.2)

Paragraph 10.2.1.3 references the CESSAR turbine generator interface requirements of subsections 5.1.4 and 7.2.3 The CESSAR FSAR sections 5.1.4 and 7.2.3 do not contain any turbine generator interface requirements. Clarify this inconsistency, provide the CESSAR interface requirements and an evaluation of how you are meeting those requirements.

RESPONSE: The response is given in amended paragraph 10.2.1.3.

<u>QUESTION 10A.9</u> (NRC Question 430.45) (10.3)

As explained in issue No. 1 of NUREG-0138, credit is taken for all valves downstream of the main steam isolation valve (MSIV) to limit blowdown of a second steam generator in the event of a steam line break upstream of the MSIV. In order to confirm satisfactory performance following such a steam line break provide a tabulation and descriptive text (as appropriate) in the FSAR of all flow paths that branch off the main steam lines between the MSIVs and the turbine stop valves. For each flow path originating at the main steam lines, provide the following information:

a) System identification

b) Maximum steam flow in pounds per hour

c) Type of shutoff valve(s)

d) Size of valve(s)

e) Quality of the valve(s)

f) Design code of the valve(s)

g) Closure time of the valve(s)

h) Actuation mechanism of the valve(s) (i.e., solenoid-operated, motor-operated, air-operated diaphragm valve, etc.)

i) Motive or power source for the valve actuating mechanism

In the event of the postulated accident, termination of steam flow from all systems identified above, except those that can be used for mitigation of the accident, is required to bring the reactor to a safe cold shutdown. For these systems describe what design features have been incorporated to assure closure of the steam shutoff valve(s). Describe what operator actions (if any) are required.

If the systems that can be used for mitigation of the accident are not available or decision is made to use other means to shut down the reactor describe how these systems are secured to assure positive steam shutoff. Describe what operator actions (if any) are required.

If any of the requested information is presently included in the FSAR text, provide only the references where the information may be found.

RESPONSE: NUREG-0138 page 1-9 states that the probability of occurrence of the above scenario is quite low. Page 1-10 states that the scenario is not analyzed by the staff and need not be considered as a design basis accident. This

scenario should, therefore, not be a design basis accident for Palo Verde Units 1, 2, and 3.

Refer to the following P&IDs:

- 13-M-SGP-001
- 13-M-SGP-002
- 13-M-FTP-001
- 13-M-CDP-001
- 13-M-MTP-001
- 13-M-MTP-002
- 13-M-ASP-001
- 13-M-GSP-001

Further response is given in paragraph 10.3.2.2.2.

QUESTION 10A.10 (NRC Question 430.46) (10.4.1)

Provide a tabulation in your FSAR showing the physical characteristics and performance requirements of the main condensers. In your tabulation include such items as: 1) the number of condenser tubes, material and total heat transfer surface, 2) overall dimensions of the condenser, 3) number of passes, 4) hot well capacity, 5) special design features, 6) minimum heat transfer, 7) normal and maximum steam flows, 8) normal and maximum cooling water temperature, 9) normal and maximum exhaust steam temperature with no turbine bypass flow and with maximum turbine bypass flow, 10) limiting oxygen

content in the condensate in cc per liter, and 11) other pertinent data. (SRP 10.4.1, Part III, Item 1).

RESPONSE: The response is given in amended paragraph 10.4.2.2 (table 10.4-1).

QUESTION 10A.11 (NRC Question 430.47) (10.4.1)

Discuss the measures taken; 1) to prevent loss of vacuum, and 2) to prevent corrosion/erosion of condenser tubes and components. (SRP 10.4.1, Part III, Item 1).

RESPONSE: The response is given in paragraph 10.4.1.2.

QUESTION 10A.12 (NRC Question 430.48) (10.4.1)

Indicate and describe the means of detecting and controlling radioactive leakage into and out of the condenser and the means for processing excessive amounts.
(SRP 10.4.1, Part III, Item 2).

RESPONSE: The response is given in paragraphs 10.4.5.2, 11.3.3.4, and 11.5.2.1.3.2, and subsection 10.4.6.

QUESTION 10A.13 (NRC Question 430.49) (10.4.1)

Discuss the measures taken for detecting, controlling and correcting condenser cooling water leakage into the condensate stream. (SRP 10.4.1, Part III, Item 2)

RESPONSE: The response is given in amended paragraph 10.4.6.2.3.

APPENDIX 10A

<u>QUESTION 10A.14</u> (NRC Question 430.50) (10.4.1)

In paragraph 10.4.1.4 you have discussed tests and initial field inspection but not the frequency and extent of inservice inspection of the main condenser. Provide this information in the FSAR (SRP 10.4.1, Part II).

RESPONSE: The response is given in amended paragraph 10.4.1.4.

<u>QUESTION 10A.15</u> (NRC Question 430.51) (10.4.1)

Indicate what design provisions have been made to preclude failures of condenser tubes or components from turbine bypass blowdown or other high temperature drains into the condenser shell (SRP 10.4.1, Part III, Item 3).

RESPONSE: The condenser and its tubes are protected from turbine bypass blowdown steam flow by a manifold having two stages of pressure reduction orifices that direct the steam flow away from the condenser tubes.

Further response is given in paragraph 10.4.1.2.

<u>QUESTION 10A.16</u> (NRC Question 430.52 (10.4.1)

Discuss the effect of loss of main condenser vacuum on the operation of the main steam isolation valves (SRP 10.4.1, Part III, item 3).

RESPONSE: As discussed in subsection 10.4.1, the main condenser has no safety function. However, the main steam

isolation valves will shut indirectly because of loss of main condenser vacuum as explained in paragraph 15.2.2.1.

QUESTION 10A.17 (NRC Question 430.53) (10.4.4)

Provide additional description (with the aid of drawings) of the turbine bypass valves and associated instrumentation and controls. In your discussion include the number, size, principle of operation, construction, setpoints, and capacity of each valve and the malfunctions and/or modes of failure considered in the design of the turbine bypass system. (SRP 10.4.4, Part III, Item 1.)

RESPONSE: The response is given in subsection 10.4.4 and section 7.7, figure 10.4-1, CESSAR Sections 10.4.4 and 7.7.1.1.5, and CESSAR Figure 7.7-6.

QUESTION 10A.18 (NRC Question 430.54) (10.4.4)

Provide the results of an analysis indicating that failure of the turbine bypass system high energy line will not have an adverse effect or preclude operation of the turbine speed control system or any safety-related components or systems located close to the turbine bypass system. (SRP 10.4.4, Part III, Item 4).

RESPONSE: See response to Question 10A.5 (NRC Question 430.41.)

QUESTION 10A.19 (NRC Question 430.55) (10.4.4)

In paragraph 10.4.4.4 you have discussed tests and initial field inspection but not the frequency and extent of inservice

testing and inspection of the turbine bypass system. Provide this information in the FSAR. (SRP 10.4.4, Part II).

RESPONSE: The response is given in amended paragraph 10.4.4.3, listing B.

QUESTION 10A.20 (NRC Question 430.56) (10.4.4)

Subsection 10.4.4 of your FSAR refers to Section 10.4.4 of CESSAR for additional discussion of the turbine bypass system. Your turbine bypass system differs from the one discussed in CESSAR, in that two of your bypass valves dump to atmosphere while in CESSAR they do not. Provide a discussion to show that your system meets the 11 design bases stated in Section 10.4.4.1 of CESSAR.

RESPONSE: The response is given in amended subsection 10.4.4.

QUESTION 10A.21 (NRC Question 282.2) (10.3.5)

Provide the steam generator secondary water chemistry control and monitoring program, addressing the following:

1. Sampling schedule for the critical parameters and of control points for these parameters for each mode of operation: normal operation, hot startup, cold startup, hot shutdown, cold wet layup;

2. Procedures used to measure the values of the critical parameters;

3. Process sampling points;

4. Procedure for the recording and management of data;

5. Procedures defining corrective actions[a] for off-control point chemistry conditions; and

6. The procedure identifying (a) the authority responsible for the interpretation of the data and (b) the sequence and timing of administrative events required to initiate corrective action.

Verify that the steam generator secondary water chemistry control program incorporates technical recommendations of the NSSS. Any significant deviations from NSSS recommendations should be noted and justified technically.

In addition to the secondary water chemistry monitoring and control program, we require monitoring of the steam condensate at the effluent of the condensate pump. The monitoring of the condensate is for the purpose of detecting condenser leakage.

RESPONSE: (Item numbers correspond to those of the question.)

1. The response is given in paragraph 10.3.5.1.

2. Procedures for measuring the values of critical parameters will reflect C-E technical recommendations or exceptions will be technically justified in subsection 10.3.5.

   The following industry procedures reflect the most recent C-E technical recommendations for measuring the respective parameters.

---

a. Branch Technical Position MTEB 5-3 describes the acceptable means for monitoring secondary side water chemistry in PWR steam generators, including corrective actions for off- control point chemistry conditions. However, the staff is amenable to alternatives, particularly to Branch Technical Position B.3.b(9) of MTEB 5-3 (96-hour time limit to repair or plug confirmed condenser tube leaks).

Parameter	Procedure
pH	ASTM, Part 31, Procedure D1293, Method B
Conductivity	ASTM, Part 31, Procedure D1125, Method B
Suspended Solids	Standard Methods, Procedure 208D or ASTM, Part 31, Procedure D1888
Silica	ASTM, Part 31, D859, Method B

3. Process sampling points are listed in paragraph 10.4.6.2.3.

4. The response is given in paragraph 10.3.5.1.

5. The response is given in paragraph 10.3.5.1.

6. The response is given in paragraph 10.3.5.1.

   The steam generator secondary water chemistry control program is described in paragraph 10.3.5.1, which reflects C-E's technical recommendations. Technical recommendations are met by the existing design. There are no significant deviations from NSSS steam generator chemistry recommendations.

   Paragraph 10.4.6.2.3 describes the method of continuously monitoring for indication of condenser leaks, which is to continuously monitor each section of the condenser hotwell, instead of monitoring condenser pump discharge.

QUESTION 10A.22 (NRC Question 410.25) (10.3)

In order to prevent blowdown of more than one steam generator, verify that the main steam isolation valves are designed to stop full main steam flow at the maximum design differential pressure in both directions in the event of a main steam line break in one steam line upstream of an MSIV and corresponding single failure (to close) in an MSIV to the other steam generator.

RESPONSE: The response is given in subsection 10.3.2.2.2.

QUESTION 10A.23 (NRC Question 410.26) (10.4.5)

The evaluation of potential flooding of essential plant areas as a result of a circulating water system failure indicates that the water level would eventually reach plant grade at which point the water leaves the turbine building. Verify that this water cannot enter safety-related structures through openings at grade or describe the protection provided for safety-related equipment from such an occurrence.

RESPONSE: The response is given in paragraph 10.4.5.2.

QUESTION 10A.24 (NRC Question 410.27) (10.4.7)

It is our position that you commit to perform a steam generator/feedwater water hammer test in accordance with the guidance for preheat type steam generators as identified in NUREG/CR-1606, "An Evaluation of Condensation-Induced Water Hammer in Preheat Steam Generators." The following procedure should be followed:

"Run the plant at approximately 15% of full power by using feedwater through the downcomer nozzle at the lowest feedwater temperature that the plant Standard Operating Procedure (SOP) allows. Switch the feedwater at that temperature from the downcomer nozzle to the economizer nozzle by following the SOP. Observe and record the transient that follows."

RESPONSE: The response is given in paragraph 10.4.7.4.

FIGURES

This page intentionally left blank

11. RADIOACTIVE WASTE MANAGEMENT

11.1 SOURCE TERMS

11.1.1 FISSION PRODUCTS

11.1.1.1 Maximum (Design Basis) Fission Product Activities in Reactor Coolant

Maximum fission product activities are used as design basis source terms for shielding and facilities design and for calculating the consequences of postulated accidents. The isotopes chosen for consideration in the maximum case are those which are significant for design purposes by reason of a combination of energy, half-life or abundance.

The mathematical model used to determine the concentration of nuclides in the Reactor Coolant System involves a group of linear, first order differential equations. These equations are obtained by applying a mass balance for production and removal for the fuel pellet region as well as the coolant region. In the fuel pellet region, the mass balance includes fission product production by direct fission yield, by parent fission product decay and by neutron activation; while the removal includes decay, neutron activation and escape to the coolant. In the coolant region the analysis includes the fission product production by escape from the fuel through defective fuel rod cladding, parent decay in the coolant and neutron activation of coolant fission products. Removal is by decay, by coolant purification, by feed and bleed operations (for fuel burnup), by leakage and other feed and bleed operations such as startups and shutdowns as well as load follow operation.

The expression derived to determine the fission product inventory in the fuel pellet region is;

$$\frac{dN_{p,i}}{dt} = (F)(Y_i)(P) + (f_{i-1}\lambda_{i-1})N_{p,i-1} + \sigma\varphi N_{p,j} - (\lambda_i + v_i + \sigma_i\varphi)N_{p,i} \qquad (1)$$

The expression derived to determine the fission product inventory in the reactor coolant region is;

$$\frac{dN_{c,i}}{dt} = (D)(v_i)\left(N_{p,i}\right) + (f_{i-1}\lambda_{i-1})N_{c,i-1} + \left(\sigma_j\varphi CVR\right)N_{c,j}$$

$$-\left(\lambda_i + \frac{\dot{Q}}{W}\eta_i + \frac{(1-\eta_i)\dot{C}}{C_o-\dot{C}t} + \frac{L}{W}\right)N_{c,i} \qquad (2)$$

where the variables are identified as –

N = Population, atoms
F = Average fission rate, fissions/Mwt – sec
Y = U-235 fission yield of nuclide, fraction (Reference 1)
P = Core power, Mwt
λ = Decay constant, sec^{-1} (Reference 2)
σ = Microscopic capture cross section cm^2 (Reference 3)
φ = Thermal neutron flux, neutron/cm^2 –sec
v = Escape rate coefficient, sec^{-1}
f = Branching fraction
t = Time, seconds
D = Defective fuel cladding, fraction
CVR = Core coolant volume to reactor coolant volume ratio, fraction
$\dot{Q}$ = CVCS purification flow rate during power operation, lbm/sec
W = Reactor Coolant System mass during power operation, lbm
η = Resin efficiency of CVCS ion exchanger and gas stripper efficiency (subscripted for a particular nuclide)
C_o = Beginning of core life boron concentration, ppm
C = Boron concentration reduction rate because of feed and bleed, ppm/sec
L = Leakage or other feed and bleed from the reactor coolant, lbm/sec

and where the subscripts are identified as –

i = i^{th} nuclide
i-l = precursor to i^{th} nuclide for decay
j = precursor to i^{th} nuclide for neutron activation
p = pellet region
c = coolant region

It should be noted that this model does not involve the fuel plenum and gap region. Instead, escape rate coefficients are used to represent the overall release from the fuel pellets to the coolant. The escape rate coefficients are consistent with escape rate coefficients provided in the 1976 version of NUREG-0017 (Reference 4).

Shown in Table 11.1-1A are the values of parameters used to calculate the reactor coolant fission product activities.

The maximum activities are presented in Table 11.1-1B and are defined in Table 11.1-1A.

11.1.1.2 Normal Operating Source Terms Including Anticipated Operational Occurrences

The data in Table 11.1-1C represent the expected normal fission product activities for the plant with no gas stripping. The activities for this case are based on ANSI Standard N237 (Reference 6) and are intended for use in evaluating only normal operations including anticipated operational occurrences.

Table 11.1-1A
(Sheet 1 of 2)
BASIS FOR REACTOR COOLANT FISSION PRODUCT ACTIVITIES

PARAMETER	MAXIMUM	NORMAL(1)
Core Power Level (Mwt)	4200	4000
Duration of Reactor Operation (core cycles)	5	-
Equilibrium Fuel Cycle (Equivalent Full Power Days)	550	-

11.1.2 DEPOSITED CRUD ACTIVITIES

The activity of radioactive crud and its thickness on primary system surfaces have been evaluated using measured data from various operating pressurized water reactors.

Even though these reactors have different water chemistries and different materials in contact with the primary coolant, their crud activity (dpm/mg-crud), crud film thicknesses and dose rates due to this crud are remarkably similar. The half-lives, reactions and gamma decay energies for each of the long-lived isotopes in the radioactive crud are as shown in Table 11.1-1D. The long-lived isotopes are those significant isotopes remaining after 48 hours decay.

The radioactive crud originates on in-core and out-of-core surfaces. The crud plates out on the in-core surfaces and re-erodes after a short irradiation period. This irradiation period or core residence time for each isotope is determined by the following equations. (See Appendix 11B for the derivation of the core residence time equations):

Circulating Crud:

$$T_{res} = -\frac{1}{\lambda} ln\left(1 - \frac{A_i A_T 16.67}{\sum_i \varphi A_c}\right), sec \qquad (1)$$

Deposited Crud:

$$T_{res} = -\frac{1}{\lambda} ln\left(1 - \frac{A_j 16.67}{\sum_i \varphi}\right), sec, \qquad (2)$$

Where: A_i, A_j are the crud activities for each isotope (dpm/mg-crud),

A_T is the total primary system area (cm^2),

$\sum_i \varphi$ is the activation rae (d/g-sec), and

A_c is the core surface area (cm^2)

The activation cross-section $\sum_i$ is as follows:

$$\Sigma_i = \frac{(a/o)_i (w/o)_i N_o \sigma_i}{[A]_i}, cm^2/g \qquad (3)$$

Where: $(a/o)_i$ is the isotopic abundance,

$(w/o)_i$ is the elemental abundance in the crud or the element abundance in the base metal,

N_o is Avagadro number (0.6023×10^{24} a/g-mole),

$[A]_i$ is the atomic weight of isotope (i), and

σ_i is the microscopic cross-section (barns).

Circulating crud is taken to be all crud in the reactor coolant. Deposited crud is taken to be all crud which plates out on in-core surfaces.

The measured average and maximum crud activities (dpm/mg-crud) as taken from References 5 and 7 through 19 for those reactors considered in the determination of the core residence times are as shown in Table 11.1-1E. The average and maximum core residence times as determined by the above expressions, the activation rates in Table 11.1-1F and the system parameters in Table 11.1-1G are as shown in Table 11.1-1H. As all the Fe-59 residence times are long, its activity (A_i) is assumed saturated. The averages (T_{res}) of the maximum residence times are also given in Table 11.1-1H.

The calculated crud activities (A_i) are determined utilizing the averages (T_{res}) of the maximum core residence times, the system parameters in Table 11.1-1I and the following equation:

$$A_i = \Sigma_i \varphi \left(1 - e^{-\lambda_i T_{res}}\right) \frac{A_c}{A_T} (0.06), dpm/mg - crud \qquad (4)$$

As the averages (T_{res}) of the maximum residence times are used and in general these (T_{res}) are a factor of 2 to 4 higher than a straight average residence time, the resulting calculated crud activities will be conservative. These calculated crud activities of the long-lived isotopes are as shown in Table 11.1-1J. These calculated crud activities are applied to both the circulating crud and out of core deposited curd. Using the average crud level in the reactor coolant (75ppb) of those operating reactors shown in Table 11.1-1E and the calculated crud activities (dpm/mg-crud) as shown in Table 11.1-1J, the average isotopic activities in the primary coolant are determined by the following expression:

$$A = \frac{A_i}{60} (75x10^{-9}) \rho (2.7x10^{-5}) 1x10^3, \mu ci/cm^3 \qquad (5)$$

where ρ is density of water (g/cc) and 1000 is mg/g.

The average calculated activities in the primary coolant using the above expression are shown in Table 11.1-1K. The maximum coolant activities can be higher due to "crud bursts" during shutdowns or changes in power. However, these "bursts" occur over short periods of time, and therefore, the average values are more reasonable to use for long term operation.

The equilibrium thickness of radioactive crud film (mg-crud/cm^2) has been determined by two methods:

1. The direct measurement of the film during maintenance and/or tests in operating reactors.
2. Calculating crud film thickness from measured dose rates and specific activities (dpm/mg-crud) of deposited crud.

The quilibrium crud film thicknesses for various Reactor Coolant System areas are as shown in Table 11.1-1L.

The calculated crud activities in this section are reasonable values and together with measured plateout thicknesses match measured shutdown dose rates around various equipment associated with operating reactors. However, both the crud levels and plateout thicknesses do have rather wide variations as shown in Table 11.1-1E for operating reactors and many combinations of activities and plateout thicknesses could reproduce the measured shutdown dose rates. It is for this reason that the crud activities are periodically reviewed as more measured crud activities, plateout thicknesses and dose rates become available.

The conservative evaluation of the above operating data yields circulating crud concentrations (Table 11.1-1K) which are generally consistent with those from NUREG-0017 and ANSI N237. ANSI standard N237 is used for evaluating normal operations including anticipated operational occurrences. Values from NUREG-0017 for circulating crud are used as design source terms. Average reactor coolant crud activities calculated in this section are for a 3817 MWt plant.

Reactor coolant radioactive crud specific activities provided in NUREG-0017 and ANSI 237 are based on operating information obtained from reference plants. The majority of the information is late 1970s vintage. Since the late 1970s, reactor coolant water chemistry control methodologies (e.g., pH control) and use/replacement of materials (exposed to reactor coolant) with materials less likely to generate

radioactive crud have substantially reduced the presence of radiologically significant crud in reactor coolant e.g., Co-60. This is supported by conference presentations. Reduction of radioactive crud concentrations in reactor coolant since the late 1970s and early 1980s provides support for using activated crud values from NUREG-0017 and ANSI 237.

The information provided in this section is considered to be historical. Design and expected source terms for Palo Verde are presented in Tables 11.1-1B and 11.1-1C.

(a) Denotes power of ten (10).

11.1.3 TRITIUM PRODUCTION IN REACTOR COOLANT

The principal sources of tritium production in a pressurized water reactor (PWR) are from ternary fission and neutron induced reactions in boron, lithium and deuterium that are present in the coolant, borated shim rods and control element assemblies (CEA). The tritium produced in the coolant contributes immediately to the overall tritium activity while the tritium produced by fission and neutron capture in the CEAs and borated shim rods contributes to the overall tritium activity via release through the cladding.

11.1.3.1 Activation Sources of Tritium

The activation reactions producing tritium are as shown in Table 11.1-1M. The tritium production from reactions 5 and 6 (B-11 and N-14 sources) is insignificant due to low cross

section and/or abundance and can be neglected. Reactions 1-4 (from B-10, lithium, and deuterium) are the major sources of tritium in the coolant, CEA's and borated shim rods.

The tritium production from the above sources is determined by the following expressions:

Tritium Formation Rate = Production Rate – Decay

$$\frac{dN}{dt} = \Sigma_a \phi - \lambda N$$

$$N = \frac{\Sigma_a \phi}{\lambda}\left(1 - e^{-\lambda t}\right), atoms/cm^3 \; at \; time \; (t)$$

$$activity \; (curies) = V \lambda N \times 2.7 \times 10^{-11} = \Sigma_a \phi \left(1 - e^{\lambda t}\right) V \times 2.7 \times 10^{-11}$$

Where $\sum_a \phi$ is the production rate (atoms/cc-sec)

t is the reactor operating period of interest

V is the effective core volume, borated shim rod volume or CEA volume (cm^3) and 2.7 x 10^{-11} converts disintegrations/sec to curies.

The parameters used in the calculation are as shown in Table 11.1-1N. Based on these parameters, the tritium produced annually from activation sources in the reactor coolant is included in Table 11.1-1O.

11.1.3.2 Tritium From Fission

The computer code ORIGEN II was run in to obtain the tritium generation as a product of fission only. The ORIGEN II data is based on a 5 w/o fuel enrichment and 105.5 MTU loading. The ORIGEN II value accounts for production from fissions of U-235 and also from Pu-239 as the U-235 is depleted. Tritium activity at reactor operation of 1-yr (365 days) is reported.

The amount of tritium that is released through fuel cladding can be indirectly determined using measured tritium levels from operating PWRs, subtracting the calculated tritium activity produced by neutron capture in the reactor coolant, and attributing the remaining tritium activity to release from the cladding of the fuel rods, borated shim rods and CEAs. Due to the large number of the fuel rods as compared to the number of borated shim rods and CEA’s within the core during operation, any amount of tritium released to the system will be principally from the fuel rods. The total amount of tritium produced per fuel cycle can be determined by summing the total tritium discharged in the gaseous, liquid and solid waste discharges of the plant and the tritium inventories in the Reactor Coolant System and other waste or refueling tanks that can contain tritium at the end of the fuel cycle of interest. This method has been used to analyze C-E operating data and data from other PWR’s. The results of the analysis are shown in Table 11.1-1P. Buildup of plutonium in the fuel with burnup was accounted for in the analysis. A release rate of 2% is used to estimate the annual tritium production in table 11.1-1O.

(a) Production is total measured tritium discharges plus measured system inventories.

(b) Fission curies are based on appropriate cycle average fractional fissions of U-235. U-238 and Pu.

(c) Includes cycles 1-A, 1-B and 2.

(d) (1-1) Unit #1 - Cycle #1.

(e) 1410 Ci accounted for under tritium measurement program (Ref. 11). Only 800 Ci can be accounted for using plant discharges and inventories.

11.1.3.2.1 Tritium Liquid Concentrations

The tritium concentrations in the plant are dependent on the production rate in the reactor coolant system (Note 1); the losses due to radioactive decay, plant discharges, leakage and evaporation; and the transfer of plant water. The concentrations are based upon discharging a sufficient amount of boric acid concentrator distillate (as vapor) as necessary to maintain plant tritium airborne concentrations below 10CFR20.1-20.601 limits. A tritium balance is performed on the entire plant by simultaneously solving the following differential equations for the equilibrium case. Each equation represents the tritium activity in a major water source for tritium transfer. The model used for determining the equations is shown in figure 11.1-1.

<u>RCS</u>

$$\frac{dN}{dt} = P + \lambda_6 R + \lambda_3 M - (\lambda_1 + \lambda_D + \lambda_L + \lambda_2 + \lambda_{10})N \qquad (1)$$

<u>RMWT</u>

$$\frac{dM}{dt} = [(1 - X)\lambda_9 + \lambda_{10}]N - (\lambda_D + \lambda_3 + \lambda_5)M \qquad (2)$$

<u>SFP</u>

$$\frac{dS}{dt} = (\lambda_4 + \lambda_7)\ R - (\lambda_S + \lambda_D + \lambda_8)S \qquad (3)$$

Note (1): Current design estimates for tritium production rates are less than the licensing basis values. As a result, design tritium concentrations and releases reported in this section are less than licensing basis limits.

RWT

$$\frac{dR}{dt} = \lambda_5 M + (\lambda_2 + \lambda_{RT})N + \lambda_8 S - (\lambda_7 + \lambda_D + \lambda_4 + \lambda_6 + \lambda_R)R \qquad (4)$$

where:

RCS = reactor coolant system

RMWT = reactor makeup water tank

SFP = spent fuel pool

RWT = refueling water tank (includes refueling pool)

BAC = boric acid concentrator

N = tritium activity in the reactor coolant system (Ci)

M = tritium activity in the reactor makeup water tank (Ci)

S = tritium activity in the spent fuel pool (Ci)

R = tritium activity in the refueling water tank (or refueling pool) (Ci)

P = tritium production rate in reactor coolant (Ci/yr)

t = time (yr)

λ_L = leakage constant =

$$\frac{\text{Primary-to-secondary leakage (gal/yr)}}{\text{RCS water volume (gal)}}, \ (yr^{-1})$$

λ_D = tritium decay constant $= \dfrac{\ln 2}{\text{half} - \text{life}}, \ (yr^{-1})$

λ_6 = RWT fraction used as RCS makeup after refueling =

$$\frac{\text{Refueling pool water used as RCS makeup (gal/yr)}}{\text{RWT water volume (gal)}},$$

(yr^{-1})

λ_3 = RMWT makeup fraction to RCS =

$$\frac{\text{RMWT makeup to RCS (gal / yr)}}{\text{RMWT water volume (gal)}}, \ (yr^{-1})$$

λ_1 = RCS letdown fraction to boric acid concentrator

$$\text{(BAC)} = \frac{\text{letdown flow (gal / yr)}}{\text{RCS water volume (gal)}}, \ (yr^{-1})$$

λ_2 = RCS water fraction left after draining prior to refueling =

$$\frac{\text{RCS water available for mixing (gal / yr)}}{\text{RCS water mass (gal)}}, \ (yr^{-1})$$

X = fraction of flow sent to CVCS BAC that is discharged

from the plant (unitless)

λ_9 = RCS letdown fraction to BAC distillate =

$$\frac{\text{BAC distillate flow (gal / yr)}}{\text{RCS water volume (gal)}}, \ (yr^{-1})$$

λ_7 = RWT transfer fraction to SFP =

$$\frac{\text{fuel transfer flow (gal / yr)}}{\text{RWT water volume (gal)}}, \ (yr^{-1})$$

λ_S = SFP evaporation fraction =

$$\frac{\text{SFP evaporation rate (gal / yr)}}{\text{SFP water volume (gal)}}, \ (yr^{-1})$$

λ_4 = SFP makeup =

$$\frac{\text{SFP evaporation rate (gal / yr)}}{\text{RWT water volume (gal)}}, \ (yr^{-1})$$

λ_5 = RWT makeup =

$$\frac{\text{RWT net losses}\,(\text{gal / yr})}{\text{RMWT water volume}\,(\text{gal})},\ (\text{yr}^{-1})$$

λ_8 = SFP transfer fraction to refueling pool =

$$\frac{\text{fuel transfer flow}\,(\text{gal / yr})}{\text{SFP water volume}\,(\text{gal})},\ (\text{yr}^{-1})$$

λ_{RT} = RCS letdown fraction to RWT =

$$\frac{\text{BAC bottoms flow}\,(\text{gal / yr})}{\text{RCS water volume}\,(\text{gal})},\ (\text{yr}^{-1})$$

λ_5 = RWT evaporation fraction =

$$\frac{\text{refueling pool evaporation rate}\,(\text{gal / yr})}{\text{RWT water volume}\,(\text{gal})},\ (\text{yr}^{-1})$$

λ_{10} = RCS transfer fraction to RMWT =

$$\frac{\text{RCS processed leakage}\,(\text{gal / yr})}{\text{RCS water volume}\,(\text{gal})},\ (\text{yr}^{-1})$$

The leakage constant (λ_L) includes a primary-to-secondary leak rate of 100 pounds per day. Other leakage (λ_{10}) is assumed to be recycled to the RMWT after collection and processing by the liquid radwaste system.

The evaporation fractions (λ_S and λ_R) include year-round evaporation from the SFP and evaporation from the refueling pool during refueling only (this is the only time the refueling pool contains water).

Normal RMWT (λ_{11}) makeup is from a demineralized water source that uses nontritiated water, and is, therefore, not considered in the analysis.

Makeup to the RCS (λ_3) is from the RMWT. This is equal to the letdown flow to the BAC (λ_1) plus the leakage from the RCS ($\lambda_L + \lambda_{10}$).

The volume from the refueling pool, spent fuel pool and RCS are assumed to be instantaneously and homogeneously mixed at the start of each refueling outage.

Utilizing the above equations and the assumptions given in table 11.1-1Q, under the design basis of limiting the tritium airborne concentration to 1/2 of the 10CFR20.1-20.601 limit in the most restrictive building, the equilibrium tritium concentrations and inventories are determined. This also determines the approximate vapor discharge of boric acid concentrator distillate necessary to maintain concentration below this level, for equilibrium conditions. The annual expected distillate flow is 358,000 liquid gallons per year as vapor. The annual design distillate flow is 643,000 liquid gallons per year as vapor. Equilibrium tritium liquid concentrations and inventories for the RCS, RMWT, RWT, SFP, refueling pool, and secondary system are given in table 11.1-2.

11.1.3.2.2 Tritium Airborne Concentrations

Tritium airborne concentrations for various buildings are reported in subsection 12.2.2.

Table 11.1-1Q
ASSUMPTIONS USED IN DETERMINING TRITIUM ACTIVITIES
(Sheet 1 of 2)

No.	Assumption
1.	Equilibrium tritium production rate in reactor Coolant is: Average = 921 curies per year Maximum = 1375 curies per year
2.	Tritium activities are based on the maximum building airborne tritium concentration being 1/2 of 10CFR20.1-20.601 limits.
3.	Reactor coolant leakage is as per NUREG-0017.
4.	The tritium balance is as per figure 11.1-1.
5.	Boric acid is concentrated to 4400 ppm boron from an average RCS concentration of 750 ppm boron.
6.	Core cycle and primary coolant parameters are per Table 11.1.1A.
7.	Instantaneous mixing of the Reactor Coolant System, Refueling Pool and Spent Fuel Pool is assumed at the start of each outage.
8.	Primary-to-secondary leakage is as per NUREG 0017.
9.	Leakage from the secondary system in the turbine building is as per NUREG 0017.
10.	Primary coolant flow to the boric acid concentrator is based on 1,345,000 gal/cycle.
11.	Spent fuel pool parameters: Refueling and normal temperature = 125F Liquid volume = 311,000 gallons Surface area = 1320 square feet Air speed across SFP = 20 feet per minute
12.	Refueling pool parameters: Refueling temperature = 125F Liquid volume = 506,000 gallons Surface area = 2130 square feet Air speed across pool = 20 feet per minute
13.	Tank and RCS volumes: RMWT = 380,000 gallons RWT = 680,000 gallons RCS = 68,100 gallons

Table 11.1-1Q
ASSUMPTIONS USED IN DETERMINING TRITIUM ACTIVITIES
(Sheet 2 of 2)

No.	Assumption
14.	Containment building parameters: Air temperature = 104F Free volume = 2.6 x 10^6 cubic feet Normal purge rate = 2200 cubic feet per Refueling rate = 33,000 cubic feet per minute
15.	Fuel building parameters: Air temperature = 104F Free volume = 7.36 x 10^5 cubic feet HVAC exhaust = 42,686 cubic feet per minute
16.	Auxiliary building parameters: Air temperature = 104F Free volume = 1.37 x 10^6 cubic feet HVAC exhaust rate = 58,400 cubic feet minute
17.	Turbine building parameters: Air temperature= 104F Free volume = 7.13 x 10^6 cubic feet HVAC exhaust rate = 474,160 cubic feet per minute
18.	Secondary system volume is 2.32E+05 gallons

Table 11.1-2
TRITIUM LIQUID ACTIVITIES

System	Concentration (μCi/g)		Inventory (Ci)	
	Expected	Maximum	Expected	Maximum
Reactor coolant system (RCS)	0.37	0.41	138	152
Reactor makeup water tank (RMWT)[a]	0.13	0.02	181	26
Refueling water tank (RWT)	0.74	0.7	1900	2000
Refueling pool[b]	0.41	0.42	790	778
Spent fuel pool (SFP)	0.42	0.42	490	500
Total	--	--	3499	3456

a. Note that the inventory is smaller for the higher production rate. This is due to the increased fraction of total BAC distillate vapor necessarily discharged before reaching the RMWT to maintain a 1/2 MPC in the containment in the maximum case.

b. Refueling pool inventory is included in the RWT inventory.

11.1.3.2.3 Tritium Releases

Plant tritium activity is reduced as a result of either natural radioactive decay or airborne release through plant ventilation systems and boric acid concentrator distillate vapor. Table 11.1-3 summarizes the tritium releases per unit based on the model described in paragraph 11.1.3.2.1 for distillate vapor release, and on the model described in subsection 11.3.3 for ventilation system releases. Gaseous tritium releases by source are given in table 11.3-6.

Table 11.1-3

TRITIUM RELEASES (Ci/yr/unit)

Source	Expected Tritium Releases	Maximum Tritium Releases
Boric acid concentrator distillate vapor exhaust	501	998
HVAC systems exhaust	420	377
Total	<1224	<2347

11.1.4 NEUTRON ACTIVATION PRODUCTS

11.1.4.1 Nitrogen-16 Activity

Nitrogen-16 is produced by the $^{16}O(n,p)^{16}N$ reaction. Nitrogen-16 decays by beta emission and high energy gamma emission 78% of the time. The gamma energies are 6.13 Mev, 73% of the time and 7.10 Mev, 5% of the time. The nitrogen-16 half life is 7.13 seconds. The threshold energy for the reaction is 10.2 Mev.

The maximum nitrogen-16 activity at the pressure vessel outlet nozzle is 7.42(+06) disintegrations/cm^3-sec. This activity is applicable for stretch power conditions with the original steam generators (SG) and for power uprate conditions with replacement steam generators and is based on the following expression and reactor parameters.

$$\text{Activity (disintegrations/cm}^3\text{ - sec)} = \frac{\Sigma\varphi\left(1-e^{-\lambda\tau_c}\right)e^{-\lambda t_r}}{\left(1-e^{-\lambda t_t}\right)}$$

Where:

- $\sum\varphi$ is the reaction rate (dis/cm^3 - sec)
- t_c is the core transit time (sec),
- t_t is the total primary loop time (sec),
- t_r is the time from the active core outlet to the point of interest (sec to outlet nozzle) and
- λ is the decay constant (0.097 sec^{-1})

11.1.4.2 Carbon-14 Production

Carbon-14 is produced in the RCS by activation of O^{17} and N^{14} isotopes. The greatest amount of C^{14} is produced by the O^{17} (n,α) C^{14} reaction. A lesser amount of C^{14} is produced by the N^{14} (n, ρ) C^{14} reaction. The production of C^{14} from both sources can be calculated by using the following equation:

$$Q = N_o\ \sigma_o\ \phi\ \nu\ \rho\ t\ s$$

Where:

- N_o = atom concentration in the RCS water, (atoms gram H_2O)
- σ_o = thermal neutron cross section (cm^2)
- φ = thermal neutron flux, 4.4×10^{13} n / cm^2 - sec
- ν = effective core water volume, 2.46×10^7 cm^3
- p = coolant density, 0.64 grams/cm^3

t = full power run time for 1 cycle, 500 days (4.32×10^{7} sec)

s = 1.03×10^{-22} Ci / atom

Q = production rate, Ci / cycle

For C-14 production from O^{17} activation, $N_o = 1.24 \times 10^{19}$ atoms O^{17}/gram (H_2O) and $\sigma_o = 2.4 \times 10^{-25}$ cm^2 are used in the above equation. For carbon-14 production from N^{14} activation, $N_o = 1.07 \times 10^{18}$ atoms N^{14}/gram (H_2O) and σ_o 1.8×10^{-24} cm^2 are used in the above equation.

The production of C^{14} from these sources during one 500 day full power run time cycle will be 18.5 curies.

11.1.5 FUEL EXPERIENCE

Refer to CESSAR Section 11.1.5.

Fuel experience is discussed in Section 4.2.3.2.10. On the basis of experience, it is expected that the failed fuel fraction during normal operation will be less than 0.12 percent.

11.1.6 LEAKAGE SOURCES

Systems containing radioactive liquids or gases are potential sources of leakage to the environment. Liquid leakage is made up from such potential sources as pump seals and valve packings. Table 11.1-3A provides a listing of leakage values from valves and pumps. Leakage from systems containing potentially radioactive liquids is collected in radioactive sumps and sent to the liquid radwaste system (LRS).

Radioactive liquid leakage sources processed by the LRS are summarized in table 11.2-8.

Primary-to-secondary system leakage is expected to be less than 100 pounds per day under normal conditions. Leakage from the secondary system into the turbine building is expected to be less than 1700 pounds per hour of main steam and 5 gallons per minute of liquid from the condensate. The main steam leakage activity is assumed to become instantly airborne. Noble gases dissolved in the liquid leakage are assumed to become airborne, as they are for other buildings' liquid leakage. A partition factor (PF) of 0.0075 for iodines dissolved in plant liquid leakage is assumed for calculating airborne iodine activities. A PF of 0.1 is assumed for calculating airborne tritium activities from plant liquid leakage. A PF of 0.0001 is conservatively assumed for calculating airborne activities of other isotopes from plant liquid leakage.

A daily leakage rate of 3% of the noble gas inventory and 0.001% of the iodine inventory in the primary coolant is assumed released to containment atmosphere.

Airborne releases inside the plant are handled by the appropriate ventilation system. The containment, auxiliary, radwaste, turbine, and fuel building HVAC systems are discussed in section 9.4. Airborne activity in the plant is monitored by area monitors and airborne monitors before release from the plant. Airborne releases are discussed in subsection 11.3.3.

Means of controlling leakage from the reactor coolant pressure boundary are discussed in subsection 5.2.5.

Table 11.1-3A
LEAKAGE ASSUMPTIONS FROM C-E SUPPLIED EQUIPMENT

<u>Valves</u>	
Dish Leakage	10 cc/hr/inch Seat Diameter
Steam Leakage	10 cc/hr/inch Stem Diameter
<u>Pumps</u>	
Centrifugal	50 cc/hr
Positive displacement	1 gallon/hr
Flanges	30 cc/hr

11.1.7 FUEL POOL FISSION PRODUCT AND CORROSION PRODUCT ACTIVITIES

The fuel pool cooling and cleanup system (FPCCS) described in subsection 9.1.3 is comprised of two purification loops and one cooling loop with redundant heat exchangers. One purification loop and the cooling loop act on the spent fuel pool, and the other purification loop acts on the refueling pool. Since the loops return the flow to the respective pool from which flow was taken, the only exchange of water between the two pools is through the fuel transfer tube as a result of fuel transfer.

The primary source of activity in the pools is the reactor coolant water available for mixing with the refueling pool water upon reactor vessel head removal. Upon shutdown for refueling, the RCS is cooled down for a period of approximately 2 days until the reactor coolant temperature is less than 125F. During this time, the primary coolant is letdown through the CVCS system to degas and reduce radioactive impurities in the coolant. The gas space of the volume control tank is vented to help reduce fission gas activity and hydrogen concentration to

less than 5 cc/kg of water at STP before head removal. This letdown process, therefore, accomplishes the removal of combustible gases to safe levels and the removal of noble gases and dissolved fission and corrosion product activities. At the end of this cooldown and letdown period, the coolant above the reactor vessel flange is drained. The head is unbolted and the refueling pool is filled with 506,000 gallons of water from the refueling water tank. The remaining coolant volume of 68,100 gallons is then assumed to be instantaneously and homogeneously mixed with the water in the refueling pool and the 390,000 gallons in the spent fuel pool. After refueling, the spent fuel pool is isolated and the water in the refueling pool is returned to the refueling water tank. This series of events determines the total activity in the pools. Activities are all at a maximum at the start of refueling as it is conservatively assumed that reactor coolant water mixes with refueling pool and spent fuel pool water instantly and completely upon head removal. The maximum spent fuel pool activity level is defined as the activity that would result in the highest dose relative to the design of shielding structures. The expected and maximum refueling pool and spent fuel pool peak concentrations under the assumptions listed in table 11.1-4 are given in table 11.1-5. Equilibrium tritium concentrations given are based on the assumptions and methods presented in subsection 11.1.3.

The spent fuel pool activity contribution from stored defective fuel elements is assumed to be negligible. Due to the cooldown and letdown prior to refueling, the majority of the fission products available for release will evolve from the elements.

Table 11.1-4
ASSUMPTIONS USED IN DETERMINING REFUELING ACTIVITIES

No.	Assumption
1.	Expected case values are based on primary coolant activities given in Table 11.1-1C and maximum case values are based on primary coolant activities given in Table 11.1-1B. Specific radionuclides listed in Table 11.1.1B differ from those listed in Table 11.1.1C due to different models used to determine maximum versus expected case source terms.
2.	Water from the RCS, SFP and RWT is instantaneously homogeneously mixed upon removal of the reactor head.
3.	The spent fuel pool volume is 311,000 gallons.
4.	68,100 gallons of primary coolant are mixed with 506,000 gallons of refueling pool water and 311,000 of spent fuel pool water upon removal of the reactor head.
5.	Decontamination factors (DF) of purification equipment are: Xe,Kr,H,N / I,Br / Cs,Rb / Particulates / Others Fuel pool filter: 1 / 1 / 1 / 100 / 1 Fuel pool ion exchangers: 1 / 100 / 2 / 1 / 100
6.	Fuel pool purification train flowrate is 150 gallons per minute for both the refueling pool and the spent fuel pool.
7.	Activity losses due to evolution from the pool are negligible.
8.	Any Isotope with specific activity less than 1.0E-10 is considered to be insignificant and is not reported.

Decontamination factors (item 5):

	Xe,Kr,H,N	I,Br	Cs,Rb	Particulates	Others
Fuel pool filter	1	1	1	100	1
Fuel pool ion exchangers	1	100	2	1	100

Table 11.1-5

a. Specific radionuclides listed in CESSAR Table 11.1-1B differ from those listed in CESSAR Table 11.1-1C due to different models used to determine maximum versus expected case source terms.

b. A "-" indicates a radionuclide not in the source term list or is insignificant.

c. Values shown are representative of a core power of 3876 MWt with the original steam generators. For a core power of 3990 MWt with the replacement steam generators the values shown should be corrected by the ratio of core power.

11.1.8 SECONDARY SYSTEM SOURCES

The secondary system will become contaminated if steam generator tube leaks exist coincident with failed fuel. This primary-to-secondary leakage is expected to be less than 100 pounds per day. Secondary system steam and condensate leakage are listed in sections 11.3 and 11.2, respectively. Equilibrium secondary system activities in the steam generator liquid and steam, and in the main condenser hotwell, have been derived using assumed conditions of primary coolant activity, primary- to-secondary leakage, secondary system leakage, and certain secondary system process parameters, as listed in table 11.1-6.

Radionuclides will be removed from the secondary system by the following means:

- Steam generator blowdown demineralizer treatment
- Condensate polishing demineralizer treatment
- Radioactive decay
- Exhaust through the main condenser vacuum pumps
- Exhaust through the gland seal system
- Main steam leakage to the turbine building
- Condensate leakage to the turbine building sump
- Removal of nonrecyclable secondary samples

The model used to determine the secondary system activity concentrations is given in figure 11.1-2.

The set of equations developed from the model used to determine equilibrium secondary activities are:

Steam Generator Liquid Activity

$$X_L = \frac{Q\,X_p}{C_1 - \alpha K_{FT}\dfrac{B^2}{C_2} - K_{SG} R_3 - \dfrac{R_2}{DF_{PDM}}\left(K_{SG} C_4 + \dfrac{C_5 B}{C_2\,DF_{IX}} + \dfrac{K_{SG} C_3}{R_2 + \lambda M_{CON}}\right)} \tag{5}$$

Main Steam Activity

$$X_S = K_{SG}\,X_L \tag{6}$$

Main Condenser Hotwell Activity

$$X_2 = X_L\left(K_{SG} C_4 + \frac{C_5\,B}{C_2\,DF_{IX}} + \frac{K_{SG}\,C_3}{R_2 + \lambda M_{CON}}\right) \tag{7}$$

where:

$$C_1 = K_{SG} S + B + M_L \lambda$$

$$C_2 = \alpha B K_{FT} + (1 - \alpha) B + \lambda(M_{FTLIQ} + K_{FT} M_{FTVAP})$$

$$C_3 = R_5 - R_6/DF_{GSS}$$

$$C_4 = \frac{K_{AE} R_1 + R_4}{R_2 + \lambda M_{CON}}$$

$$C_5 = \frac{R_7}{R_2 + \lambda M_{CON}}$$

The parameters used in these equations are defined below:

X_P = primary coolant concentration (μCi/g)

X_L = steam generator liquid concentration (μCi/g)

X_S = main steam concentration (μCi/g)

X_2 = main condenser hotwell concentration (μCi/g)

Q = total primary-to-secondary leak rate (lbm/h)

S = main steam total flowrate (lbm/h)

B = total blowdown rate (lbm/h)

M_L = total mass of all steam generator liquid (lbm)

M_{CON} = mass of condenser hotwell (lbm)

M_{FTLIQ} = mass of blowdown flash tank liquid (lbm)

M_{FTVAP} = mass of blowdown flash tank vapor (lbm)

λ = isotopic decay constant (h^{-1})

α = mass fraction of blowdown that exits flash tank as vapor

DF_{IX} = Combined isotopic decontamination factor of blowdown demineralizers

DF_{PDM} = isotopic decontamination factor of condensate polishing demineralizers

DF_{GSS} = 1/fraction of gland seal system activity that exits system

K_{AE} = fraction of activity entering condenser that goes to hotwell

K_{SG} = steam generator internal partition coefficient

K_{FT} = flash tank internal partition coefficient

R_1 = main steam flowrate to main condenser (lbm/h)

R_2 = condensate flowrate (lbm/h)

R_3 = total extraction steam flowrate to high pressure feedwater heaters (lbm/h)

R_4 = total extraction steam flowrate to low pressure feedwater heaters (lbm/h)

R_5 = main steam flowrate to gland seal system (lbm/h)

R_6 = gland seal exhaust flowrate (lbm/h)

R_7 = blowdown flash tank condensate flowrate (lbm/h)

Assumptions used in determining the secondary system activities are listed in table 11.1-6. Expected and design basis secondary activities are given in table 11.1-7.

The equilibrium concentration of tritium expected to be present in the secondary system is 3.53E-05 μCi/cc, and is calculated based on the assumption and methods presented in subsection 11.1.3.

11.1.9 GASEOUS SOURCE TERM

As stated in Section 3.5 of the Environmental Report, there are no liquid releases from PVNGS. Therefore, the data required for the liquid source term calculation are not applicable to PVNGS. The data required for the gaseous source term calculation for PWRs using the format given in Chapter 4 of NUREG-0017, April 1976, "Calculation of Releases of Radioactive Materials in Gaseous and Liquid Effluents from Pressurized Water Reactors" are summarized on a per unit basis as follows:

Table 11.1-6
ASSUMPTIONS USED IN DETERMINING SECONDARY SYSTEM ACTIVITIES (Sheet 1 of 2)

No.	Assumptions		
1.	Primary coolant activities are per Table 11.1-1B for the maximum case and per Table 11.1-1C for the expected case.		
	Note: Specific radionuclides listed in 11.1-1B differ from those listed in Table 11.1-1C due to different models used to determine maximum versus expected case source terms.		
2.	Primary-to-secondary leak rate is 100 pounds per day for the expected case and 1 gallon per minute at primary coolant temperature for the maximum case.		
3.	Secondary system flowrates are as follows (note that the design blowdown rate is used for the maximum activities case and the expected activities case):		
		Expected Case	Maximum Case
	Steam flowrate (lb/h)	1.79E7	1.79E7
	Total blowdown rate (lb/h)	9.0E4	9.0E4
	High-pressure extraction steam flow rate (lb/h)	5.4E6	5.4E6
	Low-pressure extraction Steam flowrate (lb/h)	2.6E6	2.6E6
	Gland steal exhauster moisture flowrate = 310 lb/h		
	Steam leakage = 1700 lb/h		
4.	Secondary system masses are:		
	Total steam generator liquid mass = 3.55E5 lbm		
	Main condenser hotwell mass = 8.52E5 lbm		
	Blowdown flash tank liquid mass = 2.89E4 lbm

SOURCE TERMS

A. General

1. Maximum core thermal power is 4200 MWt (Table 11.1-1A).

2. Expected tritium released is 921 Ci/yr (Bounded by value reported in Section 1.11.3) (Table 11.1-1O).

B. Primary System

1. Normal primary coolant mass is 645,421 pounds (Table 11.1-1A).

2. Average letdown rate is 72 gallons per minute (Table 11.1-1A).

3. Average purification flow is 72 gallons per minute (Table 11.1-1A).

4. Average shim bleed flow is 0.725 gallon per minute (Table 11.1-1A).

C. Secondary System

1. Two vertical U-tube steam generators with iodine and nonvolatile carryover factor of 1/400

2. Total secondary steam flow is 1.79E+07 pounds per hour.

3. Mass of liquid per steam generator is 178,000 pounds.

4. Average primary-to-secondary leakage rate is as per NUREG 0017.

5. Average steam generator blowdown rate is 4.5E+04 pounds per hour per SG. Flashed steam from the

blowdown flash tank is returned back to the system via the number 4 feedwater heaters. Two blowdown demineralizers provide a total DF of 1 for noble gases, tritium, and nitrogen, 10 for Cs and Rb, and 100 for all others.

6. If the condensate demineralizers are in service, a DF of 1 is assumed to maximize the gaseous source term.

7. A detailed description of the condensate demineralizers is given in subsection 10.4.6.

D. Liquid Waste Processing Systems

As stated above, liquid source term data is not applicable to PVNGS. Refer to section 11.2 for a discussion of processing capability and system description.

E. Gaseous Waste Processing System

Gaseous source term data is provided in subsections 11.3.1 and 11.3.2, tables 11.3-4 and 11.3-7, and engineering drawings 13-N-GRF-001 and 01, 02, 03-N-GRP-001.

F. Ventilation and Exhaust Systems

Refer to subsection 11.3.3 for ventilation and exhaust data. In addition:

1. Data regarding provisions for reducing radioactivity releases through the ventilation or exhaust systems, DFs assumed, and their bases are provided in table 11.3-7.

2. Release rates are provided in table 11.3-6.

3. Data on release points are provided in PVNGS Environmental Report - Operating License Stage, Section 3.1.3.1. However, the condenser air removal system has since been routed to the plant vent.

4. The plant vent is a 72-inch x 84-inch rectangular duct discharging vertically. The fuel building exhaust is a 60-inch circular duct discharging vertically.

5. Containment building internal circulation filtration data are provided in subsection 9.4.6 and table 11.3-7.

11.2 LIQUID WASTE MANAGEMENT SYSTEMS

The liquid waste management systems consist of the secondary chemistry control system (SCCS), fuel pool cooling and cleanup system (FPCCS), and liquid radwaste system (LRS).

The SCCS and FPCCS are discussed in subsections 10.4.6 and 9.1.3, respectively. The liquid waste management systems are not shared between units.

Radioactive laundry is typically handled by private contractors. Some radioactive laundering may be performed on site using temporary laundering equipment. Liquid waste from on-site laundry activities is routed to the liquid radwaste system for processing. Administrative controls limit on-site laundry additives to prevent generation of mixed use waste.

11.2.1 DESIGN BASES

11.2.1.1 Design Objectives

The function of the liquid waste management systems is to collect and process radioactive or potentially radioactive liquid wastes generated during plant operation.

The principal design objectives of the liquid waste management systems are:

A. To collect liquid wastes generated during plant operation which contain potentially radioactive material.

B. To provide sufficient processing capacity, redundancy, and flexibility to meet the concentration limits of

10CFR20.1-20.601 during periods of equipment downtime and during operation at design basis fuel leakage.

C. To control releases of radioactive materials within the numerical design objectives of 10CFR50, Appendix I, in maintaining releases "as-low-as-is-reasonably-achievable (ALARA)."

D. To purify the radioactive liquid wastes to enable reclaimed water to be reused in the plant.

The liquid waste systems, as designed, contain items of reasonably demonstrated technology that, when added to the system and in order of diminishing cost-benefit return, can, for a favorable cost-benefit ratio, effect reductions in dose to the population reasonably expected to be within 50 miles of the site. Section 5.2 of the Environmental Report-Operating License Stage provides a summary of the results of the cost-benefit analysis performed to demonstrate that the design of the liquid waste system meets the ALARA guidelines set forth in Appendix I to 10CFR50.

A discussion of the ability of the liquid waste systems to provide sufficient capacity, redundancy, and flexibility to control wastes in order to prevent radioactive liquid releases and minimize solidified waste is given in subsection 11.2.2.

11.2.1.2 System Design

The components of the LRS are listed in table 11.2-1. Included are equipment sizes and/or capacities, process flowrates, storage capabilities, materials of construction, and design temperatures and pressures. Applicable codes and standards of

process equipment are listed in table 11.2-2. The ability of the SCCS, FPCCS, and LRS to process surge waste volumes in excess of the design assumptions is discussed in subsection 11.2.2.

The layout of LRS components is indicated in engineering drawings 13-P-OOB-002 through -011. The seismic and quality group classifications for the LRS components and piping are provided in table 3.2-1. There are no provisions or pathways for the release of radioactive liquids directly from the LRS to the environment.

NOTE

> Liquids with activity levels less than the release limits cited in the Offsite Dose Calculation Manual (ODCM) are discharged to the onsite evaporation ponds.

Equipment design provisions have been incorporated to reduce maintenance radiation exposure, equipment downtime, liquid leakage, and gaseous releases of radioactive materials to the building atmosphere. Where practical, welded connections are used in lieu of flanged ones. Butt welds and plug valves are used where justified in the liquid waste systems to reduce crud trap formation. Redundant or backup pumps and process lines allow for flushing and maintenance of mechanical components without restricting system operation. Pumps are provided with mechanical seals to minimize leakage. Less frequent equipment maintenance is provided for by utilizing corrosion-resistant materials.

a. Manufacturer's standard for the intended service. Hydrotesting is 1.5 times the design pressure.

Provisions have also been incorporated to control the release of radioactive materials due to overflows or leakage from potentially radioactive liquid tanks. Overflow of atmospheric tanks is minimized by the installation of level instrumentation and high level alarms that are annunciated in respective control rooms to alert operators of potential overflow situations. In addition, overflow lines of indoor tanks are routed to their respective building sump whose contents are sent to the LRS for processing. Overflow protection of outdoor LRS tanks is provided by interconnecting the overflow lines of the redundant tanks and routing the common flow to a sump, as in the case of the LRS recycle monitor tanks. There are no potentially radioactive pressurized tanks in the LRS.

Table 11.2-3 provides a list of the potentially radioactive LRS atmospheric tanks and the design provisions incorporated to prevent releases by the control of tank overflow. Control of liquid releases due to tank leakage is provided for by plant design. Indoor tanks are surrounded by curbs or are in compartments provided with thresholds to contain any leakage. Radioactive leakage is directed to the same sump as the tank overflow indicated in table 11.2-3. Outdoor LRS tanks, that is, the holdup tanks and recycle monitor tanks, are surrounded by a dike capable of preventing runoff in the event of a tank overflow. As discussed in subsection 2.4.13, release of the contents of the refueling water tank to the groundwater results in concentrations at the site boundary well below the maximum permissible concentrations in water listed in 10CFR20.1-20.601, Appendix B, Table II. The specific activities and total isotopic inventories in the outdoor LRS tanks are comparable

Table 11.2-3

LRS ATMOSPHERIC RADIOACTIVE TANK OVERFLOW PROTECTION

LRS Tanks	Location	Level Monitoring	Potential Overflow Alarm	Method for Containing Overflow
LRS Tanks				
High TDS holdup tanks				
LRN-TO1 A	Outside radwaste building	Radwaste control room (LI-4)[a]	Radwaste control room (LAHL-4)	Overflow from one LRS holdup tank flows to the other holdup tanks with the ultimate overflow of all three tanks directed to the radwaste building sump
LRN-TO1 B	Outside radwaste building	Radwaste control room (LI-5)	Radwaste control room (LAHL-5)	
Low TDS holdup tank				
LRN-TO1 C	Outside radwaste building	Radwaste control room (LI-6)	Radwaste control room (LAHL-6)	See above.
Chemical drain tanks				
LRN-TO5 A	Auxiliary building (elevation 51'6")	Radwaste control room (LI-18)	Radwaste control room (LAHL-18)	Overflow from one drain tank flows to the other drain tank with the ultimate overflow of both tanks directed to the auxiliary building nonengineered safety feature sump.
LRN-TO5 B	Auxiliary building (elevation 51'6")	Radwaste control room (LI-19)	Radwaste control room (LAHL-19)	
Recycle monitor tanks				
LRN-TO4 A	Outside radwaste building	Radwaste control room (LI-66)	Radwaste control room (LAHL-67)	Overflow from one monitor tank flows to the other tank with the ultimate overflow of both tanks directed to the radwaste building sump.
LRN-TO4 B	Outside radwaste building	Radwaste control room (LI-67)	Radwaste control room (LAHL-67)	
Concentrate monitor tanks				
LRN-TO3 A	Radwaste building (elevation 100')	Radwaste control room (LI-79)	Radwaste control room (LAHL-79)	Overflow from one concentrate tank flows to the other tank with the ultimate overflow of both tanks directed to the radwaste building sump.

a. Refer to engineering drawings 01, 02, 03-N-LRP-001, -002, -003.

to that in the refueling water tank. Radioactive liquid accumulating within the retention walls surrounding these outside tanks are directed to the same sump as the tank overflow indicated in table 11.2-3.

Liquid releases from the liquid waste management systems to the evaporation ponds are limited to releases of liquid with activity less than the release limits cited in the Offsite Dose Calculation Manual (ODCM). Liquid leakage from the waste systems is collected by gravity drainage in respective sumps. The contents of these sumps are pumped to the LRS holdup tanks. Liquid radioactive wastes are demineralized by ion exchange and distillation. Radioactive wastes unsuited for plant recycle are prepared for shipment in accordance with NRC and DOT regulations. Evaporative losses from the liquid waste systems are filtered and monitored by the plant ventilation systems prior to discharge to the plant vent.

11.2.2 SYSTEM DESCRIPTION

11.2.2.1 Secondary Chemistry Control System

The SCCS is described in section 10.4. High-conductivity regenerant solutions are produced as a result of blowdown demineralizer and condensate polishing demineralizer regeneration. If significant steam generator tube leaks exist coincident with failed fuel, which necessitates that the regenerants be processed by the LRS, they are processed via the high or low TDS tanks as required. The specific activities of the regenerant solutions, based on the assumptions given in table 11.2-4, are listed in table 11.2-5. Secondary chemistry

control system expected specific activities are also listed in table 11.2-5. Maximum radionuclide inventories of SCCS components are given in table 12.2-3.

Table 11.2-4
ASSUMPTIONS USED IN DETERMINING SCCS ACTIVITIES

Item	Assumption
1.	Reactor is operating with an expected activity level as given in Table 11.1-1C.
2.	Primary-to-secondary leak rate is per NUREG 0017, Rev 1
3.	Full flow condensate polishing demineralizers (CPD) are not online.
4.	Blowdown demineralizer decontamination factors (DF) are as per NUREG 0017, Rev 1
5.	Blowdown flowrate: Maximum downcomer blowdown flow for one Steam Generator

11.2.2.2 Fuel Pool Cooling and Cleanup System

The FPCCS is described in subsection 9.1.3. Fuel pool specific activities are listed in table 11.1-5, based upon design assumptions discussed in subsection 11.1.7. The expected specific activities of the FPCCS, based on the assumptions given in table 11.2-6, are listed in table 11.2-7. Maximum radionuclide inventories of FPCCS components are given in table 12.2-4.

Table 11.2-6
ASSUMPTIONS USED IN DETERMINING FPCCS ACTIVITIES

Item	Assumption
1.	Reactor operated prior to refueling with an expected RCS activity level as given in Table 11.1-1C.
2.	Initial activity in the SFP at the start of refueling is negligible.
3.	68,100 gallons of water with primary coolant is uniformly and instantly mixed with the RWT and SFP liquid upon head removal.
4.	Refueling pool and SFP activities listed in table 11.1-5 are the peak for the cycle, taken just after reactor vessel head removal
5.	The FPCCS purifies 150 gal/min from the SFP and 150 gal/min from the refueling pool in separate loops which return the flow to the pool from which it was taken.
6.	The fuel pool ion exchanger decontamination factors are Kr, Xe, H, / I, Br, / Cs, Rb, / Particulates, / Others DF = 1 / 100 / 2 / 1 / 100
7.	The fuel pool filter decontamination factors are: Kr, Xe, H, / I, Br, / Cs, Rb, / Particulates, / Others DF = 1 / 1 / 1 / 100 / 1
8.	Fuel pool ion exchanger outlet activities listed are based on peak refueling pool and spent fuel pool activities.

11.2.2.3 Liquid Radwaste System

Each unit of PVNGS is equipped with an identical and independent LRS. The principal functions of the LRS are:

A. To collect for processing radioactive and potentially radioactive liquid wastes from the plant.

B. To process liquid wastes to the high degree of purity necessary for recycle in the plant, since liquid releases are precluded by plant design.

C. To minimize the quantity of liquid waste transferred to the solid radwaste system for solidification and ultimate disposal.

The piping and instrumentation diagram (P&ID) of the LRS is shown in drawing numbers 01, 02, 03-N-LRP-001, -002 and -003.

Input waste streams to the LRS, are identified in table 11.2-8. This table includes annual average daily input flowrates and specific activities of the input streams as a fraction of primary coolant activity.

Input waste streams can be segregated to facilitate treatment. Wastes containing a high degree of total dissolved solids (TDS), including wastes from the chemical waste neutralizer tanks, chemical drain tanks, and the auxiliary, containment, radwaste, and fuel building sumps, are collected for processing in the high TDS holdup tank or in the low TDS tank. Wastes containing a low degree of TDS, including radioactive wastes from the turbine building, auxiliary steam condensate receiver tank, LRS adsorption bed, and recycle monitor tanks, are collected for processing in the high TDS tank or low TDS holdup

Table 11.2-8
WASTE INPUTS TO THE LRS (Sheet 1 of 2)

LRS Inputs	Expected Flow (gal/d-unit)	Design Flow (gal/d-unit)	Activity[a]
<u>High TDS Holdup Tanks</u>			
Containment sump	530	530	[b]
Auxiliary building floor drains	200	200	0.1 PCA
Chemical drain tank	440	440	See chemical drain tank inputs
Laboratory drains	400	400	0.002 PCA
	700	700	0.001 PCA
Total	2270	2270	
<u>Low TDS Holdup Tank</u>			
Turbine building floor drains	7,200	7,200	100% of main steam activity
Secondary system samples	1400	1400	100% of main steam activity

a. PCA = primary coolant activity.
b. 20 gpd @ 0.1 PCA, 10 gpd @ 1.67 PCA, and 500 gpd @ 0.001 PCA.

Table 11.2-8
WASTE INPUTS TO THE LRS (Sheet 2 of 2)

LRS Inputs	Expected Flow (gal/d-unit)	Design Flow (gal/d-unit)	Activity
Low TDS Holdup Tank (cont.)			
Total	8600	8600	
Chemical Drain Tanks			
Decon station waste plus showers	40	40	NUREG 0017
Primary system samples	200	200	0.05 PCA
Handwash Sink Drains	200	200	NUREG 0017
Total	440	440	

tank. Samples from the high and low TDS tanks are available by placing the tanks in a recirculation lineup and drawing a sample of the pump discharge. Turbine building drains are normally nonradioactive, activity being present only when there are primary-to-secondary leaks. To avoid processing more waste through the LRS than necessary, nonradioactive turbine building drains are processed by the chemical waste system. Besides the low TDS tank, an additional holdup tank is provided to accommodate overflow from either the low TDS or the high TDS holdup tank and is normally isolated from the supply headers. If necessary, this tank can be used to collect either low TDS or high TDS liquid waste. An internal mixing header uniformly mixes the contents of each holdup tank prior to and during processing. Acidic or caustic agents may be added for pH control, and antifoaming agents may be added if surfactants exist in the tank contents. Decontamination facility wastes from Unit 1 only and radio-chemistry laboratory wastes are collected in the chemical drain tanks prior to processing.

High TDS wastes are pumped directly from the holdup tank to the LRS evaporator for processing. The evaporator concentrates the waste up to 50 wt% total dissolved solids excluding neutralized boric acid which is concentrated up to 25 wt%. The evaporator concentrate is pumped to the concentrate monitor tanks and ultimately to the solid radwaste system. The concentrate monitor tanks are kept in a continuous recirculation mode while they contain radioactive concentrate. Samples are taken from an analysis point off the pump discharge. The distillate from the evaporator is passed through the LRS adsorption bed and mixed bed ion exchangers arranged in series and then is sent to

the recycle monitor tanks. The monitor tanks' liquid content is then stored for eventual use as makeup for the primary coolant system, the secondary system, or the spent fuel pool. The monitor tanks' contents may also be sent back to the low TDS holdup tank should further processing be desired.

Low TDS wastes are pumped from the holdup tank through the LRS ion exchanger prefilter for removal of larger particles, through the adsorption bed for removal of organics, and through the two mixed bed ion exchangers arranged in series for removal of trace radioisotopes, to the recycle monitor tanks. Waste from the low TDS tank may also be processed by the LRS evaporator in the same manner as High TDS.

Wastes collected in the chemical drain tanks are normally pumped to the high TDS or low TDS holdup tank for processing.

Boric acid from the chemical volume and control system (CVCS), although normally processed through the boric acid concentrator and sent to the refueling water tank, can also be processed through the LRS evaporator should the boric acid concentrator become nonfunctional. When processing boric acid, the LRS evaporator receives CVCS flow from the CVCS holdup tank pumps. Concentrated boric acid is sent to the concentrate monitor tanks and then to approved portable processing equipment. Distillate is sent to the adsorption bed and mixed bed ion exchangers for further processing and is eventually used as plant makeup water.

The LRS may also receive concentrated boric acid from the CVCS boric acid concentrator, should it be desired to dispose of the boric acid. In this case, concentrator bottoms are sent to the

LRS concentrate monitor tanks and ultimately to approved portable processing equipment.

Spent resin from the beds is sluiced with water from the reactor water makeup tank and is pumped to either the low activity or high activity spent resin tanks, or to a portable waste processing system. New resin for the mixed bed demineralizers is added manually from a drum containing new resin.

Liquid radwaste system expected process point specific activities, based on the assumptions given in table 11.2-9, are listed in table 11.2-10. Maximum LRS component inventories are listed in table 12.2-5.

11.2.2.4 Operating Procedures

Operation of the liquid waste management systems consists of a series of automatic and operator-controlled operations.

Collection is generally accomplished automatically, and processing paths are selected by the operator. To reduce the potential for radioactivity being introduced into the condensate storage tank, PVNGS procedures stipulate that the LRS recycle monitor tanks must be sampled prior to pumping down to the condensate storage tank. Besides the normal processing paths, certain other paths are incorporated for the changeout of specified equipment and the switching to redundant equipment.

Table 11.2-9
ASSUMPTIONS USED IN DETERMINING LRS ACTIVITIES

Item	Assumption				
1.	LRS waste inputs are as per table 11.2-8.				
2.	Primary coolant activity is as per Table 11.1-1C.				
3.	Equipment parameters are as per table 11.2-1.				
4.	Both the low TDS holdup tank and a high TDS holdup tank are processed simultaneously.				
5.	Decontamination factors (DF) of LRS process equipment are as follows:				
		Nobel Gases, Tritium	Halogens	CS,RB	Other
	LRS ion exchanger prefilter	1	1	1	1
	LRS adsorption bed	1	1	1	1
	First LRS mixed mixed bed demineralizer	1	100	2	100
	Second LRS mixed bed demineralizer	1	10	10	10
	LRS evaporator (feed:distillate)	1	10^3	10^4	10^4

Table 11.2-10

A filter remains online until the pressure drop across it reaches the design limit. When the limit is reached, the process flow is either stopped or diverted to a redundant filter. The filter cartridge is then replaced by the method described in subsection 11.4.2.

A demineralizer remains online until the pressure drop across the vessel reaches the design limit, the resin bed is exhausted, or when the shift manager or control room supervisor determines it necessary to place the demineralizer offline. When the demineralizer is to be changed out, the process flow is terminated, the vessel isolated, and spent resin sluiced to the low activity spent resin tank, the high activity spent resin tank, or to the portable waste processing system. New resin is manually loaded into the vessel and processing continues.

The evaporator is operated on either a batch or semicontinuous basis, depending upon the system load. In the event of evaporator outage, liquid can be processed via ion exchange.

Operations of the SCCS and FPCCS are discussed in detail in subsections 10.4.6 and 9.1.3, respectively.

11.2.2.4.1 LRS Operation

The LRS is normally utilized to process floor and equipment drains. During periods of primary-to-secondary leakage, however, the LRS may also receive and process wastes generated in the turbine building, such as floor drains and demineralizer regenerants. Design inputs to the LRS are tabulated in table 11.2-8. The LRS can be divided into three process

trains; those liquids containing a low degree of total dissolved solids, those containing a high degree of total dissolved solids, and those containing chemicals. The LRS is designed so that the three trains may operate simultaneously.

Although the LRS is designed to separate the low and high degree of total dissolved solids, the current operations of the low and high TDS holdup tanks do not separate the inputs. As a result of this, all TDS holdup tanks are currently processed as high TDS waste described in section 11.2.2.4.1.2.

11.2.2.4.1.1 Low Total Dissolved Solids Wastes. The low TDS holdup tank normally collects wastes from the turbine building sump as shown in engineering drawings 01, 02, 03-N-LRP-001, -002 and -003. This sump contains radioactivity when steam generator tube leaks exist coincident with failed fuel. The primary sources of this sump are equipment and floor drains and condensate polishing and blowdown demineralizer regenerants. Other infrequent low TDS inputs include flows from the auxiliary steam condensate receiver tank, and the recycle water monitor tanks. Flow from the LRS adsorption bed may also be recirculated to the low TDS holdup tank if necessary for further removal of organics. When the low TDS holdup tank has been filled (as indicated by a high level alarm in the radwaste control room) or reaches some predetermined level, the contents are then recirculated and sampled for radiological and chemical analysis. Based on the analysis, acid, caustic, or an antifoaming agent is added, if necessary. The holdup tank contents are then recirculated for uniformity of flow composition while a portion of the flow is processed through an

ion exchanger prefilter, the LRS adsorption bed, and two mixed bed demineralizers arranged in series, and is finally sent to the recycle monitor tanks. The prefilter removes large particles, the adsorption bed removes organic contaminants, and the mixed bed demineralizers remove ionic species. Demineralized water collected in the recycle monitor tanks is then stored until needed for plant makeup or recycled to the low TDS holdup tank for further processing. Flow from the low TDS holdup tank is normally terminated manually upon a low level alarm, but is terminated automatically upon a low-low level signal. Flow is terminated or diverted to an alternate path by operator action based on a high-pressure drop across the prefilter, adsorption bed, or ion exchangers, an exhausted resin bed, or when the shift manager or control room supervisor determines it necessary. Low TDS waste may also be processed with the LRS evaporator in the same manner as high TDS waste described in section 11.2.2.4.1.2 below.

11.2.2.4.1.2 High Total Dissolved Solids Wastes. The high TDS holdup tank normally collects radioactive wastes from the auxiliary building, fuel building, containment radwaste and radwaste building sumps, the chemical waste neutralizer tank, and the chemical drain tanks. When the high TDS holdup tank has been filled (as indicated by a high level alarm in the radwaste control room) or reaches some predetermined level, the contents are then recirculated and sampled for radiological and chemical analysis. Based on the analysis, acid, caustic, or an antifoaming agent is added, if necessary. The holdup tank contents are then recirculated for uniformity of flow

composition while a portion of the flow is pumped directly to the LRS evaporator for processing. The evaporator is designed to operate on a batch or semicontinuous basis and the process flow is concentrated up to 50 wt% total dissolved solids excluding neutralized boric acid which is concentrated to 25 wt%. When the desired concentration is achieved, as indicated by evaporator density instrumentation, the evaporator concentrate is pumped to the concentrate monitor tanks and then to approved portable processing equipment. Evaporator distillate is further processed by the adsorption bed and mixed bed demineralizers before reaching the recycle monitor tanks. Flow from the high TDS holdup tank is normally terminated manually upon a low level alarm, but is terminated automatically upon a low-low level signal. A low-low TDS tank level signal will also shift the evaporator to standby. Flow is terminated or diverted to an alternate path by operator action based on evaporator or holdup pump malfunction, high-pressure drop across the adsorption bed or ion exchangers, an exhausted resin bed, or when the shift manager or control room supervisor determines it necessary.

11.2.2.4.1.3 Chemical Wastes. The chemical drain tanks collect potentially radioactive liquids from the radiochemistry lab and the decontamination facility (Unit 1 only) as shown on engineering drawings 01, 02, 03-N-LRP-001, -002 and -003. Normally these wastes are sent to the high TDS holdup tank for processing.

11.2.2.4.1.4 Abnormal Operation. The LRS design inputs are listed in table 11.2-8 and the design assumptions are listed in

table 11.2-9. Inputs in excess of those tabulated for the design basis operation can be caused by a single isolated occurrence condition, such as back-to-back refueling or equipment outages. Each 30,000-gallon high or low TDS holdup tank has sufficient capacity to allow for a waste evaporator outage of 48 hours concurrent with abnormal secondary chemistry requiring one condensate polishing demineralizer regeneration per day under the following conditions:

- Availability of the LRS ion exchanger processing capability.
- The online LRS holdup tanks are 50% full.
- The waste neutralizer tanks are full.
- Normal inputs continue to accumulate.

However, should additional capacity be required, the second high TDS holdup tank will accommodate the additional input.

Most LRS process equipment is backed up by redundant equipment within the LRS itself. Liquid radwaste system holdup tanks, chemical drain tanks, recycle monitor tanks, concentrate monitor tanks, and prefilters are all redundant. At least two redundant pumps are available for each service, with the exceptions being the evaporator main recirculation pump, the recycle monitor pump, and the evaporator steam condensate pump. The capability of further demineralization is provided by the option to recirculate flow through the demineralizers as many times as necessary. During equipment outages, the redundant equipment ensures that the liquid waste can be processed for

recycle to the plant or can be sent to portable processing equipment for packaging and disposal.

Vendor connections are available to allow processing of TDS Holdup Tank contents prior to entering the evaporator and during an evaporator outage or malfunction.

11.2.3 RADIOACTIVE RELEASES

During processing by the liquid waste management systems, radioactivity is removed so that the bulk of the liquid is restored to clean water which is recycled for plant use. The radioactivity removed from the liquids is concentrated in filters, ion exchange resins, and evaporator bottoms. The concentrated wastes are processed for packaging and eventual shipment to an approved offsite disposal location. There are no provisions or significant pathways for the release of radioactive liquids to the environment from PVNGS. All liquid waste is either processed and recycled for plant use or prepared for shipment in accordance with NRC and DOT regulations.

NOTE

> Liquids with radioactivity levels less than the release limits cited in the Offsite Dose Calculation Manual (ODCM) are discharged to the evaporation ponds. Therefore, evaporation pond leakage represents a potential (though insignificant) liquid release pathway. Liquid releases due to evaporation or through ground pathway will not exceed the concentration or dose limits for effluents in 10CFR20.1001-20.2401, Appendix B, Table 2, Column 2 and 10CFR50.

This page intentionally left blank

11.3 GASEOUS WASTE MANAGEMENT SYSTEMS

Separate gaseous waste management systems are provided for each unit of Palo Verde Nuclear Generating Station (PVNGS). The systems are:

A. The gaseous radwaste system (GRS) which collects and stores for decay high activity gases vented from station processing equipment.

B. Low activity waste gas systems which filter waste gas prior to release to the atmosphere. The low activity waste gas systems are the building ventilation exhaust systems, the condenser air removal system, and the turbine gland sealing system.

The condenser air removal system and the turbine gland sealing system are described in subsections 10.4.2 and 10.4.3, respectively.

The building ventilation systems are described in section 9.4. The low activity waste gas systems design is not discussed in this section, except for those portions of the systems relating to gaseous waste management.

11.3.1 DESIGN BASES

11.3.1.1 Gaseous Radwaste System Design Bases

The GRS collects and processes radioactive or potentially radioactive waste gas. This gas, containing primarily hydrogen, is collected and stored in an oxygen-free system to guard against a hydrogen explosion and to allow for radioactive

decay. The GRS has been sized to provide the capability of holding radioactive gas for a 45-day decay period.

After holdup, as appropriate, the stored gases are sampled and then discharged at a controlled rate through a filter and a radiation monitor to the radwaste building exhaust. The radwaste building exhaust dilutes and filters the waste gas prior to release through the plant vent. The GRS limits the release of gaseous activity so that personnel exposure and activity releases in restricted and unrestricted areas are as low as is reasonably achievable (ALARA) within the guidelines set forth in 10CFR50, Appendix I.

11.3.1.1.1 Gaseous Radwaste System Equipment Description

The GRS is comprised of a collection header, a waste gas surge tank, two waste gas compressors, and three waste gas decay tanks. One compressor normally is used while the other is on standby. The waste gas surge tank accommodates gas surge volumes and allows for intermittent compressor operation. The waste gas decay tanks allow for radioactive decay. Subsequent to decay, the gas is discharged through a filter and a radiation monitor at a controlled rate to the ventilation exhaust for dilution prior to discharge. Radiation monitoring is provided on the discharge line from the waste gas decay tanks and on the main plant vent as described in section 11.5. The discharge line radiation monitor is interlocked to shut the discharge line isolation valves on high radiation level. The building ventilation exhaust systems are described in sections 9.4 and 12.2.

Components of the GRS are listed in table 11.3-1. Included are equipment flowrates and/or capacity, material of construction, and the design temperatures and pressures. All of the GRS equipment is similar to equipment that has been successfully used in other nuclear plant radwaste systems. The basic flow diagram of the GRS is shown in engineering drawing 13-N-GRF-001, and the piping and instrumentation diagram of the GRS is shown in engineering drawings 01, 02, 03-N-GRP-001.

The equipment layout of the GRS is presented as part of the radwaste building equipment layout in engineering drawings 13-P-OOB-002 through -011. The layout provides design features consistent with the recommendations of NRC Regulatory Guide 8.8 to minimize occupational radiation exposure to plant personnel. Waste gas compressors, surge tank, and gas decay tanks are segregated and shielded in separate compartments. In addition, nitrogen purging removes radioactive gases from components requiring maintenance. This aids in reducing radiation exposure to the operator. Redundant compressors minimize downtime of the system.

Table 11.3-1
GASEOUS RADWASTE SYSTEM PROCESS EQUIPMENT DESCRIPTION

Equipment	Quantity	Flowrate/ Capacity	Material of Construction	Design Pressure/ Temperature (psig/°F)
Gas surge tank	1	760 ft^3	Carbon steel with plastic lining	380/200
Compressors	2	10 std ft^3/min	Stainless steel	380/150
Waste gas decay tank	3	760 ft^3	Carbon steel with plastic lining	380/200

Piping runs are located in shielded pipe chases. Drain line routings prevent accumulation of drainage inside the piping. Local samples are drawn into a centrally-located sampling station, which is provided with a nitrogen purge and process piping shielding to minimize radiation exposure to the operator.

The maximum GRS component inventories are listed in table 12.2-5.

Sizing of the GRS is based on the most severe anticipated operational occurrences that could occur during normal operation as demonstrated in table 11.3-2. The volume of gas to be stored is determined by calculating the gas generated in the most restrictive time period in the core cycle.

During this 30-day interval, it is assumed that the gas stripper operates continuously, the volume control tank is vented twice, the reactor drain tank is vented continuously and

one RCS degassing occurs. Based on these assumptions, the GRS has capacity for a minimum of 45 days holdup, including anticipated operational occurrences. Calculated radioactive releases (see subsection 11.3.3) assume a 45-day holdup even though the average holdup time may be far greater.

11.3.1.1.2 Codes and Standards

Codes and standards applicable to the gaseous waste management system are listed in table 11.3-3. The GRS is located in the non-Seismic Category I radwaste building.

The GRS is designated as a non-Seismic Category I system with the exception of the containment isolation valves and connecting piping which are Seismic Category I. The gas decay tanks, compressors, surge tank, and interconnecting piping from the tanks, through and including the first normally closed isolation valve, are non-Seismic Category I, ANSI safety class 3, and Quality Group D (augmented).

11.3.1.1.3 Valves

Manual, remotely operated, and automatic valves used in the GRS are designed to minimize gas leakage. Engineering features such as diaphragms, bellows seals, and soft seats are employed in the system to prevent or minimize leakage. Each valve in the GRS is designed to meet the temperature, pressure, and code requirements for the specific application for which it is used.

Table 11.3-2
GASEOUS RADWASTE SYSTEM DESIGN ASSUMPTIONS

Item	Normal or Expected	Design
Primary system normal degassing	Continuous operation of gas stripper on letdown flow of 72 gal/min and 30 cc/kg dissolved gas (0.32 standard ft^3/min)	Continuous operation of gas stripper on letdown flow of 72 gal/min and 30 cc/kg dissolved gas (0.32 standard ft^3/min)
Plant degassing	One plant degassing per year (275 standard ft^3/year)	One plant degassing during the 30-day interval (275 standard ft^3)
Volume control tank	One venting per year (408 standard ft^3 per venting)	Two ventings per 30-day interval (816 standard ft^3 per interval)
Reactor drain tank	Continuous venting at 0.02 standard ft^3/min	Continuous venting at 0.02 standard ft^3/min

11.3.1.1.4 Compressors

Each compressor employs a double-diaphragm arrangement with an additional leak detection spacer diaphragm located between the two main diaphragms. Failure of either the top or bottom diaphragm results in a pressure increase in the leak detection spacer. The rise in pressure triggers a pressure switch, initiates an alarm, and automatically trips the compressor. The compressor is then shut down and isolated for repairs, and the standby compressor is started. As long as the second diaphragm remains intact, there is no possibility for gas to leak in or out of the system at this point. Only in the unlikely event of simultaneous failure of both diaphragms does the potential for leakage exist.

Table 11.3-3
EQUIPMENT CODES, GASEOUS RADWASTE SYSTEM

EQUIPMENT	CODES			
	Design and Fabrication	Materials[a]	Welder Qualifications and Procedure	Inspection and Testing
Tanks	ASME Code Section VIII, Div. 1	ASME Code Section II	ASME Code Section IX	ASME Code Section VIII Div. 1
Compressors	Manufacturer's[b] Standards	ASME Code Section II or Manufacturer's Standard	ASME Code Section IX (as required)	ASME[c] Section III, Class 3; or Hydraulic Institute
Piping and valves	ANSI B31.1	ASTM or ASME Code Section II	ASME Code Section IX	ANSI B31.1
Gaseous discharge filter and gas compressor prefilter	ASME Code Section VIII, Div. 1	ASME Code Section II	ASME Code Section IX	ASME Code Section VIII, Div. 1

a. Material manufacturer's certified test reports were obtained whenever possible.

b. Manufacturer's standard for the intended service. Hydrotested to 1.5 times the design pressure.

c. ASME Code Stamp and material traceability not required.

11.3.1.1.5 Instrumentation

The GRS instrumentation is shown in engineering drawings 01, 02, 03-N-GRP-001. The oxygen analyzers are discussed in subsection 9.3.2. The GRS radiation monitors are discussed in section 11.5. Compressor instrumentation necessary for operation can be read at a local panel outside the compressor room. Remote indication and alarms are provided in the radwaste system control panel area in the radwaste building. Gaseous radwaste system alarm conditions are retransmitted to the main control room.

The automatic isolation valves in the decay tank discharge header are interlocked to close on high radiation signals from the waste gas header monitor, high discharge flow, or low radwaste building exhaust flow. Therefore, even during the improbable instance where the discharge valve from the wrong decay tank is inadvertently opened, the release would be automatically terminated when the radiation setpoint is exceeded. The resultant activity released to the environment would be within plant technical specification limits for radioactive gaseous releases.

11.3.1.1.6 Hydrogen Control

The major sources of hydrogen in the GRS are the off-gases from the gas stripper, the volume control tank, and the reactor drain tank. These sources will produce a gas consisting primarily of hydrogen and nitrogen with trace quantities of oxygen and fission gases. These sources are piped to the waste gas surge tank from which gas is compressed into decay tanks.

The GRS and its input sources are initially purged at plant startup with nitrogen. The surge tank and gas surge header are monitored for oxygen, and hydrogen is assumed to be greater than 4% when in service as described in subsection 9.3.2. The oxygen analyzer continually samples upstream of the surge tank at the surge header and at the gas surge tank. An alarm on high oxygen (2%) from either of these sources is annunciated in the main control room and in the radwaste control room. Operating personnel can be dispatched to mitigate the situation via nitrogen dilution, purge, etc. An alarm on high-high oxygen (3.75%) from either of these sources is annunciated in the main control room and in the radwaste control room. Under these conditions the waste gas compressors will automatically trip, and nitrogen will be automatically injected into the GR system down stream of the check valve V-003. Automatic nitrogen injection will isolate the system and dilute oxygen concentration down stream of check valve V-003 (from the check valve to holdup tanks) to less than four percent per volume. In addition, low surge tank pressure automatically initiates an alarm to alert operating personnel of a tank leak which could potentially result in oxygen inleakage to the system. Thus, it is not necessary for the waste gas surge header, surge tank, decay tanks, valves, piping, and compressors to be designed to withstand an internal hydrogen explosion.

After a suitable storage period, the gas is released to the radwaste building exhaust vent, through a split path. The primary path is controlled by a flow controller at a rate of 45 standard cubic feet per minute or less. The secondary path flows through a pressure reducer to allow flow through a

radiation monitor at approximately 5 standard cubic feet per minute. The total release rate is 50 standard cubic feet per minute or less. The release rate is governed by the requirements of 10CFR20.1-20.601 and 10CFR50, Appendix I. The air flowrate through the vent is 25,500 standard cubic feet per minute, which results in a hydrogen concentration of less than 1%, well below the combustion limit of hydrogen in air. The gaseous discharge isolation valves will automatically shut on high discharge flowrate, low radwaste building exhaust, or high radiation level in the discharge line.

Potential buildup of hydrogen in the ventilation exhaust systems can come from storage tanks that contain liquids previously processed through the gas stripper. Consequently, with a gas stripper efficiency of 99.9% and a maximum hydrogen pressure of 50 psig (administrative limit) in the volume control tank, the maximum hydrogen concentration that can exist in the gas space above a liquid surface downstream of the gas stripper is 0.44%, well below the combustion limit of hydrogen in air.

Another potential source of hydrogen is liquids fed to the equipment drain tank and chemical drain tanks, but these will contain only small quantities of dissolved hydrogen. The sources of dissolved hydrogen in these tanks are reactor coolant system leakage and reactor coolant system samples.

These liquid sources release most of their dissolved hydrogen while being depressurized from system pressure to atmospheric pressure. This liquid is then diluted with other drains that contain no dissolved hydrogen.

Thus, the contents of the equipment drain tank and chemical drain tanks contain a low concentration of dissolved hydrogen at atmospheric pressure, precluding a hydrogen buildup in the gas space over the liquid surface of these tanks.

11.3.1.1.7 Cost-Benefit Analysis

Refer to Appendix 5B of the Environmental Report - Operating License Stage for the cost-benefit analyses.

11.3.1.2 Low Activity Waste Gas Systems

Low activity waste gases are routed to building vents through particulate filters. Personnel exposures and activity releases from these wastes in restricted and unrestricted areas are within the ALARA guidelines set forth in 10CFR50, Appendix I, when combined with the releases from the GRS.

11.3.2 SYSTEM DESCRIPTIONS

11.3.2.1 Gaseous Radwaste System

As shown in the GRS piping and instrumentation diagram (01, 02, 03-N-GRP-001), the GRS has a collection header, a waste gas surge tank, two waste gas compressors, and three waste gas decay tanks. One compressor is normally used, while the other is on standby. Liquid seals are not incorporated in the system design.

Sources for the GRS include the gases from:

- Reactor drain tank
- Volume control tank

- Refueling failed fuel detectors
- Gas stripper
- Reactor vessel vent

The high activity gases accumulate in the waste gas surge tank and are compressed and stored in the waste gas decay tanks. When the surge tank pressure reaches 3 psig, the compressor selected for operation starts automatically and starts charging the online decay tank. If the surge tank pressure reaches 3.5 psig, the standby compressor will automatically start. Operation of either compressor automatically stops when the surge tank pressure decreases to 1.5 psig, corresponding to a compressor suction pressure of 0.5 psig. When decay tank pressure reaches 350 psig, an alarm is actuated and compressor operation is terminated manually. Identical compressors are provided to minimize system downtime.

Each decay tank is sampled prior to discharge. No special mixing is considered necessary for the gas. Each sample is analyzed for radioactivity and the concentration, volume, and total radioactivity are recorded. Isotopic content of the waste gases is determined and recorded as specified in the station manual procedures.

The maximum rates and quantities of radionuclides released from the gaseous waste decay tanks will be in accordance with the limits imposed by the plant technical specifications. The rate of release from the decay tanks into the ventilation exhaust is limited so as not to exceed the release limits of 10CFR20.1-20.601. Releases are conducted to meet the ALARA objectives of 10CFR50, Appendix I.

Each tank is capable of being isolated. Only one tank is valved into operation at any one time to diminish the amount of radioactive gas that can be released due to a postulated rupture of a decay tank or connected piping.

Gaseous radwaste system capacity is based on the design assumptions listed in table 11.3-4. The sources, annual volume, and average flowrate into the GRS are shown on table 11.3-4 for maximum design operation assuming continuous gas stripping.

Bounding activity inputs to the GRS are listed in table 11.3-5. These inputs are based on reactor coolant gaseous activities shown in Table 11.1-1C. To maximize the activity into the GRS tanks the gas stripper is assumed to degas the primary coolant for 8.2 hours immediately prior to shutdown. This model was selected to yield upper bound sources. More detailed models which account for actual operation are less conservative.

11.3.2.2 Condenser Air Removal System

The mechanical operation and description of the condenser air removal system is discussed in subsection 10.4.2. The piping and instrumentation diagrams that indicate processing equipment, normal flow paths through the system, redundancy in equipment, system interconnections, and seismic and quality group interfaces are also presented in subsection 10.4.2.

11.3.2.3 Turbine Gland Sealing System

The mechanical operation and description of the turbine gland seal system are discussed in subsection 10.4.3. The piping and

instrumentation diagrams that indicate processing equipment, normal flow paths through the system, redundancy, system interconnections, and seismic and quality group interfaces are also presented in subsection 10.4.3.

Table 11.3-4
MAJOR SOURCES, VOLUMES, AND FLOWRATES OF
GASES TO THE GASEOUS RADWASTE SYSTEM

Source	Gas	Annual Volume (Standard ft^3)	Maximum[a] Flowrate (Standard ft^3/min)	Annual Flowrate (Standard ft^3/min)
Volume control tank	H_2	2,500		0.006
	N_2	610	20	0.002
	O_2	65		1.6E-4
Gas Stripper[b]	H_2	142,000		0.338
	N_2	2,950	20	0.007
	O_2	40		9.5E-5
Reactor drain tank	H_2	0		0
	N_2	7,759	20	0.02
	O_2	0		0
Refueling failed fuel detector	H_2	0		0
	N_2	2,000	20	0.005
	O_2	0		0

a. Flowrates are estimated expected maximums, not continuous.

b. Gas stripper values assume continuous gas stripping.

[1]Contributions from particulate isotopes are negligible due to partitioning in the VCT, RDT and Gas Stripper. Only Noble Gasses and Halogens are reported.

11.3.2.4 Building Ventilation Systems

The plant building ventilation systems discharge radioactive gaseous waste resulting from equipment leakage and are discussed in section 9.4. The radioactive sources are discussed in section 12.2.

11.3.3 RADIOACTIVE RELEASES

Expected annual releases from the GRS were estimated for normal operations using failed fuel corresponding to ANSI N237. The input activities are defined in subsection 11.3.2. The holdup time is considered to be 45 days. Results are shown in table 11.3-6. Estimated releases from the condenser air removal system, turbine gland sealing system, containment building, auxiliary building, fuel building, and turbine building for component activities which0 are consistent with ANSI N237 are also listed in this table. Expected effluent site boundary concentrations are also listed in table 11.3-6. These concentrations are based on the worst sector annual average atmospheric dispersion factor, presented in section 2.3.

Table 11.3-7 lists the assumptions that are used to calculate the airborne releases. Source terms and assumptions based upon Regulatory Guide 1.112, Revision 0, are used where appropriate.

During normal operation, including transients associated with anticipated operational occurrences, the potentially

significant points of airborne radioisotope releases are:

- Plant vent stack
- Fuel building ventilation exhaust
- Turbine building

Condensate	0.0075[a]
Main condenser vacuum pump/ gland seals	0.0075[a]
Expected primary coolant activity (PCA)	As per Table 11.1-1C
Expected secondary system activity	As per table 11.1-7
Expected tritium releases	As per table 11.1-3

a. From NUREG-0017

Table 11.3-7
ASSUMPTIONS FOR ESTIMATING RADIOACTIVE RELEASES (PER UNIT)
(Sheet 2 of 3)

Item	Assumption
Gaseous radwaste system input activity	As per table 11.3-5
Mass of primary coolant, lb	6.454×10^5
Filter efficiencies	
HEPA, %	95(b)
Charcoal, %	70(c)(d)
Flows using HEPA filters	Containment normal exhaust Auxiliary building exhaust Turbine building vacuum pump exhaust Radwaste building exhaust
Flows using charcoal filters	Containment normal exhaust Turbine building vacuum pump exhaust
Containment parameters	
Net free volume, ft^3	2.6×10^6
Purge rate (power access), ft^3/min	1200

b. Conservative assumption to allow for up to 1% HEPA bypass and penetration leakage

c. Regulatory Guide 1.140

d. Conservative assumption to allow for up to 1% carbon absorber bypass and penetration leakage (Refer to generic letter 83-13).

Table 11.3-7
ASSUMPTIONS FOR ESTIMATING RADIOACTIVE RELEASES (PER UNIT)
(Sheet 3 of 3)

Item	Assumption
Power access purge frequency, No./yr	51
Power access purge duration, h	16
Purge rate (refueling)	33,000
Auxiliary building parameters	
Net free volume, ft^3	13.7×10^5
HVAC exhaust flowrate, ft^3/min	58,400[d]
Turbine building parameters	
Net free volume, ft^3	7.13×10^6
HVAC exhaust flowrate, ft^3/min	474,160[d]
Boric acid concentrator distillate discharged, gal/y	358,000 as vapor[e]
Chemical and volume control system parameters	As per section 9.3.4
Gaseous radwaste system parameters	
Discharge rate, standard ft^3/min	50
Gas decay tank holdup time, d	45
Turbine gland seal exhauster moisture flowrate, lb/h	310

e. The discharge rate is based on the amount of primary water that must be discharged to maintain tritium airborne concentrations in the most restrictive building to a less than one-half of the 10CFR20.1-20.601 MPC limit for restricted areas. The discharge rate is not a function of water usage but rather a function of the RCS tritium production rate and the equilibrium tritium concentration at which the RCS is maintained. Refer to section 11.1.3.2.1 for additional information concerning tritium production and release.

11.3.3.1 Plant Vent Stack

The auxiliary building and radwaste building ventilation exhausts and containment purge exhaust are all directed to the plant vent alongside the turbine building. Exhaust to the atmosphere is vertical at 145 feet above grade. The effluent velocity is a minimum of 2000 feet per minute and has a maximum temperature of 120F.

11.3.3.2 Fuel Building Ventilation Exhaust

The fuel building ventilation exhaust is directed to a cylindrical vent in the roof of the fuel building. Exhaust to the atmosphere is vertical at 116 feet above grade. The vent is designed for a minimum effluent velocity of 2000 feet per minute, and has a maximum temperature of 120F.

11.3.3.3 Turbine Building Ventilation Exhaust

The operating deck of the turbine building exhausts to four power roof ventilators located on top of the turbine building. The turbine building lube oil room, demineralizer room and battery room exhaust through their own exhaust fans to the outside atmosphere. The turbine building exhaust to the atmosphere is through four cylindrical, 97-inch ID vents. Exhaust to the atmosphere is vertical at 248.7 feet above grade. The vents are designed for a minimum effluent velocity at 2000 feet per minute, and have a normal temperature of 120F.

11.3.3.4 Condenser Air Removal System

Air and noncondensable gases are removed from the shell side of the condenser by four mechanical vacuum pumps. Normally three

vacuum pumps are operating, with one pump drawing air from each condenser shell and the fourth pump is in standby. The vacuum pumps discharge to atmosphere via the plant vent unless radioactivity is detected by the radiation monitor in the discharge line. If radiation is detected, the vacuum pump discharge is automatically shifted to a charcoal adsorption train consisting of a moisture separator, electric heater, prefilter, activated charcoal filter, post-exhaust filter, and post-exhaust filter blower. The exhaust is routed to the plant vent, at 2400 feet per minute (minimum). The charcoal adsorption train electric heaters add heat as required to maintain 20F of superheat in the exhaust line.

11.3.3.5 Turbine Gland Sealing System Exhaust

The turbine gland sealing system exhausts to the same exhaust stack as the condenser vacuum pumps and normally exhausts directly to atmosphere, but will automatically shift exhaust paths to the charcoal adsorption train on high radioactivity.

11.3.3.6 Dilution Factors

Atmospheric dispersion (X/Q) factors are discussed in detail and tabulated in section 2.3. For annual releases, the worst sector annual average X/Q is used to calculate offsite concentrations.

11.3.3.7 Estimated Concentrations

Effluent site boundary concentrations for the total system are compared with 10CFR20.1-20.601 in table 11.3-6 for normal operation at failed fuel corresponding to ANSI N237. This

table demonstrates that the 10CFR20.1-20.601 limits are met. This also meets the intent of 10CFR50, Appendix A, GDC 60.

11.3.3.8 Estimated Doses

Estimated doses from gaseous releases are presented in Appendix 5B of the Environmental Report - Operating License Stage.

11.4 SOLID WASTE MANAGEMENT SYSTEM

Solid waste management is provided by the solid radwaste system (SRS) which is designed to provide holdup and transfer capabilities for radioactive waste streams generated by plant operation, and to store these wastes until they are shipped offsite for processing or disposal. The system is located in the radwaste building, which is designated to withstand an operating basis earthquake. In addition to the SRS, there are two facilities which supplement solid waste management capabilities. The Dry Active Waste Processing and Storage (DAWPS) facility provides a centralized location for handling, processing, packaging, and storage of radioactively contaminated trash and maintenance of radioactive contaminated plant equipment in accordance with the requirements of 10 CFR Part 20 and NRC Generic Letter 81-38. The Low Level Radioactive Material Storage Facility (LLRMSF) provides an interim storage capacity for radioactive materials prior to reuse, shipment for processing or disposal, or transfer to other licensees.

11.4.1 DESIGN BASES

The design bases of the solid waste management system are:

A. The SRS provides the capability for processing and packaging concentrated waste solutions from the miscellaneous waste evaporator, spent resins from radioactive ion exchangers, and chemical drain tank wastes.

B. The SRS provides a means for packaging and disposal of spent radioactive cartridge filters and solid wastes from the LRS and CVCS.

C. The SRS provides a means of compacting and packaging miscellaneous dry radioactive materials, such as paper, rags, contaminated clothing, gloves, and shoe coverings, and a means for packaging contaminated metallic materials and incompressible solid objects, such as small tools and equipment parts.

D. The SRS provides a method of processing and packaging blowdown demineralizer resin and condensate polishing resin in the event that they become contaminated.

E. The DAWPS facility provides a centralized location for handling, processing and storage of radioactive laundry and material used or generated during the operation and maintenance of PVNGS. Maintenance activities may also be performed at the DAWPS facility in accordance with the requirements of 10 CFR Part 20. The radioactive material includes dry active waste (DAW) and plant components undergoing maintenance. The total radioactive inventory of all radioactive material in the DAWPS facility is limited to 15 curies.

DAW generated at PVNGS is packaged and shipped for off-site vendor processing or direct disposal. Some DAW may be compacted on site with the radwaste baler. Potentially contaminated dry waste is monitored in the DAWPS facility and released for disposal.

F. The LLRMSF provides for the interim storage of low-level radioactive material generated at PVNGS in accordance with Generic Letter 81-38. Radioactive material will not be processed in the LLRMSF. Liquid radioactive material and/or mixed waste will not be stored in the facility.

The shielding design is sufficient to satisfy the criteria established in 10CFR20 and 40CFR190. ALARA principles were emphasized during the configuration/ layout of the storage area. The storage area is accessible by a crane and/or forklift. The facility contains storage racks and an underground vault. A HVAC filtration system is available to minimize a release of potentially airborne radioactive material (i.e., container breach).

A control room is provided for monitoring the storage area (video camera) and is the central location for entry and exit into the Radiological Controlled Area (RCA). A RCA yard is provided on the outside of the LLRMSF building. A restricted area fence surrounds the LLRMSF building and the RCA yard.

G. The Old Steam Generator/Old Reactor Vessel Closure Head Storage Facility (OSG/ORVCHSF) provides long-term on-site storage of large contaminated components that are byproducts of nonroutine maintenance activities. Specifically, the OSG/ORVCHSF is designed to safely store the six Old Steam Generators and three Old Reactor Vessel Closure Heads (with

associated Control Rod Drive Mechanisms) for Unit 1, 2, and 3. The Old Steam Generators Storage facility is designed and built to Uniform Building Code (UBC) and ACI 318. The Building seismic category is provided in Table 3.2-1.

The maximum and expected input volumes to the SRS from each source of solid waste material are presented in table 11.4-1. The SRS input activities associated with the expected input volumes are presented in table 11.4-2.

Codes and standards applicable to the solid radwaste system are listed in table 3.2-1.

Collection, solidification, packaging, and storage of radioactive wastes will be performed so as to maintain any potential radiation exposure to plant personnel to as low as is reasonably achievable (ALARA) levels, consistent with the recommendations of Regulatory Guide 8.8 and within the dose limits of 10CFR20.1001-20.2401. Some of the design features incorporated to maintain ALARA criteria include remote system operation, remotely actuated flushing, quick disconnect, equipment layout permitting the shielding of components containing radioactive materials, and use of shielded casks for in-plant movement of high activity waste. Additional ALARA provisions of the SRS are described in section 12.1.

Packaging and transport of radioactive wastes will be in conformance with 10CFR71. Packaged wastes will be shipped in conformance with 49CFR170-178. Collection, solidification, packaging, and storage of radioactive wastes will be performed in conformance with 10CFR50.

Table 11.4-1
SRS INPUT VOLUMES (PER UNIT)

Source (Form)	Expected Volume (ft^3/yr)	Maximum Volume (ft^3/yr)	Bases
Wet Waste			
Evaporator concentrates	3,224	69,877	Regulatory Guide 1.112 April 1976
Spent resin	430	430	Reference 1
Chemical drain tank	0	294	Note 1
Blowdown demineralizer resin	0	282	Note 2
Condensate polishing resin	0	1,872	WASH 1258
Dry Waste			
Compactable and noncompactable dry wastes	11,091	11,091	AIF/NESP-008 (2)
Filters			
Cartridge filters (dry)	10.3	34.2	Reference 1
Total (ft^3/yr)	14,755	83,880	

Notes: 1. The chemical drain tank contents are normally processed by the liquid radwaste system. Maximum volume is based on an additional complete flush of each tank directly to the SRS per year.

2. Blowdown demineralizer resin is not normally changed more than once per year. Maximum volume is based on change out of both demineralizers during one year.

11.4.2 SYSTEM DESCRIPTION

11.4.2.1 General Description

The SRS is subdivided into four subsystems:

- Spent resin transfer subsystem
- Wet waste processing subsystem
- Dry waste disposal subsystem
- Filter handling and disposal subsystem

The original waste solidification subsystem (Hittman Nuclear) has been abandoned in place. The Hittman solidification subsystem remains installed in the plant, but the descriptive text related to its operation has been deleted. The description of the waste solidification subsystem has been replaced with a description of the wet waste processing subsystem. This subsystem consists of bypass lines that allow wet wastes to be transferred to portable processing equipment.

Plant layout drawings illustrating the packaging, storage, and shipping areas of the radwaste building are presented in engineering drawings 13-P-OOB-003 and -004. The equipment capacities of the SRS and its input streams are presented in table 11.4-3. The SRS piping and instrumentation diagram number is 01, 02, 03-N-SRP-001, -002 and -003. The process flow diagram of the SRS is found on drawing 13-N-SRF-001.

11.4.2.2 Component Description

A description of the SRS components is given in table 11.4-3 and equipment codes are given in table 11.4-4. The following is a functional description of the major system components:

A. Spent Resin Tanks

The high activity and low activity spent resin tanks are provided to hold up spent resin for decay prior to processing by the wet waste processing subsystem. Resin removal from the tanks is through a line which begins near the dilution nozzles at the bottom of the tank and exits at the top of the tank. Dilution water is injected at the bottom head near the resin removal line to facilitate dilution and mixing of the resin as the slurry enters the resin outlet pipe. Resin flow into the tanks is via the inlet pipe through the top head.

The capacity of the spent resin tanks is high enough to allow the simultaneous change out of all the high activity ion exchangers in one tank and one of each of the low activity ion exchangers in the other. Air or nitrogen connections are provided as a backup method for fluidizing the ion exchanger and spent resin tank beds.

B. Resin Transfer/Dewatering Pump

The resin transfer/dewatering pump is a progressive cavity pump which provides sluicing water to transfer resin from the auxiliary building and radwaste building ion exchangers to the spent resin tanks. The pump also dewaters the spent resin tanks. Sizing of the resin transfer/dewatering pump was based on the minimum slurry velocity needed to transport resin in suspension.

C. Shipping Containers and Shields

Shipping containers and transportation casks, used to transport radioactive material offsite, whether leased or purchased, will be in accordance with applicable DOT and NRC regulations. Shields used to transfer or store radioactive material onsite are not required to meet DOT or NRC regulations.

D. Radwaste Baler (Dry Waste Compactor)

The radwaste baler located in the low level storage area is used to package low-radiation level, solid compressible wastes into standard 55-gallon drums. The primary function of the baler is to reduce the volume of wastes that often contain a large void space. Potentially airborne radioactive material which escapes from the drum during compaction is exhausted by the baler exhaust fan through a HEPA filter into the low level storage area. The drums of compacted waste are moved by the bridge crane, forklift, or dolley and stored in the appropriate storage areas depending on dose rates and disposal options.

11.4.2.3 System Operation

11.4.2.3.1 Liquid Waste and Spent Resin Disposal

The wet waste processing subsystem operates on a batch basis to process evaporator concentrates, and spent resins. The system is designed to transfer and store spent blowdown demineralizer resin and spent condensate polishing resin if required.

Table 11.4-3

Disposable liners	Consum-able	Boxes: 54.3-3000 ft^3 Drums: 55-89 gals Liners/HIC: 14.8-285.1 ft^3	Varies per Specifications
Radwaste baler (SRN-M01)	1	55-gallon drums	Carbon steel and stainless steel

Table 11.4-4
EQUIPMENT CODES

Equipment	Codes		
	Design and Fabrication	Materials[a]	Inspection and Testing
Pressure vessels	ASME Code Section VIII, Div. 1	ASME Code Section II	ASME Code Section VIII, Div. 1
Atmospheric or 0 to 15 psig tanks	ASME Code[b] Section III, Class 3, or API 620 & 650, AWWA D-100	ASME Code[b] Section II	ASME Code[b] Section III, Class 3 or API 620; 650 AWWA D-100
Piping and valves	ANSI 31.1	ASTM or ASME Code Section II	ANSI B 31.1
Pumps	Manufacturer's[c] Standards	ASME Code Section II or Manufacturer's Standard	ASME Code[b] Section III Class 3; or Hydraulic Institute

a. Material manufacturer's certified test reports were obtained whenever possible.

b. ASME Code Stamp and material traceability not required.

c. Manufacturer's standard for the intended service. Hydrotesting is 1.5 times the design pressure.

Sufficient capacity is provided to process radioactive wastes resulting from normal plant operations and anticipated operational occurrences.

Liquid waste solutions are processed by using approved technologies and procedures. Spent resins, including spent blowdown and condensate polisher resins, if required, are processed by transferring the resin into an approved disposal container and dewatering and drying the resin to meet burial requirements.

Liquid inputs from the concentrate monitor tanks and the spent resin tanks are fed into portable processing equipment and packaged into disposal containers or shipped off-site for further processing by a vendor.

The containers are surveyed for external contamination. If surface contamination is detected, the container is decontaminated as necessary. The containers are then moved to appropriate storage area for decay while awaiting shipment to a burial facility.

Complete waste processing and absence of free liquid prior to shipment is assured by the implementation of a process control program consistent with the recommendations of Branch Technical Position ETSB 11-3. The process control program is described and controlled in departmental procedures. Potential waste overflows are contained in the processing area to facilitate cleanup. Bypass lines and connections are provided to enable spent resins from the spent resin tanks and the radwaste and auxiliary building ion exchanger to be sent directly to portable processing equipment or disposal container located in

the truck bay area. In addition, a bypass of the spent resin tanks is provided to allow sluicing directly from the ion exchangers in the radwaste and auxiliary buildings to the portable processing equipment connection in the truck bay area.

11.4.2.3.2 Dry Waste Disposal

Dry waste, components, and equipment that have been contaminated during operation or maintenance are handled, processed, and packaged by qualified plant personnel or by outside contractors specializing in such activities.

11.4.2.3.3 Filter Handling and Disposal

The filters are separated into two classifications:

- Cartridge type filters with disposable elements
- Unshielded low activity filters with disposable elements

The following are cartridge type filters:

- One reactor makeup water filter (subsection 9.3.4)
- One boric acid filter (subsection 9.3.4)
- One reactor drain tank filter (subsection 9.3.4)
- Two seal injection filters (subsection 9.3.4)
- Two fuel pool filters (subsection 9.1.3)
- Two liquid radwaste system filters (subsection 11.2)
- Two purification filters (subsection 9.3.4)

The cartridge filters are located in shielded compartments in the auxiliary building. Filters that constitute a substantial radiation source are accessed from above by removing a concrete shield plug and replacing it with a working lead shield plug. (See engineering drawing 13-P-OOB-004 for filter locations.)

The filter vessel pressure seal is opened and the filter cartridge is lifted through a small hole in the working shield into the filter transfer cask. The lifting operation is done using a lifting winch and grapple attached to the transfer cask. After the filter cartridge is inside the transfer cask, the monorail hoist places the transfer cask onto the bottom section which is then pinned to the transfer cask. The transfer cask is then transferred via monorail to the radwaste building high level storage area. The monorail sets the transfer cask on the laydown area where the bottom section is unfastened. The transfer cask is placed over an empty space in a storage container or over the opening in a disposal container. Typically, filters are accumulated in a storage container until sufficient filters are available for packaging. After a disposal container has been filled with filters, the container is capped and decontaminated as necessary. The container is then transferred to an appropriate storage area to await shipment to a processing facility or, to a burial facility.

The following are unshielded low-activity filters:

- Two waste gas compressor prefilters (section 11.3)
- One gaseous radwaste system discharge filter (section 11.3)

- One blowdown demineralizer filter (subsection 10.4.6)

The gaseous radwaste system (GRS) filters are located in the radwaste building (elevation 140 feet) shown on engineering drawing 13-P-OOB-005. To change a GRS filter, it is isolated, drained, purged with nitrogen, and vented. The vessel flanged cover is opened and the filter element is manually transferred to the solid radwaste area for processing. The blowdown demineralizer filter is located outside the turbine building. To change it, the filter is drained, vented, manually changed, and transferred for storage or disposal. Unshielded low-activity filters are normally changed on high-differential pressure; however, radiation surveys performed allow changing frequencies to be adjusted to minimize man-rem exposure.

11.4.2.4 Packaging, Storage, and Shipment

All radioactive wastes will be prepared for shipment in containers which meet the requirements of U.S. Department of Transportation (DOT) and NRC regulations. Wet wastes are processed to an acceptable form for disposal or shipped in accordance with NRC and DOT regulations to a licensed waste processor. Dry, solid wastes are packaged in acceptable containers for processing or disposal.

All containers are capped prior to interim storage and offsite shipment.

Shielded transportation casks will be used when required.

Packaged radwaste is stored in a storage area and shielded as necessary. Unused, uncontaminated shipping containers are stored in allocated storage areas onsite. The solid radwaste

storage area is segregated into high-level and low-level storage areas. The shielded storage area for high-level solid radwaste contains 945 square feet (42 large containers stacked two high or 294 drums stacked two high) of usable floor area. The low-level storage area contains 350 square feet of usable floor area. Both the high and low level storage areas are designed to allow a 30-day decay of the expected annual waste volumes shown in table 11.4-5 prior to shipment offsite.

Containers can normally be shipped immediately after filling, provided the proper shielding is available, without exceeding DOT radiation limits. If 49CFR173 dose limitations cannot be met with the available shielding, the liners are stored and allowed to decay until the appropriate shielding is available. Onsite storage for decay of short-lived radionuclides is accomplished both prior to processing in liquid storage tanks and after processing in the waste storage area.

The maximum and expected annual volumes, including estimated curie content, of solid radwaste to be shipped offsite are given in tables 11.4-5 and 11.4-6 based on the following assumptions:

A. Evaporator concentrates are processed and stored in an appropriate storage area for 1 month (i.e., 1-month decay) prior to shipment.

B. Spent resin beads are stored for 6 months prior to drying. Resin is stored in an appropriate storage area for 1 month (i.e., 1-month decay) prior to shipment.

C. Cartridge filters are packaged and stored in the appropriate storage area for 1 month (i.e., 1-month decay) prior to shipment.

11.4.2.5 Dry Active Waste Processing and Storage (DAWPS) Facility

The DAWPS facility is designed to provide centralized handling, processing, packaging, and storage of radioactively contaminated trash generated during the operation and maintenance of PVNGS. The performance of maintenance on radioactively contaminated plant equipment may also be performed in the DAWPS facility in accordance with the requirements of 10 CFR Part 20. The contaminated trash, dry active waste (DAW), is composed of rags, paper, plastic, rubber, wood, glass, concrete, and metal and is, for the most part, low in its content of radioactivity.

The DAWPS facility serves as the centralized location for processing of contaminated trash, temporary storage of radioactive materials, tools, and interim storage of package waste until shipment to a burial site. The facility is a prefabricated metal building of approximately 17,500 square feet and approximately 60,000 cubic feet of storage space.

The building is divided in three basic compartments: 1) storage area, 2) processing area, and 3) offices and change area.

The DAWPS storage area provides storage for dry active waste (DAW), and other radioactive materials, such as tools and equipment. Radioactive material is packaged into containers

that meet NRC and/or DOT requirements for shipping or disposal. All storage drums and boxes are decontaminated before being placed into the waste storage area. Ventilation for this area shall be provided by the use of natural draft through louvers and an extractor fan. Packages are stored in accordance with administrative controls to ensure that exposures are maintained ALARA and within 10CFR20.1001-20.2401 and administrative limits.

The processing area contains the sorting, processing, and a receiving area for incoming material to be processed, an emergency eye-wash station, and an analytical work area (smear station). The processing area is equipped with a ventilation supply fan and evaporative cooler. The air return system is provided with prefilters, HEPA filters, and an access porthole for radiation monitoring equipment. While processing radioactive materials or performing maintenance on equipment, the processing area is maintained under negative pressure in relation to offices, storage, and outside areas, or administrative controls employed to ensure against the release of unmonitored airborne radioactivity.

Heating and cooling of the offices and restroom/locker room is accomplished by the use of air conditioning equipment.

Radiation protection for the DAWPS facility is as per section 12.5, Radiation Protection Program.

11.4.2.6 Low Level Radioactive Material Storage Facility (LLRMSF)

The LLRMSF is designed to store radioactive material and equipment generated only at PVNGS. The radioactive material to be stored in this facility will only be solid or dried materials. The LLRMSF consists of one building, approximately 21000 square feet, within a rectangular fenced restricted area. The interior spaces includes a truck bay with loading dock for handling of materials, a 30 ton bridge crane, a low level radioactive material warehouse, and a higher low level radioactive material below grade storage vault. A Control Room will serve for remote operations of the bridge crane.

The construction of the facility is of 24 inch concrete walls up to 16 feet above the warehouse floor. The wall thicknesses reduces to 10 inches above 16 feet and continues to the roof. The roof construction is prefabricated concrete tees and an additional layer of a minimum of 2 inches of concrete poured on top. Internal to the facility, the Control Room is constructed of 24 inch concrete walls, with a 4 inch prefabricated concrete roof. All walls, roofs, and the storage vault lids are considered radiation barriers.

Although the facility is an independent structure away from the power block, it still interfaces with several Plant systems. The following is a list of those systems:

Electrical	Security Alarm
Fire Protection Water	Domestic Water
Fire Alarm	Communication

HVAC equipment is provided to maintain environmental parameters and habitability. A heat pump is provided for the storage area and truck bay area to maintain environmental temperatures suitable for the areas. An exhaust fan equipped with efficiency pre-filters, HEPA filters and an access porthole for radiation monitoring equipment is provided to maintain the storage and truck bay areas under a negative pressure to the Control Room and outside areas. This is to ensure against an unmonitored or unfiltered air release.

A separate heat pump is provided for the Control Room to maintain a comfortable environmental condition suitable for occupancy. Outside make-up air is provided to maintain the Control Room under a positive pressure relative to the storage and truck bay areas.

Radiation protection of the LLRMSF is as per section 12.5, Radiation Protection Program.

11.4.2.7 Old Steam Generator and Old Reactor Vessel Closure Head Storage Facility (OSG/ORVCHSF)

The OSG/ORVCHSF provides long-term on-site storage of large contaminated components that are byproducts of non-routine maintenance activities. Specifically, the OSG/ORVCHSF is designed to safely store the six Old Steam Generators, three Old Reactor Vessel Closure Heads with associated Control Rod Drive Mechanisms, and three reactor head lift rigs for Unit 1, 2, and 3. The design features, building description, and the radioactive material contents of the OSG/ORVCHSF are described in Section 12.2.1.9.

11.5 PROCESS AND EFFLUENT RADIOLOGICAL MONITORING AND SAMPLING SYSTEMS

The process and effluent radiological monitoring systems monitor and furnish information to operators concerning activity levels in selected plant process systems and plant effluents. The area radiation monitoring instrumentation, also described in this section, supplements the personnel and area radiation survey provisions of section 12.5 to ensure proper personnel radiation protection.

The systems consist of permanently-installed sampling and/or monitoring devices together with a program and provisions for specific routine sample collections and laboratory analyses. The overall systems are designed to assist the operator in evaluating and controlling the radiological consequences of normal plant operation, anticipated operational occurrences, and postulated accidents. Resultant radiation exposures and releases of radioactive materials in effluents to unrestricted areas for normal operation are maintained as low as is reasonably achievable.

11.5.1 DESIGN BASES

11.5.1.1 Normal Operations and Anticipated Operational Occurrences

11.5.1.1.1 Process Monitoring System

The process monitoring system is designed to perform the following functions:

A. Provide assistance to operators to ensure the proper functional performance of the selected systems being monitored.

B. Provide for early detection of radioactive leakage into normally nonradioactive systems, including primary-to-secondary leakage, primary-to-atmosphere leakage, and process system leakage into normally non-radioactive systems. Included is the capability of both the containment building gaseous channel and the containment building particulate channel each to detect independently an increase in the reactor coolant system-to-containment atmosphere leak rate as two of the methods of leak detection required to follow the recommendation of NRC Regulatory Guide 1.45, except as noted in section 1.8.

C. Provide continuous remote indication and recording of airborne radioactive contamination in the form of particulates and iodines in areas where personnel normally have access, except in areas where the potential for airborne activity releases is negligible, in order to follow the recommendations of NRC Regulatory Guide 8.8 for control of occupational exposure to radiation.

11.5.1.1.2 Effluent Monitoring System

The effluent monitoring system is designed to perform the following functions in order to meet the requirements of

10CFR20.1- 20.601, 10CFR50, and follow the recommendations of Regulatory Guide 1.21 during normal operations, including anticipated operational occurrences:

A. Provide continuous representative sampling, monitoring, recording, and indication of gaseous radioactivity levels, and, as a minimum, continuous representative sampling of particulate and iodine radioactivity levels along principal effluent discharge paths.

B. Provide the capability, during the release of gaseous wastes from the waste gas decay tanks, to alarm and initiate automatic closure of the waste gas discharge valve before the limits of the Technical Specifications are exceeded.

C. Provide radiation level indication and alarm annunciation to the control room operators whenever Technical Specification limits for release of radioactivity are approached or exceeded.

D. For continuous effluent paths, provide a means for collection and laboratory analysis of required routine samples.

E. For batch releases, provide a means for collection and laboratory analysis of required routine samples prior to release.

11.5.1.1.3 Area Monitoring System

The area monitoring system is designed to perform the following functions in order to meet the requirements of 10CFR20.1-20.601, 10CFR50, Appendix A, and 10CFR70.24 and follow the recommendations of Regulatory Guides 8.2, 8.8, and 8.12 during normal operations, including anticipated operational occurrences:

A. Immediately alert plant personnel entering or working in nonradiation or low radiation areas of increasing or abnormally high radiation levels which, if unnoticed, could possibly result in inadvertent overexposures.

B. Inform the control room operator of the occurrence and approximate location of an abnormal radiation increase in nonradiation or low radiation areas.

11.5.1.1.4 Criteria for Location of Area Monitors

A. Areas that contain a liquid, gaseous, or particulate radiation source that potentially can produce a dose rate during normal operation greater than 2.5 mrem/h (zones 3, 4, and 5) are provided with an area monitor unless one of the following conditions exists:

   1. Another area monitor in the vicinity is capable of monitoring the area; there is line-of-sight access between the monitor and the area in question, and the monitor alarm point would be the same value for all areas served. An example would be the

compressed waste storage area and the full drum delay storage area which are served by one area radiation monitor.

2. The frequency of personnel access to the area is minimal, which is defined as access required only for infrequent repairs, unscheduled maintenance, or periodic surveillance. Examples would be the piping penetration rooms and the shutdown cooling heat exchanger areas. (Portable monitors are used to monitor such areas during personnel access.)

3. The probability of accidental release within the area is minimal; i.e., an area with only sealed containers or where the material in the space during normal operations has a low activity level. These areas include the volume control tank area and the recycle water monitor tank pump area.

4. Process monitors are provided that perform a function equivalent to an area radiation monitor in an area in which gaseous or airborne particulate activity is the major constituent. An example would be the radwaste building ventilation systems which are provided with gaseous process monitors to monitor for leakage from the waste gas compressors and waste gas decay tank valves.

B. Areas in which the new and spent fuel is received and stored, specifically the containment and fuel building, are provided with detectors which indicate

and alarm in the presence of abnormal radiation levels.

C. The location of each area radiation detector is indicated on the radiation monitor location figures 11.5-1 through 11.5-6. The radiation monitor location figures indicate the general location of the equipment, which may vary from unit to unit.

11.5.1.2 Postulated Accidents

The process, effluent, and area monitoring systems, collectively referred to as the radiation monitoring system (RMS), are designed to perform the following functions in order to meet the requirements of 10CFR50, 10CFR100, and follow the recommendations of NUREG-0737 and NRC Regulatory Guides 1.13, 1.97, and 8.12 for postulated accidents:

A. Provide the capability to alarm and initiate containment purge isolation in the presence of high airborne radioactivity within the containment which could potentially cause an offsite dose in excess of 10CFR100 limits.

B. Provide the capability to alarm and initiate isolation of the fuel building from the normal ventilation system and actuation of fuel building essential ventilation in the unlikely event of a fuel handling accident in the fuel building.

C. Provide the capability to alarm and initiate isolation of the control room normal ventilation system and

actuation of control room essential filtration in the unlikely event that radioactivity is introduced into the control building intake plenum.

D. Provide long-term, post-accident monitoring of ventilation exhaust from the auxiliary building ESF equipment areas following a loss-of-coolant accident.

E. Inform the control room operator of the occurrence and approximate location of abnormal radiation increases in a zone adjacent to the containment containing piping, electrical, or hatch penetrations.

F. Inform the control room operator and personnel in the immediate vicinity of the monitor of an abnormal radiation increase inside buildings where access is required to service equipment important to safety post-accident.

G. Provide long-term, post-accident monitoring of effluents from the plant vent, fuel building vent, main condenser vent, and the main steam relief and atmospheric dump valves.

11.5.2 SYSTEM DESCRIPTION

The installed radiation monitoring system was supplied as two separate orders. As consequence, there are differences in design and configuration. References to each order appear as "old scope" and "new scope". The old scope equipment includes monitors in loops 1, 2, 4, and 5 (see engineering drawing

13-N-997-184), and all of the portable air moveable units. New scope monitors comprise loops 3, 6, and 7.

Some of the major differences between the two configurations include remote versus local mounting of the control microcomputer and indication and control panel type and nomenclature.

Old scope monitors have the detection and/or sampling equipment and microcomputer included as part of the same assembly, while new scope monitors separate these assemblies. Further, the microcomputers, while providing similar functions, are electronically different.

Indication and display panels are also different. For old scope monitors, these include local indication and control (LIC), portable indication and control (PIC), and remote indication and control (RIC) units. New scope monitors employ KELIC's, KEPIC's, and KERIC's to fulfill these same functions. For control on a local basis (at the skid) some new scope monitors also offer a KESMIC or skid mounted indication and control unit. These new and old scope display units are not interchangeable. Additionally, old scope unit alarms are designated as "high" and "high high", corresponding to new scope "alert" and "high" functions.

Specific differences between new and old scope configurations are described in the system operation/maintenance manuals. Only general information as to function and capability will be referenced here.

In addition to the “old scope” and “new scope” equipment, the steam generator blowdown discharge monitors are installed with a local microcomputer which is connected to the system via a communications translator in loop 3.

11.5.2.1 Continuous Process, Effluent and Area Radiation Monitoring and Sampling

The requirements of the system design bases for continuous monitoring are satisfied by an integrated, microcomputer-based system of monitor channels with the associated sampling and auxiliary equipment as noted in table 11.5-1. Several detector channels are provided as part of common area monitoring.

Refer to section 9.3.4.5.6 for descriptions of the NSSS scope radiation monitors which are not part of the computer-based monitoring system.

Section 11.5.2.1.1 provides a description of system hardware including design features such as instrumentation, types and locations of readouts, annunciators, and alarms, provisions for emergency power supplies, and provisions for decontamination and replacement. Paragraph 11.5.2.1.2 provides information concerning redundancy, diversity, and independence of components. Paragraphs 11.5.2.1.3, 11.5.2.1.4, and 11.5.2.1.5 provide a description of the function and location of each process, effluent, and area monitor. Paragraph 11.5.2.1.6 provides a description of provisions for calibration, maintenance, and inspection.

Engineering drawing 13-N-997-184 is a basic block diagram of the RMS.

Table 11.5-1 is a tabulation of basic information describing each of the continuous process, effluent, and area radiation monitors and sampler, including monitor location, design background dose rate, type of monitor and measurement made, sampler and/or detector type, reference nuclide, range of activity concentrations or dose rates to be monitored and expected concentrations or dose rates, alarm setpoint, provisions for power supplies, and automatic actions initiated.

Bases for the ranges listed in table 11.5-1 are as follows:

A. For process monitors, the ranges include:

   1. Maximum calculated concentrations during normal operations and anticipated operational occurrences.

   2. The highest sensitivity commercially available when purchased in order to detect process system leakage and airborne contamination as early as possible.

B. For effluent monitors, the ranges include:

   1. Maximum calculated concentrations for normal operations, anticipated operational occurrences, and postulated accidents.

   2. Minimum concentrations that must be detected in order to allow automatic and/or operator actions

to avoid exceeding Technical Specifications for the release of radioactivity.

C. For area monitors the range extends from a minimum value of the radiation zone I upper limit to a maximum of the saturation limit of commercially available Geiger-Müeler tube detectors. Area ion chamber detectors meet Regulatory Guide 1.97 range requirements.

In order to satisfy the above criteria, fuel building vent and plant vent are provided with two monitoring skids. The two skids, together, provide overlapping low, mid, and high range monitoring channels which span a range of at least 11 decades.

Bases for the setpoints provided in table 11.5-1 are as follows:

A. For ESF monitors the listed setpoint is the maximum acceptable value considering measurement uncertainties and statistical error. Setpoints at or below these values will provide sufficient operator notification and/or initiation of automatic action as soon as possible in the presence of process system leakage, airborne contamination, or an accident condition.

B. For non-ESF effluent monitors, the noble gas channel setpoint is determined in accordance with the Offsite Dose Calculation Manual. Particulate/iodine setpoints are based on ALARA considerations.

Table 11.5-1
CONTINUOUS PROCESS AND EFFLUENT RADIATION MONITORING (Sheet 1 of 13)

Sampler/Monitor Location (Instr. Tag No.) (P&I Dwg. Ref.)(l)	Quantity Per Unit	Designated Location For Environmental Qualification (a)	Design Background (mr/h Co-60)	Sampler Type	Detector Type (b)	Activity Measured (c)	Reference Nuclide (t)	Range (µ Ci/cm^3)	Expected Concentrations (µ Ci/cm^3)	Alarm Setpoint (µ Ci/cm^3)	Response Time at Min. Nuclear Cooling Water (NCW) System Monitor (XJ-SQN-RU-6) (Drawing 01, 02, 03-M-NCP-001, -002 & -003)	1	Outside (Yard)	0.5	Off-Line/Liquid	γ	Gross γ	Cs-137	10^{-6} -10^{-1}	LMD	(p)	1 Min.	Instr.	Alarm only.

a. Refer to paragraph 11.5.2.1.1.6.

b. "γ" - NAI γ scintillation detector coupled with photomultiplier tube
"β" - Plastic phospor β scintillation detector coupled with photmultiplier tube
"SCA" - Single channel analyzer
"G-M" - Geiger-Mueller detector
"Ion" - Ion chamber

c. Area - Area Radiation (mostly γ)
"β-γ" - Total activity (β and γ)
"γ Dose" - Gamma radiation in R/hr
"Gross γ" - Total gamma activity
"Gross β" - Total beta activity
"I-131" - Activity from volatile I-131
"Nitrogen 16" - Activity from N-16

d. Time interval for a monitor to indicate 90% of it's final value from a step change in the input concentration. Particulate/Iodine channels assume a clean filter condition.

e. "INSTR": 120 V-ac non-1E instrument power
"(M)": Motor: 480 V-ac non-1E power
"VITAL 'A'": 120 V-ac vital instrument power, channel A
"VITAL 'B'": 120 V-ac vital instrument power, channel B

f. Automatic actions initiated on HIGH-HIGH alarm only. HIGH alarm annunciates but does not initiate a control action.

g. Blower Motor: 480 V-ac Class 1E power, train A.

h. Blower Motor: 480 V-ac Class 1E power, train B.

i. "LMD" - Less than minimum detectable.

k. Range for Particulate and Iodine channels given for continuous monitoring. Analysis of filters and iodine cartridges is typically better than 10^{-12} µCi/cc for lower end.

l. Area and process monitors are shown on radiation monitor locations, figures 11.5-1 through 11.5-6.

m. Seismic Category I, Class 1E powered. Performs no ESF function.

n. Detector and annunciator are located in containment. Microprocessor is located in auxiliary building.

o. In accordance with Technical Specifications.

p. Variable in accordance with ALARA.

q. Non-1E backed up by train A diesel.

r. Pump power is non-1E.

s. In accordance with the Offsite Dose Calculation Manual.

t. Basis nuclide for range and expected concentration determination only.

u. Monitor has additional setpoint basis. ESF basis is related to Part 100 limits; ODCM basis will always be more conservative.

v. Set to alert personnel to increasing concentrations during a containment purge which may result in alarming the plant vent monitor.

w. Set to alert personnel to increasing primary-to-secondary leakage.

x. Refer to table 11.1-7 for main steam concentration.

y. Environmental qualification not required because it completes its design function before exposure to a harsh environment.

z. Environmental qualification not required because this device is used for normal operations and is not required to function for mitigation of any initiating event considered by PVNGS EQ Program.

aa. Time to alarm and initiate CPIAS less than 4 seconds for ESF function when Technical Specifications setpoint of 2.5 mR/hr is used.

bb. In accordance with the Technical Requirements Manual.

cc. In accordance with the Technical Specification Bases

dd. Refer to table 7.3-12

ee. set to alert personnel to increasing radiation levels.

ff. in accordance with the Emergency Plan

Table 11.5-1
CONTINUOUS PROCESS AND EFFLUENT RADIATION MONITORING (Sheet 2 of 13)

Sampler/Monitor Location (Instr. Tag No.) (P&I Dwg. Ref.)(l)	Quantity Per Unit	Designated Location For Environmental Qualification(a)	Design Background (mr/h Co-60)	Sampler Type	Detector Type (b)	Activity Measured (c)	Reference Nuclide (t)	Range (μ Ci/cm^3)	Expected Concentrations (μ Ci/cm^3)	Alarm Setpoint (μ Ci/cm^3)	Response Time at Min. Detectable Conc.(d)	Power Supply(e)	Automatic Actions Initiated(f)
<u>NON-ESF MONITORS</u> (cont)													
Auxiliary Steam Condensate Receiver Tank Inlet (RTI) Monitor (XJ-SQN-RU-7)	1	Auxiliary Bldg.	2.5	Tank Recirc./Liquid	γ	Gross γ	Cs-137	10^{-6} -10^{-1}	LMD	(p)	1 Min.	AC Power(q)(r)	Alarm and divert aux. stm. condensate to liquid radwaste system.
Auxiliary Bldg. Ventilation Exhaust Filter Inlet (ABFI) Monitor (XJ-SQN-RU-8) (Drawing 01, 02, 03-M-HAP-001, -002, -003 & -004)	1	Auxiliary Bldg.	0.5	Off-Line/Fixed Paper Particulate Filter	β	Gross β	Cs-137	10^{-11} -10^{-4} (k)	LMD	(p)	15 Min.	AC Power (q)(r)	Alarm only
				Off-Line/Fixed Charcoal or Silver Xeolite Cartridge	γ/SCA	I-131	I-131	10^{-11} -10^{-4} (k)	6 X 10^{-10}	(p)	15 Min		Alarm only
Auxiliary Bldg. Lower Levels (ABLL) Ventilation Exhaust Monitor (XJ-SQN-RU-9) (Drawing 01, 02, 03-M-HAP-001, -002, -003 & -004)	1	Auxiliary Bldg.	2.5	Off-Line/Gas	β	Gross β	Kr-85	10^{-6} -10^{-1}	9 x 10^{-6}	(p)	1 Min.	AC Power (q)	Alarm only
Auxiliary Bldg. Upper Levels (ABUL) Ventilation Exhaust Monitor (XJ-SQN-RU-10) (Drawing 01, 02, 03-M-HAP-001, -002, -003 & -004)	1	Auxiliary Bldg.	2.5	Off-Line/Gas	β	Gross β	Kr-85	10^{-6} -10^{-1}	LMD	(p)	1 Min.	AC Power (q)	Alarm only
Waste Gas Decay Tank (WGDT) Monitor (XJ-SQN-RU-12) (Drawing 01, 02, 03-N-GRP-001)	1	Radwaste Bldg.	50	Inline/Gas	β	Gross β	Kr-85	10^{-3} -10^{+2}	1 x 10^{-1}	(s)	1 Min.	Instr.	Alarm and initiate close of the waste gas discharge valves.

C. For non-ESF area monitors, the nominal trip setpoint is set in accordance with ALARA.

11.5.2.1.1 General Description

Refer to engineering drawing 13-N-997-184. In order to optimize the reliability, flexibility, maintainability, and detection sensitivity and accuracy of the RMS, it is primarily digital in nature.

11.5.2.1.1.1 Field Unit. At each location where radiation is sampled and/or monitored by one or more channels, the sampling/detecting/auxiliary equipment is a single assembly and is referred to as a "field unit". For some monitors, the field unit also contains the control microcomputer, while in others, it is a remote assembly. Each field unit is capable of automatic continuous stand-alone operation, even if communications with the control room are interrupted. These capabilities include:

A. Acquisition and storage of radiation levels, setpoints, conversion factors, and other applicable monitor operating parameters. Data storage capacity for this purpose provides for complete storage of the preceding twenty-four 10-minute averages, 24 hourly averages, and 24 daily averages of radiation level and the complete files of critical parameters (setpoints, conversion constants, etc.) for all channels within the field unit.

B. Control of all monitor field unit functions.

C. A plug-in receptacle to which can be attached a portable indication and control (PIC) unit or post-accident monitor portable indication and control (KEPIC) unit to provide complete local control capability. (Not available on new scope monitors with local indication and control panels.)

The PIC/KEPIC unit is a self-contained electronics package, suitable for hand carrying. The unit includes digital readouts, hand switches, and circuitry to provide the following capabilities to the operator when plugged into the RMS field unit microcomputer.

1. When a LOCAL-REMOTE switch located on the PIC/KEPIC unit is in the REMOTE position, the PIC operator is able to request and receive indication of the currently stored value of 1) any critical parameter, or 2) radiation level information, for any channel operated by the connected microcomputer.

2. When the LOCAL-REMOTE switch on the PIC/KEPIC is in the LOCAL position, the PIC operator is able to completely control all functions of the connected microcomputer normally exercised at remote indication and control units. Whenever the LOCAL-REMOTE switch on the PIC/KEPIC is in LOCAL, the affected microcomputer is

automatically disconnected electrically from REMOTE indication and control.

D. For each area monitor, a permanently-mounted local indication and control (LIC) unit or post-accident monitor local indication and control (KELIC) unit. When the channel is operating, this unit indicates radiation level in mr/h and visually and audibly annunciates the presence of a high-high level alarm.

E. The steam generator blowdown discharge monitor field unit has a local analog display for the lower 3 decades (10^{-7} to 10^{-4} μCi/cc), with indication of power, computer fault, and alarm. A RS-485 port is provided for local configuration and data retrieval. Password verification is required to manipulate monitor configuration.

11.5.2.1.1.2 Communications and Remote Indication and Control.

11.5.2.1.1.2.1 ESF Monitors. Each ESF field unit has its own dedicated cable over which it communicates digitally with a dedicated microcomputer-controlled (old scope only) remote indication and control (RIC) module (KERIC for postaccident or new scope, safety-related indicator units) located in one of the RMS control room cabinets. Complete remote indication and control of each safety-related field unit is exercised at the RIC/KERIC. Each ESF RIC/KERIC automatically outputs a signal to the balance of plant ESF actuation system whenever a high-high (high for new scope equipment) radiation level setpoint is

exceeded at the field unit. In this way each ESF monitor is completely independent from any other monitor.

11.5.2.1.1.2.2 Non-ESF Monitors. Most of the non-ESF field units are connected together for communications in a single "daisy-chain" loop configuration along with the centralized server and associated workstations. Exceptions to this configuration are indicated on engineering drawing 13-N-997-184. There are workstations located in the RMS HP office, count room, and the unit control room. Each field unit in turn communicates digitally with the RMS server by passing messages from node to node around the loop. The equipment in the loop is designed such that field unit-RMS server communications is single failure-proof to industry standards.

In a parallel, identically configured loop with the RMS server are two interface modules, located in the ESF control room cabinets (one in the "A" cabinet and one in the "B" cabinet), which are connected, through qualified isolation devices, to each ESF monitor. These interface modules cannot interfere with the operation of the ESF monitors, but are automatically fed radiation level and alarm status data for each safety monitor. In this manner, complete radiation level and alarm status is normally available for display at the workstations for both ESF and non-ESF monitors.

11.5.2.1.1.3 <u>General System Performance</u>.

11.5.2.1.1.3.1 Measurement Capability. Radiation monitoring system process channels have the capability to measure and display radiation levels over a five decade (at least 11

decades for the fuel building vent and plant vent) range specified in table 11.5-1 for each channel. Radiation monitoring system area channels measure and display radiation levels over a five decade range, from 10^{-1} to 10^{4} mr/h for normal operation and 10^{-1} to 10^{4} R/h for post-accident operation.

A. For calibration purposes, minimum detectable levels (lower limit of range) for all process channels are detected under sample conditions of standard temperature and pressure.

B. Minimum detectable levels for all process channels are detected in the presence of a Co-60 external radiation field (design background) of a level specified for each process channel in table 11.5-1.

C. Minimum detectable levels for all process channels are detected at a minimum statistical confidence level above background of 95%.

D. Response times, defined as the time interval for a monitor to indicate 90% of its final value from a step change in the input concentration, are as follows:

   1. For area channels, the time is less than 30 seconds.

   2. For liquid and gas channels, the time is less than 1 minute.

   3. For particulate and I-131 channels, the time is less than 15 minutes.

4. Response time of every channel is approximately inversely related to radiation level at the detector for levels greater than the required minimum detectable level.

11.5.2.1.1.3.2 System Accuracy.

A. For all area radiation monitors, the displayed dose rate in the incident radiation energy range from 0.1 to 3 MeV is normalized to within +/- 20% when referenced to the response due to Co-60. For the incident range of 3 MeV to 7 MeV, the displayed dose rate may over respond in excess of these values.

For the normal range GM area monitors, a generic deadtime correction is applied. Furthermore, a "keep alive" background for the check source is maintained to give an indication of detector failure and will produce a conservative upscale bias of about 0.2 mR/hr which will be significant in the lower decade of operation. Site calibration of the GM area detectors uses a Cs-137 source which produces a conservative dose response for energies of both lower and higher incident gamma energies. The calibration tolerance for GM area detectors is typically +/- 10% with a linearity test of +/- 20% and a maximum allowed deadtime bias of 50% at the highest reading of 1.0E+04 mR/hr. The GM monitor range is 0.1 to 1.0E+04 mR/hr.

For the post-accident personnel, equipment access, primary coolant, and containment high-range ion

chamber area monitors, site calibration is based on an electronic calibration of the amplifier and readout unit with the internal "keep alive" sources used as an indication of proper detector operability due to ALARA concerns over high dose rates. The personnel and equipment access monitors have a range of 0.1 to 1.0E+04 R/hr. The primary coolant monitors have a range of 1.0 to 1.0E+05 R/hr. The containment high-range monitors have a range of 1.0 to 1.0E+07 R/hr.

B. For process liquid and gas channels, the displayed activity concentration is accurate to ±25% of the actual concentration present in the sampler for an unknown mixture having the same radiation emissions as the reference isotope. The reference isotopes for gas channels are Xe-133, Kr-86, and Kr-85, and for liquid channels, is Cs-137. Monitor displayed values in the lowest decade of operation may exceed actual activity concentration by greater than +25% due to inherent detector background. Monitor ranges are shown in table 11.5-1.

C. For process particulate and iodine channels, the displayed activity concentration is accurate to ±25% of the actual concentration present in the sample line for an unknown mixture having the same radiation emissions as the reference isotope based on a clean filter condition. The reference isotope for particulate channels is Cs-137 and for iodine channels is I-131.

Instantaneous monitor displayed values in the lower decades of operation may differ from actual activity concentration by greater than ±25% due to background interference from filter loading. Monitor ranges are shown in table 11.5-1.

11.5.2.1.1.3.3 Nonsaturating Design. Each RMS radiation channel has a nonsaturating design so that it indicates a level higher than its design range upper limit when exposed to a radiation level up to 100 times this limit.

11.5.2.1.1.4 Performance of ESF Monitors. Each separate ESF channel performs the following specific functions:

A. Provides continuous remote indication at the control room cabinet of current radiation level and channel status. These parameters are also available, upon request, at the display and control consoles (DCU).

B. Provides, upon demand, remote indication at the control room cabinet of the currently stored value of any channel critical parameter.

C. Provides complete remote manual control of the channel functions specified in paragraph 11.5.2.1.1.1. This control is exercised through operation of the RIC/KERIC unit.

D. Provides, upon demand, remote indication at the control room cabinet of historic trend values.

E. Provides an output control signal to the BOP ESFAS whenever a high-high (high, for new scope) radiation level is present. Each of these signals is brought to a relay which opens to alarm. Fail open contacts are connected to terminal strips located in the associated control room cabinet.

F. Provides the following isolated digital outputs, wired to the interface module referred to in paragraph 11.5.2.1.1.2.1:

1. Current radiation level

2. Channel alarm status

11.5.2.1.1.5 Performance of Non-ESF Monitors. Non-ESF channels perform the following specific functions:

A. Provides remote indication of current radiation level and channel status upon request, at the communication console in the control room, the workstation in the RMS HP office, and the count room of the associated unit. This information is provided in the form of graphical displays and provides real-time information to help the operator monitor radiation levels in plant effluent pathways as well as internal areas and processes.

B. Provides, upon demand, remote indication at the workstation of the currently stored value of any channel critical parameter.

C. Provides complete remote manual control of the field unit functions specified in paragraph 11.5.2.1.1.1. This control is exercised at the workstation.

11.5.2.1.1.6 Environmental Qualification.

11.5.2.1.1.6.1 Each ESF monitor which is required to function in a harsh environment resulting from an initiating event within the scope of the PVNGS EQ program is environmentally qualified in accordance with section 3.11 per location as specified in table 11.5-1.

11.5.2.1.1.6.2 ESF monitors and RMS control room cabinets are designated Seismic Category I and are seismically qualified as described in section 3.10. This equipment is also classified as Quality Class Q, and a quality assurance program has been implemented for this equipment.

11.5.2.1.1.7 Design and Fabrication Details.

11.5.2.1.1.7.1 Materials of Construction. Materials of construction for pressure-bearing surfaces wetted by process liquids or waste gas is austenitic stainless steel, type 304. Materials of construction for surfaces wetted by sampled air are austenitic stainless steel.

Materials for fasteners of stainless steel parts (bolts or nuts) and pump wearing parts (wear rings or seals) are austenitic stainless steel or other ASTM-specified material suitable for the water chemistry and/or radiation environment of the sampler.

11.5.2.1.1.7.2 Sampling Assembly. Each process or effluent channel includes a sampling assembly which consists of a sampler and the associated piping, fittings, and other components as required to transport the sample through the system. The sampling assembly is a closed sealed system and includes a sampling pump, valves, interconnecting piping, filters, fittings, flow and pressure transducers, and other local control and instrumentation elements as required. Sampler piping and connections are welded except where maintenance considerations make flanged or Swagelok joints necessary. Sampler outlet piping connections are located to minimize cleaning requirements and background buildup due to the adherence of radioactive particles to the sampler walls. For liquid samplers, welding of pressure-containing components is performed in accordance with ANSI B31.1. For ESF monitors, welding of pressure-containing components is performed in accordance with AWS D1.1-1972 (with 1973 revisions). Welding of other equipment is performed in accordance with industry standards.

For liquid and process channels, the sampler is a lead-shielded steel chamber. For particulate and iodine channels, the sampler is a lead-shielded filter assembly. Four π shielding is furnished for all process and effluent detectors except induct gas monitors and high range ion chambers for which background is not significant.

Airborne particulate and iodine monitors and samplers (see table 11.5-1) sample in accordance with the principles and methods of ANSI N13.1-1969, Guide to Sampling Airborne

Radioactive Materials in Nuclear Facilities. For normal range monitors, the particulate and iodine sample flow is maintained constant over the normal expected range of filter paper and/or charcoal cartridge differential pressure by an automatic control system. Accident range monitors employ manual sample flowrate control. Flow indication and local high- and low-sample flow alarm signals (old scope only) are provided. These signals actuate the channel failure alarm. New scope monitors provide remote low-sample flow alarms only. Sampling assembly fittings are provided which allow grab sampling of the monitored airstreams.

Refer to subsection 18.II.F.1.2 for TMI-related information pertaining to the particulate collection and iodine adsorption efficiency.

11.5.2.1.1.7.3 Detector Assembly. The detector assembly is a completely weatherproofed assembly and is capable of withstanding the design pressure and temperature of the piping system or environment of which it is a part, without leakage, collapse of the tube walls, or damage to the detector.

On process and effluent monitoring skids, the detector is installed in the sampler assembly.

A preamplifier is used with the detector to ensure reliable transmission of a high-quality signal to the channel microcomputer.

Scintillation detectors are beta- or gamma-sensitive detectors suitable for analysis of photopeaks up to 3 MeV. Photo-

multipliers are shielded to prevent gain changes due to orientation or stray magnetic fields. The case surrounding the detector assembly is constructed of a corrosion-resistant material suitable for continuous outdoor operation. The preamplifier is integral to the detector assembly, while the check source can be either internal or external, depending upon monitor and scintillator type.

For the steam generator blowdown discharge monitor, the detector is Am-241 doped to generate a continuous radiation signal that is monitored for quality and efficiency. The preamplifier is located in the microcomputer.

Geiger-Mueller (GM) detectors are halogen quenched beta-gamma sensitive tubes of sufficient size and wall thinness to detect the minimum specified dose rate. Area monitors with GM tubes have internal check sources and preamplifiers while GM detectors utilized on post-accident monitors incorporate an internal check source but external preamplifier. Ion chambers used inside the containment are fully qualified to post-LOCA conditions in accordance with IEEE 323-1974 and IEEE 344-1975. Ion chambers used outside the containment are qualified to the zone they are located in and cover the full range of γ dose for that area. Each ion chamber contains an internal "keep-alive" source consisting of a small amount of radioactive material. Signal conditioning and amplification is provided by a preamplifier installed at the monitor microcomputer.

11.5.2.1.1.7.4 Motors. The liquid sampler pump (RTI monitor only) and each airborne sampler blower motor is a standard 460 V-ac, three-phase motor.

Motor controllers include auxiliary contacts for use in the failure circuit of the respective radiation monitoring channels.

Remote motor control is provided via each workstation for non-ESF field units and via each RIC unit for ESF field units. Local motor control switches and indicating lights at the field unit are provided.

11.5.2.1.1.7.5 Power Supply. Electrical power having the following characteristics is made available as listed in table 11.5-1 for each monitor.

- Grounded, 60 Hz, three-phase, 480 V-ac ±10% (for motors only)
- Ungrounded, 60 Hz, single-phase, 120 V-ac ±10%

To protect data normally stored in field unit microcomputers, minimize system downtime following power failures and the impact on real-time performance of the RMS, field units have the following electrical power, failure and recovery modes:

A. For a short-term (less than 4 hours) sustained loss of power to a field unit, the affected microcomputer:

   1. Senses the impending loss of power and conducts an orderly shutdown. Battery backup power

supplies are rechargeable and provide a minimum of 4 hours of backup power to read/write memory.

2. Upon restoration of power, restarts immediately and automatically and functions normally without loss of any data stored in memory at the time of power loss.

B. For a long-term (4 hours or greater) sustained loss of power, loss of data stored in read-write memory can occur. For field unit microcomputers, sufficient program is located in read-only memory circuits so that, upon subsequent restoration of power, recovery to full functional status can be effected.

C. The RMS server, Control Room workstation, and HP office workstation are provided with an uninterruptable power supply system to maintain full system operation in times of short-term (less than 10 minutes) power failure. For long-term power outages, sufficient data is located in startup files so that, upon subsequent restoration of power, recovery to full functional status is effected automatically.

11.5.2.1.1.7.6 Output Relays. Alarm output relays are provided in the field unit for the XJ-SQN-RU-07, RU-12, RU-141 and RU-200 non-ESF monitors. They are also provided in the RIC/KERIC unit for each ESF monitor. The ESF monitor relays initiate the automatic control actions listed in table 11.5-1 to the BOP ESFAS circuits. All of the relays have fail-open

contacts. The relays are deenergized in the presence of a high-high (high for new scope equipment) alarm.

11.5.2.1.1.7.7 ESF Monitor Interface Units. These units include isolation devices (SRMS isolation modules) and interface electronics necessary to receive the following digital information from each of the ESF channels and communicate it to the non-ESF communications loop:

- Radiation level
- Channel failure alarm
- Channel test signal
- Alert radiation alarm (referenced as High Alarm for old scope)
- High radiation alarm (referenced as High-High alarm for old scope)

These interface units are located in the channel A and channel B sections of the ESF RMS control room cabinets.

11.5.2.1.1.7.8 The RMS Computer System includes the following devices:

- RMS Server: communicates with the microcomputers to retrieve current data, download parameters to the microcomputers (Non-1E only), and provide remote control (Non-1E only). Archives data received from the microcomputers. Provides alarm processing for local

points and propagates alarm processing for alarms remotely processed in the microcomputers.

- HP Office Workstation: communicates with RMS Server to display information to the user in a graphical format, sounds audible alarms, and allows the user to issue commands to the Non-1E microcomputers from the HP Office.
- HP Office Printer: permits on demand printing.
- Control Room Workstation: communicates with RMS Server to display information to the user in a graphical format, sound audible alarms, and allows the user to issue commands to the Non-1E microcomputers from the communications console in the control room.
- Count Room Workstation: communicates with RMS Server to display information to the user in a graphical format, sound audible alarms, and allows the user to issue commands to the Non-1E microcomputers from within the RCA.

Operator interface is provided through a series of graphical displays available on demand at any workstation.

Primary Displays/Functions include the following:

A. System Overview

The System Overview display provides the following current information for all monitors in the system:

1. Monitor Alarm Status
2. Channel Alarm Status

3. Channel Radiation/Radioactivity Levels

B. Operator Monitor

Displays all current information needed by the operator to quickly assess the status of the monitor and perform all remote commands. The display includes current channel readings, current alarm conditions, 1 hour historical trends of each channel, acknowledge alarms command and other pertinent commands. All commands require confirmation and security password.

C. Database Display

Displays all current parameters/readings transmitted to the RMS Server from the microcomputer. Parameter fields that may be changed are editable and may be downloaded to the monitor. Downloads require confirmation and security password.

D. Current Alarms Display

Displays all current alarm messages in the system. Messages are colored according to alarm level, and prioritized according to level (1 is the highest):

Red: Level 1 (High Alarm, Detector Saturation)

Yellow: Level 2 (Alert Alarm)

Orange: Level 3 (Equipment Failure, Condition Alarm)

Blue: Level 4 (User Defined)

Alarm messages are colored according to alarm level, unless the message is unacknowledged and cleared, then

the message is green. An acknowledgement field indicates an operator has responded to the alarm.

Associated with this display is a RMS Alarms Button. This button will be displayed independently of the current display the user is viewing and cannot be covered by other displays (or applications) as long as the system is running. The button color (solid or flashing) will reflect the current alarm status of the system, as described above. When the user clicks on the RMS Alarms Button, the system navigates to the Current Alarms Display which provides the operator with more detailed information regarding the current alarms.

E. System Messaging Application

Displays the most recent event messages, including: alarm messages, equipment failures, activities in progress, communication errors, operator commands, and operator comments.

F. Archive Retrieval Display

Retrieves data from the archive file based on point name (1 to 6 per retrieval), retrieval interval (start date, stop date or duration), archive source file (25 hour, 35 day, or 365 day files), resolution and destination (trend, tabular, ASCII file, or linear regression).

Secondary Displays/Functions are also provided to aid the operator in assessing various situations or scenarios that are

not described in detail here. For a complete description of system capabilities, the Radiation Monitoring System Computer System Requirements document should be referenced.

11.5.2.1.1.7.8.1 Automatic Controls. The RMS Server/Workstations can provide automatic control of each Non-1E monitor/channels through the manipulation of database parameters of the associated field unit microcomputer.

A. Automatic activation of the check source and monitoring for proper response at regular intervals specified in the channel critical parameter file.

B. Automatic restoration of a monitor to the RMS Server communication polling if the restore enable is set for the monitor.

11.5.2.1.1.7.8.2 Remote Manual Controls. The RMS Server/Workstations can also provide remote manual control of each monitor through the Operator Monitor Displays. Remote manual control includes the following, as applicable to the particular monitor/channel type:

A. Remote manual activation of the check source.

B. Remote manual startup or shutdown of sampling auxiliary equipment for maintenance.

C. Remote manual acknowledgment of alarms. Note that local alarm indication will not clear until locally acknowledged.

D. Changes to the monitor/channel memory resident critical parameters values.

Password security assures positive administrative control over access to the remote manual controls.

11.5.2.1.1.7.8.3 Annunciation and Recording. Provides real time annunciation and historical chronologically indexed logs of all events that affect the status of the RMS equipment. A change in status of any monitor or channel of monitor will cause a level, equipment, or condition alarm. Logs may be printed on demand. The presence of an alarm will generate an audible annunciation (if applicable), an alarm message on the Current Alarms Display, change in the color of monitor or channel wherever displayed in the system, and the RMS Alarms Button will reflect the condition. Local alarms must be cleared locally.

The RMS Server transmits the radiation levels of all channels to ERFDADS every 10 seconds.

11.5.2.1.1.7.9 ESF RMS Control Room Cabinets. The RIC/KERIC units output relays, digital-to-analog converters and recorders are mounted in control room cabinet assemblies. The cabinets also house the ESF monitor interface units (refer to paragraph 11.5.2.1.1.7.7). The freestanding NEMA 12 panels are divided into four sections, two for old scope (channel A equipment and channel B equipment), and two for the new scope, (channel A equipment and channel B equipment). Cabinet cooling is provided. The cabinets and contents are designated Seismic

Category I and are designed, constructed, and anchored accordingly. The cabinets are located adjacent to the non-ESF RMS control room cabinets away from the main control board area. New scope and old scope control room cabinets are not identical. While function and purpose is the same, design is different. Additional information is available in the operation-maintenance manuals.

11.5.2.1.1.7.10 Remote Indication and Control Units. Each RIC/KERIC unit is of modular design and rack-mounted. It is microcomputer controlled (old scope only) and connected by standard dual twisted wire pairs (TWP) to its associated field unit microcomputer. The RIC/KERIC unit includes a front panel with digital readouts, hand switches, and circuitry to satisfy the functional requirements of paragraph 11.5.2.1.1.4. The RIC/KERIC unit provides IEEE 323 qualified data recording.

11.5.2.1.1.7.11 Intentionally blank

11.5.2.1.1.7.12 Intentionally blank

11.5.2.1.1.7.13 Non-ESF RMS Control Room Cabinet. This cabinet is located adjacent to the ESF RMS control room cabinets. It houses the gas stripper monitoring system interface units. The gas stripper monitor is not connected to the remainder of the RMS. It does provide separate alarm and indication functions in the Control Room.

11.5.2.1.1.7.14 Portable Monitor Connection Boxes. At 18 locations throughout the unit, portable monitor connection

boxes are hardwired into the nonsafety communications loops. These connection boxes contain receptacles for plug-in jacks attached to portable area monitors which can be temporarily connected to the loop for remote display and control during inservice inspection and other radioactive maintenance. When no jack is connected to a box, it is designed to appear as a short in the nonsafety communications loop.

11.5.2.1.1.7.15 Portable Area Monitors. Each of the portable area monitors includes a single area channel. The complete detector assembly and electronics package is mounted together and is capable of being hand-carried. The detector is connected to the electronics package and is detachable for separate mounting. The electronics package is connected to plug-in jacks.

11.5.2.1.2 Redundancy, Diversity, and Independence

11.5.2.1.2.1 In order to satisfy the design bases for postulated accident conditions defined in paragraph 11.5.1.2, ESF channels are designed to monitor area and/or airborne radiation levels at key locations and provide alarm outputs to the balance of plant engineered safety features actuation system (BOP ESFAS). In keeping with this function, ESF channels are designed in accordance with IEEE Standards 279, 308, 323, 336, 338, 352, 379, 383, and 384.

11.5.2.1.2.2 ESF monitors and their associated RIC units form independent and redundant sensor channels A and B for three

safety feature actuation signals, CREFAS, FBEVAS, and CPIAS as follows:

- XJ-SQA-RU-29: CREFAS - channel A
- XJ-SQB-RU-30: CREFAS - channel B
- XJ-SQA-RU-31: FBEVAS - channel A
- XJ-SQB-RU-145: FBEVAS - channel B
- XJ-SQA-RU-37: CPIAS - channel A
- XJ-SQB-RU-38: CPIAS - channel B

11.5.2.1.2.3 Single Failure. Each pair of ESF monitors is designed to accommodate any random single failure without precluding the initiation of a safety features actuation signal when a true initiating radiation level exists. IEEE 379 is used as the guide for application of the single failure criterion.

11.5.2.1.2.4 Redundancy. For each safety feature actuation signal listed above, channels A and B are mutually redundant. A redundant element is defined as one whose function is totally duplicated by one or more identical (functionally) and mutual independent elements. Two identical elements are not redundant if they are not independent.

11.5.2.1.2.5 Independence. Redundant channels are electrically and physically isolated from each other such that

events (including faults) affecting one channel does not affect the other in any way.

11.5.2.1.2.6 Diversity. Diversity is provided for the FBEVAS signal by utilization of an area radiation monitor as channel A and an airborne gas radiation monitor as channel B.

11.5.2.1.3 Process Radiation Monitoring

11.5.2.1.3.1 Essential Cooling Water (ECWA, ECWB) (XJ-SQN-RU-02 and XJ-SQN-RU-03) Monitors. These two channels monitor the essential cooling water system trains A and B. A high activity alarm indicates a reactor coolant or reactor auxiliary system leak into the cooling water system. Upon receiving an indication that activity in the system is increasing, the alternate loop may be made operable, and the individual cooler outlets may be sampled to determine the defective component.

Each ECW monitor is situated in a bypass loop around an ECW pump which provides the necessary sample driving head. These monitors have been upgraded for pressure boundary components as referenced in Table 3.2-1.

11.5.2.1.3.2 Steam Generator Blowdown (SGB1, SGB2) (XJ-SQN-RU-04 and J-SQN-RU-05) Monitors. A monitor is located in each steam generator blowdown or downcomer sample line. A high activity alarm indicates primary-to-secondary leakage.

11.5.2.1.3.3 Nuclear Cooling Water System (NCW) (XJ-SQN-RU-06). The nuclear cooling water system is monitored for radioactive in-leakage. A high activity alarm indicates a leak from a reactor auxiliary system. Individual cooler outlets may be sampled to determine the defective component.

The NCW monitor is situated in a bypass loop around the NCW pump which provides the necessary sample driving head.

11.5.2.1.3.4 Auxiliary Steam Condensate Receiver Tank (RTI) (XJ-SQN-RU-07) Monitor. Auxiliary steam condensate returning from the boric acid concentrator and LRS evaporator is monitored before it leaves the receiver tank. A high activity alarm indicates radioactive leakage into the tubes of an evaporator during blowdown of the shell side, or due to improper operation. Upon a high-high alarm, the RTI monitor automatically diverts the condensate to the liquid radwaste system. This monitor draws and returns a sample from the sampled tank. A pumping system, to generate the required sample driving head, and a sample cooler, to cool the sample to less than 120F, are provided. The sample cooler is cooled by nuclear cooling water.

11.5.2.1.3.5 Auxiliary Building Ventilation Exhaust Filter (ABFI) Inlet (XJ-SQN-RU-08) Monitor. The auxiliary building ventilation exhaust is continuously monitored for airborne radioactive particulates and iodines.

The significant noble gas sources in the auxiliary building are monitored as listed in paragraphs 11.5.2.1.3.6 and

11.5.2.1.3.7. The exhaust from these areas is monitored directly before dilution in the building ventilation system. Auxiliary building exhaust is monitored by the plant vent effluent monitor.

11.5.2.1.3.6 Auxiliary Building Lower Levels Ventilation (ABLL) Exhaust (XJ-SQN-RU-09) Monitor. The combined ventilation exhaust from the train A penetration room and the rooms housing the letdown heat exchanger, the associated valve gallery, and the charging pumps is continuously monitored for gaseous activity. A high activity alarm indicates equipment leakage.

11.5.2.1.3.7 Auxiliary Building Upper Levels Ventilation (ABUL) Exhaust (XJ-SQN-RU-10) Monitor. The combined ventilation exhaust from the gas stripper room, the letdown ion exchanger room, associated valve galleries, and the sampling room is continuously monitored for gaseous activity. A high activity alarm indicates equipment leakage.

11.5.2.1.3.8 Waste Gas Decay Tank (WGDT) (XJ-SQN-RU-12) Monitor. This in-line channel monitors the decay tank discharge header for gaseous activity. A high alarm indicates an operational occurrence; e.g., inadvertent discharge or incorrect valve line up. The monitor initiates isolation of the decay tank discharge header on a high-high activity alarm.

11.5.2.1.3.9 Radwaste Building Ventilation Exhaust Filter (RBFI) Inlet (XJ-SQN-RU-14) Monitor. The radwaste building

ventilation system is continuously monitored for airborne particulate activity. The only significantly abundant isotopes which could be released from sources within the radwaste building are noble gases and particulates; therefore, an I-131 monitor is not provided. The only significant airborne noble gas leakage sources are monitored as listed in paragraph 11.5.2.1.3.10. Radwaste building exhaust is monitored by the plant vent.

11.5.2.1.3.10 Waste Gas System Area Combined Ventilation (WGVE) Exhaust (XJ-SQN-RU-15) Monitor. The waste gas system area combined ventilation exhaust is continuously monitored for gaseous activity. A high activity alarm indicates leakage from waste gas processing equipment or the associated valve gallery.

11.5.2.1.3.11 Control Room Ventilation Intake Monitors, (CRVA, CRVB) Channels A and B (XJ-SQA-RU-29 and XJ-SQA-RU-30). These gaseous channels monitor the control room ventilation supply for any inleakage of activity from the environment. Two monitors sample from the ventilation air intake duct as close to the intake point as possible. These monitors actuate the control room essential ventilation system. Refer to section 7.3 for a discussion of the safety function of these monitors.

11.5.2.1.3.12 Containment Building Refueling Purge Exhaust (CBPB) Monitor, Channel B (XJ-SQB-RU-34). The containment building refueling purge exhaust is continuously monitored for a gaseous activity release.

11.5.2.1.3.13 Containment Building Atmosphere Monitor, (CBB) Channel B (XJ-SQB-RU-01). The containment building atmosphere is continuously monitored for particulate, iodine, and gaseous activity. The sample is drawn from the containment building in a closed system, is monitored outside the containment, and then is returned to the containment building atmosphere after it passes through the samplers. The particulate and gaseous channels serve as two methods of RCPB leak detection in accordance with Regulatory Guide 1.45 except as noted in section 1.8. This monitor is designated Seismic Category I.

In order to obtain a representative sample of containment air, the sample line inlet is located on the operating level between two of the normal cooling units intakes. While shown on the 100-foot 0-inch elevation in figure 11.5-2, the sample point is actually on the 93-foot elevation. This location also facilitates RCPB leak detection by these monitors.

The CB-B monitor is located just outside the containment building. It samples the containment atmosphere through piping penetrations. Containment isolation valves (refer to subsection 6.2.4) shut on CIAS when containment pressure reaches the containment isolation pressure setpoint. Therefore, the CB-B monitor is designed to function properly subsequent to an event where pressure is applied to the sampler piping.

11.5.2.1.3.14 NSSS Process Radiation Monitor, (XJ-SQN-RE-155D). The process radiation monitor (PRM) is designed to provide information on both the long-term trends

and rapid changes in the level of radioactivity in the reactor coolant. The monitoring is continuous with the PRM located adjacent to the reactor coolant purification letdown line. Rapid escalations in reactor coolant activity may result from phenomena that is not related to the integrity of the fuel. Therefore, the PRM is not designed to provide an indication of the number of failed fuel rods. The PRM monitors the count rate of gross gamma activity in the reactor coolant. Determination of the percent of reactor power generated in fuel rods containing cladding defects or their vicinity in the core requires the analysis of the isotopic ratio of specific nuclides in the coolant. This is done to distinguish between fuel failures and other phenomena which may escalate activity levels such as iodine spiking or corrosion product releases. The determination of the actual number of fuel rods containing cladding defects requires the process of fuel assembly sipping.

The PRM is not designed to provide quantitative indication of fuel failure. The PRM alarm setpoint is adjusted to an activity value which is just above that normally measured in the coolant. Annunciation of the alarm would then indicate escalation in the reactor coolant activity level. The action upon receipt of the alarm is operator investigation of the cause and initiation of corrective action if required. The PRM does not provide any automatic control functions.

The PRM is used to monitor trends in reactor coolant activity. Plant procedures will require investigation of the cause of significant escalation, whether or not an alarm setpoint is reached. Technical Specifications describe limiting conditions

for operation and surveillance requirements concerning reactor coolant system specific activity, and requires chemical analysis of reactor coolant for gross activity and iodine activity. The required periodic measurements of dose equivalent I-131 will be used to monitor cladding integrity during operation. Should these trends indicate cladding failure, the reports described in the Technical Requirements Manual will be made to the NRC. A program of fuel assembly leak detection inspection will be conducted at the next refueling to determine the location and number of failed fuel rods, if a significant number is indicated.

The primary coolant activity monitoring subsystem is discussed in CESSAR Section 9.3.4.

11.5.2.1.3.15 Condenser Vacuum Pump/Gland Seal Exhaust (CVSE) (XJ-SQN-RU-141) Monitor. The vacuum pumps and gland seal condenser remove gases from the secondary system. The exhaust is continuously monitored for gaseous activity resulting from primary-to-secondary system leakage. There are two (2) detectors installed in the system. One detector (channel B) is installed in the vacuum pump combined discharge piping, while the second detector (channel A) is installed in the combined vacuum pump and gland seal discharge. The exhaust is piped to be combined with the plant vent exhaust and is monitored for effluent releases by monitors XJ-SQN-RU-143 and XJ-SQN-RU-144. No other airborne monitors are provided for the turbine building. The monitor provides automatic initiation of filtration (channel A only) of the condenser vacuum pump/gland

seal exhaust whenever the monitor channel is in a high-high alarm condition.

11.5.2.1.3.16 Main Steam Nitrogen-16 Monitor (XJ-SQN-RU-142). The main steam lines are monitored for the presence of N-16 gamma radiation by a 3 X 3 inch NaI scintillation detector mounted adjacent to each steam line. The presence of N-16 in the main steam lines is an indication of primary-to-secondary leakage.

11.5.2.1.3.17 Steam Generator Blowdown Discharge Monitor (XJ-SQN-RU-200). The steam generator blowdown discharge line to the retention tank is continuously monitored for radioactivity. A high alarm terminates the discharge by isolating the line in order to prevent significant levels of radioactivity in the retention tank.

11.5.2.1.4 Effluent Radiation Monitoring

The effluent radiation monitors have complete digital readout and control from the RMS office and the main control room. The high range monitors have three particulate and iodine sampler channels. Channels 1 and 2 are operator selectable with no fixed sample time intervals. Channel 3 is used as a timed grab sample with the sample time set by the operator. These sampler channels utilize sample cartridges that require analysis to determine isotopic concentrations. The installed particulate and iodine sample collection media uses minimal absorption of noble gases. Samples are preconditioned as necessary to assure accurate results without damaging the sample assemblies. Each

monitor is controlled by a remote microprocessor. This microprocessor is linked by a "daisy chain" to a RMS server which provides data to workstation to generate multiple informational displays on request by the operator. Monitors are provided with an open structural construction that provides for easy maintenance and good heat dissipation. Multiple detectors are used to achieve the dynamic range required.

Refer to subsection 18.II.F.1.1 for TMI-related information pertaining to noble gas effluent monitors.

11.5.2.1.4.1 This section intentionally blank.

11.5.2.1.4.2 Plant Vent (XJ-SQN-RU-143 and XJ-SQN-RU-144) (PVLR, PVHR) Monitor. The plant vent exhaust is continuously monitored for particulate, I-131, and gaseous activity.

A low and high range monitor is used to cover a range of eleven decades with one decade of overlap. Shielded particulate and iodine samples exist and are removed for analysis.

11.5.2.1.4.3 Fuel Building Ventilation Exhaust Monitor, (FBLR, FBHR) Channel B (XJ-SQB-RU-145 and XJ-SQB-RU-146). The fuel building exhaust is continuously sampled for particulate and I-131 activity, and monitored for gaseous activity. The gaseous channel also monitors the fuel building ventilation exhaust for release of activity due to a fuel handling accident. The FBLR monitor performs the safety function of isolating the normal ventilation system and activating the essential ventilation system (initiates a FBEVAS signal) on a

high-high activity alarm. Refer to section 7.3 for a discussion of the safety function of the fuel building ventilation exhaust monitor. During normal operation, the only significantly abundant isotope which would be released from the fuel building is tritium; therefore, gaseous activity is monitored and particulate and I-131 sampling capability is provided.

A low and high range monitor is used to cover a range of eleven decades with one decade of overlap. Particulate/iodine cartridge samples exist in the low and high range monitor and are removed for analysis. High range cartridge samplers are shielded.

11.5.2.1.5 Area Radiation Monitoring

One function of area radiation monitors (except for XJ-SQA-RU-37 and XJ-SQB-RU-38) listed in table 11.5-1 is to indicate and alarm locally and remotely the area dose rate to ensure proper personnel radiation protection. Several of the area monitors also perform other additional functions or have unique characteristics.

11.5.2.1.5.1 Central Calibration Facility Area (XJ-SQN-RU-24) (CFA) Monitor. The CFA monitor is located in a small outbuilding in the yard of Unit 1 which is shared by all three units as a central calibration facility.

11.5.2.1.5.2 INTENTIONALLY LEFT BLANK

11.5.2.1.5.3 Fuel Pool Area Monitor, Channel A (FPAA) (XJ-SQA-RU-31). The monitor is located on a wall over-looking the fuel pool where it monitors for a release of activity due to a fuel handling accident in the fuel building. The monitor performs the safety function of isolating the normal ventilation system and activating the essential ventilation system on a high-high dose rate alarm. Refer to section 7.3 for a discussion of the safety function of the monitor.

11.5.2.1.5.4 Refueling Area Monitor, Channel A (RMAA) (XJ-SQA-RU-33). The monitor is located on a wall overlooking the refueling cavity where it monitors for a release of activity due to a fuel handling accident in the containment.

11.5.2.1.5.5 Power Access Purge Area Monitors, Channels A (PAPA) and B (PAPB) (XJ-SQA-RU-37 and XJ-SQB-RU-38). The monitors are located between the containment power access purge exhaust duct and the refueling purge exhaust duct just outside the containment wall. During power operations, these channels monitor the duct for airborne radioactivity concentrations which could potentially result in an offsite dose exceeding 10CFR100 limits. These monitors perform the safety function of isolating the containment building purge supply and exhaust ducts (initiate CPIAS signals) on a high-high dose rate alarm. Refer to section 7.3 for a discussion of the safety functions of the monitors.

11.5.2.1.5.6 Main Steam Line (XJ-SQN-RU-139 and XJ-SQN-RU-140) Monitor. One area monitor with a collimating lead shield is mounted adjacent to each main steam line in the main steam support structure. Refer to figure 11.5-3. These monitors measure direct dose rates from the main steam line to identify radioactive effluent from the atmospheric dump and main steam relief valves. There are a total of four detectors with one remote microprocessor for each two detectors.

11.5.2.1.6 Inspection, Calibration and Maintenance

11.5.2.1.6.1 Maintenance. Outdoor sampling systems are housed in outdoor-type weatherproof enclosures. The enclosures are designed to permit performance of all control and routine maintenance and cleaning operations from the front or top of the enclosure. Interior wiring is run in conduit to terminal boards mounted in junction boxes.

Instrument air is supplied for flushing of gaseous or airborne monitors. Taps for connecting demineralized water are supplied for flushing all liquid monitors.

The interior surface finish of the sample chamber is designed to minimize contamination by absorption or adherence of radioactive material thereto and to facilitate cleaning by use of a cleaning solution. Sample chambers are removable to allow ultrasonic decontamination or replacement.

Equipment design incorporates plug-in electronic cards and rack-mounted system modules wherever possible to facilitate removal and replacement or repair.

11.5.2.1.6.2 Calibration and Inspection. A remotely operated check source or in the case of ion chamber detectors, an internal radioactive "keep-alive" source is provided with each detector assembly. The check source and keep-alive source are usable as convenient methods to provide a qualitative check of the associated detection and readout equipment. The check source provides a count rate sufficient to verify detector operation when the detector is near the bottom of its range. The keep-alive source provides a sufficient background current from the detector to the monitor to continuously verify detector operation.

Primary calibrations were performed by the manufacturer for each type of detector used in the RMS. As part of the primary calibration, detectors were exposed to known radiation fields or radioactivity concentrations, as applicable, that were traceable to the National Bureau of Standards (NBS), currently known as the National Institute of Standards and Technology (NIST). These calibrations determined detector sensitivity and efficiency for each type of detector used in the RMS. Due to design configuration control and in the case of the process monitors, fixed analysis geometry, additional primary calibrations of the monitors used in the field are not necessary. Subsequent calibrations need only verify that the monitor's response measured in the field correlates to the monitor's response measured during the primary calibration by using transfer calibration sources or by direct measurement.

The general method for performing field calibrations consists of the following steps:

1. Verifying the monitor electronic alignment.

2. Evaluating monitor response to known radiation fields, field calibration sources, or electronic input in order to verify that the monitor's efficiency is similar to that measured during the primary calibration.

3. Evaluating the linearity of the monitor's response using radioactive sources or electronic inputs.

The specific method of correlating a monitor's field response to the primary calibration depends on the type of detector and function of the monitor.

Scintillation (beta and gamma) detectors and Geiger-Mueller (GM) detectors used as process and effluent monitors are calibrated in the field using field calibration sources. These calibration sources relate the detector's response measured in the field to the response measured during the primary calibration that used a similar model of detector and transfer calibration sources in a geometry that is the same as the field calibration sources.

GM detectors used as area monitors (including area monitors that monitor process streams) are calibrated by placing the detector in a calibrated radiation field and verifying that monitor readings are consistent with the radiation field. Due to ALARA considerations, area monitors using ion chamber detectors (including area monitors that monitor process and effluent streams) are calibrated electronically by inputting known electronic signals into the monitor and verifying

response through its entire range. Ion chamber detector response is verified in the field using the internal radioactive keep-alive source. For all ion chamber detectors, with the exception of those used in the containment high range area monitors (RU-148 and RU-149), detector response is evaluated by ensuring a minimum response from the keep-alive source is present. For RU-148 and RU-149, the ion chambers used were exposed to an NIST (NBS) traceable radiation field by the manufacturer during the primary calibration. As part of this calibration, the background keep-alive source response was measured. During subsequent field calibrations, the response of the keep-alive source is verified to be consistent with that measured during the primary calibration. This provides the necessary traceability and in situ calibration response checks for the containment high range area monitors as required in NUREG-0737.

The RMS channels are checked and inspected periodically. Grab samples are collected for the isotopic analysis in accordance with the schedule in table 11.5-3. Setpoint checks are done on a monthly basis (except for RU-148, RU-149, RU-150, and RU-151 which are performed at the frequency specified in TSR 3.3.105.1), and calibration is performed at least every 18 months (except for RU-148, RU-149, RU-150, and RU-151 which are performed at the frequency specified in TSR 3.3.105.2) or at the indication of equipment malfunction. Instruments are serviced as required.

Field calibration of the indicated channels is performed following any equipment maintenance that can change the

accuracy of the instrument indication. It also may be scheduled if the check source indicates an abnormal response. Critical parameters are verified as part of the calibration process.

11.5.2.2 Routine Sampling

The requirements of the system design bases for routine continuous and discrete sampling of radioactivity are satisfied by a system of liquid, gaseous, and airborne samplers, laboratory equipment for sensitive radio-chemical analyses, and a program of procedures for obtaining and analyzing representative samples when and where appropriate. This section provides a detailed description of system hardware and procedures in general, including the types of sample nozzles and other sampling equipment used, the procedures to obtain representative samples, and analytical procedures.
Table 11.5-2 is a tabulation of basic information describing each of the sampling locations, including the basis for selecting the location, expected flow, composition, concentrations, and the types of effluents released at the location. Table 11.5-3 is a tabulation of basic information describing the schedule of analyses performed on each sample for each type of release, including the type of analyses performed (quantities measured), frequencies of performance, and analytical sensitivities

Table 11.5-2
ROUTINE SAMPLING

Sampling Location	Basis for Location Selection	Expected Process Flowrate	Sample Composition	Expected Concentrations ($\mu Ci/cm^3$)	Types of Effluent Releases (Refer to Table 11.5-3)
Waste gas decay tanks	Determination of identity and quantity of radionuclides being released; calibration check of WGDT monitor	0-50 standard ft^3/min	H_2, N_2	1.0×10^{-1} Kr-85	Batch release of fission and activation gases
Containment building atmosphere (CB-B) monitor	Determination of identity and quantity of radionuclides to be released during containment purge; calibration check of CB-B monitor	30,000 standard ft^3/min preaccess 2,000 mini-purge	Containment atmosphere	5.0×10^{-4} Xe-133 LMD[a] I-131 2.4×10^{-10} Cs-137	Batch release of fission and activation gases and tritium; releases of airborne radioactive iodines
Plant vent monitor	Determination of identity and quantity of radionuclides being released; calibration check of PV monitor	143,570 standard ft^3/min including 30,000 standard ft^3/min containment purge	Ventilation exhaust air	LMD [a]	Continuous releases of fission and activation gases and tritium; releases of airborne radioactive particulates; releases of airborne iodines
Fuel building vent monitor	Determination of identity and quantity of radionuclides being released; calibration check of fuel building monitor	43,000 standard ft^3/min	Ventilation exhaust air	LMD[a]	Continuous releases of fission and activation gases and tritium; releases of airborne particulates; releases of airborne radioactive iodines

a. "LMD" – Less than minimum detectable

Table 11.5-3
SCHEDULE OF SAMPLE ANALYSES AND SENSITIVITES (Sheet 1 of 2)

Gaseous Release Type	Sampling Frequency	Minimum Analysis Frequency	Type of Activity Analysis	Lower Limit of Detection (LLD) (μCi/ml)
A. Waste Gas Storage	P Each Tank Grab Sample	P Each Tank	Principal Gamma Emitters[1]	1.0E-04
B. Containment Purge	P Each Tank[3] Grab Sample	P Each Tank[3]	Principal Gamma Emitters[1]	1.0E-04
			H-3	1.0E-06
C. 1. Plant Vent **2. Fuel Bldg. Exhaust**	M[3] Grab Sample	M[3]	Principal Gamma Emitters[1]	1.0E-04
			H-3	1.0E-06
	Continuous	4/M Charcoal Sample	I-131	1.0E-12
			I-133	1.0E-10
	Continuous	4/M Particulate Sample	Principal Gamma Emitters[2] (I-131, Others)	1.0E-11
	Continuous	M Composite Particulate Sample	Gross Alpha	1.0E-11
	Continuous	Q Composite Particulate Sample	Sr-89, Sr-90	1.0E-11
D. All Radwaste Types as listed in A., B., and C., above	Continuous	Noble Gas Monitor	Noble Gases Gross Beta or Gamma	1.0E-06

1. The principal gamma emitters for which the LLD specification applies include the following radionuclides: Kr-87, Kr-88, Xe-133, Xe-133m, Xe-135, and Xe-138 for gaseous emissions.

2. The principal gamma emitters for which the LLD specification applies include the following radionuclides: Mn-54, Fe-59, Co-58, Co-60, Zn-65, Mo-99, Cs-134, Cs-137, Ce-141 and Ce-144 for particulate emissions.

3. Analyses shall also be performed following SHUTDOWN, STARTUP, or a THERMAL POWER change exceeding 15% of the RATED THERMAL POWER within a 1-hour period if 1) analysis shows that the DOSE EQUIVALENT I-131 concentration in the primary coolant has increased more than a factor of 3; and 2) the noble gas activity monitor on the plant vent shows that effluent activity has increased by more than a factor of 3.

Table 11.5-3

SCHEDULE OF SAMPLE ANALYSES AND SENSITIVITES (Sheet 2 of 2)

FREQUENCY NOTATION FOR TABLE 11.5-3

NOTATION	FREQUENCY
M	At least once per 31 days.
4/M	At least 4 times per month at intervals no greater than 9 days and a minimum of 48 times per year.
P	Completed prior to each release.
Q	At least once per 92 days.

11.5.2.2.1 Sampling Equipment and Procedures

Sampling equipment and procedures are provided to assure that representative samples are obtained. Prior to sampling, large tanks of liquid waste are well-mixed in as short a time interval as practicable to assure that any sediments or particulate solids are distributed uniformly in the waste mixture. Sample lines are flushed for a sufficient period of time prior to sample extraction in order to remove sediment deposits and air and gas pockets. Periodically, a series of samples is taken during the interval of discharge to determine whether any differences exist as a function of time and to assure that individual samples are indeed representative of the effluent mixture. Periods of collection are kept as short as practicable, and polyethylene collection bottles are used to preclude the loss of radioactive material by deposition on the walls of the sample container or volatilization.

Effluent ventilation ducts and stacks are sampled continuously in accordance with ANSI N13.1-1969 for radioactive gases, particulates, and iodines. The containment atmosphere is sampled continuously for radioactive gases, particulates, and iodines by the containment building atmosphere radiation monitor. The sample is drawn from a point between the containment normal air-conditioning unit suctions. A containment atmosphere gas sample is collected for analysis prior to the initiation of a containment purge batch release. This sample is analyzed for tritium and the principal gamma emitters in accordance with the Offsite Dose Calculational

Manual (ODCM). Containment purge batch release contribution to the plant release will be incorporated into the continuous sample collected at the plant vent release point. Particulate, iodine, and noble gas samples will be collected four times per month for all continuous effluent airborne radiation monitors and samplers. Where composite samples are used, they are collected in proportion to the volume of each batch of effluent releases or in proportion to the rate of flow of the effluent stream. Prior to analysis, the composite is thoroughly mixed so that it is in proportion to the rate of flow of the effluent stream. Prior to analysis, the composite is thoroughly mixed so that the sample is representative of the average effluent release.

11.5.2.2.2 Analytical Procedures

Samples of process and effluent gases and liquids are analyzed in the laboratory by the following techniques as appropriate:

- Gross beta counting
- Gross alpha counting
- Gamma spectrometry
- Liquid scintillation counting
- Radio-chemical separations

Instrumentation available for laboratory measurement of radioactivity is described in paragraph 12.5.2.2.

Gross alpha analysis of air particulate is performed by direct counting of the filters. This method is checked periodically by counting duplicate samples, sources, and samples of known activities.

Gamma spectrometry is used for isotopic analysis of gaseous and airborne particulate and iodine samples.

Gaseous tritium samples are collected by condensation and/or absorption. Liquid samples for tritium analysis are purified prior to analysis. Samples are counted on a liquid scintillation counter.

11.5.3 EFFLUENT MONITORING AND SAMPLING

11.5.3.1 Implementation of General Design Criterion 64

Refer to subsections 11.5.1 and 11.5.2 for a detailed description of the means which are provided for monitoring effluent discharge paths for radioactivity that may be released for normal operations, including operation occurrences and from postulated accidents.

11.5.4 PROCESS MONITORING AND SAMPLING

11.5.4.1 Implementation of General Design Criterion 60

Refer to subsections 11.5.1 and 11.5.2 for a detailed description of the means which are provided for automatic closure of isolation valves in gaseous effluent discharge paths.

11.5.4.2 Implementation of General Design Criterion 63

Refer to subsections 11.5.1 and 11.5.2 for a detailed description of the means which are provided for monitoring of radiation levels in radioactive waste process systems.

APPENDIX 11A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

APPENDIX 11A

<u>QUESTION 11A.1</u> (NRC Question 460.1) (1.8, 11.2, 11.3, and 11.4)

Provide a table under section 1.8 comparing the design features of the liquid, gaseous and solid radwaste systems with the positions of Regulatory Guide 1.143 (July 1978), "Design Guidance for Radioactive Waste Management Systems, Structures, and Components Installed in Light-Water-Cooled Nuclear Power Plants." For each item for which an exception is taken, the applicability of the proposed exception should be justified. If sufficient justification is provided in other sections for the individual items, cross-references to those sections will be adequate.

RESPONSE: PVNGS complies with the position of Regulatory Guide 1.143 including implementation of quality assurance requirements for the radwaste management systems. (Refer to sections 9.3, 11.2, 11.3, 11.4, and 17.2.)

<u>QUESTION 11A.2</u> (NRC Question 460.7)

Provide the data required for radioactive source term calculations for PWRs using the format given in Chapter 4 of NUREG-0017, April 1976, "Calculation of Releases of Radioactive Materials in Gaseous and Liquid Effluents from Pressurized Water Reactors."

RESPONSE: The response is given in subsection 11.1.9.

<u>QUESTION 11A.3</u> (NRC Question 460.8) (9.3 and 11.2)

Section 9.3 of the FSAR states that the turbine building liquid wastes will be pumped to the evaporation pond if the effluent quality will meet the standards for pH, conductivity

and radioactivity. Explain how tests will be conducted for the radioactivity of these wastes, and also give information on the ultimate disposal of the wastes that get collected in the evaporation pond.

RESPONSE: The response is given in paragraph 9.3.3.2.1.3.1.

QUESTION 11A.4 (NRC Question 460.9)

Describe the provisions for preventing overflow and/or containing the tank contents in the event of failure of the reactor makeup water tank.

RESPONSE: The response is given in subsection 9.3.4.

QUESTION 11A.5 (NRC Question 460.10) (11.3)

Information on hydrogen and oxygen gas analyzers is inadequate. Since the system is not designed to withstand a hydrogen explosion, at least one gas analyzer should be provided, operating continuously between the compressor and the storage tanks, with automatic control functions to prevent the formation or buildup to explosive hydrogen-oxygen mixtures in the storage tanks. Annunciating alarms should be provided locally and in the control room (see the acceptance criteria of the Standard Review Plan, Section 11.3, Rev. 1, "Gaseous Waste Management Systems"). Also, provide information such as the number of sample points, sampling frequency at each point, alarm provisions and control features for the described sequential monitoring system.

RESPONSE: The response is given in amended paragraph 9.3.2.3 and subsection 11.3.1.

APPENDIX 11A

QUESTION 11A.6 (NRC Question 460.11) (11.3)

In Table 11.3-5, Krypton-89 estimated input concentration to the gaseous radwaste system from the reactor drain tank is shown as $4.5 \times 10^{+3}$ μCi/cm^3. This appears to be too high when compared to values contained in NUREG-0017, and should be confirmed or corrected.

RESPONSE: The response is given in amended table 11.3-5.

QUESTION 11A.7 (NRC Question 460.12) (11.3)

Describe the provisions included in the design of the gaseous waste treatment system to stop continuous leakage paths (see the requirement stated under Acceptance Criteria II.3 of SRP Section 11.3, Rev. 1).

RESPONSE: There are no continuous leakage paths in the gaseous waste treatment system as defined under Acceptance Criteria II.3 of SRP Section 11.3, Rev. 1.

QUESTION 11A.8 (NRC Question 460.13) (11.3)

Comparison with NUREG-0017 suggests that table 11.3-6 of the FSAR on annual releases of gaseous effluents contains some errors. For example, estimates of noble gas to be released from the containment building and Xe-133 to be released from the auxiliary/radwaste buildings are lower than would be expected. This table should be reevaluated and corrected if appropriate.

RESPONSE: The response is given in amended table 11.3-6.

APPENDIX 11A

<u>QUESTION 11A.9</u> (NRC Question 460.14) (11.3)

The system design provides for the return of the flashed steam from the blowdown flash tank to the secondary system via the No. 4 feedwater heaters (see paragraph 10.4.6.2.2 of the FSAR). Also, a charcoal/HEPA filtration system is provided for the main condenser air removal system exhausts (see table 11.3-7 of FSAR). Since these two augments have already been included in the system design, they should be excluded from the cost-benefit analysis (see Tables 5B-8 through 5B-11 of the Environmental Report) as per I.d of Appendix I to 10CFR Part 50.

RESPONSE: The response is provided in the revised Appendix 5B to the ER-OL and incorporated into Supplement 2 to the ER-OL.

<u>QUESTION 11A.10</u> (NRC Question 460.15) (11.4)

Clarify whether wastes collected in the evaporation pond will be an additional input to the solid radwaste system (SRS) input volumes. If so, provide estimates of the volumes and activities of these wastes.

RESPONSE: All potentially radioactive inputs to the evaporation pond will be tested for radioactivity prior to discharge into the evaporation ponds. Those wastes determined radioactive will be sent to the liquid radwaste system for processing. Therefore, waste collected in the evaporation pond will not be an additional input to the solid radwaste system.

APPENDIX 11A

QUESTION 11A.11 (NRC Question 460.16) (11.4)

Explain how the SRS output activities provided in table 11.4-6 for evaporator concentrates, spent resin beads, cartridge filters and disposable crud filters are related to their corresponding input activities provided in table 11.4-2.

RESPONSE:

The following assumptions were utilized in establishing SRS output activities in table 11.4-6:

1. Evaporator concentrates are solidified and stored in the high activity storage area for 1 month (i.e., 1-month decay) prior to shipment.

2. Spent resin beads are stored for 6 months prior to solidification. Solidified resin is stored in the high activity storage area for 1 month (i.e., 1-month decay) prior to shipment.

3. Cartridge filters are solidified and stored in the high activity storage area for 1 month (i.e., 1-month decay) prior to shipment.

4. Disposable crud filters are stored for one month (i.e., 1-month decay in the high activity storage area) prior to shipment.

QUESTION 11A.12 (NRC No. 460.18) (11.5)

We have reviewed your submittal dated April 6, 1981, relating to TMI Action Plans II.F.1, Attachments 1 and 2, and III.D.1.1 of NUREG-0737. We find your information scant and very inadequate. Please provide the information on these action items as required by NUREG-0737. For guidance, you may refer to

submittals on these action plans for other PWRs such as San Onofre, Units 2 and 3, and Summer Nuclear Station, which have been found acceptable by the staff.

RESPONSE: An expanded discussion of noble gas monitoring and effluent sampling per Attachments 1 and 2 to NUREG-0737, Item II.F.1, is provided in subsections 18.II.F.1.1 and 18.II.F.1.2.

Paragraph 12.1.3.6 also addresses leak reduction design measures per Item III.D.1.1 of NUREG-0737. Measurement and testing of covered systems will not take place until the startup of these systems. Accordingly, expansion of the LLIR for operational leak reduction testing cannot be provided until after startup.

APPENDIX 11B

DERIVATION OF

CORE RESIDENCE TIMES

CONTENTS

APPENDIX 11B

DERIVATION OF CORE RESIDENCE TIMES

The derivation of the core residence times for circulating crud as shown in Section 11.1.2.1 is as follows:

Circulating Crud:

The number of radioactive atoms (N_f) in the crud film on in-core surfaces at any time is:

$$\frac{dN_f}{dt} = \Sigma_i \varphi - \lambda_i N_f \qquad \text{B1}$$

Solving for N_f yields the following:

$$N_f = \frac{\Sigma_i \varphi}{\lambda_i}\left(1 - e^{-\lambda_i t_{res}}\right) \text{atoms/g} \qquad \text{B2}$$

Where:

	$\sum_i \varphi$	is the activation rate for each isotope, i (d/g-sec),
	λ_i	is the decay constant for each isotope ($secs^{-1}$), and
	t_{res}	is the desired core residence time (seconds).

The number of radioactive atoms (N_c) released to the reactor coolant at any time is:

$$\frac{DN_c}{dt} = N_f[ER]A_c - (\alpha + \beta + \lambda_i)N_c \text{atoms/sec}$$

Solving for N_c yields the following:

$$N_c = \frac{Nf[ER]AC}{(\alpha+\beta+\lambda_i)}\left(1 - e^{-(\alpha+\beta+\lambda_i)t}\right) \qquad \text{B3}$$

Where:

	ER	is the erosion rate (g/cm^2-sec),
	A_c	is the core surface area (cm^2),

α is the plateout rate (sec^{-1})

β is the purification cleanup rate (sec^{-1}), and

λ_i is the decay constant (sec^{-1})

Total amount of crud (M_C) released to the reactor coolant any time is:

$$\frac{dM_c}{dt} = [ER]A_T - (\alpha + \beta)M_c \qquad B4$$

Where M_C includes both radioactive and nonradioactive material.

Solving for M_C yields:

$$M_c = \frac{[ER]A_T}{(\alpha+\beta)}\left(1 - e^{-(\alpha+\beta)t}\right)\text{grams} \qquad B5$$

Where: ER is the erosion rate (g/cm^2-sec),

A_T is the total system area (cm^2),

α is the plateout rate (sec^{-1}), and

β is the purification cleanup rate (sec^{-1}).

The activity (A_i) of the crud released to the reactor coolant is:

$$A_i = \frac{\lambda_i N_c}{M_c}, \text{ dps per gram of crud in reactor coolant} \qquad B6$$

Substituting the values of N_C and M_C into the above expression and assuming λ_i is small when compared to α and β, the activity of the crud is as follows:

$$A_i = \Sigma_i \varphi\left(1 - e^{-\lambda_i t_{res}}\right)\frac{A_c}{A_t}(0.06) \text{ dpm/mg - crud} \qquad B7$$

Where 0.06 is a constant changing dps/g-crud to dpm/mg-crud.

This activity (A_i) is also assumed to be the activity of the crud which plates out on out-of-core surfaces.

Solving equation (B7) for t_{res} yields equation (1) in UFSAR Section 11.1.2.

Deposited Crud

The activity (A_j) of the deposited crud is:

$$A_j = \lambda_i N_f = \Sigma_i \varphi \left(1 - e^{-\lambda_i t_{res}}\right) 0.06 \qquad \text{B8}$$

Solving equation (B8) for t_{res} yields equation (2) in UFSAR Section 11.1.2.

12. RADIATION PROTECTION

12.0 ORGANIZATION AND METHODOLOGY

This chapter describes the radiation protection measures considered during the design and construction of the Palo Verde Station as well as the operating policies used to ensure that internal and external radiation exposures to station personnel, contractors, and the general population due to station conditions, including anticipated operational occurrences, will not only be within applicable limits, but will be as low as is reasonably achievable (ALARA).

12.0.1 CHAPTER 12 INFORMATION

The information contained in this chapter can be characterized into two types, 1) the information that describes how the shielding installed at Palo Verde was designed and determined adequate, and 2) the organization and responsibilities, equipment and facilities, and procedures for maintaining the radiation exposures identified above within current limits and ALARA. The difference between this information is the information described in item 1 is considered original licensing information and is treated as historical, whereas the information in item 2 is expected to reflect the current implementation of the health physics program. Historical information is not expected to be actively maintained as the plant design changes and has been identified as “Original Licensing” or "Historical Information."

12.0.2 RADIATION PROTECTION MEASURES

Radiation protection measures include: separation of radioactive components into separately shielded cubicles; use of shielding designed to adequately attenuate radiation emanating from pipes and equipment which are sources of significant ionizing radiation; use of remotely operated valves or hand-wheel extensions; ventilation of areas by systems designed to minimize inhalation and submersion doses; installation of permanent radiation monitoring systems; control of access to the site and to restricted areas; training of personnel in radiation protection; and development and implementation of administration policies and procedures to maintain exposures ALARA.

12.1 ENSURING THAT OCCUPATIONAL RADIATION EXPOSURES ARE ALARA

12.1.1 POLICY CONSIDERATIONS

It is the policy of the management of Arizona Public Service Company (APS), operating agent for PVNGS, to keep occupational radiation exposure to personnel ALARA. Administrative programs and procedures, in conjunction with facility design, ensure that the occupational radiation exposures to personnel will be kept ALARA.

12.1.1.1 Original Design and Construction Policies

The ALARA philosophy was applied during the initial design of the plant and implemented via internal design reviews and documentation. These reviews were conducted and documented

consistent with the recommendations of Regulatory Guide 8.8. A description of these reviews and their scope is provided in appendix 12B. In addition, the design was reviewed for ALARA considerations by the APS Senior Health Physicist, a certified health physicist.

The plant design was reviewed, updated, and modified as necessary during the design and construction phases. Engineers reviewed the plant design and integrated the layout, shielding, ventilation, and monitoring designs with traffic control, security, access control, maintenance, inservice inspection, and radiation protection aspects to ensure that the overall design produced a plant which will achieve exposures that are ALARA.

Piping containing radioactive fluids was routed as part of the engineering design effort. This ensured that lines expected to contain significant radiation sources were adequately shielded and properly routed to minimize exposure to personnel.

Onsite inspections were also conducted, as necessary during construction, to ensure that the shielding and piping layout meets established criteria. During construction, visual inspections were made to ensure that there were no major defects in the shield walls as they were placed. During initial power operations, radiation surveys were conducted to ensure that the shielding meets design requirements during normal operation and maintenance of the plant.

12.1.1.2 Operation Policies

The Nuclear Administrative and Technical Manual is one of the major means of promulgating the operational ALARA policy. This policy is demonstrated in the radiation protection program, the training program, and station procedures.

Section 12.5 of this chapter describes the Radiation Protection Program and also provides an overview of the organizational structure and responsibilities.

The responsibilities and qualifications of the personnel who fill supervisory positions are discussed in subsections 13.1.2 and 13.1.3.

It is the responsibility of both the director, nuclear training, and the radiation protection manager to implement radiation protection training for company employees and contractors commensurate with the requirements of 10CFR19 and Regulatory Guide 8.8. The radiation protection manager, verifies that personnel follow the radiation protection procedures designed to ensure that exposures are maintained ALARA. To ensure compliance with this policy, the radiation protection manager is charged with the responsibility to promptly advise higher management of practices which exceed their authority to correct. In addition, periodic reviews of the ALARA program (annually at a minimum), including review of radiation exposure records and operating procedures are conducted.

Personnel requiring access to the restricted area and/or radiological controlled areas will receive training as

necessary to permit access to these areas. These personnel will be tested to evaluate each worker's knowledge, competency, and understanding relative to the training provided.

Prior to the initial startup of the first unit, station procedures to be used for work involving significant personnel radiation exposure were reviewed to verify that the procedures adhere to the ALARA philosophy. Revisions to station procedures involving significant personnel radiation exposure will continue to receive an ALARA review. System or station modifications affecting personnel radiation exposure will also be reviewed to see that the ALARA concept is applied.

The radiation protection manager will periodically survey station operations to identify situations in which exposures can be reduced.

12.1.2 ORIGINAL DESIGN CONSIDERATIONS

This section discusses the methods and features by which the policy considerations of subsection 12.1.1 are applied to the original plant design. Provisions and designs for maintaining personnel exposures ALARA are presented in detail in subsections 12.3.1, 12.3.2, and 12.5.3.

12.1.2.1 General Design Considerations for Shielding and ALARA Exposures

General design considerations, shielding, and methods employed to maintain in-plant radiation exposures ALARA consistent with the recommendations of NRC Regulatory Guide 8.8, Section C.1, have two objectives:

A. Minimizing the necessity for and amount of personnel time spent in radiation areas.

B. Minimizing radiation levels in routinely occupied plant areas in the vicinity of plant equipment expected to require personnel attention.

Plant operating personnel are protected as necessary by shielding wherever a potential radiation hazard may exist. The shielding performs the following additional functions:

A. Assists in maintaining radiation exposure to plant control room personnel within the limits of 10CFR50, Appendix A, Criterion 19, in the unlikely event of an accident.

B. Protects certain components from excessive activation or excessive radiation exposure.

C. Facilitates access for maintenance of components.

In order to maintain exposure ALARA, a design radiation zone classification system was developed and used during the design process. Plant areas were classified in accordance with table 12.1-1.

12.1.2.1.1 Neutrons

Neutron shielding design considerations were as follows:

A. Shielding was designed to ensure the area does not become a scattering source, producing excessive doses in other regions.

B. Shielding was designed to ensure that neutron activation does not result in doses exceeding the permitted shutdown dose rates in the region.

C. Neutron radiation damage limits of equipment were not exceeded unless provisions are made for periodic replacement.

Table 12.1-1

RADIATION ZONE CLASSIFICATION

Zone Designation	Dose Rate (mrem/h)
1	Less than 0.5
2	0.5 to 2.5
3	2.5 to 15
4	15 to 100
5	Over 100

12.1.2.1.2 Gamma Radiation

Gamma radiation shielding design considerations were as follows:

A. Shielding was designed to reduce gamma dose rates throughout the plant to levels consistent with expected occupancy during normal operation as specified by the design radiation zones.

B. As a minimum, shielding was designed to reduce gamma dose rates from sources external to a radioactive compartment to levels comparable to dose rates resulting from equipment within that compartment. This design ensured that in a compartment undergoing maintenance, the radiation levels due to operating equipment in adjacent compartments would be the lesser of the zone 3 limit (15 mrem/hr) or the operational dose rate of the equipment under repair.

C. Shielding was provided to attenuate radiation from sources external to equipment compartments so that expected maintenance could be performed without exceeding exposure limits.

D. Shielding was designed to reduce gamma radiation after reactor shutdown to levels which allow access for required maintenance operations.

E. Gamma radiation damage limits for the equipment are not exceeded unless provisions were made for periodic replacement.

12.1.2.2 Facility Layout General Design Considerations for ALARA

In order to implement an ALARA program, the following design guidelines were considered to the extent practical during plant design.

A. Facility General Design Considerations

1. The layout for personnel access, routing of piping and location of components was in a manner to minimize personnel radiation exposure during both operation and maintenance. Access control and traffic patterns were evaluated to assure that radiation exposures were maintained ALARA. In the interest of maintaining doses ALARA, access to a given design radiation zone generally did not require passing through a higher design radiation zone.

2. Radioactive components of the same system were grouped together as practical to minimize radioactive piping runs. Ion exchangers and spent resin collection system components were located as close to the radwaste solidification area as practical. Radioactive wastes were assumed to be stored in shielded enclosures separated from normally accessible areas.

3. Due to the desirability of low background radiation levels, the counting room was located away from highly radioactive components.

4. Due to frequent access requirements, control panels, readout devices, and transmitters, where possible, were located in low radiation zones (design radiation zone 2 or less) in order to minimize operator exposures.

5. In order to reduce radiation exposures due to sampling operations, sample stations were isolated insofar as practical from other radioactive equipment, and exposed sample piping is minimized. Primary and secondary system samples taken within the containment except for safety injection tanks were piped to the plant laboratory to minimize the need to access the containment.

B. Shielding Design Guidelines

1. Significantly radioactive components such as tanks, filters, ion exchangers, pumps, and heat exchangers were located in shielded compartments.

2. In those process systems whose components contain major sources of radiation, valves and instrumentation were separated by shielding from the components.

3. Although use of permanent shielding is preferred, portable or temporary shielding and convenient means for handling it was provided where shielding was required but fixed shielding was impractical. Access and the capability of the structure to

support such portable or temporary shielding was been evaluated during design review.

4. Access to shielded compartments is generally by means of shielded labyrinth arrangements such that direct exposure to radioactive equipment from normal access areas was eliminated. For highly radioactive passive components such as tanks, ion exchangers, and filters, completely enclosed compartments were provided with access via a shielded hatch, or labyrinth entry way with a locked gate.

5. Where space limitations preclude the use of ordinary concrete for shielding, lead, iron, or high density concrete was used instead.

6. Use of removable concrete shielding blocks for frequent personnel access or equipment removal was been avoided by design when practical.

7. Redundant radioactive components were located in separate shielded compartments, where practical, to allow for maintenance on one while the other remained in service. If radioactive components were located in the same compartments, space was provided for installation of temporary shielding during maintenance.

8. As a general rule, radioactive equipment was separated by shielding from nonradioactive equipment to facilitate maintenance on the latter.

9. When corrugated steel decking was used as forming for concrete floor slabs, the minimum thickness of the resulting slab satisfies the specified shielding requirement.

10. Voids such as those created by embedded HVAC ducts or piping were avoided where practicable in shield walls. Unavoidable large voids in shield walls or slabs were evaluated to determine their effect upon shielding requirements.

11. Shielding requirements for periodic operations such as filter handling were determined on the basis of ALARA considerations including level of radioactivity and frequency and duration of exposure.

C. Guidelines for the Control of Radioactive Contamination

1. Large tanks containing radioactive fluids were enclosed in watertight compartments or were surrounded by curbs. Threshold berms were provided for other radioactive equipment compartments to control the spread of contaminated leakage.

2. Sloped floors and floor drains were provided for radioactive equipment compartments including valve galleries and pipe chases. Radioactive drains were designed to minimize "backgassing."

3. Radioactive equipment drains were piped directly to one of the drainage systems instead of allowing contaminated fluid to flow across the floor to the floor drain. The use of temporary flexible tubing to direct fluids to local floor drains or to portable containers during venting and draining operations may be acceptable when the frequency of operation and volume of fluid involved do not make the use of direct connections to a collection system cost effective.

4. Suitable coatings were applied to floors and walls susceptible to radioactive contamination in order to facilitate decontamination operations.

D. Valve Gallery Design Guidelines and Considerations

Valve galleries were provided for valves serving equipment containing or processing highly radioactive material. Valve galleries provide shielding from the process equipment to personnel operating or servicing valves as follows:

1. The amount of exposed piping in the valve gallery is minimized.

2. When possible, a shielded pipe chase is provided adjacent to the valve gallery for the purpose of routing radioactive piping. Such pipe chases are located below valve galleries, if practical, in order to minimize crud deposition in valves.

3. If the radiation level within a valve gallery is high, valve stem extensions through the valve gallery wall to an adjacent corridor are supplied for frequently operated valves so that they may be operated from a design radiation zone 2 area.

4. Sufficient space is provided in valve galleries to facilitate maintenance on valves.

E. Radioactive Piping Design Guidelines

1. Radioactive piping was not field-routed.

2. Piping was routed so that it does not exceed applicable design radiation zone level.

3. Radioactive piping routed through design radiation zone 1 or zone 2 areas are enclosed in a shielded pipe chase, if required.

4. Radioactive piping was routed through the highest design radiation zones practical.

5. Potentially radioactive piping was routed behind components or structures which provide shielding to areas where maintenance is likely to be performed.

6. Radioactive pipes were routed close to floors, ceilings, and walls where practical, but were kept away from doors and entrances outside containment.

7. When practical, radioactive piping was separated from nonradioactive piping.

8. If practical, valves or instrumentation was not located within radioactive pipe chases.

9. Piping layout provides sufficient space for installing and maintaining special equipment or tools as required.

10. Piping insulation was designed for quick removal in any radiation area where routine maintenance and/or inservice inspection was anticipated.

11. Care was taken in routing radioactive piping to minimize background radiation interference with area radiation monitoring sensors.

F. Inservice Inspection Guidelines

Provisions were made for inservice inspections to minimize potential personnel exposures. By design, high radiation zones permit prompt ingress and egress and have adequate space to accommodate the work force, special tools, laydown space, removal of internals, temporary shielding, and auxiliary ventilation systems as may be required during inservice inspection.

G. Crud Trap Design Guidelines

1. The length of pipe runs was minimized for radioactive piping when possible.

2. Low points and dead legs in radioactive piping were minimized.

3. Placement of valves at piping low points was minimized.

4. Valves have flow characteristics that result in a smooth flow path through the valve to minimize the velocity change and resulting potential for crud trapping.

5. Internal surfaces of liquid flow paths are smooth and as free as practical from abrupt discontinuities in cross-sections.

6. Lines were sized to achieve turbulent flow where practical (Re >10,000).

7. Thermal expansion loops were raised instead of depressed, if possible.

8. Flow paths avoid abrupt changes in direction. Bends of several pipe diameters or long radius elbows were utilized wherever practical.

9. Butt welds, where practical, were used on radioactive process piping whose nominal pipe diameter is greater than 2 inches. Backing rings were not used.

10. The use of screwed fittings in radioactive piping systems was avoided, where practical. If such fittings were required, a seal weld was applied.

11. Flanged joints or suitable rapid disconnect fittings were used in cases where maintenance requirements clearly indicate that such

construction was preferable (e.g., for pump maintenance).

12. The origin of branch process lines having little or no flow during normal operation were taken off above the horizontal midplane of the main process pipe, where practical.

13. Strainers were located in process streams immediately downstream of ion exchangers to minimize the introduction of resin fines into process systems and to mitigate the consequences of a resin retention screen break.

In addition, the following special considerations were given to piping which processes spent resins:

14. Ball, plug, or diaphragm valves were used, depending upon the function, in spent resin lines. Strainer, check, and Y-valves were not utilized in piping systems which process spent resins.

15. Orifices were not utilized in spent resin piping systems.

16. Butt welds were employed where practical for spent resin piping regardless of size. Large radius elbows, or large diameter bends, were used where practical in routing all such piping.

17. Ninety-degree tees were not used in spent resin piping systems except to introduce clean services such as air, nitrogen, or water into such lines.

Dead legs were avoided and any necessary flushing connections were taken off above the horizontal centerplane of the resin piping.

18. Spent resin lines were sized to achieve turbulent flow to minimize resin deposits and subsequent buildup.

19. Provisions were made for the ion exchangers as well as the resin lines to be pressurized with air, nitrogen, or water to clear plugged lines. The water or nitrogen is introduced at a tee downstream of each valve, and the leg of the tee is above the resin line to avoid clogging of the clean service inlet line.

H. Component Isolation, Draining, and Flushing Considerations

1. Serviceable radioactive components can be isolated and drained.

2. Major components of radwaste systems have redundant drainage capability so that the failure of a single drain will not prevent cleaning or purging of such a system.

3. High-point vent and low-point drain connections were provided where practical in piping systems which process highly radioactive fluids. These connections were placed to facilitate flushing of the associated process equipment.

4. Vent and drain connections were equipped with suitable fittings so that flushing and/or drain system piping can be temporarily connected.

5. Isolation valves for vent and drain connections were located as close to the process piping as practical.

I. Penetration Design Considerations

1. Penetrations through the primary shield were designed to minimize neutron streaming and the resultant activation of the steam generators and reactor coolant pumps and piping.

2. When possible, radioactive and nonradioactive piping were separated within the penetration area, with provisions for the utilization of temporary shielding for maintenance purposes.

3. In general, piping, electrical, and HVAC penetrations through radiation shields were designed to minimize radiation streaming into accessible areas. The following considerations apply:

   a. Cross-sectional areas of penetrations were minimized.

   b. Where practical, penetrations were oriented so there is an offset between the radiation source and accessible areas.

   c. If such an offset orientation was impractical, the penetration was located as far above the

floor elevation as possible to minimize direct exposure of personnel.

d. If the above methods were not utilized, alternative means are employed. For piping penetrations, the alternatives include grouting the annular space of the penetration or utilizing shield collars around the piping at the openings of the penetration to reduce radiation streaming.

For ventilation and electrical penetrations, use of baffle shields to eliminate streaming into accessible areas is acceptable.

12.1.2.3 ALARA General Equipment Design Considerations

In order to maintain exposures ALARA, the following design guidelines were considered to the extent practical in plant design.

12.1.2.3.1 Radioactive Equipment Design Considerations

Radioactive equipment design considerations relative to equipment contamination and service time include:

A. Reliability, durability, construction, and design features of equipment, components, and materials to reduce or eliminate the need for repair or preventive maintenance.

B. Servicing convenience of anticipated maintenance or potential repair, including ease of disassembly and

modularization of components for replacement or removal to a lower radiation area for repair.

C. Provisions, where practical, to remotely or mechanically operate, repair, service, monitor, or inspect equipment (including inservice inspection in accordance with American Society of Mechanical Engineers (ASME) Section XI).

D. Redundancy of equipment or components to reduce the need for immediate repair when radiation levels may be high.

12.1.2.3.2 Equipment General Design Considerations

Equipment general design considerations directed toward minimizing radiation levels in proximity to equipment or components requiring personnel attention included:

A. Provision for draining, flushing, or, if necessary, remotely cleaning equipment and piping containing radioactive material.

B. Design of equipment, piping, and valves to minimize the buildup of radioactive material and to facilitate flushing of crud traps. The use of cobalt containing alloys in systems exposed to primary coolant has been minimized except where very hard erosion resistant surfaces are necessary (e.g., stellite seat materials on valves). C-E-supplied components which will be exposed to primary coolant have less than 0.2% cobalt, nominally. Refer also to Table 5.2-5 through 5.2-31B.

C. Provisions for minimizing the spread of contamination into equipment service areas, including direct drain connections.

D. Provisions for isolating equipment from radioactive process fluids.

E. Provision for a spent fuel pool cleanup system to maintain the radiation level of the fuel pool area within the design radiation zone 2 limit. See table 12.1-1 for the description of design radiation zones.

F. Heat exchangers have been provided with corrosion-resistant tubes with tube-to-tube sheet joints fabricated to minimize leakage.

   Impact baffles are provided and process fluid velocities are limited as necessary to minimize erosive effects. Provisions are made for removal of the tubes for maintenance.

G. Pumps in radioactive systems have been purchased with mechanical seals to reduce seal servicing time. Additionally, smaller pumps are provided with flanged connections for ease in removal. Pump casings were provided with drain connections for draining the pump for maintenance.

H. Water was used as the fluidizing medium in tanks from which resin is transported. Resin tanks incorporate integral self-cleaning screens in overflow connections

to retain resins within the tank. Overflow connections for radioactive tanks have been piped to the liquid radwaste system (LRS).

I. Filters were supplied with the means to either remotely backflush the filter or to perform cartridge replacement with remote tools.

J. Demineralizers were designed to remotely remove spent resins hydraulically and replace new resins from a remote location. Resin strainers were designed for full system pressure drop.

K. Evaporators were provided with chemical addition connections to allow the use of chemicals for descaling operations.

L. The reactor head laydown area was designed to substantially reduce both the dose to those changing O-ring seals and personnel working in adjacent areas.

An interior shield wall separates the O-ring changeout from the radiation field under the hemispherical head. An exterior shield wall isolates the activated flange and external surfaces from adjacent work activities.

M. Frequently operated valves of highly radioactive systems were designed for remote operation. Motor operators, air operators, and reach rods have been provided where necessary. The criteria for selecting valve operators were as follows:

1. Valves located in design radiation zones 3, 4, and 5 which are operated frequently (for example, on a weekly basis or more often) are equipped with a remote actuator such as a reach rod, an electric motor actuator, or a pneumatic actuator and position indicator. These valves are controlled from the applicable control station or operating aisle.

2. Valves which are operated occasionally (for example, one to twelve times a year) were classified as follows:

   a. Valves which are located in design radiation zone 4 or less may be manually operated directly.

   b. Valves which are located in design radiation zone 5 have been equipped with a reach rod, or if a reach rod cannot be installed, an electric motor actuator or pneumatic actuator and a position indicator.

3. Valves which are operated infrequently during normal plant operations (for example, less than once a year) are manually operated directly unless their operation results in excessive personnel exposure. In cases where the operation of such a valve may lead to exposures in excess of 0.1 man-rem per year, consideration was given to fitting the valve either with a simple reach

rod if feasible, or a remote actuator and position indicator if necessary. The 0.1 manrem per year was derived from a judgmental evaluation of the potential exposure savings versus the cost to provide and maintain a remote operator throughout plant life.

4. A mechanical reach rod assembly is used where an electric motor or pneumatic actuator is not necessary. Directional changes and rod lengths are kept to a minimum. This allows easier maintenance if needed, and minimizes radiation exposure.

5. Valves which are operated after an accident are provided with a means of remote operation in cases where the operation of such a valve may lead to exposures in excess of 1.25 rem.

N. Leakage of radioactive material is minimized by use of appropriate valve gaskets and valve packing. For example, one of the following is provided for radioactive valves 2-1/2 inches and larger:

1. Packing contains grafoil or graphite yarn

2. Diaphragm or bellows seal valves are used where minimal leakage is required.

Radiation tolerant materials are used in valves in accordance with their radioactive service. Chemical seals are provided on instrument sensing lines for

process piping which may contain highly radioactive solids to reduce the servicing time required to keep the lines free from solids.

O. Primary instrument devices, which for functional reasons are located in high radiation areas, have been designed for uncomplicated removal for calibration or servicing. Some instruments, such as thermocouples are provided in duplicate in highly radioactive areas to reduce access and service time.

P. The sample laboratory is equipped with adequate shielding and a fume hood. The sample laboratory and sample stations are equipped with a sink or funnel arrangement so that sample lines may be purged to the LRS or chemical and volume control system prior to sampling. Also, sample lines incorporate the capability of being flushed.

Q. A remotely operated resin dewatering system is employed to minimize exposure during radwaste processing. Remotely operated equipment is provided where practical to minimize operator radiation exposure.

12.1.2.4 General Design Considerations to Keep Post-Accident Exposures ALARA

The facility layout was designed to assist in keeping occupational exposures ALARA even after a design basis accident. While exposures will be significantly higher than

during normal operation, required access is provided to vital areas and systems without exceeding 5 rem/hr. Zone maps showing dose rates in the event of a LOCA with sump recirculation are provided in drawing 13-N-RAR-018 through -028. Zone maps for the hypothetical condition of a LOCA with an intact primary but with a degraded core are provided in drawings 13-N-RAR-029 through -038. A discussion of the source terms for these events is provided in subsection 12.2.3. The dose rates projected for these two sets of drawings do not assume decay beyond that corresponding to the onset of recirculation. Even so, virtually unrestricted access will be permitted within the control and diesel generator buildings, as well as portions of the upper floor of the auxiliary building (such as the Auxiliary Building area of the operations support center).

The only other area where post-accident access will be required is to the hydrogen monitors/recombiners. Projected dose rates without the recombiners in operation, but at the onset of recirculation, are expected to be approximately 10 to 30 rem/hr (sump recirculation).

As the recombiners have to be installed within 72 hours after the DBA, the area will not be accessed until dose rates have dropped due to decay to about 1/10 the doses noted above. Thus, the installation dose rate (assuming sump recirculation) will be less than 5 rem/hr. While the dose rate would be greater than 5 rem/hr for an intact primary-degraded core event, the recombiners would not need to be installed since an

intact primary would not be consistent with hydrogen generation inside the containment. If hydrogen generation were postulated, this would necessitate a break or opening in the primary. Consequently, sump recirculation would be available with the concomitant release of noble gases and dilution by the refueling water tank. These consequences would lead to the doses noted above for the sump recirculation mode of cooling (i.e., dose rates less than 5 rem/hr).

ESF grade filtered ventilation is provided for auxiliary building rooms below elevation 100 feet (refer to section 9.4). This will reduce airborne sources due to recirculation and/or containment leakage. Non-ESF grade filtered ventilation is available for use to reduce airborne sources above elevation 100 feet in the auxiliary building (refer to section 9.4). The use of non-ESF filtration is acceptable since there are no recirculation components above elevation 100 feet. Thus, the only significant source of airborne activity is containment leakage. This leakage has already been accounted for in off-site dose analyses which assumed direct containment leakage to the atmosphere. Secondly, this filter discharges via the plant vent. The plant vent will be monitored in accordance with NUREG-0737 and Regulatory Guide 1.97, Revision 2, to provide notification of decreased filter efficiency.

Therefore, considering direct and airborne sources, access can be provided to those vital areas necessary for control of the plant and personnel exposures will meet GDC 19 and NUREG-0737 limits.

12.1.3 OPERATIONAL CONSIDERATIONS

In accordance with APS policy and consistent with the recommendations of Regulatory Guides 8.8 and 8.10, the radiation exposure of plant personnel will be kept ALARA by means of the radiation protection program discussed in section 12.5. The radiation protection policies and practices contained therein are promulgated through the training program discussed in section 13.2, through the Radiation Protection Division of the Nuclear Administrative and Technical Manual discussed in subsection 12.1.1 and section 12.5.

Based upon the experience of other utilities, the design of PVNGS was reviewed so that this information could be incorporated into the design as previously discussed in subsection 12.1.1.

The criteria and/or conditions under which various operating, maintenance, and inspection procedures are implemented and some of the techniques that are used to ensure that occupational radiation exposures are ALARA are discussed below.

From the Atomic Industrial Forum (AIF) National Environmental Studies Project report,[(1)] it has been determined that the majority of exposure at operating PWRs is received during plant outages from maintenance and inspection activities and not from normal operating activities. This is logical since operators can normally stay outside shield walls to read instruments or operate valves and have to enter cubicles containing radioactive equipment for short periods of time only to check equipment, whereas maintenance and inspection personnel usually

must go inside cubicles or behind shield walls and must be in close proximity to the lines, valves, instruments, or other pieces of equipment which are radiation sources in order to perform their job. The major sources of exposure, as defined in the AIF report, are steam generator repairs (88% of exposure at one plant, 27% at the average plant), reactor vessel head removal (6%), and inservice inspection (6%) accounting for a total of 40% of the annual exposure at the average PWR.

Since the above sources cause the major exposures, some of the ALARA techniques that may be used to reduce these exposures are discussed in sections 12.1.3.1 through 12.1.3.5.

12.1.3.1 General ALARA Techniques

A. Use permanent shielding, where practical, by having workers stay behind walls or in areas of lower radiation level when not actively involved in work. As practical, use temporary shielding if the total exposure, which includes the exposure received during installation and removal of shielding, is reduced.

B. Systems and major pieces of equipment which are subject to crud buildup have been equipped with connections which can be used for flushing. Prior to performing maintenance work, consider the practicality and effectiveness of flushing and/or chemically decontaminating the system or piece of equipment in order to reduce the crud levels and personnel exposure.

C. Work conducted in radiological controlled areas will require a radiation exposure permit (REP). Refer to section 12.5. The purpose of the REP is to carefully prepare for the job so that it can be performed in a proper and safe manner with minimum personnel radiation exposure.

D. On complex jobs involving exceptionally high radiation levels, "dry runs" may be made, and in some cases mockups may be used to familiarize the workers with the exact operations they must perform at the jobsite. At the completion of the job, a debriefing session may be held to determine if the work could have been completed more efficiently. This information should be recorded. In addition, if any personnel contaminations or internal contamination was encountered during the job it should be recorded. This information will provide guidance at the preplanning stage of future similar operations. These techniques will assist in improving worker efficiency and thus will minimize the amount of time spent in the radiation field.

E. As much work as practical should be performed outside radiation areas. This includes items such as reading instruction manuals or maintenance procedures, adjusting tools or jigs, repairing valve internals, and prefabricating components.

F. For long-term jobs, consideration should be given to setting up remote monitoring systems so that work can be monitored from a lower radiation area.

G. On some jobs, special tools or jigs may be used when their use would permit the job to be performed more efficiently or would prevent errors, thus reducing the time in the radiation field. Special tools may also be used if their use would increase the distance from the source to the worker, thus reducing the exposure rate. Unless special tools or jigs are necessary to accomplish the job, special tools or jigs should be used only if the total exposure, which includes that received during installation and removal, is reduced.

H. Entry and exit points should be set up in areas so that personnel are exposed to as low a level of radiation as practical. This will be done because personnel may spend a significant amount of time changing protective clothing and respiratory equipment in these entry-exit areas. These entry and exit points are set up to limit the spread of contamination from the work area.

I. Protective clothing and respiratory equipment should be selected on the basis of worker protection and habitability.

J. Plastic glove boxes, which can be taped around valves or other fixed components, and plastic bags should be used where practical so that personnel can work on equipment without being exposed to the contamination

produced during the work, and to limit the spread of contamination.

K. Individuals should be instructed to stay in the lowest radiation area consistent with performing their assigned jobs.

L. Personnel will wear electronic dosimeters for work in high radiation areas so that they can determine their accumulated exposure at any time during the job. This is in addition to their TLD.

M. On jobs with exceptionally high radiation levels, worker exposures should be monitored using a remote monitoring or timing device to ensure that personnel do not receive more exposure than intended. The individual monitoring the workers exposure should be in a low dose rate area.

12.1.3.2 Specific ALARA Considerations for Steam Generator Repair

The techniques in paragraph 12.1.3.1, except for listing J, are normally used when inspecting and plugging steam generator tubes.

After access to the steam generator primary heads is obtained, covers are installed, if practical, over the hot and cold leg nozzle openings with a layer of material to prevent tools and debris from entering the pipes. If personnel are required to work inside the primary head for a significant amount of time, consideration is given to adding temporary shielding.

Normally, however, this is not worthwhile since at least half the exposure is due to shine from crud inside the steam generator tubes which cannot be easily shielded because the tube sheet area must normally be kept clear for inspection or tube plugging.

12.1.3.3 Specific ALARA Considerations for Reactor Head Removal and Installation

Techniques described in paragraph 12.1.3.1, except for listings B, J, and M, are normally used when removing and installing the reactor head. Quick disconnect electrical cables and reactor head ventilation ducts which can be quickly removed are used to reduce time spent in radiation areas. Temporary shielding can be installed around the outer control rod drive mechanisms to reduce exposure if crud collects in the control rod drive housing. A multiple stud tensioner is normally used to reduce radiation exposures by expediting removal and installation of the reactor head.

12.1.3.4 Specific ALARA Considerations for Inservice Inspections (ISI)

Techniques in paragraph 12.1.3.1 are normally used when performing ISI. Remote testing devices will be used in the conduct of the examinations, where practical. Written and possibly photographic or videotape records will be made of preservice inspection operations that have potential for future significant radiation exposure to personnel. By training the examiners and alerting them to the specific problems that they

can expect to encounter, less time will be spent in radiation areas.

12.1.3.5 Specific ALARA Considerations for Other Operations Involving Radiation Exposure

Other operations such as refueling, radwaste handling, spent fuel handling, loading and shipping, routine maintenance, sampling, and calibration are discussed in subsection 12.5.3.

1. National Environmental Studies Project, Compilation and Analysis of Data on Occupational Radiation Exposure Experienced at Operating Nuclear Power Plants, SAI Services, September 1974.

12.2 RADIATION SOURCES

This section discusses and identifies the sources of radiation that form the basis for shield design calculations and the sources of airborne radioactivity used for the design of personnel protective measures and for dose assessment.

12.2.1 CONTAINED SOURCES

The shielding design source terms are based on full-power operation with 1% fuel cladding defects. Sources in the primary coolant include fission products released from fuel clad defects, and activation and corrosion products. The sources in the reactor coolant corresponding to 1% defects are discussed in Section 11.12. Throughout most of the reactor coolant system, activation products, principally nitrogen-16 (N-16), are the primary radiation sources for shielding-design. For all systems transporting radioactive materials, conservative allowance is made for transit decay, while at the same time providing for daughter product formation.

The design sources are presented in this section by building location and system and were used to develop the final shield design. The information contained in Section 12.2.1 is considered original licensing information and is treated as historical[1]. The plant shielding design is such that the personnel doses should be below the limits established by

[1]Plant shielding source terms for the current plant configuration with power uprate and Replacement Steam Generators have been evaluated. These impacts are minor and do not appreciably alter the plant shielding design. Plant Radiation Zone Maps as described in UFSAR Section 12.3.1.2 remain unchanged.

10CFR Part 20.1 - 20.601 and the design features are consistent with the guidelines of Regulatory Guide 8.8 Revision 3.

Location of the equipment discussed in this section is shown in the general arrangement drawings of section 1.2.

12.2.1.1 Containment

12.2.1.1.1 Reactor Core

The primary radiations emanating from the reactor core during normal operation are neutrons and gamma rays. A conservative assumption of 105% of normal operating power of 3800 MWt was originally used to calculate total dose rate outside the primary and secondary shields. These calculations therefore remain valid for the power uprate to 103% of the original power rating of 3800 MWt. CESSAR Section 12.2.1.1.1 contains historical neutron and gamma spectras.

12.2.1.1.2 Reactor Coolant System

Sources of radiation in the reactor coolant system are fission products released from fuel and activated corrosion products that are circulated in the reactor coolant. These sources and their bases are listed in Section 11.1.

The activation product nitrogen-16 is the predominant activity in the reactor coolant pumps, steam generators, and reactor coolant piping. The N-16 activity in each of the components depends on the total transit time to the component. The derivation of N-16 activity is shown in Section 11.1.4.

See Section 11.1 for activity and crud thickness values.

12.2.1.1.3 Main Steam Supply System

Radioactivity in the main steam supply system is based on a steam generator tube leakage rate of 1 gallons per minute concurrent with 1% failed fuel. These sources are listed in table 12.2-1. These sources were developed assuming that the condensate polishing demineralizers are not in use. It is assumed that the blowdown rate to the blowdown demineralizers is 1% of the main steam rate.

12.2.1.1.4 Spent Fuel Handling and Transfer

The spent fuel assemblies are the predominant long term source of radiation in the containment after plant shutdown for refueling. A reactor operating time necessary to establish near-equilibrium fission product buildup for the reactor at rated power is used in determining the source strength. As a result of new core design, dose analysis were performed to assess the maximum expected fuel composition. The results showed that dose rates to the fuel pool equipment and personnel in the area remained within established limits as discussed in Section 9.1.4.3.4.

12.2.1.1.5 Processing Systems

12.2.1.1.5.1 Chemical and Volume Control System (CVCS). Radiation sources in the CVCS consist of radionuclides carried in the reactor coolant. Nitrogen-16 (N-16) is the predominant radiation source in the reactor coolant system. The design of the CVCS ensures that most of the N-16 has decayed before the letdown stream leaves the containment by placing a delay mechanism in the letdown flow to obtain an additional

95 seconds decay of N-16. All CVCS system heat exchangers other than the regenerative heat exchanger are located in the auxiliary building.

A. General Design Bases

The shielding design was based on the maximum expected activity in each component as listed in Tables 12.2-2a, b, c, d, and e. This information is considered original licensing information and not expected to be updated.

B. Specific Component Bases

1. Regenerative Heat Exchanger

Total tube volume (letdown) 2.0×10^4 cm^3

Total shell volume (charging) 1.6×10^5 cm^3

Letdown has RCS specific activities

Charging has volume control tank (VCT) specific activities

2. Letdown Heat Exchanger

Total tube volume is based on 69 gallons of water with reactor coolant specific activity.

3. Seal Injection Heat Exchanger

Total tube volume is based on 15 gallons of water with volume control tank specific activity.

C. Ion Exchangers (Table 12.2-8)

1. Purification Ion Exchanger

Total curie inventory is based on a resin buildup of 1.2 effective years. This ion exchanger is

used for lithium removal and normal purification of RCS letdown. When it is used for lithium removal it is on line an average of 58 days prior to placing it in service as a purification ion exchanger for 292 days.

All nuclides except Xe, Kr, Rb and Cs have a decontamination factor (DF) of 10 and efficiency of 90%, Xe and Kr have a DF of 1.0 and efficiency of 0%, Rb and Cs have a DF of 2.0, and efficiency of 50%.

2. Preholdup Ion Exchanger

Total curie inventory is based on resin buildup of 1.0 effective year (292 days). All nuclides except Xe, Kr, Rb, Cs, have a decontamination factor (DF) of 10 and an efficiency of 90%, Rb and Cs have a DF of 100 and efficiency of 99%, Xe and Kr have a decontamination factor of 1 and an efficiency of 0%.

Sources processed by the prehold-up Ion-exchanger include 1.1 x 10^6 gallons of letdown previously processed through the purification Ion exchanger and purification filter, 200 gpd from the Reactor Drain Tank (RDT) and 50 gpd from the Equipment Drain Tank (EDT).

3. Boric Acid Condensate Ion Exchanger

Total curie inventory is based on resin buildup of 1.0 effective year (292 days). Anion

decontamination factors of 10, and efficiency of 90% were used. All other ions have a decontamination factor of 1 and an efficiency of 0%. Total liquid processed is 1.83 x 10^5 gallons.

D. Filters (Table 12.2-9)

Total curie inventories on all CVCS filters are based on crud buildup of 292 days. All CVCS filters remove crud with a decontamination factor of 10 and an efficiency of 90%.

E. Tanks (Table 12.2-10)

1. Reactor Drain Tank (RDT)

The total curie inventory in the RDT is based on a water volume of 2565 gallons and an equivalent vapor volume of 217 ft^3. The tank vapor-liquid phases are in equilibrium and the tank liquid activity fraction is 1.0 of the RCS.

2. Equipment Drain Tank (EDT)

The total curie inventory in the EDT is based on a water volume of 5102 gallons and an equivalent vapor volume of 895 ft^3. The tank vapor-liquid phases are in equilibrium and the tank liquid activity fraction is 0.1 of the RCS.

3. Volume Control Tank (VCT)

The total curie inventory in the VCT is based on the average water volume in the tank of 3170 gallons of RCS letdown and an effective vapor

volume of 292 ft^3. Gas stripping was considered and the VCT vapor gas is in equilibrium with the liquid.

4. Hold-up Water Tank (HT)

   The total curie inventory in the HT is based on the average volume of 246,930 gallons. Gas stripping was considered and the tank vapor-liquid phases are assumed not in equilibrium. Activity in the tank is based on holdup of 200 gpd from the RDT, 50 gpd from the EDT and 3,767 gpd from RCS letdown.

5. Reactor Make-up Water Tank (RMWT)

   The total curie inventory in the RMWT is based on a water volume of 492,954 gallons. Activity in the tank is based on 9.9×10^5 gallons processed by the Boric Acid Concentrator.

6. Refueling Water Tank (RWT)

   The total curie inventory in the RWT is based on a water volume of 697,818 gallons. Activity in the tank is based on 1.8×10^5 gallons processed by the Boric Acid Concentrator.

12.2.1.1.5.2 Steam Generator Blowdown System. Radiation sources in the steam generator blowdown system shown in table 12.2-3 are based on the primary-to-secondary leakage rate and failed fuel rate stated in paragraph 12.2.1.1.3. However, the liquid is assumed to be processed through the steam generator blowdown system at the maximum rate of 1% of main steam rate. High-conductivity solutions resulting from regeneration of blowdown demineralizers will normally be processed in the chemical waste neutralizing tanks (see section 10.4), in the absence of primary-to-secondary leakage. Radioactive high-conductivity solutions will be processed by the LRS (see section 11.2).

12.2.1.1.5.3 Condensate Polishing System. For shielding and dose assessment purposes, the condensate polishing system does not yield substantive doses since radioactivity will be present in the demineralizers only in the event of coincident steam generator tube leaks and condenser tube leaks. Space for shielding has, however, been reserved should dual tube leaks occur. Demineralizer inventory for dual leakage is shown in table 12.2-3.

12.2.1.2 Auxiliary Building

12.2.1.2.1 Shutdown Cooling System

The pumps, heat exchangers, and associated piping of the shutdown cooling system (SDCS) are potential carriers of radioactive materials. For plant shutdown, the SDCS pumps and heat exchanger sources of radioactivity result from the radioactive isotopes carried in the reactor coolant, discussed in Section 12.2.1.1.2, after 4 hours of decay following shutdown and dilution.

Table 12.2-1h provides a listing of the maximum specific source strenghts (MeV/gm-sec) in the SDCS.

TABLE 12.2-1h

SHUTDOWN COOLING SYSTEM (SDCS) SPECIFIC SOURCE STRENGTHS

*number in parentheses denotes power of ten

12.2.1.2.2 Nuclear Cooling Water System

The nuclear cooling water system is normally nonradioactive or of very low level activity due to inleakage. The process

radiation monitor (section 11.5) for this system has a sensitivity of 1×10^{-6} $\mu Ci/cm^3$ of Cs^{137} uniformly distributed throughout the nuclear cooling water system. For shielding and dose assessment purposes, the nuclear cooling water system does not yield substantive doses.

12.2.1.3 Fuel Building

12.2.1.3.1 Spent Fuel Storage and Transfer

The predominant radioactivity sources in the spent fuel storage and transfer areas in the fuel building are the spent fuel assemblies. Spent fuel assembly sources are discussed in Section 12.2.1.1.4. For shielding design, the spent fuel pool is assumed to contain the design maximum number of fuel assemblies. Of these, 241 spent fuel assemblies are assumed to be from unloading the full core with 72 hours decay, and 81 assemblies are assumed to be from previous refueling operations with 90 days decay. Shielding during dry fuel storage, transfer, and transport operations is provided by the NAC-UMS® transportable storage canister (TSC), transfer cask (TFR), and vertical concrete cask (VCC) as applicable. In addition to this shielding, the NAC-UMS® Certificate of Compliance (CoC) requires a minimum decay time of five years for assemblies selected for dry fuel storage.

12.2.1.3.2 Spent Fuel Pool Cooling and Cleanup System

Sources in the spent fuel pool cooling and cleanup (SFPCC) system are a result of transfer of radioactive isotopes from the reactor coolant into the spent fuel pool during refueling operations. The reactor coolant activities for fission,

corrosion, and activation products are decayed for the amount of time required to remove the reactor vessel head following shutdown, are reduced by operation of the CVCS purification ion exchangers, and are diluted by the total volumes of the water in the reactor vessel, refueling pool, and spent fuel pool. This activity then undergoes subsequent decay and accumulation on the SFPCC filters and ion exchangers as discussed in subsection 11.1.7. These sources are listed in table 12.2-4.

During dry fuel storage as described in section 9.1.4.2.3.2, the annulus flush system may use temporary ion exchange vessels to reduce the radioactivity of the spent fuel pool water contained within the cask loading pit to minimize the contamination transferred to the transportable storage canister. These vessels accumulate similar activity to that listed in Table 12.2-4 for the spent fuel pool purification system. Dose rates are controlled in accordance with Chapter 12.5.

12.2.1.4 Turbine Building

12.2.1.4.1 Main Steam Supply and Power Conversion Systems

Potential radioactivity in the main steam supply and power conversion systems is a result of steam generator tube leaks and fuel cladding defects as discussed in paragraph 12.2.1.1.3. This radioactivity is sufficiently low so that no radiation shielding for equipment in secondary systems, other than portions of the steam generator blowdown system (paragraph 12.2.1.1.5.2), is required in order to meet the design radiation zone requirements.

12.2.1.5 Radwaste Building

12.2.1.5.1 Liquid and Solid Radwaste Systems

Radioactive inputs to the radwaste system sources include fission and activation product radionuclides produced in the core and reactor coolant. The components of the radwaste systems contain varying degrees of activity.

The concentrations of radionuclides present in the process fluids at various locations in the radwaste systems, such as pipes, tanks, filters, ion exchangers, and evaporators, are discussed in section 11.1. Shielding for each component of the radwaste systems is based on maximum activity conditions as shown in table 12.2-5. Pumps are modeled using the appropriate geometries and process point activities.

12.2.1.5.2 Gaseous Radwaste System

Radiation sources for each component of the waste gas system are based on operation with the maximum activity conditions as given in sections 11.1 and 11.3. Tabulation of the maximum activities is shown in table 12.2-5.

12.2.1.6 Sources Resulting from Design Basis Accidents

The radiation sources from design basis accidents include the design basis inventory of radioactive isotopes in the reactor coolant, plus postulated fission product releases from the fuel. Accident parameters and sources are discussed and evaluated in chapter 15.

12.2.1.7 Stored Radioactivity

The principal sources of activity not enclosed by plant structures are the independent spent fuel storage installation (ISFSI), the refueling water tank (RWT), the holdup tank (HT), the reactor makeup water tank (RMWT), and the condensate storage tank (CST). The annual dose to an individual at the site boundary due to normal operation of the ISFSI is limited to the values specified in 10CFR72.104. The CST is expected to contain concentrations of radionuclides that yield a surface dose rate of 0.25 mrem/h or less. Radionuclide inventories of the RWT, RMWT, and HT are listed in Table 12.2-2e.

Spent fuel is stored in the spent fuel pool until it is placed in dry fuel storage systems for storage at the ISFSI or the spent fuel shipping cask for transport offsite. Storage space is allocated in the radwaste building for storage of spent filter cartridges and processed spent resins, evaporator bottoms, and chemical wastes. Radioactive wastes stored inside plant structures are shielded so that there is design radiation zone I access outside the structure. If radiation levels outside the structure exceed the design radiation zone limit, or it becomes necessary to temporarily store radioactive wastes outside plant structures, radiation protection measures are taken by the radiation protection staff to assure compliance with 10CFR20.1001 - 20.2402 and to be consistent with the recommendations of NRC Regulatory Guide 8.8.

The dry active waste processing and storage (DAWPS) facility and the low-level radioactive material storage facility

(LLRMSF) are part of the Solid Waste Management System, and are described in 11.4.

The DAWPS facility was built to the standards of RG 1.143 and GL 81.38, but was not determined to require designed shielding. The isotopic composition of material stored at the DAWPS facility is based on the station waste stream shown in Table 11.4-2, SRS Input Activities (Ci/yr/unit). The curie content, form, isotopic distribution, and use of radioactive materials in the DAWPS facility are described in 11.4.1. The 15 Curie limit is based on minimizing exposure at the site boundary in the event of a fire in the DAWPS facility.

The LLRMSF was designed for the interim storage of up to 60,000 Ci of dry and solidified radioactive waste. The Curie limit and isotopic distribution of this waste are based on Solid Radwaste System Output Activities, reflected in Table 11.4-6, SRS Output Activities (Ci/yr/unit) using a nominal 5 year period of waste accumulation. Material stored in the LLRMSF shall be in strong tight containers suitable for the material contained and the intended storage duration. Repackaging which may be required based on disposal site criteria will not be conducted in the LLRMSF. Repackaging due to container failures will be handled on location.

An Independent Spent Fuel Storage Installation (ISFSI) was built at Palo Verde to store spent fuel which no longer requires active cooling. Refer to Independent Spent Fuel Storage Installation 72.212 Evaluation Report for a description of the form and use of radioactive material stored at the ISFSI. Refer to Engineering Calculation 13-NC-RC-0203 for the

isotopic composition, Curie content, models and parameters used for calculating source magnitudes, and method for source term specification for material stored at the ISFSI.

12.2.1.8 Field Run Pipe Routing

The procedures for routing of radioactive piping are discussed in paragraph 12.1.2.2. Radioactive piping was routed as part of the engineering design effort. Radioactive piping was not field-routed.

12.2.1.9 Old Steam Generator and Old Reactor Vessel Closure Head Storage Facility (OSG/ORVCHSF)

The OSG/ORVCHSF is a long term storage facility designed to store the six old steam generators, three old reactor vessel closure heads and associated control element drive mechanisms, and three old reactor vessel closure head lift rigs from the three units.

The old steam generator section of the facility is constructed of concrete with 18″ walls and roof, 10″ general flooring, and 6′ thick load bearing slabs. The old reactor vessel closure head section of the facility is constructed of concrete with 30″ perimeter walls, an 18″ common wall with the old steam generator storage facility, 24″ roof, and 18″ general floor. The radiological design of the OSG/ORVCHSF provides adequate shielding to satisfy Palo Verde licensing basis requirements as per 10 CFR Part 20 and incorporates ALARA design features as per Regulatory Guide 8.8.

The building's radiological design has been evaluated for the storage configuration. The maximum dose rate at the RCA and Restricted boundary, considered the outside walls of the facility, is below the total effective dose equivalent to members of the public; does not exceed 0.1 rem in a year, as specified in 10 CFR 20.1301, Dose limits for individual members of the public. Per UFSAR Table 12.1-1, this results in a radiation zone classification of zone 1 allowing unrestricted access to the Site areas outside the facility, and zone 4 (OSG Section)/zone 5 (ORVCHSF Section) within the facility.

The OSG/ORVCHSF is classified as non safety related, non quality related (NQR), and non power generation structure. The OSGSF that houses the original Unit 2 steam generators is designed to the requirements of the Uniform Building Code (UBC). The remaining portion of the OSGSF that houses the original Unit 1 and 3 steam generators, and the ORVCH portion of the facility that houses the three Unit's reactor vessel closure heads are designed to the requirements of the International Building Code (IBC). The buildings' designs for dead, live, wind, seismic, and flood loads meet or exceed the UFSAR requirements for seismic category II structures.

The OSG/ORVCHSF is a stand-alone facility that does not interface with any plant structures or systems during any mode of plant operation. No offsite or onsite electrical power is provided, there is no forced or natural ventilation, and there are no normally open penetrations providing access to the stored radioactive material. There is no normal release path for the radioactive material within the facility.

The OSG/ORVCHSF is not designed for normal occupancy, and access is infrequent. Personnel access is controlled physically by the use of large concrete tilt panels or shield blocks and administratively by requiring specific approval from Radiation Protection personnel.

The OSG/ORVCHSF is located North East of Unit 1 cooling towers and West of Low Level Radioactive Material Storage Facility as shown on Site General Arrangement Plan, drawing number 13-C-ZVA-003.

The old steam generators are enclosed by the installation of nozzle covers and plugs, welded in place, and the exterior surfaces are coated with a fixative to minimize the spread of loose surface contamination.

The reactor vessel closure heads are enclosed by the installation of a 3" thick metal bottom plate, applying a fixative to the exterior surfaces, and securely covering the ORVCH with a heavy tarp to minimize the spread of loose surface contamination. The enclosures for the old steam generators and old reactor vessel closure heads provide radiation shielding, prevents access to the internal surfaces, and prevents the release of radioactive material into the storage facility.

The six steam generators have a nominal envelope volume of 18,050 ft3 each; for a total volume of 108,300 ft3.

The three reactor vessel closure heads have a nominal envelope volume of 7,172 ft3 each; for a total volume of 21,516 ft3.

The expected waste volume contained within the facility is approximately 130,000 ft3 and is comprised of the six steam

generators, three reactor vessel closure heads, and three reactor vessel closure heads’ lift rigs.

The total radioactivity of the six old steam generators is determined to be 8.45E+03 Curies. The total radioactivity associated with the three old reactor vessel closure heads is determined to be 1.95E+01 Curies. Table 12.2-5a Palo Verde Old Steam Generator and Old Reactor Vessel Closure Head Storage Facility Radioactivity Content provides the radioactivity by item, isotope, and level. The characterization considers the activation of the material and deposition of activation and fission product material on the items. The material is in a solid form.

The original steam generators and reactor vessel closure heads no longer serve a design function, are permanently removed from service, and are placed in storage until final disposal is accomplished. The expected storage time is until Plant decommissioning, not precluding the possibility for earlier disposal.

The source term used as the shielding design input for the old steam generators was 261 Ci of Co-60 per steam generator, and the geometry for the calculation is a horizontal cylinder; see calculation number A0-NC-ZL-0203.

The highest source term used as the shielding design input for the old reactor vessel closure heads was 6.87 Ci of Co-60, and the geometry for the calculation is a vertical cylinder; see calculation number A0-NC-ZL-0206.

Measured dose rates on contact with the facility’s outside walls are less than 0.05 mR/hr.

Radiation surveys are performed semi-annually outside of the structure to ensure the radiation levels meet 10 CFR part 20 requirements. Collection ports are provided to monitor airborne radioactive contaminants without entry into the facility. A water collection sump is provided inside the structure with a sump monitoring port to accommodate checking the collection sump without entry into the facility.

12.2.2 AIRBORNE RADIOACTIVE MATERIAL SOURCES

This section deals with the models, parameters, and sources required to evaluate airborne concentrations of radionuclides during plant operations in various plant radiation areas where personnel occupancy is expected.

Leakage sources are dependent upon the concentrations of radionuclides in the primary system, secondary system, spent fuel pool, and the refueling pool. The assumptions and parameters required to evaluate the isotopic airborne concentrations in the various applicable regions are listed in table 12.2-6. The chemical and volume control system (CVCS) and the spent fuel pool cooling and cleanup system (SFPCCS) were designed to purify reactor coolant through ion exchangers after reactor shutdown and cooldown. This ensures that the effect of activity spikes will not significantly contribute to the containment airborne activity during refueling operations. The contribution to airborne activity due to reactor vessel head removal is considered negligible as the reactor vessel head vent is connected to the gaseous radwaste system.

The detailed listing of the expected airborne isotopic concentrations in the applicable regions is presented in table 12.2-7. The final design of the plant ensures that the expected airborne isotopic concentrations in the applicable regions are well below the maximum permissible concentration for the critical organ for the appropriate isotope for occupational workers, as adjusted on the basis of expected weekly occupancy in the regions.

12.2.2.1 Model for Calculating Airborne Concentrations

Plant areas with airborne radioactivity are characterized by a constant leakrate of a radioactive source at a constant source strength with a constant exhaust rate of the contaminant. This leads to a peak or equilibrium airborne concentration of the radioisotope in the regions as calculated by the following equation:

$$C_i(t) = (L\,R)_i\,A_i\,(P\,F)_i\,\frac{\left(1 - e^{-\lambda_{Ti}t}\right)}{\left(V\,\lambda_{Ti}\right)} \qquad (1)$$

where:

$(L\ R)_i$ = leak or evaporation rate of the i^{th} radioisotope in g/s, in the applicable region,

and

A_i = activity concentration of the i^{th} leaking or evaporating radioisotope in μCi/g

$(P\ F)_i$ = partition factor or the fraction of the leaking activity that is airborne for the i^{th} radioisotope

λ_{Ti} = total removal rate constant for the i^{th} radioisotope in s^{-1} from the applicable region

$= (\lambda_{di} + \lambda_e)$

(λ_{di} and λe are the removal rate constants in s^{-1} due to radioactive decay and the exhaust

from the applicable region respectively for the i^{th} radioisotope)

t = time interval between the start of the leak and the time at which the concentration is evaluated in seconds

V = free volume of the region in which the leak occurs in cm^3

C_i (t) = airborne concentration of the i^{th} radioisotope at time t in $\mu Ci/cm^3$ in the applicable region

From the above equation, it is evident that the peak or equilibrium concentration, $C_{Eq,i}$ of the i^{th} radioisotope in the applicable region will be given by the following expression:

$$C_{Eq,i} = (L\ R)_i\ A_i\ (P\ F)_i\ /\ (V\ \lambda_{Ti}) \qquad (2)$$

With high exhaust rates, this peak concentration will be reached within a few hours.

a. Numbers in parentheses denote powers of 10.

1. Particulate isotopes are unlikely to become airborne due to their high affinity for chemical binding and large atomic mass. Particulate concentrations are assumed to be less than 1.0E-13 µCi/cc.

12.2.3 SOURCES USED IN NUREG-0737 POST-ACCIDENT SHIELDING REVIEW

The post-accident shielding review described in paragraph 12.1.2.4 used initial core releases equivalent to those recommended in Regulatory Guides 1.4 and 1.7, and Standard Review Plan 15.6.5, and considered two LOCA events. The first was a LOCA with recirculation accomplished via the containment sump. The second was a LOCA with an intact primary with recirculation accomplished via the shutdown cooling system. The following core releases were used in the review:

A. Source A: Containment airborne: 100% noble gases, 25% iodines - see table 12.2-8.

B. Source B: Reactor coolant: 100% noble gases, 50% halogens, 1% solids - see table 12.2-9

C. Source C: Containment sump: 50% halogens, 1% solids - see table 12.2-10.

Volumes used for each source were:

A. Source A: Containment free volume of 2.6×10^6 cubic feet.

B. Source B: Reactor coolant system (RCS) volume of 1.37×10^4 cubic ft.

C. Source C: The minimum volume of water, 8.99×10^4 cubic feet present at the time of recirculation. (RCS + refueling water tank + safety injection tanks.)

A LOCA with sump recirculation is represented by sources A and C. An intact primary-degraded core LOCA is represented by sources A and B (source A was not reduced even though there is no mechanism to assume noble gases in both sources). The

systems assumed to be operating for each event are shown in table 12.2-11. The results of the shield review are presented in paragraph 12.3.1.3.

Time integrating dose curves, normalized to initial time equals zero, were developed for the sources as an aid in developing post-accident access plans. These curves are presented as figures 12.2-1 (A) (source A), 12.2-2 (A) (source B), and 12.2-3 (A) (source C).

Table 12.2-11
SYSTEMS USED IN POST-ACCIDENT SHIELDING REVIEW[a][b]

Source Type	LOCA with Sump Recirculation	LOCA - Degraded Core - Intact Primary
A	• Containment air • Hydrogen control system	• Containment air • Hydrogen control system
B		• Safety injection system • Containment spray system • Shutdown cooling system • Post-accident sampling system • Letdown system[c]
C	• Safety injection system • Containment spray system • Shutdown cooling system • Post-accident sampling system • Letdown System[c]	

a. Where redundant systems exist, both are assumed in use.

b. Radwaste systems not used post-accident.

c. Portions up to purification filter inlet.

12.3 RADIATION PROTECTION DESIGN FEATURES

12.3.1 FACILITY DESIGN FEATURES

Specific design features to maintain personnel exposures as low as reasonably achievable (ALARA) are discussed in this section. The design features recommendations given in Regulatory Guide 8.8, Paragraph C.2, are utilized to minimize exposures to personnel.

Facilities and equipment of a specialized nature for handling special nuclear source and byproduct material are not required except for fuel handling and radioactive waste processing. Fuel handling and radwaste processing equipment are described in section 9.1 and chapter 11, respectively. Materials handled in the radiochemistry laboratory and low activity sealed sources used for laboratory calibration purposes do not require special handling equipment. Unsealed sources and radioactive samples that pose an airborne contamination hazard are handled in conventional hoods which exhaust to the auxiliary building ventilation system, described in section 9.4.

12.3.1.1 Plant Design Description for ALARA

Equipment and plant design features employed to maintain radiation exposures ALARA are based upon the design considerations of section 12.1 and are outlined here for several general classes of equipment (paragraph 12.3.1.1.1) and several typical plant layout situations (paragraph 12.3.1.1.2).

12.3.1.1.1 Common Equipment and Component Designs for ALARA

Refer to CESSAR Section 12.3.1.2 for components in CESSAR scope

12.3.1.1.1.1 Filters. Filters in the auxiliary building that accumulate radioactive particles are supplied with the means to perform cartridge replacement with remote tools. Cartridge replacement of the blowdown demineralizer filter may utilize long-handled tools, as needed to maintain exposures ALARA.

Cartridge filters have adequate space for removal, cask loading, and transport. A filter handling system has been incorporated into PVNGS for all filters that could constitute a substantial radiation source. The use of the handling system is based upon ALARA principals. In use, the handling system is placed over the filter in the space normally occupied by its concrete hatch. The lead base of the system adequately attenuates cartridge radiation. A leaded glass window provides the operator with a complete view of the filter housing and cartridge while he is performing the changeout with remote tools. The cartridge can then be lifted into a shield cask placed on the base. The shielding provided by the filter handling system ensures the operators exposure is maintained ALARA while removing and transporting filters. An overhead monorail is used to transport cask and cartridge to the radwaste storage area.

12.3.1.1.1.2 Ion Exchangers. With the exception of potentially radioactive blowdown processing system ion exchangers, ion exchangers for radioactive systems are designed

so that spent resins can be remotely and hydraulically transferred to spent resin tanks and that fresh resin can be loaded into the ion exchanger remotely.

Underdrains and downstream strainers are designed for full system pressure drop. The ion exchangers and piping are designed with provisions for being flushed with compressed air or nitrogen, or demineralized water.

12.3.1.1.1.3 Evaporators. The liquid radwaste system (LRS) evaporator is provided with chemical addition connections to allow the use of chemicals for descaling operations. Space is provided to allow uncomplicated removal of heating tube bundles. The nonradioactive components are separated from those that are radioactive by a shield wall. Instruments and controls necessary for evaporator operation are located on the design radiation zone 2 side of the shield wall. Frequently operated valves in radioactive lines are capable of being operated from the design radiation zone 2 side of the shield wall.

12.3.1.1.1.4 Pumps. Pumps in radioactive and potentially radioactive systems are provided with mechanical seals to reduce seal servicing time. These pumps include those in the nuclear cooling water, essential cooling water, safety injection, containment spray, spent fuel pool cooling, radwaste, and chemical and volume control systems. Pumps and associated piping are arranged to provide adequate space for access to the pumps for servicing. Pumps in the above systems

are provided with flanged connections for ease in removal. Pump casings are provided with drain connections for draining the pump for maintenance. Plant layout ensures that maintenance can be performed in such a way that exposure to major radiation sources is minimized.

12.3.1.1.1.5 Tanks. Tanks in radioactive and potentially radioactive systems are provided with sloped bottoms and bottom outlet connections whenever practical.

A. Tanks with flat bottoms sloped toward the outlet include:

   1. Reactor makeup water tank
   2. Radwaste holdup tanks
   3. Refueling water tank
   4. Chemical and volume control system holdup tank
   5. Liquid radwaste evaporator condensate storage tanks
   6. Condensate storage tank
   7. Chemical waste tanks
   8. Liquid radwaste monitor tanks

   These tanks have outlet connections located on the side of the tank as near to the bottom as possible.

B. Tanks with rounded bottoms and low point outlet connections include:

1. Spent resin tanks
2. Volume control tank
3. Reactor drain tank
4. Chemical drain tank
5. Equipment drain tank

Overflow lines are directed to the LRS to control contamination within plant structures. Tanks are contained in separate compartments with drains directed to the LRS or the chemical and volume control system.

12.3.1.1.1.6 Heat Exchangers. Heat exchangers are provided with corrosion-resistant tubes of stainless steel or other suitable materials with tube to sheet joints welded or expanded to minimize leakage. Impact baffles are provided, and tube side and shell side velocities are limited to minimize erosive effects.

12.3.1.1.1.7 Instruments. Instrument devices are located in low radiation zones and away from radiation sources whenever practical. Primary instrument devices, which are located in high radiation areas for functional reasons, are designed for easy removal for calibration. Readout devices are located in design low radiation areas, such as corridors and the control room, for servicing.

Some instruments (such as thermocouples) are provided in duplicate in high radiation areas to reduce access and service time. In the containment most instruments are located outside the secondary shield.

Integral radiation check sources or LED check sources are provided for response verification for airborne radiation monitors and safety-related area radiation monitors. These check sources provide a method to remotely response check each detector.

12.3.1.1.1.8 Valves. To minimize personnel exposures due to valve operation, motor-operated, diaphragm, or other remotely actuated valves are used in highly radioactive systems that require frequent valve operation.

Valves are located in valve galleries and are shielded from major system components wherever Possible. Long runs of exposed piping are minimized in valve galleries. In areas where manual valves are used in frequently operated process lines, either valve stem extenders or shielding is provided, so that personnel need not enter the high radiation area for normal valve operation. The criteria for selecting valve operators are detailed in paragraph 12.1.2.3.2.

For valves located in radiation areas, provisions are made to drain adjacent radioactive components when maintenance is required.

Valves for clean, nonradioactive systems are separated from radioactive sources and are located in readily accessible areas.

Manually operated valves in the filter and high activity ion exchanger valve compartments required for normal operation and shutdown are equipped with reach rods extending through the valve gallery walls. Personnel do not enter the valve galleries during flushing operations. The valve gallery shield walls are designed for maximum expected filter and ion exchanger activities.

For most larger valves (2-1/2 inches and larger) in lines carrying radioactive fluids, a grafoil or graphite yarn is used as a packing component. Diaphragm or bellows seal valves are used where minimal leakage is required.

12.3.1.1.1.9 Piping. The piping in pipe chases is designed for the life-time of the unit. There are no valves or instrumentation in pipe chases. Wherever radioactive piping is routed through areas where routine maintenance is required, pipe chases are provided to reduce the radiation contribution from these pipes to levels appropriate for the inspection requirements. Piping containing radioactive material is routed to minimize radiation exposure to the unit personnel.

12.3.1.1.1.10 Floor Drains. Floor drains and properly sloped floors are provided for each room or cubicle containing serviceable components containing radioactive liquids. Local

gas traps or porous seals are not used on radwaste floor drains. Gas traps are provided at the common sump or tank.

12.3.1.1.1.11 Sample Stations. Sample stations for routine sampling of process fluids are located in the radiochemical laboratory in the auxiliary building. Shielding is provided at the sample stations. Valves in sample lines are provided with reach rods as necessary to minimize personnel exposure during sampling.

12.3.1.1.1.12 Clean Services. Whenever possible, clean services and equipment such as compressed air piping, clean water piping, ventilation ducts, and cable trays are not routed through radioactive pipeways.

12.3.1.1.1.13 Reactor Coolant System Leakage Control. Exposures from airborne radionuclides to personnel entering the containment will be minimized by controlling the amount of reactor coolant leakage to the containment atmosphere. Examples of such controlled leakage are listed below:

1. Primary pressurizer safety valve leakage is directed to the Reactor Drain tank, as discussed in Section 5.2.2.
2. Instrumentation is provided to detect abnormal reactor coolant pump seal leakage. The reactor coolant pumps are equipped with two stages of seals plus a vapor or backup seal as described in Section 5.2.5.2.2. Additionally, the space between the double O-ring seal on the reactor vessel closure head is monitored to detect leakage past the inner

O-ring. Leakage is directed to the reactor drain tank, as discussed in subsection 5.2.5.

12.3.1.1.2 Common Facility and Layout Designs for ALARA

This section describes the design features utilized for standard type plant processes and layout situations. These features are employed in conjunction with the general equipment designs described in paragraph 12.3.1.1.1, and include the features discussed in the following sections.

12.3.1.1.2.1 Valve Galleries. Valve galleries are provided with shielded entrances for personnel protection. Where practical, the valve galleries are divided so that personnel requiring access are exposed only to valves and piping associated with one component at any given location. Floor drains are provided to control radioactive leakage. To facilitate decontamination in valve galleries, concrete surfaces are covered with a smooth-surfaced coating, which allows easy decontamination.

12.3.1.1.2.2 Piping. Pipes carrying radioactive materials that pose a radiation hazard are routed through controlled access areas. Each piping run is individually analyzed to determine the potential radioactivity level and surface dose rate. Where it is necessary that radioactive piping be routed through corridors or other low radiation areas, shielded pipeways are provided. Whenever practical, valves and instruments are not placed in radioactive pipeways. Whenever

practical, equipment compartments are used as pipeways only for those pipes associated with equipment in the compartment.

When practical, radioactive and nonradioactive piping are separated to minimize personnel exposure. Should maintenance be required, provision is made to isolate and drain radioactive piping and associated equipment.

Piping is designed to minimize low points and dead legs. Drains are provided on piping where low points and dead legs cannot be eliminated. Long radius elbows. or bends of several pipe diameters, are utilized whenever practicable for pipes carrying radioactive material.

Piping, carrying resin slurries or evaporator bottoms, is run vertically as much as possible.

Whenever possible, branch lines having little or no flow during normal operation are connected above the horizontal midplane of the main pipe.

12.3.1.1.2.3 Penetrations. To minimize radiation streaming through penetrations, as many penetrations as practicable are located with an offset between the source and the accessible areas. If offsets are not practical, penetrations are located as far as possible above the floor elevation to reduce the exposure to personnel. If these two methods are not used, alternate means are employed, such as baffle shield walls or grouting the area around the penetration.

12.3.1.1.2.4 Contamination Control. Access control and traffic patterns are considered in the basic plant layout to minimize the spread of contamination. Equipment vents and drains from highly radioactive systems are piped directly to the collection system instead of allowing any radioactive fluid to flow across to the floor drain. All-welded piping systems are employed on radioactive systems to the maximum extent practicable to reduce system leakage and crud buildup at joints.

Decontamination of potentially contaminated areas and equipment within the plant is facilitated by the application of suitable smooth-surface coatings to the concrete floors and walls.

Sloped floors and floor drains are provided in potentially contaminated areas of the plant. In addition, radioactive and potentially radioactive drain systems are separated from non-radioactive drain systems. Rooms with equipment or tanks that contain radioactive fluids have curbs to contain potential spills or leaks. Large tanks containing radioactive fluids are enclosed in water tight compartments or are surrounded by curbs.

In controlled access areas where contamination is expected, radiation monitoring equipment is provided (section 11.5 and subsection 12.3.4). Those systems that become highly radioactive, such as the spent resin lines in the radwaste system, are provided with flush and drain connections.

12.3.1.1.2.5 Equipment Layout. In systems where process cleanup equipment is a major radiation source, pumps, valves, and instruments are separated from the process component. This allows servicing and maintenance of these items in reduced radiation areas. Control panels are located in low radiation areas (design radiation zone 1 or 2).

Major components (such as tanks, ion exchangers, and filters) in radioactive systems are isolated in individual shielded compartments. Labyrinth entranceway shields or shielding doors are provided for each compartment from which radiation could stream or scatter to access areas and exceed the design radiation zone dose limits for those areas. For potentially high radiation components (such as ion exchangers and tanks), completely enclosed shielded compartments with hatch openings or labyrinth entryways with locked gates are used. For some infrequently serviced components, completely enclosed shielded compartments with removable concrete block walls are used. Nonradioactive equipment that requires maintenance is located outside radiation areas.

Exposure from routine in-plant inspection is controlled by locating, whenever possible, inspection points in properly shielded, low-background radiation areas. Radioactive and nonradioactive systems are separated as far as practicable to limit radiation exposure from routine inspection of non-radioactive systems. For radioactive systems, emphasis is placed on adequate space and ease of motion in a properly shielded inspection area. Where longer times for routine

inspection are required, and permanent shielding is not feasible, sufficient space for portable shielding is provided. For example, a remotely operated device is provided for inservice inspections of the reactor vessel. Access to high-radiation areas is under the supervision of the radiation protection personnel.

12.3.1.1.2.6 Field-Run Piping. Radioactive process piping design (i.e., routing or shielding) is not performed in the field.

12.3.1.1.2.7 Packaged Units. Each package unit is skid-mounted with all motors and pumps located on the periphery at the skid for ease of access and for quick removal to low-radiation area for maintenance or repair. Package components are provided with provisions for flushing, draining, and chemical cleaning. Heat exchangers are readily accessible for maintenance. As many control elements as possible are mounted remotely from the radioactive components so that the package can be remotely controlled and monitored. Components are designed with a minimum of crevices to reduce the accumulation of radioactive materials.

12.3.1.2 Design Radiation Zoning and Access Control

Access into the plant structures, plant yard areas and the low-level radioactive material storage facility is regulated and controlled.

Plant areas are categorized as design radiation zones according to expected maximum radiation levels and anticipated personnel occupancy with consideration given toward maintaining personnel exposures ALARA. Each design radiation zone defines the radiation level range to which the aggregate of contributing sources must be attenuated by shielding. Each room, corridor, and pipeway of every plant building is evaluated for potential radiation sources during normal, shutdown, spent resin transfer, and emergency operations; for maintenance occupancy requirements; for general access requirements; and for material exposure limits to determine appropriate zoning. The design radiation zone categories employed and their descriptions are given in table 12.1-1. The specific design zoning for each plant area is shown in drawings 13-N-RAR-001 through -017 and 13-N-RAR-039 (dry cask transfer operations). Frequently accessed areas, e.g., corridors, are shielded for design radiation zone 1 or zone 2 access. Licensing documents, ISFSI 72.212 Evaluation Report and NAC-UMS Universal Storage System FSAR 72-1015, provide information regarding ISFSI radiation protection design features. The area inside of the ISFSI is classified as a Radiation Zone 3.

The control of entry or exit of plant operating personnel to controlled access areas, and procedures employed to ensure that radiation levels and allowable working time are within the limits prescribed by 10CFR20.1001-20.2402 is described in section 12.5.

12.3.1.3 Radiation Zones - Post-Accident

Radiation zone maps were developed in accordance with NUREG-0737 to review potential access throughout the plant post-accident period. The facility layout assists in keeping occupational exposures ALARA even after a design basis accident. While exposures will be significantly higher than during normal operation, required access is provided to vital areas and systems without exceeding 5 rem/hr. Zone maps showing expected dose rates in the event of a LOCA with sump recirculation are provided as drawings 13-N-RAR-018 through -028. Zone maps for the hypothetical condition of a LOCA with an intact primary but with a degraded core are provided as drawings 13-N-RAR-029 through -038. The source terms correspond to those noted in subsection 12.2.3. The dose rates projected for these two sets of drawings do not assume decay beyond that corresponding to the onset of recirculation.

Even so, virtually unrestricted access will be permitted within portions of the upper floor of the auxiliary building (such as the Auxiliary Building area of the operations support center) and the lower levels of the control building. Continuous occupancy will be permitted in the control room, satellite technical support center (STSC), TSC, and diesel generator building, as dose rates will be 15 mrem/hr or less. Estimated radiation levels in vital areas were based on radiation sources from the post-accident operation of the following systems: containment, safety injection/shutdown cooling/containment spray, chemical and volume control system (up to purification

filter inlet), post-accident sampling, and hydrogen recombiners. The gaseous radwaste system will not be used post-accident. Palo Verde does not have a standby gas treatment system or an equivalent.

12.3.2 SHIELDING

The bases for the nuclear radiation shielding and the shielding configurations are discussed in this section.

12.3.2.1 Design Objectives

The basic objective of the plant radiation shielding, in conjunction with a program of controlled personnel access to, and occupancy of, radiation areas, is to reduce personnel and population exposures to levels that ALARA. Shielding and equipment layout and design are considered in ensuring that exposures are kept ALARA during anticipated personnel activities in areas of the plant containing radioactive materials, utilizing the design recommendations given in Regulatory Guide 8.8, Paragraph C.2, where practical.

An analysis of the PVNGS shielding design was performed to determine if TMI level source strengths would inhibit maintenance access or violate 10CFR50, Appendix A, General Design Criterion (GDC) 19. The review demonstrated that personnel radiation exposures in vital areas during post-accident activities will meet the criteria of NUREG-0737 and the GDC 19 design basis. The design review of plant shielding

discussed fulfills the NRC requirements outlined in NUREGs-0578 and -0737 as well as in Regulatory Guide 1.97, Revision 2.

Four plant conditions are considered in the nuclear radiation shielding design: normal full-power operation; shutdown; spent resin transfer; and emergency operations (for required access to safety-related equipment).

The shielding design objectives for the plant during normal operation (including anticipated operational occurrences), and shutdown operations are:

A. To ensure that radiation exposure to plant operating personnel, contractors, administrators, visitors, and proximate site boundary occupants are ALARA and within the limits of 10CFR20.1-20.601.

B. To assure sufficient personnel access and occupancy time to allow normal anticipated maintenance, inspection, and safety-related operations required for each plant equipment and instrumentation area.

C. To reduce potential equipment neutron activation and mitigate the possibility of radiation damage to materials.

The shielding design objectives for emergency operations are:

A. To ensure that radiation exposure to plant personnel in vital areas are maintained within the requirements of NUREG 0737.

B. To ensure that the control room, and TSC will be sufficiently shielded so that the direct dose plus the

inhalation dose (calculated in chapter 15) will not exceed the limits of 10CFR50, Appendix A, General Design Criterion 19.

C. To ensure that radiation exposure to an individual at site Exclusion Boundary Area (EAB) and Low Population Zone (LPZ) are maintained within 10 CFR 100 requirements.

12.3.2.2 General Shielding Design

Shielding is provided to attenuate direct radiation through walls and scattered radiation through penetrations to less than the upper limit of the design radiation zone for each area shown in drawings 13-N-RAR-001 through -017 and 13-N-RAR-039 (dry cask transfer operations). The shielding requirements for plant areas are presented in drawings 13-N-RAR-001 through -017 and 13-N-RAR-039. Design criteria for penetrations are consistent with the recommendations of Regulatory Guide 8.8, and are discussed in paragraph 12.3.1.1.2.

Should dose rates in excess of design zone criteria occur during PVNGS operation, PVNGS will add shielding or revise access to the affected area so as to ensure proper access control.

The material used for most of the plant shielding is ordinary concrete with a minimum bulk density of 140 pounds per cubic foot. Whenever poured-in-place concrete has been replaced by concrete blocks, design ensures protection on an equivalent shielding basis as determined by the density of the concrete

block selected. Concrete radiation shields are designed following the recommendations of Regulatory Guide 1.69 as discussed in section 1.8. Water is used as the primary shield material for areas above the spent fuel storage area.

12.3.2.2.1 Containment Shielding Design

During reactor operation, the containment protects personnel occupying adjacent plant structures and yard areas from radiation originating in the reactor vessel and primary loop components. The concrete containment wall, together with the reactor vessel and steam generator compartment shield walls, is designed to reduce radiation levels outside the containment from sources within the containment to less than 0.5 mrem/h. The containment shield is reinforced, prestressed concrete completely surrounding the nuclear steam supply system. The wall is 4 feet thick, and the dome varies from 4 feet at the springline to 3 feet 6 inches at the top.

For design basis accidents, the containment shield together with the control room shielding reduces the plant radiation intensities from fission products inside the containment to acceptable levels, as defined by 10CFR50, Appendix A, General Design Criterion 19, for the control room.

Where personnel and equipment hatches or penetrations pass through the containment wall, additional shielding is provided to attenuate radiation to the required level defined by the outside design radiation zone during normal operation and

shutdown, and to acceptable levels as defined by 10CFR50 during design basis accidents.

12.3.2.2.2 Containment Interior Shielding Design

During reactor operation, many areas inside the containment are design radiation zone 5 and normally inaccessible. However, the secondary bio-shielding is designed to reduce dose rates to approximately 15 mrem/h from direct neutron and gamma dose from the active core region. The areas that require potential access during power operation are designed to minimize neutron and gamma dose from this source of radiation. The design radiation zone maps of the containment are shown in drawings 13-N-RAR-001 through -017 (these zone maps reflect dose contribution from all radiation sources in the areas).

The main sources of radiation are the reactor vessel and the primary loop components, consisting of the steam generators, pressurizer, reactor coolant pumps, and associated piping. The reactor vessel is shielded by the concrete primary shield, reactor cavity shield, and by the concrete secondary shield which also surrounds all other primary loop components. Air cooling is provided to prevent overheating, dehydration, and degradation of the shielding and structural properties of the primary shield and reactor cavity shield.

The primary shield is a large mass of reinforced concrete surrounding the reactor vessel and extending upward from the containment floor to form the walls of the fuel transfer canal.

Refer to Section 3.B.3.1.6 for detailed discussion of the primary shield.

The reactor cavity shield, an annular mass of concrete, is below the reactor vessel nozzles between the vessel and the primary shield as shown in figure 12.3-1. This shield minimizes neutrons streaming from the annulus between the reactor vessel and the primary shield. The bottom of the cavity shield is located at about elevation 96 feet. The top of the cavity shield is located at about elevation 100 feet. Estimates of neutron dose rates vary spatially over the operating level from 50 to 60 mrem/hr at airlock and near preaccess filter unit to approximately 100 to 500 mrem/hr at locations that can view the CEDM cable structure and up to 1 to 2 rem/hr at locations along the edge of the refueling canal. Neutron dose levels outside the steam generator compartments at elevations below the operating level are expected to be negligible due to shielding by the concrete operating level floor.

The primary shield and reactor cavity shield are designed to meet the following objectives:

A. In conjunction with the secondary shield, to reduce the radiation level from sources within the reactor vessel and reactor coolant system to allow limited access to the containment during normal, full-power operation.

B. After shutdown, limit the radiation level from sources within the reactor vessel, to permit limited access to reactor coolant system equipment.

C. To limit neutron flux activation of component and structural materials.

The regenerative heat exchanger of the letdown portion of the chemical and volume control system is located in a shielded compartment that is normally design radiation zone 5. Shielding is provided for it consistent with its postulated maximum activity (subsection 12.2.1) and with the access and design zoning requirements of adjacent areas.

After shutdown, the containment is accessible for limited periods of time and all access is controlled. Areas are surveyed to establish allowable working periods. Dose rates are expected to range from 0.5 to 1000 mrem/h, depending on the location inside the containment (excluding reactor cavity). These dose rates result from residual fission products, neutron-activated materials, and corrosion products in the reactor coolant system.

Spent fuel is the primary source of radiation during refueling. Because of the extremely high activity of the fission products contained in the spent fuel elements and the proximity of design radiation zone 2 areas, extensive shielding is provided for areas surrounding the spent fuel pool and the fuel transfer canal to ensure that radiation levels remain below design zone levels specified for adjacent areas. Water provides the shielding over the spent fuel assemblies during fuel handling

(refer to figure 12.3-4). Furthermore, substantial structural barriers to limit access in the vicinity of the fuel transfer tube during fuel handling operations have been provided. Refer to figure 12.3-2 for the fuel transfer shielding arrangement.

The secondary shield is a reinforced concrete structure surrounding the reactor coolant equipment, including piping, pumps, and steam generators.

This shield protects personnel from the direct gamma radiation resulting from reactor coolant activation products and fission products carried away from the core by the reactor coolant. In addition, the secondary shield supplements the primary shield by attenuating neutron and gamma radiation escaping from the primary shield. The secondary shield is sized to allow limited access to the containment during full power operation. The thickness of secondary shield walls is 4 feet.

12.3.2.2.3 Auxiliary Building Shielding Design

During normal operation, the major components in the auxiliary building with potentially high radioactivity are those in the chemical and volume control system, the shutdown cooling system, the fuel pool cooling and cleanup system, and the primary sampling system.

Shielding is provided as necessary around the following equipment in the auxiliary building to ensure the design radiation zone and access requirements are met for surrounding areas:

A. Letdown heat exchangers and piping

B. Purification, preholdup, and deborating ion exchangers

C. Chemical and volume control tank

D. Charging pumps and piping

E. Shutdown cooling heat exchangers

F. Chemical drain tanks and pumps

G. CVCS and radwaste filters

H. Spent fuel pool cleanup ion exchangers and filters

I. Spent resin tanks and piping

J. Gas stripper

K. Seal injection heat exchanger

L. Boronometer (abandoned in-place)

M. Process radiation monitor

N. Seal injection filters

Shielding is based upon operation with maximum activity conditions as discussed in sections 11.1, 11.2, and 11.3 and subsection 12.2.1.

Depending on the equipment in the compartments, the access varies from design radiation zones 2 through 5. Corridors are shielded to allow design radiation zone 2 access. Operator areas for valve galleries are designed for design radiation zone 3 access. Frequently operated valves in high radiation areas are provided with remote actuators extending to design radiation zone 2 or zone 3 areas. (See paragraph 12.1.2.3.2, listing M.)

Removable sections of block shield walls, or concrete hatches with offset gaps to reduce radiation streaming are provided for replacement of ion exchangers, pumps, and heat exchangers.

12.3.2.2.4 Fuel Building Shielding Design

Concrete shield walls surrounding the spent fuel cask loading and storage area, fuel transfer and storage pools, and fuel transfer tube between the containment and fuel transfer pool are sufficiently thick to limit radiation levels outside the shield walls in accessible areas to design radiation zone 2. Access to the fuel transfer tube through the concrete radiation shield is provided by a heavy concrete hatch through the roof of the shield as shown in figure 12.3-3. The hatch is labeled to caution maintenance personnel that there are potentially lethal radiation fields during fuel transfer.

Water in the spent fuel pool provides shielding above the spent fuel transfer and storage areas. The relationship between dose rate over spent fuel during transfer and depth of covering water is shown in figure 12.3-4. Radiation levels at the fuel handling equipment are not expected to exceed 2.5 mrem/h.

The spent fuel pool cooling and cleanup (SFPCC) system (section 9.1) shielding is based on the maximum activity discussed in section 12.2 and the access and design zoning requirements of adjacent areas. Equipment in the SFPCC system to be shielded includes the SFPCC heat exchangers, pumps, and piping. (SFPCC filters and ion exchangers are located in the auxiliary building.)

12.3.2.2.5 Radwaste Building Shielding Design

Radwaste systems are principally located in the radwaste building. Additionally, the boric acid concentrator and the boric acid concentrate ion exchanger are in the radwaste building.

Major components or areas requiring shielding are:

- Low activity and high activity spent resin tanks
- Spent resin transfer pump
- Spent resin transfer valve gallery
- LRS evaporator and piping
- LRS concentrate tanks and pumps
- Boric acid concentrator
- Boric acid and LRS ion exchangers and their valve gallery
- Waste gas compressors and valve galleries
- Waste gas surge and decay tanks

Shielding is based on maximum expected radioactivity as noted in section 12.2. Depending on the equipment in the compartments, the access varies from design radiation zones 2 through 5. Corridors are shielded to allow design radiation zone 2 access. Operator areas for valve galleries are designed for zone 3 access. Frequently operated valves in high-radiation areas are provided with remote actuators extending to

design radiation zone 2 or zone 3 areas. (See paragraph 12.1.2.3.2, listing M.)

Removable sections of block shield walls and concrete plugs with offset gaps to reduce radiation streaming are provided for replacement of ion exchangers, if required.

Partial shield walls are placed between equipment in compartments with more than one piece of equipment to permit maintenance access (e.g., evaporator packages).

12.3.2.2.6 Turbine Building Shielding Design

Radiation shielding is not required for any equipment in the steam and power conversion system located in the turbine building. All areas in the turbine building are classified as design radiation zone 1.

12.3.2.2.7 Control Room Shielding Design

Engineering drawing 13-P-OOB-005 represents a layout drawing of the control room, showing its relationship to the containment.

The design basis loss-of-coolant accident (LOCA) dictates the shielding requirements for the control room. Consideration is given to shielding provided by the containment structure. Shielding and adequate radiation protection are provided to permit access and occupancy of the control room under LOCA conditions without personnel receiving radiation exposure in excess of 5 rem whole-body or its equivalent to other organs from all contributing modes of exposure for the duration of the

accident, in accordance with 10CFR50 Appendix A, General Design Criterion 19.

The design basis LOCA is described in section 15.6 and is based on the recommendations of Regulatory Guide 1.4. The dose to personnel, from airborne fission products inside the containment and in the radioactive cloud outside the control room, for the 30-day period following a postulated LOCA is discussed in section 15.6.

The parameters used in the demonstration of control room habitability, in addition to Regulatory Guide 1.4, are listed in section 6.4.4

12.3.2.2.8 Diesel Generator Building Shielding Design

There are no radiation sources in the diesel generator building; therefore, no shielding is required for the building.

12.3.2.2.9 Miscellaneous Plant Areas and Plant Yard Areas

Sufficient shielding is provided for plant buildings containing radiation sources so that radiation levels at the outside surfaces of the buildings are maintained below design radiation zone 1 levels. The steam generator blowdown ion exchangers, filter, and valve gallery are located inside of concrete shield walls. Plant yard areas that are frequently occupied by plant personnel are fully accessible during normal operation and shutdown. These areas are surrounded by a security fence, and closed off from areas accessible to the general public. Access to outside storage tanks that have a design contact dose rate

greater than 0.5 mrem/h is restricted by a concrete shield sufficiently high so that dose rates to personnel in plant yard areas are limited to less than 0.5 mrem/h from sources within those tanks. Where shielding penetrations and manways create a potential for dose rates to exceed 0.5 mrem/hr, access is administratively controlled as described in Section 12.5.3.

12.3.2.2.10 Low-Level Radioactive Material Storage Facility (LLRMSF) Shielding Design

The LLRMSF was designed for interim storage of solid radioactive material as defined in Generic Letter 81-38. The shielding is sufficient to accommodate a container contact dose rate of 750 mr/hr. An underground vault is provided for containers producing a dose rate in excess of 750 mr/hr. If a container producing greater than 750 mr/hr is to be stored above the vault, additional shielding (shadow shielding, storage module or credit for distance) must be implemented as necessary.

Additional shielding is to be provided on the vault lids as necessary to maintain radiological boundary criteria.

LLRMSF control room shielding is provided to protect personnel from direct radiation during a transfer of radioactive material into the storage area.

12.3.2.2.11 Independent Spent Fuel Storage Installation (ISFSI) Shielding Design

The ISFSI is designed for interim dry storage of spent nuclear fuel. The shielding is sufficient to comply with the requirements of 10CFR72.104 and 10CFR72.106. The design basis dose rate at the surface of the VCC is 50 mr/hr average. The design basis dose rate at the inlets and outlets is 100 mr/hr. The design basis dose at the owner controlled boundary is 25 mr annual whole body dose for Normal and Off-Normal conditions and 5 rem whole body for accident conditions.

For a detailed discussion of the VCC shielding properties, refer to NAC-UMS® FSAR Chapter 5. For a detailed discussion of compliance with 10CFR72.104 and 10CFR72.106 requirements, refer to NAC-UMS® FSAR Chapter 10 and ISFSI 72.212 Evaluation Report.

The ISFSI also incorporates an earthen berm to protect personnel within the owner controlled area. The ISFSI is surrounded by a security fence and is closed off from areas accessible to the general public.

12.3.2.3 Shielding Calculational Methods

The shielding thicknesses provided to ensure compliance with plant radiation zoning and to minimize plant personnel exposure are based on maximum equipment activities under the plant operating conditions described in chapter 11 and section 12.2. The thickness of each shield wall surrounding radioactive equipment is determined by approximating the actual geometry and physical condition of the source or sources. The isotopic

concentrations are converted to energy group sources using data from standard references.[(1),(2),(3),(4),(5)]

The geometric model assumed for shielding evaluation of tanks, heat exchangers, filters, ion exchangers, evaporators and piping, and the containment is a finite cylindrical volume source.

The methods and equations of Rockwell's Reactor Shielding Design Manual[(6)] are used to calculate dose rates. Buildup is calculated using Taylor coefficients presented in RSIC-10[(7)], and Broder's Method of Buildup Determination, presented in the Engineering Compendium on Radiation Shielding[(8)], is used for laminated shields.

In addition, industry-accepted computer programs are used for shielding analysis. ANISN[(9)], QAD[(10)], MICROSHIELD[(11)], and MORSE[(12)] are typical computer programs utilized for this purpose. ANISN is a multigroup, one-dimensional discrete ordinates transport program that solves the one-dimensional Boltzmann transport equation for neutrons and gamma rays in slab, sphere, or cylinder geometry. Using a finite difference technique, ANISN allows general anisotropic scattering; i.e., an L^{th} order Legendre expansion of the scattering cross-sections. Monte Carlo techniques may be used for more complicated geometries such as penetrations. QAD is a point-kernel general purpose program for estimating the effects of gamma rays and neutrons that originate in a volume distributed source. Description of the three-dimensional geometry of the

problem is accomplished by using quadratic equations to define surfaces. Two updated versions of the QAD computer program, QAD-CG[13] and QADMOD-G[14], are also used in shielding analysis. QAD-CG utilizes the Combinatorial Geometry subroutines from MORSE in place of the quadratic surface input. QADMOD-G is used for the calculation of gamma-ray fluxes or dose rates at discrete locations within a complex source-geometry configuration. MICROSHIELD is a microcomputer adaptation of the main frame computer program ISOSHLD[15] and is primarily utilized in shielding analysis of simple source-geometry configurations. ANISN is used for primary shield design and QAD is used for configurations not conveniently modeled as a cylindrical source with annular shields.

For design of the reactor cavity, a three-dimensional model was used to simulate radiation streaming from the reactor surface to the containment using the MORSE Monte Carlo program. The source terms used for the MORSE program were divided into 13 neutron energy groups.

The shielding thicknesses are selected to reduce the aggregate computed radiation level from contributing sources below the upper limit of the design radiation zone specified for each plant area. Shielding requirements are evaluated at the point of maximum radiation dose through any wall. Therefore, the actual anticipated radiation levels in the greater region of each plant area is less than this maximum dose and therefore less than the design radiation zone upper limit.

Where shielded entryways to compartments containing high-radiation sources are necessary, labyrinths or mazes are designed using general purpose gamma-ray scattering programs(16)(17) or methods summarized in RSIC-21.(18) The mazes are constructed so that the scattered dose rate, plus the transmitted dose rate through the shield wall from contributing sources, is below the upper limit of the design radiation zone specified for each plant area.

12.3.3 VENTILATION

The plant heating, ventilating, and air conditioning (HVAC) systems are designed to provide a suitable environment for personnel and equipment during normal operation and events of moderate frequency or certain infrequent events. Parts of the plant HVAC systems perform safety-related functions.

12.3.3.1 Design Objectives

The plant HVAC systems for normal plant operation and events of moderate frequency or certain infrequent events are designed to meet the requirements of 10CFR20.1-20.601 and 10CFR50.

12.3.3.2 Design Criteria

Design criteria for the plant HVAC systems include:

A. During normal operation and events of moderate frequency or certain infrequent events, the average and maximum airborne radioactivity levels to which

plant personnel are exposed are ALARA and within the limits specified in 10CFR20.1-20.601.

B. During normal operations and events of moderate frequency or certain infrequent events, the dose from concentrations of airborne radioactive material in unrestricted areas beyond the site boundary is ALARA and within the limits specified in 10CFR20.1-20.601 and 10CFR50, Appendix I.

C. The plant site dose limitations of 10CFR100 will be adhered to following those hypothetical accidents described in chapter 15.

D. The dose to control room personnel shall not exceed the limits specified in General Design Criterion 19 of Appendix A to 10CFR50 following those hypothetical accidents described in chapter 15.

12.3.3.3 Design Guidelines

To accomplish the design objectives, the following guidelines are followed wherever practical.

12.3.3.3.1 Guidelines to Minimize Airborne Radioactivity

A. Access control and traffic patterns are considered in the basic plant layout to minimize the spread of contamination.

B. Equipment vents and drains are piped directly to a collection device connected to the collection system

instead of allowing any radioactive fluid to flow across the floor to the floor drain.

C. All-welded piping systems are employed on systems containing radioactive fluids to the maximum extent practical to reduce system leakage.

D. Suitable coatings are applied to the concrete floors and walls of potentially contaminated areas to facilitate decontamination.

E. Design of potentially contaminated equipment incorporates features that minimize the potential for airborne radioactivity during maintenance operations. These features may include connections on pump casings for draining and flushing the pump prior to maintenance, or flush connections on piping systems that could become highly radioactive.

12.3.3.3.2 Guidelines to Control Airborne Radioactivity

A. The airflow is directed from areas with lesser potential for contamination to areas with greater potential for contamination.

B. In building compartments with a potential for contamination, the exhaust is designed for greater volumetric flow than is supplied to the area to minimize the amount of uncontrolled exfiltration from the area.

C. Air cleaning systems criteria for emergency systems are discussed under Regulatory Guide 1.52 in section 1.8.

   System design for both normal and emergency systems is described in section 9.4.

D. Means are provided to isolate the containment and fuel buildings upon indication of radioactive contamination to prevent the discharge of contaminants to the environment and minimize in-plant exposure.

E. Means are provided to isolate the control room to minimize inleakage of contaminated air to the operator.

F. Suitable containment isolation valves are installed to ensure that the containment integrity is maintained. See additional discussion in subsections 3.1.47, 3.1.49, and 6.2.4.

G. Redundancy and Seismic Category I classification features are provided for components of the HVAC systems required for safe shutdown of the reactor plant.

12.3.3.3.3 Guidelines to Minimize Personnel Exposure from HVAC Equipment

Access and service of ventilation systems in potentially radioactive areas are provided by component location to

minimize operator exposure during maintenance, inspection, and testing as follows:

A. Ventilation equipment rooms for outside air supply units and building exhaust system components are located in design radiation zone 2 and are accessible to the operators. Ventilation exhaust filtration units for the auxiliary and fuel buildings are located on the roofs of the respective buildings and are designated as being design radiation zone 3 areas. Work space is provided around each unit for anticipated maintenance, testing, and inspection. Filter-adsorber units generally are consistent with the recommendations of Regulatory Guide 1.52 for access and service requirements. (Refer to section 1.8).

B. Local HVAC equipment that services the normal building requirements is located in areas of low contamination when practical.

12.3.4 AREA RADIATION AND AIRBORNE RADIOACTIVITY MONITORING INSTRUMENTATION

Section 11.5 describes the function, operation, design, and locations of the radiation monitoring system (RMS). The RMS provides 28 fixed area and 16 fixed airborne monitors per unit as noted in section 11.5. Additionally, there are 18 portable monitor connection boxes located throughout each unit that can connect any of the three portable area monitors available for

each unit for use during extended maintenance. Thus, a portable monitor can be placed where necessary to provide dose rate surveillance. This will reduce doses to radiation protection personnel, while providing necessary surveillance.

Refer to section 11.5 for a further description of the radiation monitoring system, its sensitivity, and setpoints, as well as a description of how the RMS fulfills the applicable requirements of Regulatory Guides 1.21, 8.2, 8.8, 8.12, and ANSI N13.1.

12.4 DOSE ASSESSMENT

Regulatory Guide 8.19 states that Section 12.4 is used to assure that adequate attention to dose reducing design changes are maintained during the preliminary design and construction stages. Regulatory Guide 8.19 also states that the dose assessments found in Section 12.4 are intended as a search for dose reducing techniques, not for NRC regulatory enforcement purposes. The information provided in Section 12.4 is considered original licensing information and is not maintained. Annually, critical aspects of this section are reported to the NRC in accordance with 10 CFR 20.2206 and plant technical specifications. These reports provide the NRC with actual dose received at PVNGS during the previous year.

12.4.1 RADIATION EXPOSURES WITHIN THE PLANT

Within each accessible area in the plant, the peak external dose rate due to direct radiation is considered as the maximum dose rate for which the area, by design, is zoned (subsection 12.3.2). These dose rates are not expected to occur during normal operation because the plant shielding is based on maximum coolant activities corresponding to 1% defective fuel cladding. The annual average isotopic concentrations of fission products are expected to be much less than the maximum. Therefore, the actual dose rates in a given design radiation zone are expected to be significantly less than the maximum calculated dose rate in that design radiation zone. Another source of radiation exposure within the plant comes from airborne radionuclides. Radiation exposure from this source to occupational workers in the accessible areas of

the plant is usually insignificant in comparison with the exposure to direct radiation from radioactive sources. Under certain circumstances (e.g., operational access within the containment) doses from airborne activity may be a major fraction of the allowed limits.

Based on operating plant experience, numerous design features are incorporated into the design of PVNGS to minimize plant personnel exposure. The PVNGS design reflects attention to ALARA detail due to the ALARA reviews conducted during design as noted in appendix 12B. Specific design measures taken to minimize doses during maintenance and operation include the following:

A. Radioactive systems are designed such that the components which remove fission and corrosion products are placed in the process stream as early as practicable.

B. To reduce personnel exposure time at valve stations, motor-operated or pneumatic-operated valves are used where practical. Where manual valves are used, provisions are made, when necessary, for shielding the operator from the valve by use of shield walls and valve stem extensions.

C. Gauges, instrumentation, and sampling stations that require frequent visual inspections are located in corridors or on local or central control boards to minimize exposures.

D. For valve maintenance, provisions are made for drainage of associated equipment.

E. Temporary and portable shielding is provided for use by plant personnel during maintenance.

F. Radioactive liquid and gas piping is routed to minimize radiation exposure to plant personnel.

G. Other specific design features to minimize exposures are described in section 12.3. These included a remote filter handling system, reactor cavity shielding, and a delay in CVCS piping to allow for decay of nitrogen-16 prior to letdown fluid leaving containment.

The following examples of design changes are typical of those made due to ALARA reviews:

A. Installation of jib cranes inside containment to speed maintenance.

B. Permanent shielding and remote cleaning has been provided at the reactor vessel head laydown area.

From operating plant experience for pressurized water reactors (PWRs) between the years 1970 and 1974, the distribution of personnel and man-rem doses according to functions for light-water reactors is presented in tables 12.4-1, 12.4-2, and 12.4-3.(1) Based on this operating data and on reference 2, the total man-rem dose from PVNGS is estimated to be 193 man-rem/year-unit for station personnel. A survey of man-rem dose to contract maintenance personnel based upon the 1979 data of NUREG-0713 is shown in table 12.4-4. The table indicates that, on average, contractor doses are approximately 285 man-rem per nuclear power plant (BWR and PWR, combined), annually. This

tabulation does not reflect credit for the dose reduction measures designed into PVNGS (refer to section 12.3) and may be considered an upper bound of contractor exposure. Thus, total annual exposures for station and contract personnel are projected to be less than (193 + 285 =) 478 man-rem/unit. A breakdown of this estimated man-rem by job category and design radiation zone is presented in tables 12.4-5 and 12.4-6. The assumptions used in determining these doses are presented in table 12.4-7.

12.4.2 RADIATION EXPOSURE OUTSIDE THE PLANT

12.4.2.1 Construction Worker Doses

The annual individual external dose and the immersion dose received by workers at units under construction from operating units have also been estimated. These estimates, based on 2000 hours per year exposure, are summarized in table 12.4-8 for Unit 3.

Unit 3 was chosen as it will have the highest dose rate during construction of any of the PVNGS units. The total man-rem dose to construction personnel, based on the estimated labor requirements shown in table 12.4-9 are summarized in table 12.4-10.

Table 12.4-1

HISTORICAL DATA FROM OPERATING PWR PLANTS[(a)] (Sheet 1 of 2)

Year	Plant	Design Power Level (MWe)	Megawatt Year	Total No. of Personnel	Total Annual Dose (Man-Rem)
1970	Connecticut Yankee	575	424.7	734	689

HISTORICAL YEARLY AVERAGES AND GRAND AVERAGE FOR NUMBER OF PERSONNEL AND MAN-REM DOSES FOR OPERATING PWR PLANTS[a]

Year	No. of Units	Total No. of Personnel	Total Man-Rem Dose	Average No. of Personnel	Average Man-Rem Dose
1970	2	985	844	493	422
1971	3	750	822	250	274
1972	5	1,603[b]	2,408	401	482
1973	7	4,601	3,620	657	517
1974	13	7,653	5,365	589	413
1970-74	30	15,592[c]	13,059	538	435

a This table is based on the data given in table 12.4-1.

b. The entry corresponds to four plants only, since no information on personnel is available for Point Beach, Unit 1.

c. The entry corresponds to a total of 29 plants only.

Table 12.4-3

HISTORICAL DISTRIBUTION OF PERSONNEL AND MAN-REM DOSES FOR VARIOUS FUNCTIONS OF OPERATING LIGHT-WATER REACTORS[(a)]

Work and Job Function	Percentage of Total Personnel	Percentage of Total Man-Rem
Routine operations and surveillance	19.2	14
Routine maintenance	34.5	45
Inservice inspection	1.44	3
Special maintenance	28.71	20
Radwaste handling	2.08	4
Refueling	14.07	14

a. The basis for this table is the information provided in Table 5 of reference 1 for 39% of the total exposures from lightwater reactors in 1974. This includes PWRs and BWRs.

Table 12.4-4

MAN-REM EXPOSURES TO CONTRACTOR PERSONNEL, 1979

Work and Job Function	Total Man-Rem[a]	Average Man-Rem[b]
Routine operations and surveillance	487.3	11.6
Routine maintenance	1794.2	42.7
Inservice inspection	1602.4	38.2
Special maintenance	7023.9	167.2
Radwaste handling	311.5	7.4
Refueling	768.7	18.3
Total		285.4

a. From Table 8 of NUREG-0713.

b. 42 units. Refer to Table 5 of NUREG-0713.

Table 12.4-5

ESTIMATED ANNUAL PVNGS MAN-REM DOSES BY JOB CATEGORY

(HISTORICAL DATA)

Category	Man-Rem/Unit		Percentage of Total Man-Rem/Unit	
Operations		99.1		51.3

12.4.2.2 Exposures at the Site Boundary and in Uncontrolled Areas

Maximum annual exposures resulting from plant operation do not exceed applicable NRC regulations.

Estimated concentrations and doses at the site boundary due to radioactive gaseous releases are discussed in section 11.3. There are no radioactive liquid releases from PVNGS.

The direct radiation from the containment, the auxiliary building, the radwaste building, and the turbine building is negligible compared to that from the refueling water tank and holdup tank. The estimated annual dose at the nearest site boundary (from direct radiation), based on 8760 hour occupancy, is 9.5×10^{-3} mrem.

12.5 RADIATION PROTECTION PROGRAM

12.5.1 ORGANIZATION

12.5.1.1 Program Administration

The Palo Verde Nuclear Generating Station (PVNGS) operating organization is presented in subsection 13.1.2. The radiation protection manager is responsible for station radiation protection program administration. This position is also known as the director, radiation protection or director, site radiation protection. These titles may be used interchangeably throughout the UFSAR and Technical Specifications. He is also responsible for ensuring that station operations meet the radiation protection requirements of 10CFR19 and 10CFR20.1001-20.2402, and for ensuring that station operations meet the radiation protection requirements of 10CFR50, Appendix I. Commitment to the recommendations of Regulatory Guide 1.8 is discussed in section 1.8. Commitments to the philosophies embodied in Regulatory Guides 8.2, 8.8, and 8.10 are discussed in section 1.8.

Radiation protection superintendents will implement the radiation protection program. They will direct the preparation of necessary reports and procedures within their areas of responsibility. Radiation protection superintendents and the personnel reporting to them will conduct the daily functions associated with the radiation protection program including radiation surveys and associated sample collection and analysis. Backshift radiation protection surveillance will be provided by radiation protection technicians.

12.5.1.2 Program Objectives

Objectives of the radiation protection program are to ensure that personnel exposure to radiation and radioactive materials is within the requirements of 10CFR20.1001-20.2402 and that such exposure is kept as low as is reasonably achievable (ALARA). Furthermore, the objective is to control station effluent releases to ensure that these releases do not exceed the limits of the station radiological effluent controls program as specified in technical specifications.

12.5.1.3 Radiation Protection Program

The station radiation protection program will be officially initiated when appropriate portions are implemented to receive radioactive material licensed to APS and will be in effect continuously thereafter until the units are decommissioned. This program consists of rules, practices, and procedures that are used to accomplish objectives stated above in a practical and safe manner.

The radiation protection program will ensure that:

A. Personnel permitted access to radiation controlled areas receive appropriate radiation protection training.

B. Appropriate access control techniques and protective clothing are used to limit external contamination.

C. Respiratory protection equipment is used where needed to limit internal contamination.

D. Radiological controlled areas are segregated and appropriately posted to limit radiation exposure.

E. Instruments and equipment are properly calibrated so that accurate radiation, contamination, and airborne activity surveys can be performed.

F. Appropriate personnel dosimetry devices are supplied.

G. An internal dose assessment program (whole-body counting and/or bioassay) is conducted.

H. Incoming and outgoing shipments of radioactive materials are properly handled.

I. Necessary measures are performed to keep exposures ALARA.

A more detailed discussion of the procedures used to implement this program is contained in subsection 12.5.3.

The program also ensures that appropriate effluent release samples are collected and analyzed consistent with the recommendations of Regulatory Guide 1.21.

The radiation protection program will be periodically reviewed as discussed in paragraph 12.1.1.2.

12.5.2 EQUIPMENT, INSTRUMENTATION, AND FACILITIES

The radiation protection equipment, instrumentation, and facilities include an access control island, radiation protection office, radiation protection counting room, first aid room, personnel decontamination facility, locker rooms, protective clothing, fixed and portable radiation detectors, fixed and portable air samplers, and personnel dosimeters. Chemistry and radiochemistry laboratories and a radiochemistry

counting room are located near the access control island of each unit.

12.5.2.1 Radiation Protection Equipment

Equipment for personnel protection and contamination control is described in the following paragraphs.

12.5.2.1.1 Respiratory Protection Equipment

Various types of respiratory protection equipment are provided for use to protect against airborne radioactive contamination as prescribed in the Nuclear Administrative and Technical Manual. Respiratory protection equipment is normally located at, and issued from the unit tool issue rooms, however, it can be issued from other approved locations. Typical respiratory protection equipment includes:

A. Pressure demand air line respirator: A pressure demand, full-facepiece air line mask which has Mine Safety and Health Administration (MSHA) or National Institute of Occupational Safety and Health (NIOSH) approval.

B. Air supplied hood with constant flow air supply which has NIOSH approval.

C. Self Contained Breathing Apparatus: A pressure demand, full-facepiece self-contained mask which has MSHA or NIOSH approval.

D. Filter respirator: A full-facepiece filter mask which has MSHA or NIOSH approval.

12.5.2.1.2 Protective Clothing

Various types of protective clothing are stocked at the plant to protect against contamination. Typical clothing includes:

A. Body protection

1. Lab coats

2. Coveralls

3. Plastic suits

B. Head protection

1. Surgeons caps

2. Cloth hoods

C. Hand protection

1. Disposable gloves

2. Rubber gloves

3. Glove liners

D. Foot protection

1. Plastic shoe covers

2. Cloth boot covers

3. Rubber overshoes

12.5.2.1.3 Contamination Control Equipment

Contamination control equipment is used to prevent or limit the spread of radioactive contamination and to assist in its removal. The equipment is stored in appropriate locations

within the unit. Typical contamination control equipment includes items such as:

- Vacuum cleaners with absolute filters
- Mops and wringer buckets
- Disposable and reusable sheeting
- Rolls of absorbent paper
- Plastic bags of assorted sizes
- tape
- Barricade posts with radiation rope or tape
- Radiation and contamination signs
- Temporary Laundry Equipment

12.5.2.2 Radiation Protection Instrumentation

The instrumentation used by radiation protection personnel or used for radiation protection monitoring is discussed below. The categories are: laboratory type radiation detection instrumentation; portable radiation detection monitoring instrumentation; personnel monitoring instruments; fixed area radiation monitoring system; fixed airborne radiation monitoring and sampling system; and portable air sampling/ monitoring equipment. Quantities shown are minimum for the site to support normal routine operations. During periods of increased instrument usage, additional instrumentation will be supplied from the reserve instrument inventory as needed.

12.5.2.2.1 Laboratory Type Radiation Detection Instrumentation

The laboratory type radiation detection equipment, which can be used for analysis of air and smear samples, is normally located in the radiation protection counting room. However, laboratory type detection equipment may be used at the access control point or elsewhere provided background radiation levels are acceptable.

The criteria for selection of these various counters were to obtain instrumentation that could reliably and quickly count the required samples.

These instruments are calibrated prior to initial use and semiannually thereafter, when in use, with sources traceable to the National Institute of Standards and Technology. These instruments will undergo calibration checks daily or at each use, whichever is less frequent. These calibration checks will be more comprehensive than the response checks for portable instruments and will verify the instruments operation.

The types and minimum quantities of counting room instruments, with some of their peripherals, are listed below. The instruments include:

A. Scintillation type alpha counting system and peripheral equipment.

B. G.M. type beta-gamma counting system with scaler.

12.5.2.2.1.1 Radiochemistry Laboratory Counting Room Instruments. In addition to the instruments described in paragraph 12.5.2.2.1, there are two other principal instruments

that, although used primarily for the radiochemistry program, can be considered to have some radiation protection function:

A. A multi-channel analyzer (MCA) system, consisting of an intrinsic germanium detector with lead shield, connected to an MCA with a computer for data analysis and quantification of gamma emitting radionuclides.

B. A liquid scintillation counting system for low energy beta analysis.

These instruments are calibrated prior to initial use and annually thereafter, when in use, with sources traceable to the National Institute of Standards and Technology.

12.5.2.2.2 Portable Radiation Detection Survey Instrumentation

The portable radiation detection instruments include those instruments used to perform alpha, beta, gamma, or neutron surveys for radiation or contamination control. Most of these instruments are stored so that they are easily accessible to personnel in the units.

The criteria for selection of these instruments were to obtain accurate and reliable instrumentation that could be easily serviced and that would cover the entire spectrum of radiation measurements expected to be made at the station during normal operation, shutdowns, and accident conditions.

These instruments are calibrated at least every six months, when in use, with sources traceable to the National Institute of Standards and Technology. Response checks will be made daily or at each use, whichever is less frequent, to verify

that the instruments are functioning properly between calibrations.

Sufficient quantities of each type of instrument will be obtained to permit calibration and maintenance without diminishing the radiation protection capability. Quantities of the below listed types of instruments shall be maintained on hand to provide the listed minimum quantities for the site after allowing for instruments out of service (in need of calibration or repairs). These quantities are sufficient to provide for normal expected instrument usage.

A. Twelve portable G-M dose rate meters used to measure gamma dose rates up to 1000 mrem/h.

B. Twelve ion chamber type dose rate meters used to measure beta-gamma dose rates up to 5 rem/h.

C. Twelve ion chamber type dose rate meters used to measure beta-gamma dose rates up to 50 rem/h.

D. Twelve very high range gamma dose rate meters with a range up to 1000 rem/h.

E. Six ion chamber type dose rate meters used to measure beta-gamma dose rates up to 10,000 rem/h.

F. Four alpha survey meters with a range up to 500,000 cpm.

G. Four neutron survey meters with a readout covering the range of 0 to 5000 mrem/h.

12.5.2.2.3 Personnel Monitoring Instruments

Personnel monitoring instrumentation is provided to determine external and internal contamination levels and radiation doses received by personnel.

Dose measuring devices are divided into two types; record dosimeters (thermoluminescent dosimeters) and incremental dosimeters (electronic dosimeters). The criteria for selection of record dosimeters was to have devices that could be quickly and accurately evaluated by station personnel. The criteria for selection of electronic incremental dosimeters was to have devices that could easily be read by the individual, would interface with the radiological records and access control database to provide an automated access/control system, and would provide both audible and visual warnings to individuals when preset dose or dose rate thresholds are exceeded. The criteria for selection of external contamination measuring equipment were to have devices available at checkpoints and other areas that could be used to determine the location of contamination (friskers) and at the normal exit from the controlled area and security-protected area that require minimal action by personnel being checked (whole-body friskers and/or portal monitors). The principal criterion for selection of the whole-body counting system was to have a system readily available to supply information concerning internal exposure.

The friskers, portal monitors, whole-body friskers, and thermoluminescent dosimeter (TLD) readers are calibrated electronically and/or with a source at least semiannually. A response check on the friskers is performed daily. Whole-body

friskers and small article monitors are response checked weekly or whenever performance could have been affected. Portal monitors are response checked monthly or whenever performance could have been affected. The TLD readers are response checked daily. Electronic dosimeters are calibrated semiannually, the whole-body counting system is calibrated at least annually using a phantom containing various radionuclides. Calibration checks of the whole-body system are performed daily when the system is in operation.

Quantities of each type of device will be obtained to permit calibration and repair without diminishing the radiation protection supplied. The devices and minimum numbers of each for the site include:

A. Count rate meters that are used as friskers to detect beta-gamma external contamination. They are normally used with G-M detectors (at least 60).

B. One portal monitor used to check for gamma external contamination at the exit to the protected area. The portal contains several scintillation detector channels to provide head-to-foot detection capability. A sensor activates the counting circuit when a person steps into the portal. Visual and audible alarms are provided. (A backup set is available to substitute for an inoperative portal monitor).

C. Three hundred electronic dosimenters. These dosimeters have the capability to generate both audible and visual alarms when preset limits for dose and/or dose rates are exceeded.

D. One primary automatic TLD reading system with an alternate is used onsite for the determination of personnel exposures.

E. One whole-body counter, located onsite. The multi-channel analyzer and computer are programmed to analyze the data and report the radionuclides and activities detected.

F. Containers for collection of urine samples (normally used for tritium) and for fecal samples (possibly used under accident conditions) will be available. These samples are sent to a vendor for analysis.

12.5.2.2.4 Fixed Area Radiation Monitoring System

The fixed area radiation monitoring system (FARMS) is a subsystem of the permanent in-plant radiation monitoring system (RMS) and consists of three groups of monitors per unit:

- Normal range area monitors
- Post-accident range area monitors
- Portable normal range area monitors

Additionally, there is an area monitor in the central calibration facility shared by all units.

The system provides readout and alarms in the unit control room and RMS office. The fixed area radiation monitoring system's criteria for selection, detailed system description, maintenance and calibration methods and frequencies, and detector ranges, sensitivities, and locations are given in section 11.5.

12.5.2.2.5 Fixed Airborne Radiation Monitoring and Sampling System

The fixed airborne radiation monitoring and sampling system (FabRM/SS) is a sub-system of the permanent in-plant radiation monitoring system (RMS) and consists of three groups of monitors per unit:

- Normal range area monitors
- Post-accident range monitors
- Movable normal range monitors

Additionally there is one monitor in each of the two Emergency Response Facilities that monitors the ventilation systems.

The system is used to determine the levels of airborne radioactivity in plant effluent discharge paths and in in-plant areas. Airborne radioactivity levels will be maintained in accordance with PVNGS Technical Specifications.

The general criteria for selection of the fixed airborne radiation monitoring and sampling equipment were:

A. To install fixed airborne radiation monitoring and sampling equipment on the plant effluent discharge paths with alarms in the control room so that automatic (or operator) action can be taken to correct abnormal situations.

B. To install fixed airborne radiation monitoring and sampling equipment in in-plant areas where airborne activity was expected to occur or where it would need to be determined during an emergency.

The location of the fixed airborne radioactivity monitoring and sampling equipment, as well as a detailed system description, detector types, sensitivities, and ranges, and equipment calibration frequency and methods are given in section 11.5.

12.5.2.2.6 Portable Air Sampling/Monitoring Equipment

Portable air sampling/monitoring equipment is used to determine the levels of radioactivity in effluent discharge paths and in-plant areas where fixed airborne radiation monitoring and sampling equipment is not in service or is not installed as required by the Technical Specifications or Offsite Dose Calculation Manual.

The criteria for selection of the portable air sampling/ monitoring equipment were:

A. To use portable air sampling/monitoring equipment in place of fixed airborne radiation monitoring and sampling equipment as required by the Technical Specifications or Offsite Dose Calculation Manual.

B. To use portable air sampling/monitoring equipment for in-plant determinations, to monitor work areas where airborne activity levels could be high.

C. To use portable air sampling/monitoring equipment to determine airborne activity at some jobsites during maintenance and normal operation.

The air sampling/monitoring equipment is routinely maintained and detectors are calibration checked using check sources that are related to initial calibration. As long as the check

source response does not change significantly, a complete calibration will not be performed.

Air sample flowrate measuring devices for portable air samplers will be calibrated as follows:

A. Portable samplers utilized as backup equipment to fixed monitor/samplers will be calibrated at least every 18 months.

B. Portable samplers used for short-term air sampling to obtain quick grab samples such as at the beginning of a job, or during activities that could significantly increase the airborne activity level, will be calibrated at least every 6 months.

C. Portable samplers described in listing B above and utilized in emergency preparedness kits will be calibrated or replaced in the kits at least every 12 months.

Typical portable air sampling and monitoring instrumentation quantities are listed below:

A. Portable CAMs capable of measuring gross beta and/or alpha airborne activity. These monitors are capable of generating both visual and audible alarms.(6)

B. High volume air samplers used for short-term air sampling to obtain quick grab samples, such as at the beginning of a job or during activities that could significantly increase the airborne activity level.(6)

12.5.2.2.7 Radiological Records and Access Control

A computerized radiation exposure management information system is available to assist radiation protection personnel in preparation of the records and reports required by 10CFR19 and 10CFR20.1001-20.2402.

The major functions of the radiological records and access control software are:

- Maintain a personnel data and exposure file.
- Maintain a file of job-related exposure data.
- Generate required occupational exposure reports.
- Provide a tool to track the availability and assignment of dosimetry devices.
- Generate reports for radiological protection management
- Provide a data base for radiologically controlled area access control.

12.5.2.3 Facilities Related to Radiation Protection

12.5.2.3.1 Unit Radiation Protection Complex

The entire radiation protection complex discussed below, which is located at the 140-foot level in the auxiliary building, is shown in engineering drawing 13-P-OOB-005. These facilities are arranged so that the men's and women's locker rooms are outside the RCA, adjacent to the RP island complex.

The secondary chemistry laboratory, RMS facilities, and radiation protection office entrances are located outside the boundaries of the radiologically controlled area.

Radiation protection personnel occupy the radiation protection laboratory complex. They issue special dosimeters and other equipment as required by the REP. The RMS, access control, and radiation survey data can be reviewed and processed in this area.

Also within the confines of the radiologically controlled area are the first aid room, decontamination room, the RP instrument room, the radiochemistry laboratory, sample room and counting room, and the radiation protection counting room.

12.5.2.3.2 Central Calibration Facility

A central calibration facility is located near the condensate storage tank outside and north of Unit 1 (see engineering drawing 13-C-ZVA-005 and 13-P-OOB-001). The facility contains a neutron source and shielded calibration range. Thermoluminescent dosimeter neutron response checks and portable radiation measurement instrument calibrations are typically performed in this facility.

A satellite calibration laboratory is located in the Unit 1 Corridor Building to perform maintenance and calibration activities on radiation protection instrumentation. The facility contains low activity radioactive sources used during instrument calibration. The radioactive sources stored and used in the laboratory do not significantly impact background radiation levels. A radiological controlled area is established within the calibration laboratory to support work activities on contaminated equipment.

12.5.2.3.3 Decontamination Facility

The decontamination facility is located near the radwaste building of Unit 1. Liquid wastes from the decontamination facility are piped to a line common to the laundry building which goes to the Unit 1 chemical drain tanks. The solid waste generated from the decontamination facility is manually transferred to the solid radwaste system for packaging.

12.5.2.3.4 Outage Support Facility

The OSF provides a central location for the rework of contaminated plant equipment and storage pf plant components, equipment, and tools necessary to support ongoing maintenance of the units. Neither radioactive waste processing nor storage of radioactive waste is permitted in or outside of the building.

The OSF contains a large crane bay, machine shop, and an RP instrument laboratory in the primary work area on the ground floor along with a Radiation Protection controlled access and egress island, locker rooms, and a protective clothing issue station. The instruments used in the laboratory are per section 12.5.2.2.1. Office, conference, and living spaces are on the second floor. The OSF is located within the site primary Protected Area/Restricted Area fence and includes an administratively controlled area, as described in section 12.5.3.2, for the purpose of limiting exposure of individuals to radiation and radioactive materials.

The OSF drain system is not designed to support drainage of intentionally contaminated liquid. The OSF has two independent

ventilation systems so that the ventilation system in the contaminated work spaces does not return air to the ventilation system supplying non-contaminated areas of the building. Air supply for the crane bay is provided through ventilation ducts in the overhead and is cooled via roof-top chillers and, when running, the exhaust AFUs maintain the north end of the building at a slightly negative pressure relative to the environs and to the building office spaces. The crane bay ventilation exhaust system is through two AFUs located in each of the north corners of the crane bay. Each AFU contains HEPA filters and sample ports in the exhaust duct that allow for environmental effluent monitoring.

12.5.3 PROCEDURES

Radiation protection procedures are established to keep personnel radiation exposures ALARA and within the limits of 10CFR20.1001-20.2402. These procedures are discussed in paragraph 12.5.3.2. Policy and operational considerations for maintaining personnel radiation exposures are discussed in subsections 12.1.1 and 12.1.3.

12.5.3.1 Radiation and Contamination Surveys

Radiation protection personnel normally perform routine radiation and contamination surveys of accessible areas of the units. These surveys consist of radiation dose rate measurements and/or contamination smears as appropriate for the specific area. Air sampling is performed based upon the specific task being performed or if plant conditions warrant such samples. Surveys related to specific activities may be

performed if necessary prior to, during, or after activities that would be expected to produce additional significant radiation exposure to individuals. Advanced radworkers perform radiation and contamination surveys associated with activities of low radiological significance. Survey procedures and routine survey schedules are provided in the Nuclear Administrative and Technical Manual.

12.5.3.2 Procedures and Methods to Maintain Exposures ALARA

Operating, maintenance, and radiation protection procedures are reviewed, as discussed in subsection 12.1.1, to identify situations in which potential exposures could be reduced. Such ALARA considerations include:

A. Restricted Areas

Restricted areas as defined in 10CFR20.1003 are established at the protected area fence and access is controlled at that point for the purpose of protecting individuals from exposure to radiation and radioactive materials.

B. Controlled Areas

Procedures establish permanent and temporary controlled areas within the restricted areas where access is further administratively controlled for the purpose of limiting exposure of individuals to radiation and radioactive materials. Radiation and high radiation areas identified within controlled areas are posted appropriately and access control

maintained in accordance with PVNGS Technical Specifications and 10 CFR 20.

C. Radiation Exposure Permits

Procedures require radiation exposure permits for entry into radiologically controlled areas. These permits are a principal administrative means of managing personnel radiation exposure and describe the radiological controls required to perform the activity and maintain personnel radiation exposure ALARA. The permit contains information pertinent to the activity such as radiation and/or contamination levels in the area, allowable stay times, protective clothing requirements, respiratory protection equipment requirements, special personnel monitoring requirements, and temporary shielding requirements.

Radiation exposure permits require the approval of radiation protection supervision or designated alternates.

D. Selected Operating and Maintenance Activities

Operating and maintenance activities that can result in significant individual exposures are controlled by written procedures. Procedures controlling refueling, radwaste handling, spent fuel handling, radiochemical sampling, loading and shipping of radioactive materials, and procedures controlling inservice inspections, normal operation, routine maintenance, and calibrations that are expected to require issuance

of a radiation exposure permit, are reviewed for ALARA considerations, as discussed in subsection 12.1.1.

12.5.3.3 Control of Access and Stay Time in Radiation Areas

Physical and administrative controls assure that the philosophy of maintaining personnel exposures ALARA is implemented, as specified in section 12.1 and paragraph 12.5.3.2.

Authorized personnel who enter station restricted areas are issued appropriate dosimetry devices in accordance with Nuclear Administrative and Technical Manual procedures.

12.5.3.4 Contamination Control

Contamination limits for personnel, equipment, and areas are listed in the Radiation Protection Division of the Nuclear Administrative and Technical Manual. Surveys are performed as discussed in paragraph 12.5.3.1, to determine contamination levels. Areas found contaminated beyond specified limits are roped off or otherwise delineated with a physical barrier, posted appropriately, and decontaminated as soon as practical. A stepoff pad or other appropriate means may be used to prevent the spread of contamination.

Nuclear Administrative and Technical Manual procedures incorporate those recommendations of Regulatory Guide 1.39 which are considered applicable for housekeeping activities occurring during the operations phase that are comparable to those occurring during the construction phase (refer to section 1.8).

Tools and equipment used in contaminated areas are monitored prior to removal from the controlled area. If they are to be released to an uncontrolled area, they must meet uncontrolled (clean) area limits, and must be decontaminated or packaged and labelled as necessary to meet these limits. Decontamination facilities are discussed in subsection 12.5.2. If the tools and equipment are to be transferred to another controlled area through an uncontrolled area, they may be bagged, wrapped, or similarly enclosed to prevent the spread of contamination while being transferred.

Control of personnel contamination (external and internal) is provided by use of protective clothing and respiratory protection equipment as discussed in subsection 12.5.2. Each individual is responsible for monitoring himself and his clothing when he crosses a local control point or the main access control point. If contamination above allowable limits is found, the individual is decontaminated using facilities previously described in subsection 12.5.2.

12.5.3.5 Airborne Activity Exposure Control

When airborne radioactivity is detected in excess of the limits of 10CFR20.1003, the area is posted as an airborne radioactivity area, and access is controlled in accordance with paragraph 12.5.3.2.

Occupancy is restricted, process or other Engineering Controls are utilized, or respiratory protection equipment is provided to maintain exposures TEDE ALARA if personnel entry is required into areas where the source of airborne radioactivity cannot be removed or controlled. The selection of respiratory protection

equipment is established by historical data and current contamination levels, which are used to evaluate potential airborne hazards. The respiratory protection program is organized to conform to the applicable portions of ANSI Z88.2. Effectiveness of the respiratory protection program is evaluated by various types of bioassay analyses.

Respiratory equipment discussed in subsection 12.5.2 is available at unit tool issue rooms. Supplementary emergency respiratory equipment is available in the control room and in emergency kits.

The following controls are incorporated in the program:

A. Each respirator user is advised that he may leave an airborne radioactivity area for psychological or physical relief from respirator use. Each user shall leave the area in the case of respirator malfunction or any other condition that might cause reduction in the protection afforded the user.

B. Air samples and surveys are made to identify the presence of airborne radioactivity and to estimate individual exposures.

C. Procedures are established to ensure correct fitting, use, maintenance, and cleaning of respirator equipment. Each individual qualified to use respiratory protection equipment receives a quantitative fit test annually and checks each respirator for proper fit prior to use.

12.5.3.6 Personnel Monitoring

Station employees, contractor personnel, support personnel, and visitors are required to wear TLD or electronic dosimeters when in a controlled area. In addition, incremental dosimetry is issued to individuals working under a radiation exposure permit. The exposure readings of this incremental dosimetry is used for specific ALARA job exposure evaluation, as well as to indicate current individual exposure status. Use of neutron dosimeters complies with the requirements of 10CFR20.1501.

The Nuclear Administrative and Technical Manual requires bioassays, including whole-body counting, consistent with the recommendations of Regulatory Guides 8.9 and 8.26. The type of determination and the frequency of determination depends upon the work environment of the individual and the work situation.

Personnel dosimetry is evaluated on at least an annual basis and is used as the dosimetry of record for the individual unless evaluation determines an alternate exposure evaluation is more representative of the dose received.

Exposure data of personnel issued personal dosimeters in accordance with 10CFR20.1502 is maintained on NRC Form 5, or equivalent. Occupational exposures incurred by individuals prior to working at PVNGS are summarized on NRC Form 4, Occupational External Radiation Exposure History, or the equivalent. These records are maintained at PVNGS and will be preserved for the lifetime of the plant or until the NRC authorizes their disposal. Reports of overexposure to radiation workers are made to the NRC and the individual involved pursuant to 10CFR19 and 10CFR20.1001-20.2402.

12.5.3.7 Handling of Radioactive Material

Licensed sources used for calibration are used by or under the direction of personnel who have received training in the safe use and handling of sources. A radiation exposure permit will be required if such use could result in significant personnel exposure.

Suitable methods for the safe handling of radioactive materials are implemented to maintain external and internal doses at levels that are ALARA. External doses are minimized by a combination of time, distance, and shielding considerations. Internal doses are minimized by the measurement and control of loose contamination and airborne radioactivity. Nuclear Administrative and Technical Manual procedures provide instructions for handling radioactive sources.

Sealed radionuclide sources having activities greater than the quantities of radionuclides defined in Appendix C to 10CFR20.1001-20.2402 and Schedule B of 10CFR30 are subject to material controls for radiological protection. Those controls include:

A. Monitoring of packages containing radioactive materials for external dose rate and removable contamination upon receipt at the station and prior to shipment away from the station.

B. Each sealed source containing radioactive material either in excess of 100 microcuries of beta and/or gamma emitting material or 5 microcuries of alpha emitting material are leak tested every six months to determine if the removable contamination exceeds 0.005

microcuries. The following types of sources are exempted from the 6 month leak testing: 1) tritium and gaseous sources, 2) sources in storage, 3) startup sources and fission detectors. Sources in storage are leak tested prior to use or transfer to another licensee unless tested with the previous 6 months. Startup and fission detector are leak tested following repair, or maintenance, or 31 days prior to being subjected to core flux, or installed in the core. Startup sources and fission detector are not subject to leakage testing following to exposure to core flux.

C. Labeling of licensed sources with the radiation symbol, stating the activity, radionuclide, and source identification number.

D. Secure storage of sources which are not installed in an instrument or other piece of equipment.

E. Inventory of sources every year.

12.5.3.8 Radiation Protection Training

Personnel requiring access to a restricted area and/or radiological controlled area will receive training as necessary to permit access to these areas. These personnel will be tested to evaluate each worker's knowledge, competency, and understanding relative to the training provided.

General employee training is discussed in section 13.2. The training program includes instruction in applicable provisions of the NRC regulations for the protection of personnel from radiation and radioactive material 10CFR20.1001-20.2402 and

instruction to women concerning prenatal radiation exposure. The training addresses the following topics and requirements:

- Sources of radiation
- Measurement of radiation
- Biological effects
- Limits and guidelines
- As Low As Reasonably Achievable (ALARA)
- Radiation dosimetry
- Contamination
- Internal exposure
- Radiation Work Permit (RWP)
- Postings
- Radiological alarms
- Radioactive waste
- Rights and responsibilities

In addition to general employee training, radiation protection personnel and advanced radworkers also receive training in areas which apply to their specific job functions such as radiation and contamination surveys, air sampling techniques, use of portable and laboratory instrumentation, release limits, and safe handling of sources.

APPENDIX 12B

PVNGS REVIEWS TO ACHIEVE AN ALARA DESIGN

UFSAR Appendix 12B provides historical information regarding how the initial ALARA reviews were performed during the initial design of PVNGS. The section provides a brief summary of the actions, formal and informal, taken to ensure that the ALARA guideline delineated in UFSAR section 12 were met. Current PVNGS administrative procedures provide guidance to assure that modifications and design changes are reviewed to maintain exposures ALARA. Therefore, UFSAR Appendix 12B is considered historical information and is not maintained.

APPENDIX 12B
PVNGS REVIEWS TO ACHIEVE AN ALARA DESIGN

Nuclear power plant radiation exposures are received primarily during work on components in the reactor coolant and radwaste systems and on components located adjacent to those systems. Therefore, the main thrust of the PVNGS design exposure reduction effort has been directed toward these systems. It included considerations such as the following:

A. Maintenance frequency is minimized by improving component reliability and by reducing routine maintenance, inspection, and operational requirements.

B. Maintenance time is minimized by a plant layout which facilitates access during maintenance, and by satisfactory working conditions during maintenance.

C. Radiation levels are reduced in the area of maintenance-prone components by a plant layout that separates these components from highly radioactive components, and provides appropriate design features that facilitate flushing and decontamination and that minimize crud trap formation.

Incorporating these general considerations into the PVNGS design has required that all disciplines coordinate their efforts to incorporate ALARA features.

The engineer for PVNGS, Bechtel, was assigned the lead role for the implementation of ALARA design, subject to periodic audits and reviews of their performance by APS personnel.

Bechtel conducted regular, interdisciplinary reviews of the design to implement ALARA design and to establish that reasonable efforts had been made to reduce occupational radiation exposures.

Three formal levels and one informal level of approval were required before the PVNGS design was approved as meeting the ALARA guidelines delineated in sections 12.1 and 12.3.

Designers consulted informally with engineers to eliminate potential problems as the design progressed. Thus, design features were evaluated effectively during the time that the cost impact of changes was minimal. The engineers had experience in the areas of shielding, operations, maintenance and maintainability, OSHA requirements, decontamination, and health physics.

A formal multidiscipline meeting (type I) was held to review each area of the plant for concrete placement. Bulk shielding was evaluated. Walls were checked for proper thickness. Proper maintenance access was ensured. Entrance labyrinths were used as necessary. Concrete voids due to HVAC or electrical penetrations were modified or shielded. If the concerns were resolved, type I approval was given and the area was released for piping design.

A type II review of each piping system or subsystem in the plant was held. These multidiscipline meetings examined piping layouts for crud traps, proper routing (e.g., not in a doorway or corridor), and maintainability. Shielding was checked for adequacy.

After the type I and type II reviews were completed, a type III review of each building level was held. This final release for construction review examined the interface between the collective systems and plant area under review. It verified that the design evolution had proceeded along the guidelines given in the prior two levels of review.

Each review was documented by the use of the ALARA/ISI review checklist (table 12B-1).

ALARA/ISI REVIEW CHECKLIST (Sheet 3 OF 6)

Resp	VERIFICATION \ SYSTEM/AREA					
	I. GENERAL LAYOUT GUIDELINES					
J	1. Control panels, readout devices and transmitters shall be located in low radiation zones (zone 2 or less).					
N	2. Sample sites shall be isolated from other radioactive equipment.					
	3. The following shielding considerations shall be observed.					
N	a) Valves and instrumentation on process systems which contain major sources of radiation will be shielded from the system components.					
N	b) Access to shielded compartments shall normally be by means of shielded labyrinth arrangements. Highly radio- active passive components shall be in completely enclosed compartments and shall be provided with access via a shielded hatch.					
N	c) Radioactive equipment shall be separated by shielding from nonradioactive equipment to facilitate unrestricted maintenance on the latter.					
	4. Control of radioactive contamination.					
C/S	a) Large tanks containing radioactive fluids shall be enclosed in water tight compartments or be surrounded by curbs.					
PD	b) Sloped floors and floor drains shall be provided for all radioactive equipment compartments.					
PD	c) Vents and drains required for radio- active equipment maintenance shall be piped directly to a drainage system.					
	5. Valve galleries					
PD	a) Exposed piping in the valve gallery will be minimized.

13. CONDUCT OF OPERATIONS

13.1 ORGANIZATIONAL STRUCTURE OF APPLICANT

13.1.1 MANAGEMENT AND TECHNICAL SUPPORT ORGANIZATION

Arizona Public Service Company (APS), one of the owners of the Palo Verde Nuclear Generating Station (PVNGS), has the overall responsibility for management, operation and oversight of the facility. APS provides a staff of personnel that either conducts these operations or provides support services for operations. Members of the management and technical support organization staff may be located onsite or offsite.

The executive vice president, nuclear and CNO, reports directly to the chief executive officer of APS, and is responsible to provide leadership to the Nuclear Generation organization and overall management of the activities related to the operation, maintenance, and modification of the Palo Verde Nuclear Generating Station, including the entire owner controlled property.

The executive vice president, nuclear and CNO, has overall responsibility to ensure that all PVNGS activities, including operation, maintenance, and modification of the units are performed in strict compliance with regulatory requirements, consistent with the requirements for protection of the health and safety of the general public and company personnel, and in accordance with company policy.

The overall organizational structure, reporting relationships, and responsibilities for management and technical support of the facility are described in the PVNGS Operations Quality Assurance Program Description (QAPD).

The onsite operating organization and its responsibilities and authorities are further described in UFSAR Section 13.1.2, the Unit Technical Specifications, and station administrative procedures.

13.1.2 OPERATING ORGANIZATION

The responsibilities and authorities of key members of the operating organization are described in this section. The following APS positions have the responsibility and authority for directing or placing a PVNGS unit in a reduced power or shutdown condition to ensure nuclear safety:

- executive vice president and CNO
- senior vice president site operations
- site general plant manager
- operations director
- unit operations managers
- shift managers
- control room supervisors
- control room operators

13.1.2.1 Executive Vice President and CNO is responsible for:

- overall plant nuclear safety and shall take any measures needed to ensure acceptable performance of the staff in operating, maintaining, and providing technical support to the plant to ensure nuclear safety;
- ensuring that all PVNGS activities, including operation, maintenance, and modification of the units and related

nuclear facilities are performed in strict compliance with regulatory requirements, consistent with the requirements for protection of the health and safety of the general public and company personnel, and in accordance with company policy;

This position fulfills the role of the corporate officer described at 5.2.1.c of the PVNGS Unit Technical Specifications.

13.1.2.2 The <u>Senior Vice President Site Operations</u> is responsible for:

- overall PVNGS site and plant management, including operations of the nuclear power plants, spent fuel storage facility, and water reclamation facility
- providing technical and engineering support for operations, maintenance, and modification of the power plants and facilities located at the plant site
- establishing and administering policies, providing procedures, and maintaining standards of performance that ensure safe operation
- ensuring site operations are in compliance with requirements of the operating license, applicable regulations, and regulatory commitments

13.1.2.3 The Site General Plant Manager has direct line responsibility for operation and maintenance of the PVNGS nuclear plants and is responsible for direction of plant operations.

This position fulfills the role of the Plant Manager as described in 5.2.1.b of the PVNGS Unit Technical Specifications.

13.1.2.4 The Operations Director is responsible for:

- approving operational programs and procedures
- managing and directing safe operation of the facility in accordance with regulatory requirements, the Operating Licenses, and company policies, programs, and procedures
- providing programs for ensuring that surveillance testing is performed as required

13.1.2.5 Units 1, 2 and 3 Operations Managers are responsible for:

- conducting unit operations in a safe manner in accordance with the technical specifications and station procedures
- supervising the activities of the operating personnel
- coordinating the activities and performance of the shift managers to ensure that the conduct of the operating staff is consistent with protection of the health and safety of the public and is in compliance with all applicable rules, regulations, and procedures

- ensuring that identified plant deficiencies receive the appropriate work priority to maintain plant safety and reliability
- reviewing various operating logs and records for accuracy, completeness, adherence to applicable administrative procedures, regulations and technical specifications, and to maintain current knowledge of plant activities

This position satisfies the requirements of the Operations Department Leader as described in the PVNGS Unit Technical Specifications. This position will hold a senior reactor operator license to satisfy the requirements of the PVNGS Unit Technical Specifications 5.2.2.d.

13.1.2.6 Operating Shift Crews

Normally during non-outage periods, operating crews will be manned on a five shift, self-relieving 5-crew basis. An operating crew for each unit will normally consist of a shift manager and control room supervisor (who will possess senior reactor operator licenses), two reactor operators (who will possess reactor operator licenses), and four non-licensed operators (nuclear auxiliary operators). The minimum shift operating crew composition for various modes of operation is described in the PVNGS Unit Technical Specifications and in section 18.I.A.1.3.

A site Fire Department of at least five members shall be maintained onsite at all times. Fire Department composition may be less than the minimum requirements for a period of time

not to exceed two hours in order to accommodate unexpected absence of fire department members, provided immediate action is taken to restore the fire department manning to minimum requirements.

The Fire Department shall not include the Shift Manager, the STA, nor the 3 other members of the minimum shift crew necessary for safe shutdown of the unit and any personnel required for other essential functions during a fire emergency. One Reactor Operator is assigned to support the Fire Department as the Fire Team Advisor.

13.1.2.6.1 Shift Managers are responsible for the safe operation of the unit during their assigned shifts.

13.1.2.6.2 Control Room Supervisors are responsible to provide a backup to the shift manager and supervise shift personnel in the conduct of operations.

13.1.2.6.3 Limited Senior Reactor Operator (LSRO) for Refueling. The limited senior reactor operator (LSRO) for refueling is responsible to the shift manager for directly supervising core alterations and those specific evolutions or work activities that could result in core alterations.

This individual will be a senior reactor operator conditionally licensed for refueling operations and who has no concurrent duties when performing functions of the LSRO. A fully-licensed senior reactor operator with no concurrent duties may perform the functions of the LSRO.

13.1.2.6.4 Reactor Operators are responsible for:

- operating and directing operations of mechanical, electrical, and reactor systems from the control room
- reactor safety in accordance with Technical Specifications, company policies, and procedures

13.1.2.6.5 Nuclear Auxiliary Operators are responsible, under the direction of the control room supervisor, for operating plant systems and assisting in fuel handling operations, as directed.

13.1.2.6.6 Shift Technical Advisor is responsible for:

- providing advisory technical support to the Shift Manager in the areas of thermal hydraulics, reactor engineering, and plant analysis with regard to safe operation
- meeting qualification requirements specified by the Commission Policy Statement on Engineering Expertise on Shift

This page intentionally left blank

13.2 TRAINING PROGRAM

Personnel to staff PVNGS are selected to ensure they will have the qualifications necessary to satisfactorily perform their assigned functions. To augment the formal education, training and experience of station personnel, training programs have been instituted for site employees and contract personnel. The Director, Nuclear Training has overall responsibility for the conduct and administration of training programs for the staff of PVNGS.

Refer to the PVNGS Operations Quality Assurance Program Description for other training program requirements and associated responsibilities.

The Director, PV Water Resources has the overall responsibility for the conduct and administration of the Water Reclamation Facility training programs.

Training program content is described in training program descriptions.

13.2.1 TECHNICAL TRAINING PROGRAMS:

Technical training programs for the staff of PVNGS have been developed based on a systematic approach to training as defined by 10CFR55.4.

The technical training programs include those listed in 10CFR50.120, "Training and qualification of nuclear power plant personnel" and these programs are periodically evaluated by the National Nuclear Accrediting Board (NNAB).The Director, Nuclear Training has direct responsibility for administration of the

training programs identified in 10CFR50.120, "Training and qualification of nuclear power plant personnel."

13.2.2 GENERAL TRAINING DESCRIPTION

13.2.2.1 Types of Training

Station personnel may be qualified through formal education and experience, formal job training, related technical training, on-the-job training, or a combination thereof.

13.2.2.2 Qualification of Personnel

Personnel training and qualification is delineated in training program descriptions or administrative procedures. The Nuclear Training Department assists each unit staff organization in the development of training and the maintenance of personnel qualifications. Site personnel and their leaders are responsible to ensure they are qualified prior to performing assigned tasks.

13.2.2.3 General Employee Training

Site access training meets the requirements delineated in ANSI/ANS 3.1-1978 and is provided to long-term site employees and to all personnel prior to their being granted unescorted access to restricted areas. This training is implemented using industry guidance and regulatory requirements and includes topics such as instruction on evacuation signals, evacuation routes, and procedures for reporting a fire. The course requires satisfactory completion of written or computer-aided examination.

Radiological protection training is provided to personnel prior to their being granted unescorted access to radiological controlled areas. The training addresses the following topics and requirements:

- Sources of radiation
- Measurement of radiation
- Biological effects
- Limits and guidelines
- As Low As Reasonably Achievable (ALARA)
- Radiation dosimetry
- Contamination
- Internal exposure
- Radiation Work Permit (RWP)

The course requires satisfactory completion of a written or computer-aided examination.

Temporary personnel receive training based on the access level required and their knowledge and experience, as validated by written or computer-aided examination.

13.2.3 FIRE PROTECTION TRAINING

13.2.3.1 General Employee Fire Protection Training

As a portion of General Employee Training, station personnel are trained in the following aspects of fire protection:

- Station Fire Protection Program
- Station Evacuation Routes

- Fire Reporting Procedures
- Job Related Fire Prevention and Suppression
- Control of Ignition Sources

13.2.3.2 Fire Department Training

The Fire Department training program ensures that the capability to fight potential fires is established and maintained. The program consists of initial classroom instruction followed by periodic classroom training, firefighting practice, and fire drills. The program is based on specific 10CFR50, Appendix R training requirements and selected recommended practices by the National Fire Protection Association (NFPA) Standard (1987) 1001 for the equipment and practices applicable to the PVNGS Fire Department for Firefighter Level I.

Periodic classroom refresher training sessions are held to repeat the classroom instruction for all fire department members over a 24 month period. Changes to the fire protection program and plant changes impacting fire response capability are reviewed as necessary in the training sessions. Senior fire department members receive instruction in incident command.

Practice sessions are held for each shift fire department on fighting fires similar to those expected in nuclear power plants. These sessions provide Fire Department members with experience in actual fire extinguishment and use of self-contained breathing apparatus under strenuous conditions encountered in firefighting. These practice sessions are

provided at least once per year for each fire department member.

Fire department drills are performed at regular intervals not exceeding 3 months for each shift. Each fire department member is encouraged to participate in each drill, but is required to participate in at least 2 drills per year.

A sufficient number of these drills, but not less than one for each fire department shift per year, are unannounced to determine the firefighting readiness of the fire department, shift fire captain, and fire protection systems and equipment.

At least one drill per year is performed on a "backshift" for each fire department shift. The drills are pre-planned to establish the training objectives of the drill and shall be critiqued to determine how well the training objectives have been met.

Unannounced drills are planned and critiqued by the fire training officer or designee. Performance deficiencies of a fire department shift or individual fire department members are remedied by scheduling additional training for the department or individual. Unsatisfactory drill performance is followed by a repeat drill within 30 days.

At 3 year intervals, a randomly selected unannounced drill is critiqued by qualified individuals independent of the PVNGS Fire Department staff. A copy of the written report of each critique is available for review.

Fire drills as a minimum include the following:

A. Assessment of fire alarm effectiveness, time required to notify and dispatch the fire department, and selection, placement, and use of equipment, as well as firefighting tactics and strategies.

B. Assessment of each fire department member's knowledge of his or her role in the firefighting strategy for the area assumed to contain the fire. Assessment of the fire department member's conformance with established firefighting procedures and use of firefighting equipment.

C. The simulated use of firefighting equipment required to cope with the situation and type of fire selected for the drill. The area and type of fire chosen for the drill differ from those used in the previous drill so that fire department members are trained in fighting fires in various plant areas. The situation selected simulates the size and arrangement of a fire that could reasonably occur in the area selected, allowing for fire development due to the time required to respond, obtain equipment, and size up the fire, and assuming loss of automatic suppression capability.

D. Assessment of the shift fire captain's direction of the fire suppression activities as to thoroughness, accuracy, and effectiveness.

Individual records of training provided to each fire department member are maintained for at least 3 years to ensure that each member receives training in all parts of the training program.

Retraining or broadened training is scheduled for all fire department members whose performance records show deficiencies.

The Fire Department training program also includes training for personnel who inspect and test fire protection equipment, to ensure that they are certified to perform that work. The training consists of on-the-job training conducted by qualified Fire Department personnel. Written records of each individual's qualifications are maintained.

The Fire Department training program includes hazardous materials handling training. The program is based on the requirements of OSHA 29CFR1910.120, for the equipment and practices applicable to the PVNGS Fire Department. Training will consist of initial classroom and practical sessions, followed by annual refresher training.

13.2.3.3 Security Department Fire Protection Training

Instruction is provided for security personnel that addresses (a) entry procedures for outside fire departments, (b) crowd control for people exiting the station, and (c) procedures for reporting potential fire hazards observed when touring the facility.

This page intentionally left blank

13.3 EMERGENCY PLANNING

13.3.1 PRELIMINARY PLANNING (PSAR)

This section is not applicable to the FSAR.

13.3.2 EMERGENCY PLAN (FSAR)

A comprehensive emergency plan for Palo Verde Nuclear Generating Station is provided as a separate volume to this application.

Additional information, concerning agreements with offsite local, state, and federal officials and agencies, is included as an appendix to the Emergency Plan.

This page intentionally left blank

13.4 REVIEW AND AUDIT

Operating phase activities that affect nuclear safety are reviewed and audited. The review and audit program is implemented prior to initial fuel loading and is described in the PVNGS Operations Quality Assurance Program Description (QAPD).

13.5 PLANT PROGRAMS AND PROCEDURES

The PVNGS Operations Quality Assurance Program Description (QAPD) describes administrative and operating procedures that will be used by the operating organization to ensure that routine operating, off-normal, and emergency activities affecting nuclear safety are conducted in a safe manner.

This page intentionally left blank

13.6 INDUSTRIAL SECURITY

13.6.1 PRELIMINARY PLANNING (PSAR)

This section is not applicable to the FSAR.

13.6.2 SECURITY PLAN (FSAR)

A description of the physical security program for Palo Verde Nuclear Generating Station is provided as a separate part of the application withheld from public disclosure pursuant to Paragraph 2.790 (d), 10CFR Part 2, Rules of Practice.

13.7 TECHNICAL REQUIREMENTS MANUAL (TRM)

13.7.1 TRM CONTENT

The TRM includes requirements that have been relocated from the PVNGS Technical Specifications to a licensee-controlled document in accordance with the provisions specified in amendment number 117 for Units 1, 2, and 3, dated May 20, 1998. Compliance with the TRM is required in order to remain within the PVNGS design and/or licensing bases. Changes to the TRM must be controlled as described in 13.7.2.

The TRM contains specifications, administrative controls, bases, and component lists.

13.7.1.1 Component Lists

Section T7.0 of the TRM contains itemized lists of components subject to Technical Specification or TRM surveillance testing for five tables of components lists which were removed from the Technical Specifications in accordance with Generic Letter 91-08 in amendments 85, 73 and 57 for Units 1, 2, and 3, respectively. These component lists, located in TRM section 7, include:

- Remote Shutdown Disconnect Switches (T7.0.100)

  Identifies the switches subject to the requirements of Technical Specification section 3.3.11.

- Remote Shutdown Control Circuits (T7.0.200)

  Identifies the control circuits subject to the requirements of Technical Specification section 3.3.11.

- Containment Isolation Valves (T7.0.300) Identifies the containment isolation valves subject to the requirements of Technical Specification section 3.6.3.

- Motor Operated Valve Thermal Overload Protection and Bypass Devices (T7.0.400)

  Identifies the motor operated valves with bypass devices subject to the requirements of TRM section T3.8.102.

- Containment Penetration Conductor Overcurrent Protective Devices (T7.0.500)

  Identifies the overcurrent protective devices subject to the requirements of TRM section T3.8.101 (the TRM references the appropriate station procedure).

13.7.2 TRM CHANGE CONTROL

Changes to the TRM shall be made under appropriate administrative controls and reviews.

Changes may be made to the TRM without prior NRC approval provided the changes do not involve either of the following:

- A change in the Technical Specifications incorporated in the license; or

- A change to the UFSAR or TRM that requires NRC approval pursuant to 10 CFR 50.59.

Any proposed change to the TRM that involves either of the above criteria must be approved by the NRC as a PVNGS license amendment before the change may be made.

APPENDIX 13B

PROJECT DESIGN, CONSTRUCTION AND PREOPERATIONAL ACTIVITIES (Historical)

PROJECT DESIGN, CONSTRUCTION
AND PREOPERATIONAL
ACTIVITIES (Historical)

NOTE: Construction is complete for the three units of the Palo Verde Nuclear Generating Station (PVNGS). Sections 13B.1 through 13B.1.2.4 describe project design and construction (project phase) and preoperational activities and will not be updated. This information is maintained as a historical reference only.

13B.1 Design and Operating Responsibilities

The following paragraphs summarize the degree to which design, construction, and preoperational activities have been accomplished and describe the specific responsibilities and activities relative to technical support for operations.

13B.1.1 Design and Construction Activities

13B.1.1.1 Principal Site-Related Engineering Work

A. Meteorology

A preoperational meteorological monitoring program was established at the Palo Verde site in 1973 to provide a base of meteorological data that bear upon plant design, operation, and safety. The program has been conducted by NUS Corporation and supervised and assisted by the Arizona Public Service Company (APS) nuclear organization. Meteorological data continues to be collected at PVNGS and will be collected through the life of the facility.

B. Geology

Onsite and offsite PVNGS geotechnical studies have been performed by ERTEC, as required, and include determination of site suitability in accordance with 10CFR100 and inspecting and mapping excavations for Seismic Category I buildings and pipelines for PVNGS.

C. Seismology

ERTEC has completed seismic studies on site response spectra and time history as discussed in section 2.5.

D. Hydrology

NUS Corporation has completed hydrologic studies including calculation of the probable maximum flood (PMF) for the PVNGS site and calculation of ground water levels beneath the PVNGS site. Detailed information concerning hydrology is discussed in section 2.4.

E. Demography

NUS Corporation has completed demographic studies relative to population located within 50 miles of the plant site, as discussed in subsection 2.1.3, and land use studies relative to the location of industrial, transportation,

and military facilities near the plant site, as discussed in section 2.2.

F. Environmental Effects

A construction phase environmental control program was put into effect in early 1976. Groundwater and ecological monitoring programs were approved by the NRC in May of 1976. The program is designed to monitor the requirements contained in the final environmental statement for PVNGS 1, 2, and 3 for compliance and to detect unanticipated environmental impacts due to construction activities. Preoperational radiological and environmental monitoring programs have been developed to provide baseline radiological and ecological data for the PVNGS site. These programs are described in the PVNGS Environmental Report-Operating License Stage.

13B.1.1.2 Design of Plant Ancillary Systems. An evaluation of engineering progress for PVNGS Unit 1 and common areas as of December 1982 indicates an overall completion of 90% including TMI related changes and 99% including non-TMI-related changes. Refer to subsection 1.1.5 of the FSAR for the scheduled completion date.

13B.1.1.3 Review and Approval of Plant Design Features. Design control and review is performed in accordance with QA program for PVNGS 1, 2, and 3 as discussed in PVNGS 1, 2, and 3 PSAR Section 17.1.

13B.1.1.4 Site Layout With Respect to Environmental Effects and Security Provisions. In order to minimize the visual impact of the plant on the environment, the external features of the plant facilities have been designed to establish an acceptable relationship between site and plant through the use of materials and colors that are compatible with the environment.

Security provisions in accordance with 10CFR73.55 have been incorporated into the overall site development and plant design as discussed in Section 13.6.

13B.1.1.5 Development of Safety Analysis Reports. Overall responsibility for preparation of the FSAR rests with the APS Nuclear Regulatory Affairs Department. Preparation of the individual FSAR sections is assigned to the cognizant technical groups within APS, or to Bechtel for balance of plant systems, Combustion Engineering for NSSS systems, NUS for environmental programs, and ERTEC for geotechnical sections.

13B.1.1.6 Review and Approval of Material and Component Specifications. Safety-related project specifications are reviewed in accordance with the QA program for PVNGS and conform with 10 CFR 50, Appendix B, and ANSI Standard N45.21971.

13B.1.1.7 Procurement of Materials and Equipment. As of October 23, 1981, approximately 99% of the specifications for material and equipment have been awarded. Completion of this activity is scheduled by November 1982.

13B.1.1.8 Management and Review of Construction Activities. The APS Nuclear Construction Department is responsible for review, monitoring, and construction activities. As of February 1983, construction progress was as follows:

Unit 1 and Common Areas	99.0%
Unit 2	96.3%
Unit 3	58.6%
Water Reclamation Facility	99.0%

13B.1.2 Preoperational Activities

13B.1.2.1 Development of Human Engineering Design Objectives and Design Phase Review of Proposed Control Room Layouts. Prior to control room design, Bechtel Power

Corporation, in conjunction with an APS nuclear operations consultant and APS nuclear engineering personnel, performed a study of power plant control rooms. The results of this study were factored into the design of the PVNGS control rooms. Several of the features that were implemented in order to improve the man-machine interface are:

A. Indicators are dual where possible to minimize panel size.

B. Control boards are built in a "slide-along" configuration which provides a single arrangement of controls for similar pieces of equipment.

C. The control boards for the PVNGS units and for the simulator are identically designed, minimizing operator confusion between units.

D. Pushbuttons are engraved with the name of their function (e.g., "on", "open"), equipment name (engraved on a nameplate) is above the button. This alleviates the concern of having too much information on the button.

E. Related indicators and switches are grouped by operation or individual piece of equipment, rather than functional grouping to minimize operator errors.

F. The electrical distribution panel and the chemical and volume control systems (CVCS) panel are built in a mimic arrangement with colored plastic material designed to distinguish interconnections and to aid the operator in system line-ups.

G. Three common alarm displays are located at key positions on the control boards to provide the operator with immediate notification of alarm conditions. Alarm descriptions are displayed in "double-high" characters for greater visibility.

H. Control room overhead lighting level is set to minimize fatigue and glare in accordance with Human Engineering Design studies.

I. Control boards are "benchboard" style arranged in a horseshoe to minimize distances for operator response and to increase the operator’s ability to effectively monitor the control panels.

13B.1.2.2 Development and Implementation of Staff Recruiting and Training Programs. Recruiting of PVNGS operations personnel to fill the positions described in paragraph 13.1.2.1 was implemented in 1978. Key supervisory positions were filled in 1978. The

training program and its implementation schedule are discussed in section 13.2.

13B.1.2.3 Deleted.

13B.1.2.4 Development of Plant Maintenance Programs.
Maintenance planning for all safety-related equipment was conducted on a ¾ inch = 1 foot model of the PVNGS power block during the final stages of design. Key supervisory positions responsible for development of plant maintenance programs have been filled.

CHAPTER 14

INITIAL TEST PROGRAM (Historical)

14. INITIAL TEST PROGRAM (Historical)

All of the information in Chapter 14 is historical. It describes the preoperation testing and startup testing. Therefore, it is not subject to the update requirements of 10 CFR 50.71(e).

14.1 SPECIFIC INFORMATION TO BE INCLUDED IN PRELIMINARY SAFETY ANALYSIS REPORTS

This section is not applicable for the FSAR.

This page intentionally left blank

14.2 SPECIFIC INFORMATION TO BE INCLUDED IN FSAR (Historical)

14.2.1 SUMMARY OF TEST PROGRAM AND OBJECTIVES

14.2.1.1 Summary of the Startup Test Program

The startup test program includes testing activities commencing with the completion of construction and installation and ending with the completion of the power ascension testing. This test program demonstrates that components and systems operate in accordance with design requirements and meet the requirements of 10CFR50, Appendix B, Criterion XI. The startup test program results confirm that performance levels meet the operational safety requirements delineated in the FSAR, and verify the adequacy of component and system design and system operability over the operating range of the system. It also aids in the establishment of baseline performance data and serves to verify that normal operating procedures and emergency procedures accomplish their intended purposes. The startup test program consists of prerequisite testing plus the following four phases:

- Phase I — Preoperational testing
- Phase II — Fuel loading and post-core hot functional testing
- Phase III — Initial criticality and low power physics testing
- Phase IV — Power ascension testing

The administrative controls established for use during the startup program are contained in the Station Manual.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.1.1.1 Prerequisite Testing

Prerequisite testing consists of tests and inspections required to assure construction is complete and that systems are ready for phase I testing.

The startup test program is conducted in accordance with the operations quality assurance program described in section 17.2.

Prerequisite testing verifies that construction activities associated with the respective structures, components, and systems have been satisfactorily completed. Prerequisite testing consists of preliminary tests and inspections which include, but are not limited to, initial instrument calibration, flushing, cleaning, circuit integrity and separation checks, hydrostatic pressure tests, and functional tests of components. Delineation of specific prerequisite test requirements will be established in accordance with Startup Administrative Procedures.

14.2.1.1.2 Phase I Testing - Preoperational Testing

Phase I, preoperational testing, is performed to demonstrate that structures, systems, and components operate in accordance with design operating modes, throughout the full design operating range. Where required, simulated signals or inputs are used to demonstrate the full range of the systems that are used during normal operation. Systems that are not used during normal plant operation, but must be in a state of readiness to perform safety functions, are checked under various modes and test conditions prior to fuel load.

SPECIFIC INFORMATION TO
BE INCLUDED IN FSAR

Whenever practical, these tests are performed under the conditions expected when the systems would be required to function. When these conditions cannot be attained or appropriately simulated at the time of the test, the system is tested to the extent practical under the given conditions, with additional testing completed at a time when appropriate conditions can be attained.

Preoperational testing ensures that systems and equipment perform in accordance with the Safety Analysis Report. Analysis of test results is made to verify that systems and components are performing satisfactorily, and if not, to provide a basis for recommended corrective action.

An index of preoperational tests is provided in sub-section 14.2.12, and a description of each test procedure is provided in appendix 14B.

14.2.1.1.3 Phase II Testing - Fuel Loading and Post Core Hot Functional Testing

Refer to CESSAR Section 14.2.1.2 for a description of initial fuel loading and post-core hot functional testing.

14.2.1.1.4 Phase III Testing - Initial Criticality and Low Power Physics Testing

Refer to CESSAR Section 14.2.1.2 for a description of initial criticality and low power physics testing.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.1.1.5 Phase IV Testing - Power Ascension Tests

Refer to CESSAR Section 14.2.1.2 for a description of power ascension testing.

14.2.2 ORGANIZATION AND STAFFING [Historical]

14.2.2.1 Management Organization

The executive vice president, Arizona Nuclear Power Project (ANPP), has overall responsibility for defining the responsibilities, requirements, and interfaces necessary to safely and efficiently design, construct, start up, operate, maintain, and modify the Palo Verde Nuclear Generating Station (PVNGS). He is assisted in the performance of these duties by the vice president, nuclear production, and the assistant vice president, nuclear production, who are assigned the overall responsibility for ensuring the safe design, construction, startup, operation, and technical support of PVNGS.

The vice president, nuclear production, and the assistant vice president, nuclear production, are assisted in the performance of their duties by the manager, transition, and the PVNGS plant manager who are assigned the following responsibilities:

- Manager, transition - project management during the transition phase of the project including the prerequisite and phase I test programs.
- PVNGS plant manager - plant operations and the phases II through IV test programs.

Responsibilities associated with startup test programs include the preparation of test procedures, performance of applicable initial tests, and the preparation of appropriate test related documentation. Test procedures are prepared by either the Startup or Nuclear Operation Departments with assistance from the NSSS supplier, Combustion Engineering Inc. (C-E); the architect-engineer, Bechtel Power Corporation (BPC); and other vendors as required. These procedures are subject to review and comment by the appropriate project organizations.

The organizations assigned responsibility for conducting the tests are responsible for establishing specific requirements for scheduling and accomplishing testing, as well as for providing the necessary direction and coordination of groups having responsibility for specific activities in the startup test program. The organizations participating in the initial test program are discussed in the following sections.

14.2.2.2 Transition Department

The Transition Department is responsible for project management during the transition phase (subsystem transfer from construction to subsystem acceptance by operations) of the project. This includes providing central project direction and coordination of support activities by other interfacing organizations.

The Transition Department is composed of representatives from the principal interface organizations (nuclear construction, nuclear engineering, startup, operations, scheduling, C-E, and

BPC) and is headed by the manager, transition. Arizona Public Service Company (APS) quality assurance provides a representative to the Transition Department to assist in quality assurance matters.

14.2.2.2.1 Manager, Transition

The manager, transition, is responsible for the startup program, setting engineering/construction priorities to meet the startup schedules, completing systems prior to acceptance by operations, and supporting operations to full power. The manager, transition, is assisted in his duties by the unit startup manager who is assigned the responsibility for the functional and technical aspects for the startup program.

14.2.2.3 Startup Department

The Startup Department is responsible for the prerequisite and phase I test programs at PVNGS. The unit startup manager is responsible to the manager, transition, for the conduct of the startup test program through phase I testing. The functions and responsibilities of key members of the Startup Department are described in paragraphs 14.2.2.3.1 through 14.2.2.3.4.

14.2.2.3.1 Unit Startup Manager

The unit startup manager is responsible to the manager, transition, for the technical and functional aspects of the startup program including the conduct of the prerequisite and phase I programs and is specifically charged with the following additional responsibilities:

- Approval of startup administrative control procedures
- Review and approve requests for vendor assistance
- Review and recommend approval of requests for modifications or changes required during the test program
- Review progress of startup activities with contractors, vendors, and company management
- Represent the Startup Department on interdepartmental and interorganizational committees associated with the startup test program
- Delegate, as necessary, the authority to perform duties normally associated with the position of unit startup manager
- Establish and dissolve those positions/organizations not specifically chartered by this document as deemed necessary to complete phase I testing
- Approval of prerequisite and phase I test procedures
- Maintain liaison with the Bechtel project manager and the Combustion Engineering Inc. site manager, keeping them informed of status, problems, and support requirements
- Accept systems for test and operation

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.3.2 Startup Administration Manager

The startup administration manager is responsible for the development and implementation of programs necessary for the support of testing activities; including administrative controls, test procedure preparation, cost and budgeting support, material control, document control, and computerized testing and work activity tracking programs. He is also responsible for the coordination of activities involved in the receipt and release of subsystems through startup.

14.2.2.3.3 Test Working Group Chairman

The functions and responsibilities of this individual are explained in paragraph 14.2.2.8.

14.2.2.3.4 Group Supervisors

- Supervise and/or coordinate the activities of assigned personnel
- Assign test responsibility to lead startup engineers
- Issue periodic progress reports and work schedules for their startup group, as required
- Issue special reports concerning startup activities as directed by the unit startup manager
- Maintain liaison with contractors and vendors to coordinate their activities relating to the startup test programs

- Direct the work of the C-E/BPC technical personnel assigned during the startup test program
- Request, coordinate, and monitor vendor representative assistance, as required
- Review test procedures, test procedure modifications, and test results in accordance with startup administrative control procedures
- Review and recommend changes in plant design and/or construction activities to facilitate testing, operation, and maintenance

14.2.2.3.5 Lead Startup Engineer

- Assign a principal startup engineer for each assigned system or subsystem, and periodically review assignments to maintain an appropriate distribution of work load.
- Supervise the activities of and provide guidance to assigned principal startup engineers and assure that their activities are conducted in accordance with the Startup Procedures.
- Provide technical guidance and assistance in the preparation of test procedures.
- Determine the testing requirements, sequence, and test method on assigned systems. Recommend plant scheduling changes as necessary to support the testing effort.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

- Review test procedures, test procedure modifications, and test data in accordance with startup administrative control procedures.
- Recommend changes in plant design and/or construction to facilitate testing, operation, and maintenance.
- Review periodic progress reports and work schedules.
- Assist in the preparation of special reports concerning startup activities when required.
- Review system discrepancies and deficiencies and the status of their resolution and correction for assigned systems.

14.2.2.3.6 Test Directors/Principal Startup Engineers

- Conduct assigned tests using and ensuring compliance with approved test procedures.
- Suspend testing if the test cannot safely be conducted as written until the problem is resolved.
- Sign off individual steps in preoperational test procedures and ensure that required data is recorded.
- Assure required startup materials, instruments, and consumables are available to support scheduled startup activities.
- Conduct pretest and preshift startup briefings.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.3.7 Startup Engineer

- Conduct work assignments in accordance with startup administrative control procedures.
- Prepare assigned test procedures.
- Review engineering drawings and documents and prepare requests for construction and engineering changes, to facilitate both operation and maintenance.

The Startup Department will be augmented by contractor and vendor support personnel, as necessary. These personnel may be integrated into the Startup Department and function in any position designated by the startup manager.

14.2.2.4 Palo Verde Nuclear Generating Station Organization

The PVNGS station organization is described in section 13.1 and will be utilized to the fullest extent practicable in the startup test program. Plant staff personnel will support the startup test program by:

- Providing procedures.
- Performing when requested, component tests (e.g., wiring verification and instrument calibration).
- Performing preventive and corrective maintenance on permanent plant equipment accepted for startup testing.
- Operating permanently installed equipment for testing during the conduct of that startup test program.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

- Providing technical support and assistance for startup testing and related activities.
- Conducting phases II through IV test programs. The responsibility and authority of key members involved in the test program are described in paragraphs 14.2.2.4.1 through 14.2.2.4.4.

14.2.2.4.1 Technical Support Manager

- Review and approve phases II through IV test procedures.
- Review and approve phases II through IV test results as specified in Technical Specifications, Section 6.5

14.2.2.4.1.1 Engineering Manager. The engineering manager is responsible to the PVNGS plant manager for the conduct of phases II through IV test programs and the completion of outstanding prerequisite and phase I program tests on systems jurisdictionally controlled by operations personnel. In addition, he is charged with the following responsibilities:

- Maintain liaison with the technical support manager, Bechtel resident engineer, C-E site manager, and transition manager, keeping them informed of status, problems, and support requirements.
- Review and recommend the approval of requests for vendor assistance as recommended by the Engineering Department supervisors.

- Review and approval/concurrence of test procedures, test procedure changes, and test results in accordance with the Station Manual.

- Review and recommend approval of requests for construction and engineering modifications or changes required during the test program.

- Review progress of startup activities with contractors and vendors.

- Represent the Engineering Department on interdepartmental and interorganizational committees associated with the startup test program.

14.2.2.4.2 Engineering Group Supervisors

- Supervise and/or coordinate the activities of their sections.

- Assign test responsibility to responsible engineers.

- Maintain liaison with contractors and vendors to coordinate their activities relating to the preoperational test program.

- Direct the work of the C-E NSSS technical personnel assigned during phases II through IV test program.

- Request, coordinate, and monitor vendor representative assistance, as required.

- Review and recommend approval of test procedures, test procedure modifications, and test results in accordance with established procedures.

14.2.2.4.3 Test Program Director

- Direct the performance of testing activities through the assigned responsible engineers.
- Ensure that required records, reports, test results and other documents are prepared, reviewed and routed as required by Station Manual procedures.
- Recommend plant scheduling changes and work arounds as necessary to support the testing effort.
- Assure that required startup materials, instrument and consumable supplies are available to support scheduled startup activities.
- Coordinate the preparation and maintenance of phases II through IV startup test procedures with assigned station groups.
- Issue periodic progress reports and work schedules for phases II through IV activities.
- Issue special reports concerning startup activities as directed by the engineering manager.

SPECIFIC INFORMATION TO
BE INCLUDED IN FSAR

14.2.2.4.4 Responsible Engineers

- Assures that assigned test procedures are written, reviewed, and approved in accordance with the Station Manual as scheduled.
- Assures all prerequisites for assigned tests are completed prior to the performance of the test.
- Conducts assigned tests using and ensuring compliance with approved test procedures.
- Keeps the test program director informed of the status of the preparation and performance of assigned tests.
- Suspends testing if the test cannot safely be conducted as written until the problem is resolved.
- Signs off individual steps in test procedures and ensures that required data is recorded.
- Assures that required startup materials, instruments, and consumables are available to support scheduled startup activities.
- Conducts pretest and preshift startup briefings.
- A responsible engineer will be assigned by the test program director to provide overall direction for all testing activities on each shift.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.5 Combustion Engineering

Combustion-Engineering will provide onsite technical assistance to APS during the installation, startup, testing, and initial operations of each NSSS. Through this effort, C-E aids APS and assures itself that each NSSS is installed, started, tested, and operated in conformance with design intent. Combustion-Engineering onsite personnel provide technical assistance and act as technical liaison with C-E headquarters to resolve problems within C-E scope. Combustion-Engineering provides a member of the test working group. Combustion-Engineering will review and comment on test procedures involving their scope of supply.

14.2.2.6 Bechtel Power Corporation

Bechtel Power Corporation, under the direction of APS, has been designated as the engineer-constructor of PVNGS. As the engineer, BPC will provide a representative to serve as a member of the test working group and staff augmentation addressed in subsection 14.2.2. As the constructor, BPC will coordinate the construction schedules with test program requirements and provide manpower support as needed to meet the schedule, to correct deficiencies, or to make repairs.

14.2.2.7 Other Technical Specialties

In addition to the staff described in subsection 14.2.2, APS will augment the Startup Staff from other contractors and vendors as deemed necessary.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.8 Test Working Group

The function of the Test Working Group (TWG) is to advise the transition and unit startup managers of the technical adequacy of the phase I testing program. The TWG functions include coordinating organizational responsibility in areas of test procedure and test results reviews, evaluations, and approval recommendations. The TWG is headed by a chairman appointed by the transition manager and consists of the following minimum membership:

- Startup representative
- C-E project representative
- Bechtel project representative
- APS nuclear engineering representative
- Operating Department representative

If any of the TWG members are unable to attend meetings, an alternate member with full authority to act for that member is present when that member's input is required.

In addition, the TWG is responsible to the transition manager for the following functions during the startup:

- Review of phase I test procedures.
- Review of changes to phase I test procedures.
- Review of results of phase I tests.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.9 Plant Review Board

The Plant Review Board (PRB) will review procedures for use beginning with initial fuel loading as discussed in subsection 13.4.1 and, as required, prerequisite and phase I tests performed by the plant organization staff on plant systems accepted from the Startup Department. The membership of this group is described in section 13.4. In addition to the functions described in section 13.4, this group will review the results of startup tests performed in accordance with procedures requiring their review; and before fuel load, review a listing of all prerequisite and phase I carryover tests to phases II through IV, the justification for their deferral beyond fuel load and a proposed schedule for their performance.

14.2.2.9.1 Plant Review Board Test Results Review Group

Prior to initial fuel loading the PRB will establish the Test Results Review Group (TRRG). The TRRG will review and recommend approval of test procedures in accordance with Section 6.5.1 of PVNGS Technical Specifications. The TRRG will also be responsible for the review and approval recommendation of test results. The TRRG is headed by the engineering manager as established by Station Manual procedures and contains members with expertise in the following areas:

- Reactor physics
- Mechanical engineering
- Electrical engineering

- I&C
- Plant operations
- Chemistry
- Radiation protection
- Quality systems and engineering

14.2.2.10 Organizational Responsibilities

The organization chart showing lines of authority for the functional groups involved in startup testing through phase I is provided in figure 14.2-1. Additional personnel to assist the plant staff during the testing and startup period will be provided by other APS resources, Bechtel and C-E, or others as required.

Arizona Public Service Company management retains overall responsibility for preoperational testing and startup through the vice president, nuclear production. The operations manager under the PVNGS plant manager is responsible for:

- Preparation of operating and emergency procedures
- Operation of plant equipment during system testing phases I, II, III, and IV.
- Providing a TWG member.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.2.10.1 The unit startup manager under the transition manager is responsible for the activities discussed in paragraph 14.2.2.3.1.

14.2.2.10.2 The C-E project manager is responsible for the preparation of the NSSS test guidelines or procedures. The C-E site manager, reporting to the C-E project manager, is responsible for the following:

- Providing a TWG member.
- Reviewing test procedures pertaining to or interfacing with C-E-supplied systems, equipment, and changes thereto, including the reviews discussed in LLIR, Item I.C.7.
- Evaluating test results for tests pertaining to C-E-supplied systems and equipment.
- Coordinating the resolution of problems dealing with NSSS equipment.
- Providing technical consultation on matters relating to the operation and testing of C-E-supplied systems and equipment.
- Providing adequate qualified support personnel including vendor representatives as necessary.

14.2.2.10.3 The Bechtel project organization provides technical advice and consultation on matters relating to the

design, construction, operation, and testing of systems and equipment.

Accordingly, the Bechtel project organization is responsible for the following:

- Providing a TWG member.
- Reviewing test procedures pertaining to Bechtel scope of supply systems (e.g., balance of plant systems).
- Evaluating balance of plant test results.
- Coordinating resolution of problem areas by providing technical support and liaison with the Startup Organization and the Bechtel construction and design groups.
- Providing startup assistance as requested.

14.2.2.10.4 The APS nuclear engineering representative acts as a TWG member and provides liaison with APS nuclear engineering during the startup effort.

14.2.2.11 Qualifications

Staffing and qualifications of the plant organization are detailed in chapter 13, Conduct of Operations.

14.2.2.11.1 Personnel Qualification Requirements

Personnel responsible for conduct of startup program tests (including TWG/TRRG members) shall be qualified as follows:

SPECIFIC INFORMATION TO
BE INCLUDED IN FSAR

A. Minimum qualification of individuals that direct or supervise the conduct of individual prerequisite and phase I tests:

1. At the time of assignment to the function, the individual should have a Bachelor's Degree in engineering or the physical sciences or the equivalent, and 1 year of applicable power plant experience. Included in the 1 year of experience should be at least 3 months of indoctrination/ training in nuclear power plant systems and component operation of a nuclear power plant that is substantially similar in design to PVNGS. In addition, the individual will undergo indoctrination/training on the PVNGS plant, or,

2. A high school diploma, or the equivalent, and 4 years of power plant experience. Credit for up to 2 years of this 4-year experience may be given for related technical training on a one-for-one time basis. Included in the 4 years of experience should be at least 3 months of indoctrination/ training in nuclear power plant systems and component operation of a nuclear power plant that is substantially similar in design to PVNGS. In addition, the individual will undergo indoctrination/training on the PVNGS plant, or,

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

3. Be qualified to the requirements of paragraph 14.2.2.11.1, sublisting B.1 or B.2 or listing C.

B. Minimum qualifications of individuals that direct or supervise the conduct of individual phases II through IV tests:

1. At the time of assignment to the function, the individual should have a Bachelor's Degree in engineering or the physical sciences or the equivalent, and 2 years of applicable power plant experience of which at least 1 year shall be applicable nuclear power plant experience, or,

2. A high school diploma or the equivalent and 5 years of applicable power plant experience of which at least 2 years shall be applicable nuclear power plant experience. Credit for up to 2 years of nonnuclear experience may be given for related technical training on a one-for-one time basis, or,

3. Written authorization from the PVNGS plant manager that the individual is qualified to supervise or direct specific phases II through IV test(s), based on a case-by-case evaluation of the individual's qualifications relative to the specific test(s). In this case, a responsible engineer who is qualified per sublisting 1 or 2 above will be available for consultation regarding the specific test.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

Included in the experience should be at least 3 months of indoctrination/training in nuclear power plant systems and component operation of a nuclear power plant that is substantially similar in design to PVNGS. In addition, the individual will undergo indoctrination/ training on the PVNGS plant.

C. Minimum qualifications of individuals assigned to groups responsible for review and approval of phase I test procedures and/or review and approval of test results.

At the time the activity is being performed, individuals assigned to perform these activities shall have a minimum of 8 years of applicable power plant experience with a minimum of 2 years of applicable nuclear power plant experience. A maximum of 4 years of nonnuclear experience may be fulfilled by satisfactory completion of academic training at the college level.

Included in the experience should be at least 3 months of indoctrination/training in nuclear power plant systems and component operation of (1) PVNGS or (2) a nuclear power plant of substantially similar design. In addition, individuals qualifying under item 2 will undergo indoctrination/training on the PVNGS plant.

D. The review and approval of phases II through IV test procedures and the review and approval of test results will be done per Section 6.5.1 of the PVNGS Technical Specifications.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

E. Subsequent to system acceptance, the minimum qualification for individuals that direct or supervise and review/approve prerequisite and phase I test procedures and test results:

1. Startup personnel who direct or supervise the conduct of phase I tests shall be qualified to the requirements of paragraph 14.2.2.11.1, listing A.

2. Plant operations personnel who direct or supervise the conduct of prerequisite tests shall be qualified to the requirements of subsection 13.1.3. Plant operation personnel who direct or supervise the conduct of phase I tests shall be qualified to the requirements of paragraph 14.2.2.11.1, listing B.

3. Plant operation personnel who review and approve phase I test procedures and test results shall be qualified to the requirements of subsection 13.1.3.

   The review and approval of test procedures and test results will be done in accordance with the Station Manual procedures.

14.2.2.12 Utilization of the Plant Staff

The plant operating, maintenance, and engineering personnel are utilized to the extent practicable during the startup test program. The plant staff operates permanently installed and powered equipment for phases I through IV and subsequent system tests. Service personnel such as instrument, chemistry,

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

computer, radiation protection, and maintenance personnel are used extensively to perform tests and inspections applicable to their field of specialization.

Phases II through IV and subsequent test procedures and test results are reviewed by the plant staff as specified in the Station Manual.

14.2.3 TEST PROCEDURES

The unit startup manager has the responsibility for assuring the preparation and designating the approval process for prerequisite and phase I test procedures at PVNGS. The technical support manager is responsible for ensuring that phases II through IV test procedures are prepared and approved in accordance with the Station Manual. Detailed procedure guidelines and procedures provided by the appropriate design organization are utilized to develop various system test procedures. Thus, test procedures are based on requirements of system designers. If a design organization prepares sufficiently detailed procedures, these procedures may serve in lieu of test guidelines. Procedures prepared by outside organizations will undergo the same review process as procedures prepared by PVNGS plant staff.

14.2.3.1 Prerequisite Test Procedure Preparation

Prerequisite test procedures are prepared under supervision of the unit startup manager.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

Test procedures will be prepared using pertinent reference material provided by the appropriate design and/or vendor organization.

Prerequisite test procedures contain the following major divisions:

- Purpose/objective
- Reference
- Definitions and abbreviations
- Precautions and limitations
- Prerequisites (initial conditions)
- Instructions (including acceptance criteria)
- Restoration

Prerequisite test procedures are reviewed as specified in administrative procedures. At the completion of these reviews, any changes are incorporated in the test procedure by the originating organization.

The unit startup manager has approval authority for assigned prerequisite tests and may in writing delegate approval authority.

14.2.3.2 Test Procedure Preparation

Detailed test procedures for phase I tests are prepared under the unit startup manager's supervision. The test procedures for phases II through IV tests are prepared under the

supervision of the engineering manager. Each test procedure will be prepared using pertinent reference material provided by the appropriate design and vendor organizations, FSAR, Technical Specifications, and applicable regulatory guides. A test procedure is prepared for each specific system test to be performed during the four phases of the test program. Each system test procedure contains the following major divisions:

- Test objectives
- Acceptance criteria
- References
- Prerequisites
- System initial conditions
- Environmental conditions
- Special precautions
- Detailed procedure (including data collection)
- Restoration
- Documentation of test results

Phase I test procedures are reviewed as specified in startup administrative control procedures. At the completion of these reviews, any required changes are incorporated in the test procedure by the originating organization.

The unit startup manager has the approval authority for phase I test procedures.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

Startup test procedures for post-fuel load tests (phases II through IV) and changes to such procedures will be reviewed and approved in accordance with the requirements of the facility Technical Specifications.

14.2.3.3 Special Test Procedures

Special test procedures may become necessary during the phases I through IV test program for investigative purposes. The preparation, review, and approval of these special procedures are governed by administrative control procedures. Special test procedures that deal with nuclear safety are processed under the same controls as normal startup test procedures.

14.2.4 CONDUCT OF TEST PROGRAM (PHASES I THROUGH IV)

When a phase I through phase IV system test procedure has been released for performance, a test director/principal startup engineer/responsible engineer will be responsible for (1) ensuring that prerequisites are satisfactorily met or allowable exceptions are noted in accordance with Station Manual procedures, and (2) verifying that the testing is performed as required by the procedure. The test is then performed by PVNGS operating personnel or others in accordance with the approved test procedure.

The operations shift manager is responsible for the safe operation of the plant during the performance of phase I through phase IV testing. The operations shift manager takes

action necessary to assure the safe operation of the facility. He may stop any system test in progress and place the plant in a safe condition.

The test director/principal startup engineer/responsible engineer ensures that the tests are conducted in accordance with the test procedure.

Required data resulting from the test is compiled within the test procedure in specified data blanks, on specially prepared data sheets, or as otherwise specified by administrative control procedures. Personnel completing data forms or checklists will sign and date the forms. Upon test completion, the test data are compared with the test acceptance criteria, and any discrepancies noted are resolved in accordance with applicable Station Manual procedures.

Once a procedure has been approved, procedure changes will be made in accordance with the provisions of the Station Manual.

14.2.4.1 Signoff Provisions

Each approved test procedure shall contain signoff provisions for prerequisites and for all procedural steps. For component tests the person conducting the test is responsible for signing and dating each data form in the spaces provided, as the data is entered. For phases I through IV test prerequisites, the test director/principal startup engineer/responsible engineer shall initial the appropriate space in the test procedure. Signoff of the individual steps within the body of the test

procedure is the responsibility of the test director/principal startup engineer/responsible engineer.

For prerequisite tests, a qualified individual designated by the test director/principal startup engineer may sign off procedural steps and data sheets.

14.2.4.2 Maintenance/Modification Procedures

Work authorization documents, controlled in accordance with the Station Manual, are used to initiate maintenance and implement modifications on systems that are jurisdictionally turned over from the construction organization. The work authorization document assigns the organization responsible for the completion of the activity and specifies any retest requirements. Upon completion of the activity, a copy of the signed-off form is returned to the responsible testing organization to ensure retest requirements are met. Results of retests due to maintenance will be reviewed by the appropriate principal startup engineer/responsible engineer or the shift manager. Results of retests due to modifications will be reviewed and approved in the same manner as those from the original tests.

14.2.4.3 Test Performance

For prerequisite and phases I through IV testing, an individual who is qualified in accordance with paragraph 14.2.2.11.1 will be designated as the test director/principal startup engineer/responsible engineer. The official copy of the test

procedure shall be available in the test area during the performance of a preoperational or startup test. The person conducting the test is charged with responsibility for performing the test in accordance with the approved test procedure. If, during the performance of the test, it is determined that the test cannot be conducted as written, it is the responsibility of the person conducting the test to resolve the problem in accordance with approved administrative control procedures.

14.2.5 REVIEW, EVALUATION, AND APPROVAL OF PHASE I THROUGH PHASE IV TEST RESULTS

Individual test results will be reviewed and approved as provided in the Station Manual. Completed procedures and test reports will be reviewed for acceptance. The specific acceptance criteria for determining the success or failure of the test will be included as part of the procedure and will be used during the review.

The principal startup engineer/responsible engineer will present the completed test procedure and test report with remarks and recommendations to the responsible group supervisor as appropriate. The group supervisor will review the completed procedure for conformance with testing requirements as well as for acceptance of the test results. Following this review, the completed procedure and test report will be submitted to the test working group, the test results review group, or the Plant Review Board for final review, evaluation, and approval recommendation. If the as-built configuration of a system is

not capable of demonstrating its ability to meet the acceptance criteria, an engineering evaluation will be performed.

Test results for each phase of the test program will be reviewed and verified as complete (as required) and satisfactory before testing in the next phase is started. Preoperational testing on a system will not normally be started until all applicable prerequisite tests have been completed, reviewed, and approved. Prior to initial fuel loading and the commencement of initial criticality, a comprehensive review of required completed preoperational procedures will be conducted by the test working group and/or the TRRG. This review will provide assurance that required plant systems and structures will be capable of supporting the initial fuel loading and subsequent startup testing.

It is intended that phase I testing be completed prior to commencing initial fuel loading. In attempting to accomplish this task, plant systems under jurisdictional control of the Startup Department will be the responsibility of the unit startup manager to complete as delineated in paragraph 14.2.2.3.1. If prerequisite and phase I testing is incomplete at the time of system acceptance by operations personnel, the engineering manager, under the direction of the PVNGS plant manager, will ensure completion of the testing per the Station Manual administrative control procedures.

The TRRG will review and recommend to the PRB approval of phase I test procedures and test results that have not been completed at the time of system acceptance. Prerequisite tests

will be reviewed and approved in accordance with the Station Manual.

Phase I tests which will be performed after initial fuel loading will be performed under the administrative controls governing phases II through IV testing. These tests will be performed by either startup or operations personnel as determined on a case-by-case basis.

The startup testing phases (phases II, III, and IV) of the test program are subdivided into the following categories: initial fuel load, postloading hot functional testing, initial criticality, low power physics testing, and power ascension testing.

It ends with the completion of testing at 100% power. Each subdivision is a prerequisite which must be completed, reviewed, and approved before tests in the next category are started. Power ascension tests will be scheduled and conducted at pre-determined power levels. The testing plateaus to be used for PVNGS startup testing are specified in CESSAR Section 14.2.1.2. Insofar as practical, so that the safety of the plant will not be totally dependent on the performance of untested systems, systems relied upon to prevent, limit, or mitigate the consequences of postulated accidents will be tested to verify that operating requirements are met prior to exceeding approximately 25% power.

The plateaus for the power ascension testing are indicated in each test summary. Results from each test conducted at a given plateau will be evaluated prior to proceeding to the next

level. For those tests which result in a plant transient for which a realistic plant transient performance analysis has been performed, the test results will be compared to the results of the realistic transient analysis rather than the results of the transient analysis based on accident analysis assumptions.

Following completion of testing at 100% of rated power, final test results will be reviewed, evaluated, and approved.

14.2.5.1 Review, Evaluation, and Approval of Prerequisite Test Results

Prerequisite test results will be reviewed and approved in accordance with startup administrative control procedures.

14.2.6 TEST RECORDS

A single copy of each phase I through phase IV test procedure is designated as the official copy to be used for testing. The official copy and information specifically called for in the test procedure, such as completed data sheets, instrumentation calibration data, and chart recordings, are retained at PVNGS for the life of the plant in accordance with Station Manual procedures for record retention.

14.2.7 CONFORMANCE OF TEST PROGRAMS WITH REGULATORY GUIDE

The startup test program is consistent with CESSAR Section 14.2.7 and the recommendations of the following regulatory guides associated with startup: Regulatory Guides 1.9, 1.18, 1.20, 1.30, 1.37, 1.41, 1.52, 1.68, 1.68.2,

1.68.3, 1.79, 1.108, 1.116, 1.118, and 1.140 with exceptions as noted and revisions as specified in section 1.8.

14.2.8 UTILIZATION OF REACTOR OPERATING AND TESTING EXPERIENCES IN DEVELOPMENT OF TEST PROGRAM

PVNGS operations reviews reactor operating and testing experiences at other facilities similar in design and capacity to PVNGS.

This review is accomplished by circulating licensee event reports (LERs) or summaries of LERs and NRC I&E bulletins, circulars, and information notices to startup and operation personnel so that pertinent information can be utilized in the startup program.

14.2.9 TRIAL USE OF PLANT OPERATING AND EMERGENCY PROCEDURES

The schedule for the development of plant operating and emergency procedures is discussed in section 13.5. Whenever practical, test procedures reference the plant operating and emergency procedures. In the test program, plant operating procedures are used extensively in the operation of the plant. Plant emergency procedures are verified whenever possible during the test program. When practical, surveillance test procedures are performed after completion of preoperational tests.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.10 INITIAL FUEL LOADING AND INITIAL CRITICALITY

14.2.10.1 Fuel Loading

Refer to CESSAR Section 14.2.10.1 for a description of initial fuel loading. Core alterations during initial fuel loading are directly supervised by a person holding a senior reactor operator license.

14.2.10.2 Initial Criticality

Refer to CESSAR Section 14.2.10.2 and paragraph 1.9.2.4.16 for a description of initial criticality.

14.2.11 TEST PROGRAM SCHEDULE

The test program for each unit should encompass approximately 24 months. Approximately 2 months of this time has prerequisite tests as the controlling path. Preoperational and precore hot functional testing are the controlling path for about 16 months. The remaining 6 months are devoted to fuel loading, post-core hot functionals, low power physics, and power ascension testing.

The scheduling of individual tests or test sequences is made to ensure that systems and components that are to prevent or mitigate the consequences of postulated accidents are tested prior to fuel loading. Tests that require a substantial core power level for proper performance are performed at the lowest power level commensurate with obtaining acceptable test data. Safety-related systems are tested to provide reasonable

assurance that they operate satisfactorily when required, prior to exceeding 25% of rated thermal power.

Prerequisite testing followed by phase I testing will commence when construction has authorized the testing of components/ testable portions of systems by the Startup Department; however, phase I testing will not commence until jurisdiction for those components/testable portions of systems have been transferred to the Startup Department. Test procedures will contain a list of prerequisites that must be completed and verified prior to the start of a particular test. The use of prerequisites in test procedures ensures that the safety of the plant is not dependent on the performance of untested systems.

Phase I test procedures are scheduled to be approved and available for review by the NRC inspectors at least 60 days prior to their scheduled performance date. Phases II through IV startup test program administrative control procedures, the majority of the individual test procedures, and the following milestone controlling procedure documents: Fuel Loading, Post-Core HFT, Initial Criticality, Low Power Physics Test and Power Ascension, are scheduled to be approved and available for review at least 60 days prior to fuel load. The remaining individual test procedures will be scheduled for approval and available for review by the NRC inspectors at least 60 days prior to their intended performance date.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

14.2.12 INDIVIDUAL TEST DESCRIPTIONS

Individual test descriptions are listed in table 14.2-1 and are presented in appendix 14B.

FSAR paragraphs 1.9.2.4.9 and 1.9.2.4.14 through 1.9.2.4.17, 1.9.2.4.19, 1.9.2.4.21, and 1.9.2.4.22 describe deviations to testing described in CESSAR Section 14.2.12.

SPECIFIC INFORMATION TO

BE INCLUDED IN FSAR

Table 14.2-1

INDEX OF INDIVIDUAL TEST DESCRIPTIONS (Sheet 1 of 3)

Phase I Tests

See CESSAR Section 14.2.12 for a description of preoperational tests performed on equipment within the C-E licensing scope of supply. See paragraph 1.9.2.4 for exceptions to or deviations from CESSAR Section 14.2.12 test descriptions.

See CESSAR Sections 4.2.5, 5.1.4, 5.4.7.1.3, 6.3.1.3, 6A-7.0,

6B-7.0, 7.1.3, 7.2.3, 7.3.3, 8.3.1, 8.3.2, 9.1.4.6, 9.3.4.6 for BOP CESSAR system interfaces which will be tested.

CESSAR Section 14.2.12.2.8, item 2.5, requiring COLSS to be in operation is not applicable for precore RCS flow measurement.

Phase I Tests on Other Systems

1. Main steam, main steam isolation valves, and safety valves
2. Containment spray system
3. Condensate storage tank and transfer system
4. Class 1E 125 V-dc power system
5. Class 1E 4.16 kV power system
6. Class 1E 480V power switchgear system
7. Class 1E 480V power MCC system
8. Class 1E instrument ac power
9. Diesel generator electrical tests and load sequencing
10. Emergency lighting
11. Pipe shock and vibration test
12. Containment isolation actuation system
13. Auxiliary feedwater system
14. Reactor containment integrated and local leak rate tests
15. Diesel fuel oil storage system
16. Diesel generator mechanical systems
17. Essential chilled water system
18. Essential cooling water system

(Historical)

CONTENTS

CONTENTS (cont)

CONTENTS (cont)

APPENDIX 14A

<u>QUESTION 14A.1</u> (NRC comment on subsection 14.2.12) (6/18/80) (14.2.12)

Individual test descriptions not provided (will be provided by October 1, 1980).

RESPONSE: The response is given in amended subsection 14.2.12.

<u>QUESTION 14A.2</u> (NRC Question 640.1) (14.2.2.6)

Paragraph 14.2.2.7 states that the architect engineer is only required as part of the TWG to review Phase I Preoperational test procedures, although he is responsible for reviewing changes and results for both Phase I and II tests. Explain how the architect engineer can effectively review procedures changes and results without having reviewed the initial procedure, or modify paragraph 14.2.2.6 to eliminate this apparent discrepancy.

RESPONSE: The response is given in amended paragraph 14.2.2.6.

<u>QUESTION 14A.3</u> (NRC QUESTION 640.2) (14.2.7)

Section 1.8 references Section 1.8 of CESSAR in regards to Regulatory Guide 1.20. CESSAR Section 1.8 then references CESSAR Subsection 3.9.2.4, which states that the first System 80 unit that will go online will be the lead plant and will be used as the System 80 prototype. Provide a test description that satisfies the guidelines of Regulatory Guide 1.20 as described in CESSAR Subsection 3.9.2.4. The test abstract should clearly indicate which portions will be deleted

if the Palo Verde unit is not the first System 80 plant to go on-line or if subsequent Palo Verde units are to be tested.

RESPONSE: The response was provided on the CESSAR docket. See Question 14A.39.

QUESTION 14A.4 (NRC Question 640.3) (14.2.7)

Subsection 14.2.7 states the Regulatory Guide 1.18 with exceptions as noted and revisions as specified in section 1.8 will be used. Delete the following exceptions to Regulatory Guide 1.18 given in section 1.8 or provide more detailed technical justification for the reduced testing.

(1) C.1 - Not holding pressure constant for at least one hour at each level before recording strains and deflections.

(2) C.3 - Not measuring tangential deflections.

RESPONSE: The response is given in amended section 1.8.

QUESTION 14A.5 (NRC Question 640.4) (14.2.9)

Subsection 14.2.9 states that the schedule for the development of plant operating and emergency procedures is discussed in section 13.5. Section 13.5 gives only the schedule for administrative procedures (available approximately six months prior to fuel loading of Unit 1). Modify subsection 14.2.9 and/or section 13.5 to provide a schedule for the development of plant procedures as required by Regulatory Guide 1.70. This schedule should be established to maximize, where practical, the availability of plant operating and emergency procedures so

that user-testing can be accomplished during the initial test program.

RESPONSE: The response is given in amended subsection 13.5.2.

<u>QUESTION 14A.6</u> (NRC Question 640.5) (14.2.11)

Subsection 14.2.11 states that test procedures are "normally" scheduled to be approved and available for review by NRC inspectors at least 60 days prior to their scheduled performance. Provide a list of those tests that will not be available for review 60 days prior to use, or cite the "abnormal" conditions which will prevent those procedures from being available in accordance with the requirements of Regulatory Guide 1.68, Appendix B.

RESPONSE: The response is given in amended subsection 14.2.11.

<u>QUESTION 14A.7</u> (NRC Question 640.6) (14.2.12)

Provide a commitment to include in your test program any design features to prevent or mitigate anticipated transients without scram (ATWS) that may now, or in the future, be incorporated into your plant design.

RESPONSE: Any design features to prevent or mitigate anticipated transients without scram (ATWS) that are incorporated in the PVNGS plant design now, or may be incorporated into the PVNGS plant design in the future, will be included in a test program.

QUESTION 14A.8 (NRC Question 640.7)

List any tests, or portions of tests, described in subsection 14.2.12 which you do not intend to perform on each unit and provide technical justification for deletion of each.

RESPONSE: PVNGS will perform all preoperational tests referred in subsection 14.2.12 for each unit. Refer to CESSAR for scope of startup testing beyond initial unit. (Refer to CESSAR Tables 14.2-1 and 14.2-2 and FSAR paragraphs 1.9.2.4.9, 1.9.2.4.13, and 1.9.2.4.15.)

QUESTION 14A.9 (NRC Question 640.8) (14.2.12)

Our review of your initial test program description disclosed that the operability of several of the systems and components listed in Regulatory Guide 1.68 (Rev. 0), Appendix A, may not be demonstrated. Expand your FSAR to include appropriate test descriptions (or identify existing descriptions) that address the following items from Appendix A, or provide technical justification in subsection 14.2.7 for any exceptions to the guide:

(1) A.4.a. Feedwater system

(2) h. Secondary plant chemical treatment system

(3) 5.j. Radwaste building and turbine building ventilation

(4) 7.a. Containment overpressure (structural integrity)

(5) e. Functional test of containment isolation valves

(6) 10.c. Operability and leak test of sectionalizing devices in the fuel storage pool and refueling canal

(7) 13. Liquid and solid radwaste systems

RESPONSE: The response is given in amended appendix 14B test descriptions addressing the following:

1. Feedwater system
2. Secondary plant chemical treatment system
3. Radwaste building and turbine building ventilation system
4. Containment overpressure (SIT)
5. Functional test of containment isolation valves
6. Operability and leak test of sectionalizing devices in the fuel storage pool and refueling canal
7. Liquid and solid radwaste systems

QUESTION 14A.10 (NRC Question 640.9) (14.2.12)

A CESSAR interface is defined in Subsection 1.1.3 of CESSAR as a requirement that the balance of plant have a certain capability necessary for assuring that a CESSAR design scope system will fulfill its safety functions. It is not clear from your preoperational test procedure descriptions that you intend to demonstrate compliance with these interface requirements. As a minimum, your test procedure description (chapter 14 of your FSAR) should contain a generic commitment to demonstrate

compliance with all CESSAR interfaces including those contained in the following subsections of CESSAR:

(1)	4.2.5	Reactor
(2)	5.1.4	RCS
(3)	5.4.7.1.3	RHR
(4)	6.3.1.3	ECCS
(5)	6A-7.0	CSS
(6)	DELETED	
(7)	7.1.3	Instrumentation and controls
(8)	7.2.3	RPS
(9)	7.3.3	ESFAS
(10)	8.3.1	Electrical ac
(11)	8.3.2	Electrical dc
(12)	9.1.4.6	Fuel handling
(13)	9.3.4.6	CVCS

RESPONSE: The response is given in amended table 14.2-1.

QUESTION 14A.11 (NRC Question 640.10(1)) (14.2.12)

We could not conclude from our review of your individual test descriptions that comprehensive testing is scheduled for several systems and components. Therefore, clarify or expand the appropriate test descriptions to address the following items:

14B.1 - Provide assurance that the main steam relief valves will be tested at normal operating temperature and that the testing fluid will be steam.

RESPONSE: The response is given in amended section 14B.1.

<u>QUESTION 14A.12</u> (NRC Question 640.10(2)) (14.2.12)

14B.2(a) - Recently, questions have arisen concerning the operability and dependability of certain ESF pumps. Upon investigation, the staff found that some completed preoperational test procedures did not describe the test conditions in sufficient detail. Provide assurance that the preoperational test procedures for the containment spray pumps will require recording the status of the pumped fluid (e.g., pressure, temperature, chemistry, amount of debris) and the duration of testing for each pump. In addition, provide preoperational test descriptions to verify that the containment spray pumps operate in accordance with the manufacturer's head-flow curve. Include in the description the bases for the acceptance criteria. (The bases provided should consider both flow requirements for ESF functions and pump NPSH requirements, see Interface 7.13.1 of Appendix 6A in CESSAR).

RESPONSE: The response is given in amended section 14B.2. In addition, PVNGS will ensure that the preoperational test procedures for the containment spray pumps will require recording of the status of pump fluid, the duration of testing, and comparison with manufacturer's head flow curve for each pump.

<u>QUESTION 14A.13</u> (NRC Question 640.10(3)) (14.2.12)

14B.2(b) - Verify that paths for the air flow test of containment spray nozzles overlap the water flow test paths of the pumps to demonstrate that there is no blockage in the flow path.

RESPONSE: The response is given in amended section 14B.2.

<u>QUESTION 14A.14</u> (NRC Question 640.10(4)) (14.2.12)

14B.2(c) - Testing of the containment spray system should include verification of pump suction from the containment sump while in the recirculation mode.

RESPONSE: During the system flushing/cleaning phase of startup testing, the flow path from the ECCS sump to the ECCS suction headers will be verified as unobstructed.

<u>QUESTION 14A.15</u> (NRC Question 640.10(5)) (14.2.12)

14B.4 - DC Power System Test -- State your plans to verify that individual cell limits are not exceeded during the design discharge test and to demonstrate that the dc loads will function as necessary to assure plant safety at a battery terminal voltage equal to the acceptance criterion that has been established for minimum battery terminal voltage for the discharge load test. Assure that each battery charger is capable of floating the battery on the bus or recharging the completely discharged battery within 24 hours while supplying the largest combined demands of the various steady-state loads under all plant operating conditions.

RESPONSE:

(1) Section 14B.4 will be amended in the future to include the requirement to monitor individual cell voltages during the design discharge test.

(2) Section 14B.4 will be amended in the future to include the requirement to verify that dc loads will function, as necessary, at a battery terminal voltage equal to the acceptance criteria established for minimum battery terminal voltage.

(3) Section 4.0 of 14B.4 addresses the acceptance criteria of subsection 8.3.2. More specifically, paragraph 8.3.2.1.2.2 requires the battery charger to restore the battery from the design minimum charge state to the fully charged state within 12 hours while supplying the largest combined demand of all the steady-state loads regardless of the status of the plant during these demands.

It is determined that part (3) of Question 640.10(5) is sufficiently addressed.

QUESTION 14A.16 (NRC Question 640.10(6)) (14.2.12)

14B.6-7 - The acceptance criteria "undue thermal or mechanical stress" and "appropriate design documents" are unacceptably vague. Provide more specific acceptance criteria.

RESPONSE: The response is given in amended sections 14B.6 and 14B.7.

APPENDIX 14A

<u>QUESTION 14A.17</u> (NRC Question 640.10(7)) (14.2.12)

14B.4-8-a - PVNGS is a three-unit facility and, therefore, there is the possibility of subtle interconnections between units. Describe the status of the power supplied to "other" units to ensure independence during power distribution testing. The descriptions should address both normal and emergency ac and dc power distribution systems. Provide assurance that cross-ties will not exist which could cause loss of emergency bus power to one unit due to testing of the other unit.

RESPONSE: Units not undergoing testing will be protected from being affected by transients due to actions at a unit under test by the unit independent protection systems.

<u>QUESTION 14A.18</u> (NRC Question 640.10(8)) (14.2.12)

14B.4-8-b - The initial test program should verify the capability of the offsite power system to serve as a source of power to the emergency buses. Tests should demonstrate the capability of each startup transformer to supply power to its unit's emergency buses while carrying its maximum load of plant auxiliaries and the other unit's emergency buses. Tests should also demonstrate the transfer capabilities of the unit's emergency bus feeders upon loss of one source of offsite power. These tests should be performed as early in the test program as the availability of necessary components allows. Provide descriptions of the tests that will demonstrate these capabilities.

RESPONSE: Each startup transformer is capable of supplying 100% of the startup or normally operating loads of one unit

simultaneously with the engineered safety feature (ESF) loads associated with two load groups of another unit. The non-Class 1E ac buses normally are supplied through the unit auxiliary transformer, and the Class 1E buses normally are supplied through the startup transformers. In the event of failure of the unit auxiliary transformer, a turbine trip, or reactor trip, an automatic fast transfer of the 13.8 kV buses to the startup transformers is initiated to provide power to the auxiliary loads. Transfers of all buses can be initiated by the operator from the control room.

In addition, the 13.8 kV intermediate buses have access to all three transformers such that a loss of one transformer can be sustained without affecting the availability of off-site power to any of the three units.

Preferred power for Class 1E buses is supplied from the startup transformers through the 13.8 kV switchgear and the 13.8 to 4.16 kV ESF transformers.

A test abstract will be generated to demonstrate load group assignment verification and transfer capabilities of the 13.8 kV buses to the startup transformers.

QUESTION 14A.19 (NRC Question 640.10(9)) (14.2.12)

14B4-8-c - Subsection 1.8 of your FSAR states compliance with Regulatory Guide 1.41; however, it is not clear from our review of your test procedure abstracts that the intent of this guide is met. Expand your existing test abstracts to indicate this compliance. Testing in conformance with Regulatory Guide 1.41 should incorporate the following:

(a) - Provide assurance that all sources of power supply to vital buses are capable of carrying full accident loads. If some portions of the power supplies cannot be full-load tested, provide justification.

(b) - Verify that testing is conducted with only one power source at a time.

(c) - Verify that buses not under test are monitored to verify absence of voltage.

RESPONSE:

(a) The response is given in the response to 640.10(10) 14.B.4-8-d.

(b) Testing will be begun from a deenergized state with only one power source applied to the circuitry under test.

(c) Following energization of buses under test, interconnecting buses will be monitored to verify absence of voltage.

QUESTION 14A.20 (NRC Question 640.10(10)) (14.2.12)

14B.4-8-d - Your test descriptions are not sufficiently detailed to ascertain if the voltage levels at the safety-related buses are optimized for the full load and minimum load conditions that are expected throughout the anticipated range of voltage variations of the offsite power source by appropriate adjustment of the voltage tap settings of the intervening transformers. We require that the adequacy of the design in this regard be verified by actual measurement and by correlation of measured values with analytical results. Provide a description of the method for making this verification.

RESPONSE: PVNGS will measure the station distribution buses, including Class 1E buses initially and prior to loading, and record voltages. PVNGS will also measure and record the station distribution buses including Class 1E buses upon loading the bus to at least 30%. This will occur prior to completion of the initial test program.

PVNGS will measure and record grid and Class 1E bus voltages and bus loading during the startup of a large Class 1E motor and also during the starting of a large non-Class 1E motor.

The above information will be reviewed to verify analytical data.

QUESTION 14A.21 (NRC Question 640.10(11)) (14.2.12)

14B.9 - Section 1.8 of your FSAR states compliance with Regulatory Guide 1.108; however, it is not clear from our review of your test procedure abstracts that the intent of

this guide is met. Expand this test abstract, as well as 14B.16 if necessary, to indicate this compliance.

RESPONSE: Since PVNGS is committed to Regulatory Guide 1.108 as stated in section 1.8 of the FSAR, PVNGS feels that this is sufficient clarification that we intend to meet the requirements therein.

QUESTION 14A.22 (NRC Question 640.10(12)) (14.2.12)

14B.10 - Paragraph 9.5.3.2.2.3 states that emergency lighting is provided for 8 hours, not 90 minutes to 2 hours as stated in the acceptance criteria of this test. Clarify this apparent inconsistency.

RESPONSE: The response is given in amended section 14B.10.

QUESTION 14A.23 (NRC Question 640.10(13)) (14.2.12)

14B.11 - Our review of recent licensee event reports disclosed that a significant number of reported events concerned the operability of hydraulic and mechanical snubbers. Provide a description in this test abstract of the inspections or tests that will be performed following system operation to ensure that snubber operation is adequate.

RESPONSE: The response is given in amended section 14B.11.

QUESTION 14A.24 (NRC Question 640.10(14)) (14.2.12)

14B.13(a) - Our review of licensee event reports has disclosed several instances of auxiliary feedwater pump failure to start on demand. It appears that many of these failure could have been avoided if more thorough testing had been conducted during

the plant's initial test programs. In order to discover any problems affecting pump start-up and to demonstrate the reliability of your emergency cooling system, state your plans to demonstrate at least five consecutive, successful, cold, quick pump starts during your initial test program.

RESPONSE: The response is given in amended section 14B.13.

QUESTION 14A.25 (NRC Question 640.10(15)) (14.2.12)

14B.13(b) - Subsection 10.4.9 does not reference pump starting times, valve operation times, or operation of alarms, indicating instruments, or status lights. A reference for these items is required.

RESPONSE: The response is given in amended section 14B.13.

QUESTION 14A.26 (NRC Question 640.10(16)) (14.2.12)

14B.14 - Include in this test abstract a commitment to verify that containment recirculation fan motor current is within its design value at conditions representative of accident conditions. Address such issues as air density, temperature, humidity, fan speed, and blade angle.

RESPONSE: The PVNGS design does not use the containment recirculation fans post-accident. The containment spray system provides the needed mixing of the containment atmosphere post-accident.

<u>QUESTION 14A.27</u> (NRC Question 640.10(17)) (14.2.12)

14B.29 - Paragraph 7.5.1.1.5 is not an acceptable reference for acceptance criteria for this test. Provide a more specific reference.

RESPONSE: The response is given in amended paragraph 7.5.1.1.5.

<u>QUESTION 14A.28</u> (NRC Question 640.10(18)) (14.2.12)

14B.30 - Section 7.7 is not an acceptable reference for acceptance criteria for this test. Provide a more specific reference.

RESPONSE: The response is given in amended section 14B.30.

<u>QUESTION 14A.29</u> (NRC Question 640.10(19)) (14.2.12)

14B.41 - It is not clear from our review of this test abstract, and subsection 9.4.6, that the containment ventilation system will be verified to maintain the containment at less than atmospheric pressure as required by Regulatory Guide 1.68 (Rev. 0) Appendix A.7.b. Expand this abstract to clearly reflect compliance with this regulatory position.

RESPONSE: Paragraph 9.4.6.2.2c requires the containment ventilation system to maintain a negative pressure in the containment during the purge cycle.

<u>QUESTION 14A.30</u> (NRC Question 640.10(20)) (14.2.12)

14B.43(a) - Expand this test abstract to include a 100% dynamic load test and a 125% static load test.

RESPONSE: The 100% dynamic and 125% status tests were accomplished during construction certification. PVNGS will verify test documentation as part of section 2.4 of 14B.43.

<u>QUESTION 14A.31</u> (NRC Question 640.10(21)) (14.2.12)

14B.43(b) - Phrases such as "as designed", "as required", and "within specification limits" are unacceptably vague. Provide more specific references for acceptance criteria.

RESPONSE: The response is given in amended section 14B.43.

<u>QUESTION 14A.32</u> (NRC Question 640.11) (14.2.12)

Our review of licensee event reports has disclosed that many events have occurred because of dirt, condensed moisture, or other foreign objects inside instruments and electrical components (e.g., relays, switches, breakers). Describe any tests or inspections that will be performed or any administrative controls that will be implemented during your initial test program to prevent component failures such as these at your facility.

RESPONSE: A preventive maintenance program is established for electrical equipment at system turnover. Preventive maintenance tasks such as inspection and cleaning are identified for inclusion into this program. Component checks during the startup testing ensures the equipment is visually inspected for any abnormalities. System functional checks will also be performed to verify component integrity during the preoperational phase.

APPENDIX 14A

QUESTION 14A.33 (NRC Question 640.12) (14.2.12)

Provide test descriptions: 1) that will verify that the plant's ventilation systems are adequate to maintain all ESF equipment within its design temperature range (see Subsection 3.11.4 of CESSAR) during normal operations; and 2) that will verify that the emergency ventilation systems are capable of maintaining all ESF equipment within their design temperature range with the equipment operating in a manner that will produce the maximum heat load in the compartment. If it is not practical to produce maximum heat loads in a compartment, describe the methods that will be used to verify design heat removal capability of the emergency ventilation systems.

Note that it is not apparent that post-accident design heat loads will be produced in ESF equipment rooms during the power ascension test phase; therefore, simply assuring that area temperatures remain within design limits during this period will probably not demonstrate the design heat removal capability of these systems. It will be necessary to include measurement of air and cooling water temperatures and flows and the extrapolations used to verify that the ventilation systems can remove the postulated post-accident heat loads.

RESPONSE: ESF equipment HVAC are addressed in sections 14B.21, 14B.22, and 14B.23. The data obtained from the above tests will be extrapolated to verify heat removal capabilities.

QUESTION 14A.34 (NRC Question 640.13) (14.2.12)

Provide a preoperational test description to test containment penetration coolers. On those penetrations where coolers are not used, provide a startup test description that will demonstrate that concrete temperatures surrounding hot penetrations do not exceed design limits.

RESPONSE: The response is given in amended section 14B.44. In addition, the penetrations have been designed to limit the concrete temperature in the vicinity of the penetrations to 200F (ASME 3 Div 2 Article CC-3340) which will be verified during the test program. This specific requirement is identified in Specification 13-MM-500, Paragraph 4.6.3.5.

QUESTION 14A.35 (NRC I&E Question 18) (14.2.2)

Please describe the composition, membership, qualifications, duties, responsibilities, quorum requirements, meeting frequency, and documentation requirements of the Plant Review Board referenced in FSAR paragraph 14.2.2.7. In addition, your response should verify the following:

a. The scope of the reviews performed by this Board include those specified by 10CFR50.59 and Section 4.3 of ANSI N18.7-1976.

b. Organizational arrangements provide for interdisciplinary review of subject matter.

c. The qualifications of the personnel performing the review are at least equivalent to those described in Section 4.4 of ANSI 3.1-1978.

d. Reviews are documented and results are forwarded to appropriate members of management.

RESPONSE: The scope of reviews, organizational arrangements, qualifications of members, and review process of the Plant Review Board are controlled by the Technical Specifications.

<u>QUESTION 14A.36</u> (NRC I&E Question 22) (14.2.3)

Paragraph 14.2.3.2 of the FSAR includes the statement, "The Plant Manager has the approval authority for Phase I through Phase IV test procedures, and may delegate approval authority to appropriate plant personnel." Please describe the circumstances under which such authority may be delegated and the job titles or qualifications of the individuals who might receive such authority.

RESPONSE: The response is given in amended paragraphs 14.2.2.5.1, 14.2.2.5.1.1, and 14.2.2.3.2.

<u>QUESTION 14A.37</u> (NRC I&E Question 23)

Please indicate your understanding that startup test procedures for post-fuel loading tests and changes to such procedures will be reviewed and approved in accordance with the requirements stated in the facility Technical Specifications.

RESPONSE: The response is given in amended paragraph 14.2.3.2.

QUESTION 14A.38 (NRC Question 640.14) (14.2.12)

Our review of your test program description disclosed that the operability of several of the systems and components listed in Regulatory Guide 1.68 (Rev. 0), Appendix A, may not be demonstrated by your initial test program. Expand your FSAR to include appropriate test descriptions (or modify existing descriptions) to address the following items from Appendix A of the guide, or provide technical justification in subsection 14.2.7 for each exception.

A. Preoperational Testing

A.1.b(7) Atmospheric steam dump valves.

A.9.a ECCS expansion and restraint tests.

C. Low Power Testing

C.1.i Chemical tests to demonstrate ability to analyze and control water quality.

RESPONSE:

A.1.b(7). The response is given in amended section 14B.1.

A.9.a. The response is given in section 14B.11.

C.1.i. The response will be given in the CESSAR docket.

QUESTION 14A.39 (NRC Question 640.15) (14.2.7)

In response to Item 640.2 (Question 14A.3), you stated that response will be provided on the CESSAR docket. Provide a specific reference for that response.

RESPONSE: Combustion Engineering submitted the Comprehensive Vibration Assessment Program (CVAP) report from the prototype System 80 plant (i.e., Palo Verde) for NRC review in a letter from A.E. Scherer, C-E, to Darrell G. Eisenhut, NRC, dated February 16, 1984 (LD-84-008). Revision 1 of this report was submitted to the NRC in a letter from A.E. Scherer, C-E, to Hugh L. Thompson, NRC, dated March 7, 1985 (LD-85-009).

QUESTION 14A.40 (NRC Question 640.16) (14.2.11)

In response to Item 640.5 (Question 14A.6), you committed to provide copies of startup test procedures to NRC for review at least 60 days prior to fuel loading. FSAR subsection 14.2.11 should be revised to be consistent with this commitment (Amendment 12 modification).

RESPONSE: Amendment 12 reflects the PVNGS commitment to meet the intent of Regulatory Guide 1.68, Appendix B, Rev. 0. That is, to provide in a timely manner Phases I through IV test procedures to assist the NRC regional personnel in implementing their inspection program.

With regard to the Startup Test Program, Phases II through IV, the intent of amendment 12 of the PVNGS FSAR was to relax our previous statement of having all startup test procedures available for review by the NRC 60 days prior to fuel load. The anticipated length of the startup test program will be 1 year, consisting of approximately 128 test procedures to be performed at various times throughout the program for a minimum total of 240 test performances. With the large number of individual test procedures to be

provided, it is not unreasonable to specify that the approved test procedures would be available for the NRC review 60 days prior to its intended performance.

Our full intent, however, was to have 60 days prior to fuel load at a minimum, the following procedures available for the inspector's review:

(1) Administrative procedures governing the conduct of the initial startup test program.

(2) Controlling procedure documents for startup test program milestones that include prerequisites, precautions, and instructions in establishing the plant conditions required to conduct the individual test procedures:

(a) Fuel loading

(b) Post hot functional test

(c) Initial criticality

(d) Low power physics test

(e) Power ascension

In addition, a majority of the 128 individual test procedures were also to be available for the inspector's review at this time.

To avoid any confusion or misunderstanding of the wording in subsection 14.2.11, the following is proposed:

"Phase I test procedures are scheduled to be approved and available for review by the NRC inspectors at least 60 days prior to their scheduled performance date. Phases II

through IV startup test program administrative control procedures, the majority of the individual test procedures, and the following milestone controlling procedure documents: fuel loading, post-core HFT, initial criticality, low power physics test and power ascension, are scheduled to be approved and available for review at least 60 days prior to fuel load. The remaining individual test procedures will be scheduled for approval and available for review by the NRC inspectors at least 60 days prior to their intended performance date."

See FSAR subsection 14.2.11.

APS believes this revision satisfies the intent of Regulatory Guide 1.68, Rev. 0, in providing, in a reasonable time period prior to procedure performance, a procedure for the NRC inspector's review to assist them in establishing an inspection program during major milestones of the initial startup test program.

<u>QUESTION 14A.41</u> (NRC Question 640.17) (14.2.1-12)

In the FSAR chapter 14 table of figures, FSAR figures 14.2-1 and 14.2-2 state that they will be provided later. Figure 14.2-1 is referenced in FSAR paragraph 14.2.2.11 (Organizational Responsibilities), while figure 14.2-2 is not referenced in the current FSAR chapter 14 submittal. The figures should be provided or deleted (Amendment 12 modification).

RESPONSE: APS has recently undergone a realignment of the organization that resulted in additional revision to FSAR

chapter 14 since amendment 12 was submitted. See FSAR section 14.2. Figure 14.2-2 is delete from the text.

QUESTION 14A.42 (NRC Question 640.18) (14.2.12)

a. In response to item 640.10 (5) part 2 (Question 14A.15), you committed to revise the 125 V-dc power system test (section 14B.4) to demonstrate that the DC loads will function as necessary to assure plant safety at a battery terminal voltage equal to the acceptance criterion that has been established for minimum battery terminal voltage for the discharge load test. Revise section 14B.4 to demonstrate that all dc loads required for safe shutdown, as installed, will function properly at the minimum battery terminal voltage (amendment 12 modification).

b. Provide assurance that voltage measurements will be taken at each load required for safe shutdown to assure an acceptable voltage drop from the appropriate Class 1E bus to each load.

RESPONSE:

a. The APS response to NRC Question 640.10 (5) can be found in section 14A.15 of the PVNGS FSAR. Item (2) of the APS response states: "Section 14B.4 will be amended in the future to include the requirement to verify that dc loads will function, as necessary, at a battery terminal voltage equal to the acceptance criteria established for minimum battery terminal voltage."

   The APS response does not state that the minimum battery terminal voltage that is established for the discharge load test will be used as the battery terminal voltage

for the dc system test. APS has instead relied upon previous NRC guidance (telecons in December 1983 with Bill Long, NRC) to determine the upper bound starting battery terminal voltage for the dc system test. Per the previous NRC guidance, the upper bound battery terminal voltage is that voltage defined by the PVNGS Technical Specifications below which the battery is declared to be inoperable.

The purpose of the dc system test is to verify the operability of the dc loads, in the system, at the minimum operable (acceptable) battery terminal voltage. FSAR section 14B.4 will be amended to state that it will be verified that the dc loads required for safe shutdown not verified by vendor tests and systems analysis, will function properly, as installed, at a battery terminal voltage equal to the minimum acceptable battery terminal voltage (see FSAR section 14B.4).

b. As stated in the responses to 640.18a, the purpose of the dc system test is to verify the operability of the dc loads, in the system, at the minimum acceptable battery terminal voltage. By verifying the operability of the dc loads required for safe shutdown, installed in the system, at the minimum acceptable battery terminal voltage conditions, APS is assured that the dc loads will function in the manner so as to bring PVNGS to a safe shutdown. Therefore, it is our intent to only verify operability and not the voltage seen by each load.

APPENDIX 14B

PREOPERATIONAL TEST DESCRIPTION

(Historical)

CONTENTS

CONTENTS (cont)

CONTENTS (cont)

This page intentionally left blank

APPENDIX 14B

PREOPERATIONAL TEST DESCRIPTION (Historical)

14B.1 MAIN STEAM, MAIN STEAM ISOLATION VALVES, SAFETY VALVES, AND ATMOSPHERIC DUMP VALVES

1.0 OBJECTIVE

To demonstrate the functional performance of the main steam system including main steam isolation valve (MSIV) closing times, steam generator safety relief valves' operability, and atmospheric steam dump valves' operability. Steam generator safety relief valves' operability will be demonstrated with steam at temperatures and pressures representative of their service conditions.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test equipment available and test instrumentation calibrated.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls.

3.2 Verify flow paths.

3.3 Determine closing times of the MSIVs and the MSIV bypass valves.

3.4 Demonstrate operability of safety relief valves and verify seat leaktightness.

3.5 Demonstrate operability of atmospheric steam dump valves.

3.6 Verify operation of automatic drain valves.

3.7 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The main steam system operates as described in section 10.3 when using the above test methods.

14B.2 CONTAINMENT SPRAY SYSTEM

1.0 OBJECTIVE

To functionally check the operation of the containment spray system including the performance of the containment spray pumps, and to provide verification of an unobstructed flow path from the spray pumps to the spray nozzles by using water and air with overlapping flow paths.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Refueling water tank available.

2.3 System will be filled, vented, and lined up per station operation procedures for normal operation.

2.4 Instruments are calibrated.

3.0 TEST METHOD

3.1 Flow will be established with each spray pump by recirculating water from the refueling water tank.

3.2 Pump performance will be checked.

3.3 Alarms will be checked.

3.4 Air will be used to establish air flow in each spray header and flow shall be verified from each nozzle. The air flow will be established to ensure an unobstructed flow path at a point which overlaps the flow path verification utilizing water.

4.0 ACCEPTANCE CRITERIA

The containment spray system operates as described in subsections 6.2.2 and 6.5.2 when using the above test methods.

14B.3 CONDENSATE STORAGE TANK AND TRANSFER SYSTEM

1.0 OBJECTIVE

To demonstrate that the condensate storage tank and transfer system is capable of storing and transferring condensate/demineralized water to systems as required.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrumentation calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Verify automatic and manual system control functions.

3.2 Demonstrate operability of flow paths.

3.3 Verify ability of system to provide makeup water to various systems as required with either condensate transfer pump in service.

3.4 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The condensate storage tank and transfer system operates as described in subsection 9.2.6 when using the above test methods.

14B.4 125 V-DC POWER SYSTEM

1.0 OBJECTIVE

To demonstrate, by verification of the system design and by component performance testing, that the 125 V-dc power system provides a reliable source of power for startup, operation, and shutdown under normal and emergency conditions, and to verify that the four separate power sources and their respective loads are independent of each other.

2.0 PREREQUISITES

2.1 Construction activities completed on components to be tested.

2.2 Meters and relays calibrated.

2.3 Batteries fully charged with normal height of electrolyte.

2.4 Load resistor bank available for battery capacity test.

2.5 Construction activities completed on safety related equipment supplied by the battery system for the integrated system test.

2.6 Battery room ventilation available.

2.7 Appropriate ac and dc power sources available.

3.0 TEST METHOD

3.1 Inspection to verify that construction and component installation is in accordance with the system design.

3.2 Battery capacity and charger performance will be verified in both float and equalize mode.

3.3 Alarms and tripping devices will be tested.

3.4 The ground detector will be checked.

3.5 The load capacity of **the** battery will be measured by discharging the battery through a variable resistive load programmed to match the emergency discharge requirements of the battery. (Battery charger disconnected.)

3.6 Individual cell voltage will be monitored during the design discharge test.

3.7 Verify that dc loads required for safe shutdown, not verified by vendor tests and system analysis, will function properly, as installed, at a battery terminal voltage equal to the minimum acceptable battery terminal voltage. If system analysis is used, the worst case for each type load will be proven operable by an actual field test.

4.0 ACCEPTANCE CRITERIA

4.1 The 125 V-dc power system will perform the functions described in applicable portions of

subsection 8.3.2 when using the above test methods.

4.2 Dc supplied loads required for safe shutdown, not verified by vendor tests and system analysis will function, as installed and required, at a battery terminal voltage equal to the acceptance criteria established for minimum battery terminal voltage. If system analysis is used, the worst case for each type load will be proven operable by an actual field test.

14B.5 CLASS 1E 4.16 KV POWER SYSTEM

1.0 OBJECTIVE

To demonstrate the operation of the control logic and protective devices of the 4.16 kV ESF switchgear.

2.0 PREREQUISITES

2.1 Construction activities completed on items to be tested.

2.2 Permanently installed instrumentation properly calibrated and operable.

2.3 Test instrumentation available and properly calibrated.

2.4 125 V-dc power available.

2.5 All 4.16 kV feeders and buses meggered with acceptable results.

2.6 4.16 kV power is available from the normal and alternate ESF transformer sources.

2.7 Switchgear assembly, breakers, control, and protective equipment/circuits have been inspected and tested and are capable of being placed into service.

3.0 TEST METHOD

3.1 Demonstrate the operability of the 4.16 kV ESF bus normal and alternate supply breakers, locally and remotely.

3.2 Demonstrate the operability of the bus protection and lockout devices.

3.3 Demonstrate the operability of the synchronizing circuits.

3.4 Verify all metering and annunciation.

4.0 ACCEPTANCE CRITERIA

The 4.16 kV ESF buses perform as described in applicable portions of section 8.3 when using the above test methods.

14B.6 CLASS 1E 480V POWER SWITCHGEAR SYSTEM

1.0 OBJECTIVE

The 480V Class 1E switchgear shall function in such a manner as to provide electric power at the correct voltage to the loads connected to the bus.

2.0 PREREQUISITES

2.1 Construction is complete and the system is released for testing in accordance with the Startup Manual.

2.2 Sufficient load is available to be connected to the buses to demonstrate their operability.

2.3 Approved P&IDs, logic diagrams, wiring diagrams, and vendors' technical data are available.

3.0 TEST METHOD

3.1 Verify proper operation of the bus protective relaying, including undervoltage relaying, by simulation.

3.2 Verify proper operation of the breaker interlocks by simulation.

3.3 Load the bus with sufficient load to verify its ability to perform its intended function.

4.0 ACCEPTANCE CRITERIA

4.1 All interlocks and controls perform their intended function as described in appropriate design documents.

4.2 The 480V Class 1E switchgear operates as described in section 8.3.

14B.7 CLASS 1E 480V POWER MCC SYSTEM

1.0 OBJECTIVE

The 480V Class 1E motor control centers shall function in such a manner as to provide electric power at the correct voltage to the loads connected to these centers.

2.0 PREREQUISITES

2.1 Construction is complete and the system is released for testing in accordance with the Startup Manual.

2.2 Sufficient load is available to be connected to the buses to demonstrate their operability.

2.3 Approved P&IDs, logic diagrams, wiring diagrams, and vendors' technical data are available.

3.0 TEST METHOD

3.1 Verify proper operation of the bus protective relaying by simulation.

3.2 Verify proper operation of the breaker interlocks by simulation.

3.3 Load the bus with sufficient load to verify its ability to perform its intended function.

4.0 ACCEPTANCE CRITERIA

4.1 All interlocks and controls perform their intended function as described in appropriate design documents.

4.2 The 480V Class 1E motor control centers operate as described in section 8.3.

14B.8 CLASS 1E INSTRUMENT AC POWER

1.0 OBJECTIVE

To demonstrate that the four 120 V-ac vital buses and associated power supplies are capable of supporting their design loads and can be transferred to the alternate sources.

2.0 PREREQUISITES

2.1 Construction activities completed on the system(s) to be tested.

2.2 Permanently installed instrumentation properly calibrated and operable.

2.3 Test instrumentation available and properly calibrated.

2.4 All 125 V-dc power systems available to ac inverters for the vital buses.

2.5 Alternate vital bus source available.

3.0 TEST METHOD

3.1 Operability and setpoint(s) shall verified for each alarm and tripping device.

3.2A Test manual transfer switch operation (Unit 1 only).

3.2B Test automatic static transfer switch operation (Units 2 and 3).

3.3 Each bus will be load tested, using both its normal and alternate power supply, by imposing its design connected load.

4.0 ACCEPTANCE CRITERIA

The vital ac power systems will perform the functions described in applicable portions of paragraph 8.3.1.1.6 when using the above test methods.

14B.9 DIESEL GENERATOR ELECTRICAL TESTS AND LOAD SEQUENCING

1.0 OBJECTIVE

To demonstrate the capability of the emergency diesel generators and their support equipment to provide emergency power to safely shut down the reactor, remove residual heat, and maintain safe shutdown conditions upon loss of preferred power.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Provisions for loading the diesel generator are available.

2.3 Associated instrumentation has been calibrated.

2.4 Appropriate ac and dc power sources available.

3.0 TEST METHOD

3.1 Local/remote, manual/automatic mode combinations will be verified for all support equipment including the fuel systems, starting air, and switchgear.

3.2 Manual control and starting of the diesel will be demonstrated and operating parameters monitored.

3.3 Emergency starting conditions will be demonstrated and recorded.

3.4 Repetitive starting capability tests will be performed.

3.5 Load tests will be conducted to verify the performance of each unit with permanently connected and auto-connected emergency (accident) loads.

4.0 ACCEPTANCE CRITERIA

Each diesel generator set will perform as described in applicable portions of paragraph 8.3.1.1.4 when using the above test methods.

14B.10 EMERGENCY LIGHTING

1.0 OBJECTIVE

To demonstrate the transfer capability from ac lighting to emergency lighting, and verify the adequacy of the lighting provided.

2.0 PREREQUISITES

2.1 Construction activities completed on the items to be tested.

2.2 The normal, essential, and emergency lighting systems are operational, as applicable.

3.0 TEST METHOD

3.1 Emergency lighting transfer capability shall be tested by deenergizing the applicable normal or essential lighting circuits.

3.2 Performance of the emergency lighting fixtures shall be monitored to verify the duration of illumination capability.

3.3 Lighting intensity levels in the control room shall be measured.

4.0 ACCEPTANCE CRITERIA

4.1 Upon the loss of essential lighting, the emergency lighting system shall be energized automatically, with the exception of certain self-contained battery-powered emergency lighting

fixtures located in non-safe shutdown areas of the plant that are not provided with essential lighting. These fixtures are fed from the normal lighting system, and shall energize automatically upon loss of normal lighting in the area.

4.2 All self-contained emergency lighting units and all nonself-contained emergency lighting units within the control room and sections of the control room panel area required for safe shutdown shall provide illumination for a minimum continuous period of 8 hours following loss of the ac power source.

4.3 The lighting level in the control room (horseshoe area) shall be 6 fc and sections of the control room panel area required for safe shutdown shall be 3 fc.

4.4 The emergency lighting systems are capable of providing illumination in the event of loss of ac power, and shall operate as described in subsection 9.5.3.

4.5 All self-contained and nonself-contained emergency lighting units necessary for the operation of safe shutdown equipment, including access and egress routes thereto, shall provide illumination for a minimum continuous period of 8 hours following loss of the ac power source.

4.6 All self-contained and nonself-contained emergency lighting units not necessary for the

operation of safe shutdown equipment, including access and egress routes thereto, shall provide illumination for a minimum continuous period of 1-1/2 hours following the loss of ac power source.

14B.11 PIPE SHOCK AND VIBRATION TEST

1.0 OBJECTIVE

To demonstrate that essential NSSS and BOP piping is free to expand thermally as required and to verify stress analysis of piping under transient conditions.

2.0 PREREQUISITES

2.1 All construction activities completed on the piping to be analyzed.

2.2 Temporary instrumentation installed as required to monitor the vibration, shock, and deflection of the piping under test.

2.3 Baseline positions and alignments recorded.

2.4 Preservice examination of all selected snubbers conducted within 6 months of initial associated system heat up for hot functional testing and verifying the following:

(1) There are no visible signs of snubber damage or impaired operability as a result of storage, handling, or installation.

(2) The snubber location, orientation, position setting, and configuration (attachments, extensions, etc.) are according to design drawings and specifications.

(3) Snubbers are not seized, frozen, or jammed.

(4) Adequate swing clearance is provided to allow snubber movement.

(5) If applicable, fluid is to the recommended level and is not leaking from the snubber system.

(6) Structural connections such as pins, fasteners, and other connecting hardware such as lock nuts, tabs, wire, and cotter pins are installed correctly.

If the period between the initial preservice examination and initial system preoperational test exceeds 6 months due to unexpected situations, reexamination of items (1), (4), and (5) shall be performed. Snubbers which are installed incorrectly or otherwise fail to meet the above requirements shall be repaired or replaced and reexamined in accordance with the above criteria.

3.0 TEST METHOD

3.1 Piping vibration, thermal expansion, and dynamic effects testing is described in paragraph 3.9.2.1. Systems to be monitored

include: A) ASME Code Class 1 and 2 piping systems, B) high energy piping systems inside Seismic Category I structures, C) high energy portions of systems whose failures could reduce the functioning of Seismic Category I plant features to an unacceptable safety level, and D) Seismic Category I portions of moderate energy piping systems located outside containment. Safety-related piping systems to be tested are listed in table 3.2-1 as ANSI N18.2 Safety Class 1, 2, or 3.

The thermal expansion of ASME Section III, Class 1, 2, and 3 high energy piping and ASME high energy steam piping up to the turbine stop valves shall be measured at selected points. The thermal movements of snubbers associated with the above piping whose operating temperature exceeds 250F shall be verified per the following:

(1) During initial system heatup and cooldown, at specified temperature intervals for any system which attains operating temperature, verification of the snubber expected thermal movement.

(2) For those systems that do not attain operating temperature, verification via observation and/or calculation that the snubber will accommodate the projected thermal movement.

(3) Verification of the snubber swing clearance at specified heatup and cooldown intervals. Any discrepancies or inconsistencies shall be evaluated for cause and corrected prior to proceeding to the next specified interval.

Other ASME high energy steam and feedwater piping shall be visually examined to assure that it expands freely.

The steady-state vibration of ASME Section III, Class 1, 2, and 3 piping and high energy steam and feedwater piping shall be visually examined by an engineer (qualified per paragraph 14.2.2.12.1) to ascertain qualitatively the effects of flow induced vibrations.

The dynamic effects testing shall be performed on those piping systems, larger than 1 inch in diameter, which are essential to safety, and are expected to undergo significant transient behavior due to: fast valve closure, operation of pressure-relieving valves, pump starts and stops, steam hammer, water hammer, and sudden expansions during normal plant operations and trips.

Instrument lines will not be monitored. ASME Code Class 1, 2, and 3 instrument lines are designed with flexible seismic isolation devices downstream of instrument root valves. Because of

the small size of applicable instrument lines (1 inch and smaller) and short sections that are subject to system vibration, failure is considered remote and is not postulated to cause failure of Seismic Category I plant equipment. Similarly, service air or nitrogen lines 1 inch diameter and smaller that are attached to monitored systems will not be monitored.

3.2 Data acquisitions shall be accomplished with instruments possessing the accuracy and sensitivity needed to demonstrate satisfactory system performance. In each case the data acquisition system shall be designed for reliable data collection.

Thermal expansion data will consist of pipe movement and temperatures; these parameters will be monitored by measurements and visual references at cold and hot zero power conditions. However, selected piping and components will be visually monitored during plant heatup and cooldown.

Steady-state vibration data will consist of qualitative visual observation of steady-state vibration during normal system operation. When significant vibration is noted, quantitative measurements using temporary vibration monitoring instruments shall be made.

Dynamic response data will consist of pressure fluctuations, pipe acceleration/displacement, and pipe support reactions to load changes. The instrumentation used will be of high frequency response with adequate ranges to cover the physical quantity being measured.

Selected major high energy pipes with significant thermal differential shall be monitored by linear measurements at selected points. Points selected for monitoring will be tabulated in test procedures which will be available for NRC review onsite 60 days prior to the conduct of applicable tests, and will be representative of the area in which they are located or representative of identical piping and will provide meaningful and significant results. The remainder of the high- and moderate energy piping will be visually inspected by an engineer (qualified per paragraph 14.2.2.12.1).

4.0 ACCEPTANCE CRITERIA

The acceptance criteria for thermal expansion shall ensure sufficient clearance has been provided to allow free and unrestricted thermal expansion of essential plant piping and components. Where thermal deflection is measured, the deflections shall be compared to the stress analysis of the piping system.

The acceptability of steady-state vibration of piping, components, and supports shall be based on

observations by an engineer (qualified per paragraph 14.2.2.12.1). Should significant vibrations occur, an engineering evaluation shall be made by analyzing the displacement amplitudes and corresponding stress levels to the acceptance criteria. The acceptance criteria for steady-state vibration shall be that the maximum measured amplitude shall not induce a stress in the piping greater than one-half the alternating stress intensity at 10^6 stress cycles as defined in Section III of the ASME Boiler and Pressure Vessel Code.

Dynamic effects acceptance criteria will be provided for those piping systems where significant transient behavior is anticipated. Measured displacements, pressures, and temperatures shall be compared to those derived by the stress analysis.

Should any abnormalities occur while operationally testing piping systems which are not instrumented, those piping systems shall be checked for any indications of structural damage. An engineering determination shall be made as to the cause of the abnormality and its effect on structural integrity. If it is determined that structural integrity will be degraded below an acceptable level, corrective actions shall be taken, and appropriate retesting accomplished.

14B.12 CONTAINMENT ISOLATION ACTUATION SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the containment isolation actuation system.

2.0 PREREQUISITES

2.1 Construction is complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Using the built-in test panel of engineered safety features actuation system (ESFAS), test each group relay for a containment isolation activation system actuation and verify valve actuation to be correct.

3.2 Using an input signal to the plant protection system, verify that a CIAS signal is initiated by the PPS to the ESFAS and the associated containment isolation valves function by taking their designated containment isolation position.

4.0 ACCEPTANCE CRITERIA

Containment isolation actuation system operates as described in subsection 6.2.4 when using above test methods.

14B.13 AUXILIARY FEEDWATER SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the auxiliary feedwater system to:

1.1 Supply sufficient auxiliary feedwater to the steam generators for reactor startup, normal reactor cooldown, and design emergency conditions.

1.2 Respond correctly to automatic and manual system controls.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate automatic and manual system controls.

3.2 Verify system flowrates and pressures, including operation of the turbine-driven auxiliary feed-water pump over its design range of inlet steam conditions.

3.3 Verify and record pump on demand starting times and valve opening and closing times.[a][b]

3.4 Verify and record alarms, indicating instruments and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The auxiliary feedwater system operates as described in subsection 10.4.9 and manufacturer's design specifications when using the above test methods.

---

a. Pump on demand starting time verification will be done a minimum of five times. Each time must be successful and from a cold, quick start condition.

b. This applies to the turbine-driven auxiliary feedwater pump only.

14B.14 REACTOR CONTAINMENT INTEGRATED AND LOCAL LEAK RATE TESTS

1.0 OBJECTIVE

To demonstrate, prior to initial reactor operation, that leakage through the primary reactor containment and systems and components penetrating primary containment do not exceed the allowable leakage rate values as specified in the Technical Specifications.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Structural integrity test (described in paragraph 3.8.1.7) satisfactorily completed.

2.3 Leakage rate determination instrumentation available and properly calibrated.

2.4 Containment ventilation system, personnel airlock, and isolation valves are operable.

2.4 Containment inspection completed.

3.0 TEST METHOD

3.1 Perform individual local leakage tests on containment isolation valves and penetrations as described in section 6.2.

3.2 Perform a containment building integrated leakage rate test at the calculated peak internal pressure per section 6.2.

4.0 ACCEPTANCE CRITERIA

The containment leakage shall not exceed the plant technical specification limits stipulated in Section 3/4.6.1 of the Technical Specifications.

14B.15 DIESEL FUEL OIL STORAGE SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the diesel generator fuel oil storage and transfer system to provide a reliable and adequate supply of fuel oil to each emergency diesel generator.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibrations completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate operability of flow paths.

3.2 Verify automatic and manual system control functions.

3.3 Verify fuel oil transfer rate.

3.4 Verify alarms, indicating instruments and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The diesel generator fuel oil storage and transfer system operates as described in subsection 9.5.4 when using the above test methods.

14B.16 DIESEL GENERATOR MECHANICAL SYSTEMS

1.0 OBJECTIVE

To verify proper operation of the emergency diesels including their cooling, starting, and lubrication systems.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate operability of flow paths.

3.2 Verify manual and automatic controls of the cooling, starting, and lubrication systems.

3.3 Demonstrate starting and operation of the diesel engines.[a]

3.4 Verify diesel engine protective trip functions.

3.1 Verify alarms, indicating instruments, and status lights are functional.

______

a. See diesel generator electrical tests for starting and loading reliability test program.

4.0 ACCEPTANCE CRITERIA

4.1 Each diesel operates per applicable portions of section 8.3 when using the above test methods.

4.2 Each diesel generator cooling water system, starting system, and lubrication system operates as described in subsections 9.5.5, 9.5.6, and 9.5.7, respectively, when using the above test methods.

14B.17 ESSENTIAL CHILLED WATER SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the essential chilled water system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instruments available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls, including automatic start features.

3.2 Verify system flowrates.

3.3 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The essential chilled water system operates as described in paragraph 9.2.9.2 when using the above test methods.

14B.18 ESSENTIAL COOLING WATER SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the essential cooling water system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instruments available and calibrated.

2.5 Portions of fuel pool cooling system and nuclear cooling water system supplied by essential cooling water available.

3.0 TEST METHOD

3.1 Verify adequate flow to components supplied with essential cooling water.

3.2 Demonstrate manual and automatic system controls, including automatic pump starts and valve operations.

3.3 Verify alarms, indicating instruments and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The essential cooling water system operates as described in paragraph 9.2.2.1 when using the above test methods.

14B.19 FUEL POOL COOLING AND CLEANUP SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the fuel pool cooling and cleanup system to satisfy operational performance requirements with regard to design flow paths, flow capacity, and mechanical operability.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Test instrumentation available and properly calibrated.

2.4 Spent fuel pool and reactor vessel cavity construction leak tests completed.

2.5 Support systems available.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls.

3.2 Verify system flowrates.

3.3 Verify alarms, indicating instruments, and status lights are functional.

3.4 Demonstrate operability and perform leak tests of sectionalizing devices in the spent fuel pool.

4.0 ACCEPTANCE CRITERIA

The fuel pool cooling and cleanup system operates as described in subsection 9.1.3 when using the above test methods.

14B.20 ESSENTIAL SPRAY POND SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the safety-related portion of the essential spray pool system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Verify adequate flow to heat exchangers and spray nozzles.

3.2 Verify that actuation signals are properly received and executed.

3.3 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The safety-related portion of the essential spray pond system operates as described in subsection 9.2.1 when using the above test methods.

14B.21 AUXILIARY BUILDING ESSENTIAL HVAC AND FUEL BUILDING ESSENTIAL EXHAUST SYSTEMS

1.0 OBJECTIVE

To demonstrate proper operation of the auxiliary building essential HVAC system and the fuel building essential exhaust system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Test instruments available and calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Verify design air flow.

3.2 Demonstrate manual and automatic system controls.

3.3 Demonstrate ability of essential exhaust fans to maintain a negative pressure in the fuel building and the auxiliary building below elevation 100 feet 0 inch.

3.4 Perform in-place testing of filtration units as discussed in section 1.8.

3.5 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The auxiliary building essential HVAC system and the fuel building essential exhaust system operate as described in paragraphs 9.4.2.2 and 9.4.5.2, respectively, when using the above test methods.

14B.22 DIESEL GENERATOR BUILDING HVAC

1.0 OBJECTIVE

To demonstrate proper operation of the essential portion of the diesel generator building HVAC system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Diesel generator control system and required power systems available.

2.4 Test instruments available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls, including start of essential ventilation equipment when the diesel generator starts.

3.2 Verify design air flows.

3.3 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The essential portion of the diesel generator building HVAC system operates as described in subsection 9.4.7 when using the above test methods.

14B.23 CONTROL BUILDING ESSENTIAL HVAC

1.0 OBJECTIVE

To demonstrate proper operation of the control building essential HVAC system to ensure adequate environmental conditions for personnel and essential equipment for emergency conditions.

2.0 PREREQUISITES

2.1 Construction activity is completed.

2.2 Component testing and instrument calibration completed.

2.3 Test instrumentation available and properly calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls.

3.2 Verify design air flows.

3.3 Demonstrate the capability of the system to isolate and maintain the control room and habitability areas at a positive pressure.

3.4 Perform in-place testing of filtration units as discussed in section 1.8.

3.5 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The control building essential HVAC operates as described in section 6.4 and subsection 9.4.1 when using the above test methods.

14B.24 CONTAINMENT HYDROGEN CONTROL SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the system to function as designed to prevent the post-LOCA hydrogen concentration in containment from exceeding established limits.

2.0 PREREQUISITES

2.1 Construction activities completed on components to be tested.

2.2 Component testing and instrument calibration completed.

2.3 Test instrumentation available and properly calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Demonstrate automatic and manual system controls.

3.2 Verify recombiner air flow and thermal capacities meet design requirements.

3.3 Verify alarms, indicating instruments, and status lights are functional.

3.4 Perform in-place testing of filtration units as discussed in section 1.8.

4.0 ACCEPTANCE CRITERIA

The containment hydrogen control system operates as described in subsection 6.2.5 when using the above test methods.

14B.25 RADIOACTIVE WASTE DRAIN SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the equipment and floor drainage system provided for the ESF equipment rooms in the auxiliary building.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Water source available for supplying drains and sumps.

2.4 Support systems available.

2.5 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Verify flow paths.

3.2 Demonstrate automatic and manual system controls.

3.3 Verify separation of drain systems for trains A and B ESF equipment rooms.

3.4 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The drainage system for the ESF equipment rooms operates as described in applicable portions of subsection 9.3.3 when using the above test methods.

14B.26 RADIATION MONITORING SYSTEM

1.0 OBJECTIVE

To verify the proper functional operation of the radiation monitoring system.

2.0 PREREQUISITES

2.1 Construction activities completed on the radiation monitoring system.

2.2 The radiation monitor has been calibrated.

2.3 External test instrumentation has been calibrated.

2.4 Check sources are available.

3.0 TEST METHOD

3.1 Utilizing a check source, verify response of detector to a radiation field to verify proper monitor operation.

3.2 Verify the self-testing feature of each monitor, where applicable.

3.3 Verify control actuation by each monitor and record the response time where applicable.

3.4 Verify proper local and remote alarm actuation where applicable.

4.0 ACCEPTANCE CRITERIA

The radiation monitoring system operates as described in subsection 12.3.4 when using the above test methods.

14B.27 IODINE REMOVAL SUBSYSTEM (Abandoned in Place)

14B.28 NUCLEAR COOLING WATER SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the nuclear cooling water system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Test instruments available and calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Verify adequate flow to components supplied with nuclear cooling water.

3.2 Demonstrate manual and automatic system controls.

3.3 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The nuclear cooling water system operates as described in paragraph 9.2.2.2 when using the above test methods.

14B.29 POST-ACCIDENT MONITORING SYSTEM

1.0 OBJECTIVE

1.1 To verify that all instruments of the post-accident monitoring system are properly installed.

1.2 To ensure that all instruments in the post-accident monitoring system have appropriate ranges and are calibrated.

2.0 PREREQUISITES

2.1 Construction activities on the post-accident monitoring system have been completed.

2.2 Appropriate test equipment is available and has been calibrated.

2.3 Appropriate instrument power sources are available.

3.0 TEST METHOD

3.1 Verify that the range of each instrument is as specified in CESSAR Section 7.5.2.5 and CESSAR Table 7.5-3.

3.2 Verify proper calibration of each instrument in the post-accident monitoring system.

4.0 ACCEPTANCE CRITERIA

Instrument ranges and accuracies shall be as specified in paragraph 7.5.1.1.5.

14B.30 PLANT COMPUTER

1.0 OBJECTIVES

To verify that all system hardware is installed and operating properly; and that all system software responds correctly to external inputs, and provides proper outputs to the computer peripheral equipment.

2.0 PREREQUISITES

2.1 All construction and installation activities are completed on the items to be tested.

2.2 Required manufacturer's and/or owner's manuals are available.

2.3 Inherent and external test instrumentation is calibrated and available.

2.4 Support systems required for operation of the plant computer are operational.

3.0 TEST METHOD

3.1 Test programs are to be run, sequenced as specified by the manufacturer, to ascertain the reliability of computer systems to perform all required hardware functions.

3.2 External inputs to the system shall be simulated and the outputs measured using the external test instrumentation.

3.3 Computer functional programs shall be verified using proper software and/or control panel inputs, as applicable.

3.4 Alarm and indication functions shall be verified by the computer system instrumentation and/or the external test measurements, as applicable.

4.0 ACCEPTANCE CRITERIA

Plant computer system operates as described in Section 7.7.1.3.2 of CESSAR when using above test methods.

APPENDIX 14B

14B.31 LOOSE PARTS MONITORING SYSTEM

1.0 OBJECTIVE

To demonstrate that the loose parts monitoring system is properly installed and operates as designed.

2.0 PREREQUISITES

2.1 All construction activities on the loose parts monitoring system are complete.

2.2 All associated instrumentation have been calibrated.

2.3 Appropriate test instrumentation, is available and calibrated.

3.0 TEST METHOD

3.1 Verify system response to simulated loose parts.

3.2 Verify the proper operation and installation of all recording devices.

3.3 Verify and calibrate all system alarms and indicators.

4.0 ACCEPTANCE CRITERIA

The loose parts monitoring system operates as described in section 7.7, listing C, when using above test methods.

14B.32 PLANT ANNUNCIATOR

1.0 OBJECTIVE

1.1 To verify that the annunciators system is properly installed and will respond to a change of state of any field contact.

1.2 To verify that the annunciator system will transfer to the redundant power source upon receipt of a supply voltage reduction.

2.0 PREREQUISITES

2.1 All construction and installation activities are completed on the annunciators and associated systems.

2.2 Support systems required for the operation of the annunciators have been tested and are operating.

2.3 Appropriate test equipment is available and calibrated.

2.4 Appropriate ac and dc power sources are operable.

3.0 TEST METHOD

3.1 Self test features of the system shall be tested and verified to be operational.

3.2 "First out" feature shall be tested and verified operational.

3.3 Each field contact shall be actuated and appropriate annunciator response verified.

4.0 ACCEPTANCE CRITERIA

Annunciator system operates as described in section 7.6 when using the above test methods.

14B.33 SEISMIC INSTRUMENTATION

1.0 OBJECTIVES

To demonstrate proper operation of the seismic monitoring instrumentation.

2.0 PREREQUISITES

2.1 Construction activities on the seismic monitoring instrumentation have been completed.

2.2 All associated instrumentation has been calibrated.

2.3 Appropriate test instrumentation is available and calibrated.

3.0 TEST METHOD

3.1 Verify operability of internal calibration devices by recording calibration records on all applicable sensors.

3.2 Verify system response to simulated seismic events by actuating the appropriate trigger units, recording accelerograph outputs and playing back all records for analysis.

3.3 Verify and calibrate all systems alarms and indicators.

3.4 Verify the proper operation and installation of all peak recording accelerographs.

4.0 ACCEPTANCE CRITERIA

The seismic instrumentation system operates as described in subsection 3.7.4 when using the above test methods.

APPENDIX 14B

14B.34 GAS ANALYZER

1.0 OBJECTIVE

To verify the gas analyzer package will automatically monitor hydrogen and oxygen concentrations.

2.0 PREREQUISITES

2.1 Construction activities on all systems connected to gas analyzer package are complete.

2.2 Sample points are hooked up to the gas analyzer package.

2.3 Associated instrumentation has been calibrated.

2.4 System lined up for normal operation per station operating procedures.

3.0 TEST METHOD

3.1 Check proper operation of the sequence selector for automatic monitoring of inputs.

3.2 Check ability to correctly measure and record known oxygen and hydrogen concentrations.

3.3 Check alarm setpoints.

4.0 ACCEPTANCE CRITERIA

The automatic gas analyzer operates as described in subsection 9.3.2 when using the above test methods.

14B.35 IN-PLANT COMMUNICATIONS SYSTEM

1.0 OBJECTIVE

To demonstrate the adequacy of the in-plant communications system to provide communications between vital plant areas and to test the operability of the emergency evacuation alarms.

2.0 PREREQUISITES

2.1 All construction activities on the in-plant communications system are complete.

2.2 Support systems required for operation of the inplant communications system are available.

2.3 All possible plant equipment that contributes to the ambient noise level should be in operation.

3.0 TEST METHOD

3.1 Verify the unit/area evacuation system functions properly.

3.2 Verify that the telephone system functions properly, that each station is assigned to the current restriction class.

3.3 Verify the sound powered phone system functions properly.

3.4 Verify the radio communication system functions properly.

3.5 Verify the public address system functions properly.

4.0 ACCEPTANCE CRITERIA

The in-plant communications system operates as described in subsection 9.5.2 when using above test methods.

14B.36 LOCAL LAW ENFORCEMENT AGENCY OFFSITE COMMUNICATION SYSTEMS

1.0 OBJECTIVE

To demonstrate the proper operation of the local law enforcement agency (LLEA) offsite communication systems.

2.0 PREREQUISITES

2.1 All construction activities have been completed on the LLEA offsite communication systems.

2.2 Support systems required for operation of the LLEA offsite communication systems are available.

3.0 TEST METHOD

3.1 Verify proper operation of the LLEA radio.

3.2 Verify proper operation of the LLEA land lines.

3.3 Verify proper operation of 115 V-ac power sources for the LLEA land line.

4.0 ACCEPTANCE CRITERIA

The LLEA offsite communications systems operate as described in subsection 9.5.2 when using above test methods.

14B.37 CIRCULATING WATER SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the circulating water system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Intake structure flooded and water quality within limits.

3.0 TEST METHOD

3.1 Demonstrate flow paths.

3.2 Verify automatic and manual system controls function properly.

3.3 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The circulating water system operates as described in subsection 10.4.5 when using the above test methods.

14B.38 FIRE PROTECTION SYSTEM

1.0 OBJECTIVE

To demonstrate the proper operation of the fire protection system in the detection of fires and the capabilities to contain and extinguish fires.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Test equipment and instrumentation available and properly calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Demonstrate the proper operation of the fire detection system.

3.2 Demonstrate the proper operation of the fire water system.

(1) Demonstrate the head and flow characteristics of the diesel engine-driven fire water pumps, the electric motor-driven fire water pump, and the operation of all auxiliaries.

(2) Verify control logic.

(3) Verify flowrates in the various flow paths of the fire water system.

3.3 Demonstrate the proper operation of the CO_2 fire protection system.

3.4 Demonstrate the proper operation of the Halon fire protection system.

3.5 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The fire protection system operates as described in subsection 9.5.1 when using the above test methods.

14B.39 TURBINE ELECTROHYDRAULIC CONTROL

1.0 OBJECTIVE

To verify proper performance of the turbine electrohydraulic control system.

2.0 PREREQUISITES

2.1 Construction activities on the turbine electrohydraulic control system are complete.

2.2 Associated instrumentation has been calibrated.

2.3 Appropriate test equipment is available and has been calibrated.

2.4 Proper fluid levels throughout the system have been verified.

2.5 Appropriate ac and dc power sources are available and operable.

3.0 TEST METHOD

3.1 Using external instrumentation, simulate input signals and record the response of the electrohydraulic control system.

3.2 Verify proper outputs in all modes of operation.

3.3 Verify all system interlocks, overrides, annunciators, and indicators are operational.

4.0 ACCEPTANCE CRITERIA

The turbine electrohydraulic control system operates as described in paragraph 10.2.2.3 when using above test methods.

APPENDIX 14B

14B.40 GASEOUS RADWASTE SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the gaseous radwaste system to collect and process radioactive gases vented from plant equipment.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Support systems available.

2.3 Component testing and instrument calibration completed.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Verify flow paths.

3.2 Demonstrate that discharge isolation features and other system controls function properly.

3.3 Verify alarms, indicating instruments, and status lights are functional.

3.4 Verify systems ability to compress and store waste gas and release it in a controlled manner.

4.0 ACCEPTANCE CRITERIA

The gaseous radwaste system operates as described in section 11.3 when using the above test methods.

14B.41 CONTAINMENT PURGE AND HVAC SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the containment normal cooling, cleanup and purge systems, CEDM cooling system, and cavity cooling system.

2.0 PREREQUISITES

2.1 Construction activities complete.

2.2 Component testing and instrument calibration complete.

2.3 Support systems available.

2.4 Test instruments available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate manual and automatic system controls.

3.2 Verify alarms, indicating instruments, and status lights are functional.

3.3 Verify design air flows.

3.4 Perform in-place leak testing of HEPA/charcoal filtration units, except for cleanup HEPA/charcoal filters as described in response to Question 9A.38.

4.0 ACCEPTANCE CRITERIA

The containment normal cooling, cleanup and purge systems, CEDM cooling system, and cavity cooling

system operate as described in applicable portions of subsection 9.4.6 when using the above test methods.

14B.42 INSTRUMENT AIR SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the instrument air system.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate automatic and manual system controls for compressors, air dryers, valves, etc.

3.2 Verify ability of nitrogen system to backup instrument air system.

3.3 Verify instrument air quality meets design requirements.

3.4 Verify alarms, indicating instruments and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The instrument air system operates as described in applicable portions of section 9.3 when using the above test methods.

14B.43 POLAR CRANE

1.0 OBJECTIVE

To demonstrate the functional performance of the containment polar crane.

2.0 PREREQUISITES

2.1 Electric power available.

2.2 Instrumentation available and calibrated.

2.3 Construction activities are complete on the crane and associated equipment.

2.4 Construction has successfully completed certified load test.

3.0 TEST METHOD

3.1 Verify operability of trolley, bridge, and hoist.

3.2 Check hoist and trolley speeds.

3.3 Check capability of crane to position over all required containment building equipment.

4.0 ACCEPTANCE CRITERIA

4.1 Trolley, bridge, hoist, and all interlocks operate as required by purchase order specifications.

4.2 Hoist and trolley speeds are within purchase order specification limits.

4.3 Crane can position over all required equipment.

14B.44 CONTAINMENT HVAC - TENDON GALLERY AND PENETRATION COOLING SYSTEMS

1.0 OBJECTIVES

1.1 Demonstrate the manual operation of the tendon gallery normal supply fan.

1.2 Demonstrate the manual operation of the tendon gallery normal exhaust fan.

1.3 Demonstrate the operation of the penetration cooling normal exhaust fans.

1.4 Demonstrate the manual and automatic operation of the penetration cooling supply fans and their exhaust dampers.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Support systems available.

2.4 Test instrumentation available and calibrated.

3.0 TEST METHOD

3.1 Demonstrate automatic and manual system controls.

3.2 Verify and record delay times when fans start on automatic.

3.3 Verify and record alarms, indicating instruments, and status lights are functional

4.0 ACCEPTANCE CRITERIA

4.1 The tendon gallery normal supply fan will start and stop by actuation of handswitch in the control room.

4.2 The tendon gallery normal exhaust fan will start and stop by actuation of handswitch in the control room.

4.3 Penetration cooling exhaust fans will start and stop by actuation of handswitches at the local panel.

4.4 Penetration cooling supply fans will start and stop by actuation of handswitches at the local control panel.

4.5 Penetration cooling supply fans start automatically after a 60-second time delay upon receipt of a low dp signal.

4.6 Penetration cooling supply dampers open and shut as their respective fans start and stop.

4.7 Heat removal capability will be verified for the tendon gallery system.

4.8 Heat removal capability will be verified for the penetration cooling system.

14B.45 FEEDWATER SYSTEM[a]

1.0 OBJECTIVE

To demonstrate that the feedwater system is capable of supplying feedwater to the steam generators and maintaining steam generator level.

2.0 PREREQUISITES

2.1 Construction activities are complete.

2.2 All permanently-installed instrumentation is calibrated and operable.

2.3 Test instrumentation is available and calibrated.

2.5 Plant systems required to support testing are operable, or temporary systems are installed and operable.

3.0 TEST METHOD

3.1 Verify all control logic.

3.2 Demonstrate all design flow paths.

3.3 Verify the starting, head, and flow characteristics of the turbine-driven feedwater pumps at the full range of steam pressures.

3.4 Demonstrate minimum flow recirculation protection.

3.2 Verify proper operation of protective devices, controls, interlocks, instrumentation, and alarms, using actual or simulated inputs.

---
a. Portions of this test will be performed after initial fuel load.

3.6 Verify, if appropriate, proper operation, failure mode, stroking speed, and position indication of control and feedwater isolation valves.

4.0 ACCEPTANCE CRITERIA

The feedwater system performs as described in subsection 10.4.7.

APPENDIX 14B

14B.46 RADWASTE BUILDING HVAC

1.0 OBJECTIVE

1.1 To demonstrate design air quantities and a controlled airflow pattern from areas of low potential radioactivity to areas of increasingly higher radioactivity to prevent the spread of airborne radioactivity during normal operation of building HVAC supply systems (HRN-A01 A and B), exhaust systems (HRN-J01 A and B), and radwaste building control room normal air handler (HRN-A02).

1.2 To demonstrate the filtration of exhaust air particulates by system HEPA filters before passing to the plant exhaust stack.

1.3 To demonstrate a slightly negative building pressure to prevent exfiltration of conditioned space air to the atmosphere.

1.4 To demonstrate the radwaste building control room air handler recirculates conditioned airflow at prescribed temperatures using chill water or electric heating.

1.5 To demonstrate the proper operation of the oil impingement filters and air washer pumps (HPN-P01 A and B).

1.6 To demonstrate appropriate operation and position of automatic dampers (HRN-M01 to M06).

1.7 To demonstrate appropriate operation, indication and temperature rise of electric duct heaters (HRN-E01 A and B).

1.8 To demonstrate annunciation and indication of all alarms and design operation of temperature controls.

2.0 PREREQUISITES

2.1 Construction, inspection, testing, completion and release of radwaste HVAC systems according to specification.

2.2 HR-01 and HR-02 phase I testing complete.

2.3 Release of supporting and interfacing construction systems required to implement startup test activities to include:

2.3.1 DS-05 domestic water and WC01 chill water.

2.3.2 E-NHN-M14 and M27 480V MCC.

2.3.3 E-NGN-L05 and L16 480V load center.

2.3.4 E-NKN-D42 and D-43 dc distribution panel.

2.3.5 RKO1 annunciator.

2.3.6 Appropriate valve lineup and breaker and control switch positions for building HVAC systems.

3.0 TEST METHOD

3.1 Actuate handswitches (HS-1, 2, 30, 31, 60) to verify design operation, indication, and status of HVAC rotating units.

3.2 Demonstrate automatic and manual system controls.

3.3 Cycle temperature controllers to verify proper operation of HVAC rotating units and dampers (HRN-M01, M02, M03, M04, M05, and M06).

3.4 Verify alarm annunciation in response to selected alarm signals.

3.5 Verify design air and water flow paths, quantities, and temperatures to distribution and metering devices.

3.6 Perform in-place testing of filtration units as discussed in section 1.8.

4.0 ACCEPTANCE CRITERIA

Appropriate installation and operation according to specifications, submittals (vendor, manufacturer, engineering), and design drawings (instrument, electrical, and mechanical) verified.

14B.47 TURBINE BUILDING HVAC

1.0 OBJECTIVE

To demonstrate that the turbine building normal supply (HTN-A01 and A02, A, B, C) and general exhaust systems (HTN-J01A, B, C, D; HTN-J01B, A, B; HTN-J04; HTN-J03 A and B and HTN-J02 A and B) provide the designed environment for personnel and equipment during normal operation and shutdown, and appropriate exhaust for battery rooms, lube oil area, demineralizer room, and switchgear rooms.

2.0 PREREQUISITE

2.1 Construction activities completed.

2.2 IA08 instrument and service air available.

2.3 E-NGN-L08 and L15 Class 1E 480V load center available.

2.4 E-NHN-M02, M07, M11, M12, M22, M23 non-Class 1E 480V MCC available.

2.5 NK01 non-Class 1E 125 V-dc power distribution system available.

2.6 RK01 annunciator available.

2.7 Valve lineup (initial) and breaker and control switch positions for building HVAC systems completed.

3.0 TEST METHOD

3.1 Actuate hand switches (HS-1, 2, 3, 4, 5, 6, 85, 86, 87, 88, 89) to verify design operation, indication, and status of HVAC rotating supply and exhaust systems.

3.2 Cycle temperature (TC-7, 8, 9, 10, 11, 12, 60, 61, 62, 63, 64, 65, 66, 67) to verify proper operation of HVAC units and dampers (HT-M01, M02, M03, M04, M05, M06, M07, M08, M09, M010, M011, M012, M013, M014, M015).

3.3 Verify manual and automatic operation of duct heaters (HTN-E01, E02, E03, E04, E05, E06). (PVNGS Units 1 and 3 only - not required in Unit 2)

3.4 Verify automatic and manual system controls.

3.5 Verify alarm annunciation in response to selected alarm signals.

3.6 Verify design air paths, quantities, and temperatures to distribution and metering devices.

3.7 Verify proper operation of the oil impingement filters and air washer pumps (HTN-HT-P01A, B and C).

4.0 ACCEPTANCE CRITERIA

Appropriate installation and operation according to specifications, submittals (vendor, manufacturer, and engineering), and design drawings (instrument, electrical, and mechanical) verified.

14B.48 RADWASTE SOLIDIFICATION SYSTEM

1.0 OBJECTIVE

To demonstrate the capability of the system to:

1.1 Collect and convert spent resins and concentrated liquids into dry solid waste with no free water.

1.2 Transport and store solid waste until it can be shipped offsite for burial.

1.3 Compact and package miscellaneous dry radioactive material.

2.0 PREREQUISITE

2.1 All construction complete and system is turned over for testing in accordance with approved procedures.

2.2 System flushing and hydro completed.

2.3 All generic and integrated testing completed.

2.4 Supply of resins and chemicals available for use.

2.5 All required test equipment properly installed and calibrated.

3.0 TEST METHOD

3.1 Transfer resin/liquids from various tanks to waste feed tank.

3.2 Operate system in auto for various concentrations/mixes and verify operations as per purchase specification.

3.3 Operate or simulate all interlocks and/or alarms to verify they function per design.

3.4 Complete a complete drumming cycle, verify equipment operates per design.

3.5 Cut open a solidified drum after 24 hours and confirm: a) no free water; b) waste and concrete is homogeneously mixed.

4.0 ACCEPTANCE CRITERIA

4.1 The solidified mass meets the requirements for storage and shipment as referenced in section 11.4.

4.2 Complete solidification and absence of free water as per HNDC document N623-P-010 titled System Performance Test Plan.

14B.49 LIQUID RADWASTE SYSTEM

1.0 OBJECTIVE

To demonstrate that the system will:

1.1 Collect and process radioactive and potentially radioactive liquid waste.

1.2 Process liquid waste to a high degree of purity necessary for recycle into the plant.

1.3 Minimize the quantity of liquid waste transferred to the solid radwaste system.

2.0 PREREQUISITE

2.1 Construction is completed and the system is turned over for operation in accordance with the approved procedures.

2.2 Required test instruments are calibrated and installed.

2.3 Required support systems are operable.

2.4 All generic and integrated tests are completed.

3.0 TEST METHOD

3.1 Verify the head and capacity of system pumps.

3.2 Verify ΔP across heat exchangers, demineralizers, and filters at rated flow.

3.3 Verify proper operation of automatic and manual system controls.

3.4 Verify logic, interlocks, alarms, and status lights are per design.

4.0 ACCEPTANCE CRITERIA

The system operates as described in paragraph 11.2.2.3 when using the above test methods.

14B.50 SECONDARY CHEMISTRY CONTROL SYSTEM

1.0 OBJECTIVE

To demonstrate proper operation of the secondary chemistry control system (SCCS) which is an integrated system comprised of the condensate demineralization and blowdown processing subsystem and the chemical monitoring and addition subsystem.

2.0 PREREQUISITES

2.1 Construction activities completed.

2.2 Component testing and instrument calibration completed.

2.3 Test instruments available and calibrated.

2.4 Support systems available.

3.0 TEST METHOD

3.1 Verify automatic and manual system control functions.

3.2 Demonstrate operability of flow paths.

3.3 Verify ability of system to provide specified chemistry control of the secondary power cycle systems.

3.4 Verify alarms, indicating instruments, and status lights are functional.

4.0 ACCEPTANCE CRITERIA

The secondary chemistry control system operates as described in subsection 10.4.6 when using the above test methods.

14B.51 LOAD GROUP ASSIGNMENT VERIFICATION

1.0 OBJECTIVE

To demonstrate that the redundant onsite safety features electrical power systems and their associated load groups are independent of each other or any other electrical power system and to demonstrate the automatic fast transfer of the 13.8 kV buses to the startup transformer in the event of failure of the unit auxiliary transformer, a turbine trip, or a reactor trip.

2.0 PREREQUISITES

2.1 Construction activities completed on components to be tested.

2.2 Component and integrated testing completed.

2.3 Required support systems for the test are released from construction with the required component and integrated testing completed on those systems.

2.4 Plant conditions must be carefully reviewed to ensure that the equipment under test can be operated safely without any unforseen or potentially harmful consequences.

2.5 Properly calibrated test equipment is available to support the test.

2.6 Circuit breakers, control switches, and valve positions for the test have been verified.

3.0 TEST METHOD

3.1 Demonstrate the independency of the redundant onsite (ESF) electrical power systems (train A and train B) to each other and to any other electrical system.

3.2 Verify that the diesel generators respond and the appropriate switchgear, load centers, and motor control centers function correctly on a loss of offsite power.

3.3 Simulate designed accident actuation signals from the NSSS ESFAS cabinets and BOP ESFAS cabinets and verify design accident loads start.

3.4 Verify that designed accident loads associated with a given train remain inoperable when the designed actuation signals are simulated from the opposite train.

3.5 Verify that the forced shutdown loads associated with train A and train B start when required and after being allowed to reach a stable operating condition, the loads will function properly without evidence of abnormal conditions.

3.6 Verify that the Class 1E 125 V-dc control centers, after being isolated from their associated battery and battery chargers, will remain deenergized.

3.7 Verify that in the event of failure of the unit auxiliary transformer, an automatic fast transfer

of the 13.8 kV buses to the startup transformer is initiated.

3.8 Verify that in the event of a turbine trip an automatic fast transfer of the 13.8kV buses to the startup transformer is initiated.

3.9 Verify that transfers of all buses can be initiated from the control room.

4.0 ACCEPTANCE CRITERIA

The load group assignment verification and 13.8 kV buses perform as described in applicable portions of section 8.3 when using the above test methods.

15. ACCIDENT ANALYSES

15.0 INTRODUCTION

Nuclear power plant safety is evaluated by analyzing the response of the plant to postulated disturbances in process variables, and to postulated malfunctions or failures of equipment. Such analyses provide a significant contribution to the selection of Technical Specification Limiting Conditions for Operation (LCOs), Limiting Safety System Settings (LSSSs), and design specifications for components and systems from the standpoint of public health and safety. Such analyses are also a focal point of the Nuclear Regulatory Commission’s (NRC) Operating License reviews.

In this chapter, the effects of anticipated process disturbances and postulated component failures are examined to determine their consequences, to evaluate the capability built into the plant to control or accommodate such failures and situations, and to identify any limitations of expected performance. In other words, the Chapter 15 safety analyses are performed to show that, given certain design basis requirements and specifications for Systems, Structures, and Components (SSCs), overall plant response and performance will be acceptable should a Design Basis Event (DBE) occur.

The events analyzed herein include Anticipated Operational Occurrences (AOOs), off-design transients that may induce fuel failures above those expected from normal operational occurrences, and postulated accidents of low probability. These analyses include an assessment of the radiological

consequences of assumed fission product releases, up to and including the greatest potential hazard from any accident considered credible.

15.0.1 CLASSIFICATION OF TRANSIENTS AND ACCIDENTS

15.0.1.1 Format and Content

The format and content of this UFSAR chapter is structured in accordance with the guidance contained in Chapter 15 of NRC Regulatory Guide 1.70, Revision 3 [Reference 1]. Acceptance criteria for the safety analyses are derived, on a case-by-case basis, from NUREG-75/087 [Reference 2], NUREG-0800 [Reference 3], and/or licensing agreements negotiated with NRC staff, as documented in licensee correspondence and NRC safety evaluations associated with the PVNGS Operating License dockets. Chapter contents are maintained in accordance with 10 CFR 50.71(e) [Reference 4], NRC Regulatory Guide 1.181, Revision 0 [Reference 5], and Nuclear Energy Institute (NEI) Publication 98-03, Revision 1 [Reference 6], as described in UFSAR Section 1.8.

15.0.1.2 Event Categories

Each postulated initiating event has been assigned to one of the following categories:

- Increased heat removal by the secondary system
- Decreased heat removal by the secondary system
- Decreased reactor coolant flow
- Reactivity and power distribution anomalies

- Increase in Reactor Coolant System (RCS) inventory
- Decrease in RCS inventory
- Radioactive release from a subsystem or component

The assignment of an initiating event to one of these categories is made according to Reference 1, 2, and 3.

Although Reference 1 recommends that this chapter include safety analyses for Anticipated Transients Without Scram (ATWS), such analyses are not presented herein. This deviation from regulatory guidance is justified because, following publication of Reference 1, the NRC staff and Nuclear Steam Supply System (NSSS) vendors did not reach final agreement on safety analysis methodologies and acceptance criteria for ATWS events, as documented in Reference 7. In lieu of such an agreement, the NRC promulgated 10 CFR 50.62 [Reference 8], which mandated the installation of diverse plant systems to reduce the risks associated with an ATWS event. PVNGS compliance with the ATWS rule is documented in an NRC safety evaluation report dated October 18, 1990 [Reference 9], and is based on the installation of a Supplementary Protection System (DAFAS), as described in UFSAR Sections 7.2.5 and 7.3.5, respectively.

15.0.1.3 Event Frequencies

As noted in UFSAR Chapter 3, PVNGS SSCs are classified according to their importance in preventing and mitigating postulated events, using the classification system described in ANSI N18.2-1973, "Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants" [Reference 10].

ANSI N18.2-1973 divides postulated transients and accidents into four broad categories for design purposes, based on their relative estimated frequency of occurrence. The events analyzed in this chapter are likewise classified into these four broad categories, or conditions for design, which are as follows:

- Normal Operations (Condition I). Condition I occurrences are defined as operations that are expected frequently or regularly in the course of power operation, refueling, maintenance, or maneuvering of the plant.
- Incidents of Moderate Frequency (Condition II). Condition II occurrences are defined as incidents, any one of which may occur during a calendar year for a particular plant.
- Infrequent Events (Condition III). Condition III occurrences are defined as incidents, any one of which may occur during the lifetime of a particular plant.
- Limiting Faults (Condition IV). Condition IV occurrences are defined as faults that are not expected to occur, but are postulated nonetheless because their consequences include the potential for the release of significant amounts of radioactive material.

15.0.1.4 Events and Event Combinations

The events and event combinations in this chapter are presented with respect to the event-specific acceptance criteria. For each applicable acceptance criterion in an event category, only the limiting event or event combination is presented in analytical detail. As required by Reference 1, qualitative

discussions are provided for all other events or event combinations explaining why they are not limiting.

For event combinations that require consideration of a single failure, the limiting failures for the NSSS transient and accident safety analyses in this chapter are selected from those listed in Table 15.0-0. Only low probability, dependent failures (e.g., loss of off-site power following turbine trip) and independent pre-existing failures are considered credible and included in the table. Pre-existing failures are equipment failures existing prior to the event initiation that are not revealed until called upon during the event (e.g., a failure of an auxiliary feedwater pump). High probability, dependent occurrences are always included in the event analysis, if they have an adverse impact (e.g., loss of main feedwater pumps following a loss of electric power).

Table 15.0-0 lists a "Loss of Offsite power (LOP) following turbine trip" as a Single Failure to be considered in Safety Analysis. However, the LOP is treated differently depending on the event combination under consideration. The combination of the initiating event with coincident occurrences and single failures changes the event classification and acceptance criteria. For moderate frequency (Condition II) events, the LOP may be treated as the limiting single failure. In that case, the event becomes an infrequent (Condition III) event, with different acceptance criteria. One example is the Inadvertent Opening of a Steam Generator Atmospheric Dump Valve (UFSAR Section 15.1.4). This event by itself is a moderate frequency event. However, once a LOP is taken as the limiting single failure, the event becomes an infrequent event with

different acceptance criteria. For Condition IV limiting fault events, such as Loss of Coolant Accidents, Main Steam Line Break, Feedwater Line Break and Steam Generator Tube Rupture, a LOP is treated as a coincident occurrence, along with the limiting fault, and an additional single failure is then postulated. This application of the LOP to safety analysis ensures that the supporting SSCs can perform their design functions with offsite power unavailable, as required by the General Design Criteria.

Analytical assumptions regarding the availability and operation of plant SSCs (e.g., pressurizer heaters and sprays) are described in each event section on a case-by-case basis. Additionally, each safety analysis section describes the analytical credit that has been taken, if any, for administrative controls and procedures, manual equipment operation, or plant operator actions to mitigate an event.

Table 15.0-0
SINGLE FAILURES
(Sheet 1 of 3)

STEAM BYPASS CONTROL SYSTEM (SBCS)	
1.	Failure to modulate open
2.	Failure to quick open
3.	One bypass valve fails to quick close
4.	Excessive steam bypass flow
5.	Failure to generate automatic withdrawal prohibit signal during steam bypass operation
6.	Failure to generate the reactor power cutback signal
REACTIVITY CONTROL SYSTEMS	
7.	Regulating group(s) fail(s) to insert or withdraw
8.	A single Control Element Assembly (CEA) stuck[a]
9.	A CEA subgroup stuck[a]
10.	Failure to initiate or execute the reactor power cutback
11.	CEAs withdraw upon automatic withdrawal prohibit and/or CEA withdrawal prohibit
FEEDWATER CONTROL SYSTEM	
12.	Failure of reactor trip override
13.	Failure of high level override

a. Control element drive mechanism does not respond to control signal. Release of CEA(s) on trip is not inhibited.

Table 15.0-0
SINGLE FAILURES
(Sheet 2 of 3)

TURBINE-GENERATOR CONTROL SYSTEM

14. Setback without cutback

15. Failure to modulate the turbine control valves

16. Failure to setback given a cutback
(100% > initial power > 75%)

17. Failure to setback
(75% > initial power > 60%)

18. Failure to runback
(60% > initial power)

19. Failure to trip the turbine

PRESSURIZER PRESSURE CONTROL SYSTEM (PPCS)

20. Failure of spray control valves to open

21. Failure of spray control valves to close

22. Failure of backup heaters to turn on

23. Failure of backup heaters to turn off

PRESSURIZER LEVEL CONTROL SYSTEM (PLCS)

24. Backup charging pump fails to turn on

25. Backup charging pump fails to turn off

26. Letdown flow control valve fails to close

27. Letdown flow control valve fails to open

MAIN FEEDWATER SYSTEM

28. One Main Feedwater Isolation Valve (MFIV) fails to close

29. One backflow check valve fails to close

Table 15.0-0

(Sheet 3 of 3)

MAIN STEAM SYSTEM
30. One Main Steam Isolation Valve (MSIV) fails to close
31. One Atmospheric Dump Valve (ADV) fails to open
32. One Main Steam Safety Valve (MSSV) fails to reclose
AUXILIARY FEEDWATER SYSTEM
33. Failure of any one auxiliary feed pump to start
EMERGENCY CORE COOLING SYSTEM (ECCS)
34. Failure of one High Pressure Safety Injection (HPSI) or Low Pressure Safety Injection (LPSI) pump
ELECTRICAL POWER SOURCES
35. Loss of offsite power following turbine trip[b]
36. Failure to achieve fast transfer of a non-Class 1E bus to the startup transformer
37. Failure of one emergency generator to start, run or load

b. Section 15.0.2.4 describes the loss of off-site power following a turbine trip in more detail, including the time delay between turbine stop valve closure and loss of offsite power.

15.0.1.5 Section Numbering

The safety analyses in this chapter are divided into sections and subsections as described in Table 15.0-1.

Table 15.0-1
CHAPTER 15 SUBSECTION DESIGNATION

Each event of event combination section number begins with the sequence "15.W.X" where:

15	= 15	Safety analyses that are presented in UFSAR Chapter 15
W	= 1	Increase in heat removal by the secondary system
	2	Decrease in heat removal by the secondary system
	3	Decrease in RCS flow rate
	4	Reactivity and power distribution anomalies
	5	Increase in RCS inventory
	6	Decrease in RCS inventory
	7	Radioactive release from a subsystem or component
X	= 1, 2, etc.	Event title

15.0.1.6 Sequence of Events Analysis

The Sequence of Events Analysis (SEA) has been performed for each limiting event and event combination, for which detailed safety analysis results are presented in this chapter. The purpose of the SEA is to determine the following:

A. The step-by-step sequence of events from event initiation to the final stabilized condition;

B. The extent to which normally operating plant instrumentation and controls are assumed to function;

C. The extent to which plant and reactor protective systems are required to function;

D. The credit taken for the functioning of normally operating plant systems; and

E. The operation of engineered safety systems that are required.

SEAs have been specifically omitted for those events that, though representing limiting events for their category, do not result in the actuation of safety systems, or for which a detailed, quantitative analysis was not presented. For the safety analyses that appear in this chapter, the primary results of each SEA are presented in a sequence of events table and described in the text. Each sequence of events table presents a chronology of events that may be anticipated to occur during a transient, from event initiation to a final stabilized condition (or until operator action is taken to place the reactor in a safe shutdown condition). The accompanying text provides additional clarification, including

information regarding systems operation and a discussion of the effects of postulated single failures. The sequence of events table and corresponding text fulfill the regulatory guidance contained in Reference 1, by providing a step-by-step chronology and detailed discussion of systems operation for limiting transients.

The results of some SEAs are also presented in an optional format for the safety analyses, consisting of two additional tables and a figure. The first of the two optional tables is a matrix that identifies the extent to which normally operating plant systems are assumed to function during a transient. The second table specifies the Reactor Protective System (RPS) and Engineered Safety Features (ESF) that are actuated to accomplish safety functions during the course of the event. The optional figure is a Sequence of Events Diagram (SED), or a simple block diagram that provides a systematic analysis of components that are required to function during a transient. For some of the safety analyses, pertinent information that would otherwise appear on these tables of figure is instead described in the text.

The SEDs, together with the chronological list of events and the SEA symbol and acronym drawing (Figures 15.0-1), may be used to trace the actuation and interaction of the systems used to mitigate the consequences of each event. The SED is a block diagram, composed of several success paths that define a set of safety actions leading from the initiating event to the accomplishment of a specific safety function. All of the safety functions used in the SEDs are defined in Figure 15.0-1. A success path may be composed of two branches, one indicated

by a solid line, describing the sequence of events that occur in the transient analysis, and the other, indicated by a dotted line, describing an alternative or back-up path to a given means of accomplishing a safety function. An alternate dotted path is specified if the analysis assumed the action of a non-safety system in achieving a particular safety function. Non-safety systems are indicated by an "NS" in the upper right-hand corner of the system block.

The redundancy of a system or component is indicated by a fraction (e.g., 1/2, 2/4) placed beneath the system block. The numerator specifies the number of trains or components required to perform the action, and the denominator specifies the number of trains or components normally available. In cases where no alternate path exists and a single system or component is included in a success path, the symbol "S.F." will be used to indicate that no single active failure will prevent the accomplishment of the safety action.

Components or systems that require no active initiation or actuation to perform their function are considered to be passive and are marked as such with a "P" in the lower left-hand corner of the system block. The absence of a passive label implies that a component is considered to be active and must be actively initiated to perform its function.

Manual operations performed on a given system or component are indicated by placing an "M" in the lower left-hand corner of the system block. When a manual action is required, the sensed variables necessary to perform the action are shown as inputs

and the location of the input signal is shown above the input signal circle.

The system setpoint values assumed in the transient analysis, e.g., trip signal setpoints, is noted along the success path. Time delays or the time required to perform an action are shown as a number with square brackets.

All events presented in sequence of events diagrams in the main body of this chapter are shown from event initiation to achievement of the cold shutdown operating mode. Not all events require that the plant be taken to cold shutdown. The SEDs only demonstrate that for any event presented here it is possible to take the plant to cold shutdown by means of the safety actions indicated.

15.0.2 SYSTEMS OPERATION

During the course of any event various systems may be called upon to function. Some of these systems are described in Chapter 7 and include those electrical, instrumentation, and control systems designed to perform a safety function (i.e., those systems that must operate during an event to mitigate the consequences) and those systems not required to perform a safety function (see UFSAR Sections 7.2 through 7.6 and 7.7, respectively).

15.0.2.1 Reactor Protection

The Reactor Protective System (RPS) is described in UFSAR Section 7.2.

RPS trips credited in the safety analyses, including Core Protection Calculator (CPC) trips, are identified in the sequence of events description for each limiting event and event combination. Analytical trip setpoints are chosen to be consistent with, or conservative with respect to, the RPS trip setpoint allowable values delineated in the PVNGS Technical Specifications and the RPS trip setpoints delineated in UFSAR Section 7.2. Where applicable, analytical trip setpoints are adjusted to account for instrumentation loop uncertainties derived from design control calculations. The safety analyses also take into consideration the RPS response times associated with the various trip functions.

The RPS response time is the sum of the sensor response time and the reactor trip delay time. The sensor response time is defined as the time from when the value of the monitored parameter at the sensor equals or exceeds the RPS trip setpoint, until the sensor output equals or exceeds the trip setpoint. The sensor response is modeled by using a transfer function for the particular sensor used. The reactor trip delay time is defined as the elapsed time from the time the sensor output equals or exceeds the trip setpoint to the time the reactor trip breakers are fully open.

As noted in UFSAR Section 3.9.4, the Control Element Assemblies (CEAs) are designed with a maximum drop time of 4.0 seconds, where the drop time is defined as the interval between the time power is removed from the Control Element Drive Mechanism (CEDM) holding coils and the time at which the CEAs reach 90% of their fully inserted positions. For those safety analyses that model CEA insertion following a reactor trip, the

4.0-second CEA drop time is subdivided into two intervals: the holding coil delay time and the CEA insertion time. During the holding coil delay time, which is defined as the time interval between opening of the reactor trip breakers and the time at which the magnetic flux of the CEDM holding coils has decayed enough to allow for CEA motion, the CEAs are assumed to remain in their withdrawn positions. Following expiration of the holding coil delay time, the CEAs are assumed to drop 90% into the core during the remaining CEA insertion time. CEA drop time testing is conducted periodically in accordance with the PVNGS Technical Specifications and Technical Requirements Manual. Analytical treatment of CEA shutdown reactivity worth versus CEA position is described in UFSAR Section 15.0.3.3.3.

15.0.2.2 Engineered Safety Features

The Engineered Safety Feature Actuation Systems (ESFAS) and electrical, instrumentation, and control systems required for safe shutdown are described in UFSAR Sections 7.3 and 7.4, respectively. Analytical ESFAS setpoints and response times are chosen to be consistent with, or conservative with respect to, the setpoint allowable values delineated in the PVNGS Technical Specifications and the response times delineated in UFSAR Section 7.3. Where applicable, analytical ESFAS setpoints are adjusted to account for instrumentation loop uncertainties derived from design control calculations.

15.0.2.3 Control Systems

Control and instrumentation systems which may, but are not required to, perform safety functions are described in UFSAR

Section 7.7. These include various control systems and the Core Operating Limits Supervisory System (COLSS) which is a monitoring system. In general, normal operation of these control systems is assumed unless lack of operation would make the consequences of the event more adverse. In such cases, the particular control system is assumed to be inoperative, or in the most adverse mode, until the time of operator action. Although these systems are not credited for a safety function, such as mitigation during an event, some safety analyses may credit the normal operation of these systems, consistent with the plant operating procedures, for the purpose of setting initial conditions for event analysis. For example, the Feedwater Line Break (FWLB) long-term cooling analysis assumes that the Pressurizer Level Control System (PLCS) is initially in normal-automatic operation, with a programmed correspondence between the initial pressurizer water level and RCS loop average temperature. When initial conditions for an event analysis are established in this manner, the values of certain process variables (e.g., temperature, pressure, etc.) may not correspond to their respective Technical Specification limits, and a NRC review may be required to credit the initial normal operation of these systems as an element of methodology for safety analysis.

15.0.2.4 Loss of Off-Site Power Following Turbine Trip

The PVNGS off-site and on-site electric power systems are described in UFSAR Sections 8.2 and 8.3, respectively. The PVNGS turbine-generator system is described in UFSAR Section 10.2.

During normal plant operations, the Reactor Coolant Pumps (RCPs) are powered from non-Class 1E, 13.8-kV AC busses NAN-S01 and NAN-S02, which are electrically connected through the unit auxiliary transformer and the isolated phase busses to the turbine generator. The generator converts mechanical energy from the turbine to electrical power. Under normal conditions, a fast bus transfer would be initiated upon tripping of the unit auxiliary transformer output breakers, and alternate supply breakers would close within a few cycles to connect NAN-S01 AND NAN-S02 to the startup transformers. The startup transformers supply NAN-S01 and NAN-S02 during plant startup or at other times when the turbine generator or unit auxiliary transformer is out of service.

In the event of a turbine trip during normal plant operations, not involving an electrical fault or underfrequency, the turbine generator will remain synchronized to the extra high voltage transmission network until residual energy in the turbine is dissipated. The generator will motor for a short period of time, and will not trip until a sustained reverse power condition exists and the reverse power relay actuates. Reverse power relay actuation will simultaneously trip the generator exciter, the 525-kV breaker and the unit auxiliary transformer output breakers, thereby initiating a fast bus transfer. An analysis of twenty-six PVNGS trips, that occurred between 1990 and 1998, confirms that the time delay between turbine trip (i.e., turbine stop valve closure) and reverse power relay actuation has varied between 3.969 seconds and 7.55 seconds. Statistical analysis of the data indicates that the time delay would be greater than or equal to three seconds,

with a confidence level in excess of 98%. Therefore, in the event of a turbine trip with the RCPs busses connected to the unit auxiliary transformer, the RCPs will receive electrical power for at least three seconds following the turbine trip. Furthermore, a postulated single failure of a breaker to achieve a fast transfer to the backup power supply, which would result in the coastdown of two RCPs, would cause a less rapid loss of flow than the postulated loss of off-site power following a turbine trip (see Table 15.0-0), which would result in the coastdown of all four RCPs.

If the turbine generator were to trip with the RCP busses connected to the startup transformers, the RCPs would likewise receive off-site power for at least three seconds following the turbine trip. Reference 11 notes that the loss of a power generating unit on the transmission network such as the loss of a nuclear power plant due to a turbine trip, may generate frequency deviations in the transmission network which normally operates at 60 Hz. Under certain conditions the resulting electrical system instability may cause a loss of off-site power to that unit. The degree of instability is characterized by the rate of transmission network frequency degradation, which is dependent upon the magnitude of the load mismatch and the physical parameters of the transmission network. The physical response of the transmission network is dependent upon the available spinning reserve and the stiffness of the transmission network, that is, the ability to damp out frequency oscillations through load damping. Load shedding may also be utilized to restore the balance between load and power generation and to return the transmission network frequency to

60 Hz. When corrective actions are not sufficient to avert frequency degradation, loss of off-site power to the plant can occur as a result of that plant tripping offline. Most units are automatically disconnected from the transmission network between 56 Hz and 58 Hz, to prevent underfrequency damage to plant components. For System 80 plants such as PVNGS, Reference 11 conservatively assumed that a frequency of 57.6 Hz would be the setpoint at which a loss of off-site power occurs.

In order to determine the conservative lower bound for the time delay between turbine trip and loss of off-site power, Reference 11 employed the electrical grid system for the Florida Peninsula. This grid can tie into only the Georgia and Alabama grid systems, which can make up only 400 MWe through the transmission lines to Florida. Therefore, the Florida grid becomes an "electrical island" for a generation deficiency caused by the loss of a 1300 MWe unit. On curves of grid frequency response for this grid system, the effects of a generation deficiency caused by tripping of a System 80 plant were superimposed. Based on this evaluation, a 3.1 second time delay between turbine trip and loss of off-site power was calculated. This time delay is a conservative lower bound because the evaluation assumed:

A. No credit for spinning reserve and load shedding;

B. The Florida grid "electrical island" conditions (no support from neighboring grid systems);

C. Loss of a System 80 plant as a 10% generation loss, which is a much higher percentage than the actual loss (i.e., less than 3.5%); and

D. Loss of off-site power at 57.6 Hz for all System 80 plants.

Therefore, for the purpose of simulating the response of PVNGS systems during certain postulated events, a three-second delay may be assumed to occur between a main turbine trip and a loss of off-site power (see Table 15.0-0). The UFSAR Chapter 15 accident analyses that credit this three-second delay include the RCP rotor seizure event, the RCP shaft break event, steam generator tube ruptures, and, beginning with operating Cycle 11, the feedwater line break long-term cooling analysis. This constitutes a credit taken for the functioning of normally operating plant systems, as discussed in UFSAR Section 15.0.1.6.

It should be noted, however, that these analyses do not explicitly model a slight decrease in reactor coolant flow that may occur during this three second period, which might result from frequency degradation at the RCP busses. This modeling assumption is justified by further consideration of the transmission network described in UFSAR Section 8.2.2, to which the PVNGS units are electrically connected. Specifically, this transmission network can withstand the loss of a PVNGS unit, such as that resulting from a turbine trip, without system instability and with a frequency degradation of less than 0.1 Hz over the three second duration. Assuming a linear relationship between electrical frequency and reactor coolant flow, a frequency degradation of 0.1 Hz would result in only 0.17% reactor coolant flow degradation from full flow. This small amount of flow degradation is less than the conservatisms

inherent in the overall uncertainty factors for the CPCs and the Core Operating Limits Supervisory System (COLSS).

15.0.3 CORE AND SYSTEM PERFORMANCE

15.0.3.1 Mathematical Model

The NSSS response to various events was simulated using digital computer programs and analytical methods, as described below as well as in individual event analysis sections of this chapter.

15.0.3.1.1 Loss of Flow Analysis Method

The method used to analyze events initiated by failures causing a decrease in reactor coolant flowrate is discussed in UFSAR Appendix 15D.

15.0.3.1.2 CEA Ejection Analysis Method

The general methodology used to analyze the reactivity and power distribution anomalies associated with CEA ejection events is documented in the Nuclear Steam Supply System (NSSS) vendor's Topical Report CENPD-190-A [Reference 12], which was approved by the NRC for reference in license applications on June 10, 1976. Exceptions to NRC Regulatory Guide 1.77, Assumptions Used for Evaluating a Control Rod Ejection Accident for Pressurized Water Reactors [Reference 13], are described in UFSAR Section 1.8.

Fuel performance (e.g., fuel temperature and enthalpy) is evaluated with STRIKIN-II computer code (see UFSAR Section 15.0.3.1.5). For operating Cycle 10 and earlier cycles, peak RCS pressure was evaluated with the CESEC computer code (see

UFSAR Section 15.0.3.1.3.1). Beginning with operating Cycle 11, however, peak RCS pressure is evaluated with the CENTS computer code (see UFSAR Section 15.0.3.1.3.2), as approved by the NRC staff in the safety evaluation report associated with Amendment No. 137 to the PVNGS operating licenses [Reference 14]. For radiological dose assessments associated with postulated CEA ejection events, NSSS analysis codes (e.g., CESEC) are used to estimate the long-term releases from the secondary system until shutdown cooling entry occurs, as described in UFSAR Section 15.4.8.

15.0.3.1.3 NSSS Simulation Computer Programs

15.0.3.1.3.1 CESEC Computer Program

NSSS transient simulations, used in long term CEA Ejection radiological consequence evaluations, are performed with the CESEC computer code. The CESEC computer code is described in an April 1974 Topical Report [Reference 15]. The CESEC II and CESEC III versions of the code, which incorporate ATWS model modifications and additional improvements that extend the range of applicability of code models, are described in Supplements to that Topical Report [References 16, 17, 18, 19, and 20].

CESEC computes key system parameters during a transient including core heat flux, pressures, temperatures, and valve actions. A partial list of the dynamic functions included in this NSSS simulation includes: point kinetics neutron behavior, Doppler and moderator reactivity feedback, boron and CEA reactivity effects, multi-node average and hot channel reactor core thermal-hydraulics, reactor coolant pressurization and mass transport, reactor coolant system safety valve

behavior, steam generation, steam generator water level, turbine bypass, main steam safety and turbine admission valve behavior, as well as alarm, control, protection, and engineered safety feature systems. The steam turbines, condensers, and their associated controls are not included in the simulation. Steam generator feedwater enthalpy and flowrate are provided as input to CESEC.

During the course of execution, CESEC obtains steady-state and transient solutions to the set of equations that mathematically describe the physical models of the subsystems mentioned above. Simultaneous numerical integration of a set of nonlinear, first-order differential equations with time-varying coefficients is carried out by means of a simultaneous solution. As the time variable evolves, edits of the principal systems parameters are printed at prespecified intervals. An extensive library of the thermodynamic properties of uranium dioxide, water, and zircaloy is incorporated into this program. Through the use of CESEC, symmetric and asymmetric plant response over a wide range of operating conditions can be determined.

The CESEC III version of CESEC used in the analyses explicitly models the steam void formation and collapse in the upper head region of the reactor vessel and is documented in Reference 21. Other improvements to this version of CESEC include: a more detailed thermal-hydraulic model that explicitly simulates the mixing in the reactor vessel from asymmetric transients, an RCS flow model that calculates the time dependent reactor coolant mass flow rate in each loop, a wall heat model, a three-dimensional reactivity feedback model, a safety injection tank

model, and a primary-to-secondary heat transfer model that calculates the heat transfer for each generator node rather than for a steam generator as a whole.

15.0.3.1.3.2 CENTS Computer Program

The CENTS computer program is a computer code developed by the NSSS vendor for the simulation of NSSS transient behavior under normal and abnormal conditions. CENTS is intended to replace the CESEC code originally used to simulate the transient response of the NSSS. The CENTS computer code is documented in Reference 22 and has been approved by the NRC for use in the licensing analyses for PWRs originally designed by Combustion Engineering in Reference 23. The CENTS code approval was subject to five limitations:

1). The CENTS DNBR calculation for determining overall trends in thermal margin should not be used for licensing analyses.

2). The application of CENTS is limited to Combustion Engineering NSSS plants until additional information is submitted and approved.

3). CENTS should not be used for performing LOCA or severe accident licensing analyses.

4). CENTS must use only the point kinetics model in licensing applications.

5). CENTS must not be used for performing CEA ejection licensing analyses. (However, in a safety evaluation report associated with Amendment No. 137 to the PVNGS operating licenses [Reference 14], the NRC staff approved

the CENTS computer code for evaluating peak RCS pressure for CEA ejection events. NRC approval was granted on a plant-specific basis for PVNGS, rather than on a generic industry basis. Therefore, beginning with operating Cycle 11, PVNGS CEA ejection licensing analyses utilize the CENTS code for this purpose.)

Enhancements to CENTS were made by Westinghouse to more accurately model plant systems and transient behavior of the reactor. These improvements to the CENTS code are documented in Reference 31 and were approved by the NRC in Reference 32 & 33.

CENTS is a best-estimate code designed to provide a realistic simulation of the neutronics, thermal-hydraulics and plant systems response during transient conditions. CENTS computes key system parameters during a transient including core heat flux, pressures, temperatures, and valve actions. A partial list of the dynamic functions included in this NSSS simulation includes: point kinetics neutron behavior, Doppler and moderator reactivity feedback, boron and CEA reactivity effects, multi-node average and hot channel reactor core thermal-hydraulics, reactor coolant pressurization and mass transport, reactor coolant system safety valve behavior, steam generation, steam generator water level, turbine bypass, main steam safety and turbine admission valve behavior, as well as alarm, control, protection, and engineered safety feature systems. The steam turbines, condensers, and their associated controls are not included in the simulation. Steam generator feedwater enthalpy and flowrate are provided as input to CENTS.

During the course of execution, CENTS obtains steady-state and transient solutions to the set of equations that mathematically describe the physical models of the subsystems mentioned above. The RCS model is formulated with five one-dimensional conservation equations. The conservation equations are integrated implicitly by means of a simultaneous solution of the linearized conservation equations. As the time variable evolves, edits of the principal systems parameters are printed at prespecified intervals. An extensive library of the thermodynamic properties of uranium dioxide, water, and zircaloy is incorporated into this program. Through the use of CENTS, symmetric and asymmetric plant response over a wide range of operating conditions can be determined.

CENTS uses a more detailed NSSS model than CESEC. The improvements include: the addition of explicit models for determining the nodal solute concentrations and heat loss to the containment, a multi-node versus single node steam generator model, and a non-equilibrium non-homogeneous versus equilibrium homogeneous primary system model.

15.0.3.1.4 COAST Computer Program

The COAST computer program is used to calculate the reactor coolant flow coastdown transient for any combination of active and inactive pumps and forward or reverse flow in hot or cold legs. The program is described Reference 24.

The equations of conservation of momentum are written for each of the flow paths of the COAST model assuming unsteady one-dimensional flow of an incompressible fluid. The equation of conservation of mass is written for the appropriate nodal

points. Pressure losses due to friction and geometric losses are assumed proportional to the flow velocity squared. Pump dynamics are modeled using a head-flow curve for a pump at full speed and using four-quadrant curves, which are parametric diagrams of pump head and torque on coordinates of speed versus flow, for a pump at other than full speed.

15.0.3.1.5 STRIKIN-II Computer Program

The STRIKIN-II computer program is used to simulate the heat conduction within reactor fuel rods and its associated surface heat transfer. The STRIKIN-II program is described in Reference 25.

The STRIKIN-II computer program provides a single, or dual, closed channel model of a core flow channel to calculate the clad and fuel temperatures for an average or hot fuel rod, and the extent of the zirconium water reaction for a cylindrical geometry fuel rod. STRIKIN-II includes:

- Incorporation of all major reactivity feedback mechanisms.
- A maximum of six delayed neutron groups.
- Both axial (maximum of 20) and radial (maximum of 20) segmentation of the fuel element.
- Control rod scram initiation on high neutron power.

15.0.3.1.6 TORC and CETOP Computer Programs

The TORC and CETOP computer programs are used to simulate the fluid conditions within the reactor core region and to calculate fuel pin Departure from Nucleate Boiling Ratio

(DNBR). The TORC program is described in References 26 and 27. The CETOP computer program is described in Reference 28.

15.0.3.1.7 Reactor Physics Computer Programs

Numerous computer programs are used to produce the input reactor physics parameters required by the NSSS simulation and reactor core programs previously described. These reactor physics computer programs are described in UFSAR Chapter 4.

15.0.3.2 Initial Conditions

The events described in this chapter and its appendices have been analyzed over a wide range of initial conditions that encompasses a variety of steady-state operational configurations.

In accordance with Reference 1, the most adverse conditions within permitted operating bands for principal process variables have generally been used as initial conditions for the safety analyses. In this context, Reference 1 defines a permitted operating band as the permitted fluctuations in a given parameter or variable, plus any associated uncertainties. However, if the results and conclusions of a safety analysis are insensitive to the initial value chosen for a specific process variable, then a nominal value may instead be used as an initial condition for that variable.

If a process variable is delineated in or controlled by the PVNGS Technical Specifications (e.g., RCS cold leg temperature), the corresponding Limiting Conditions for Operation (LCOs) and Surveillance Requirements (SRs) are

typically utilized to define the permitted fluctuations for that variable. The permitted operating band may then be determined by accounting for instrumentation loop uncertainties, which are obtained from design control calculations. This approach ensures consistency between the physical plant, the Technical Specifications, and the safety analyses presented in this UFSAR chapter, as required by 10 CFR 50.36 [Reference 29].

If a process variable is not explicitly controlled by the Technical Specifications (e.g., steam generator water level in Mode 1), then the safety analysis guidance contained in Reference 10 may instead be utilized to determine the permitted fluctuations for that variable. Specifically, Reference 10 states that the initial conditions chosen for an analysis should account for the full range of expected normal operating conditions, including the following:

- Operating modes (for example, startup, shutdown, loops out of service, refueling);
- Systems under manual control considering alarm points, manual action required, and protective overrides; and
- Variations in plant parameters with power and core exposure.

In such a case, the selection of an initial condition will therefore be consistent with normal plant operating procedures, including control room alarm response procedures and their required operator actions.

15.0.3.3 Input Parameters

15.0.3.3.1 Doppler Coefficient

The fuel temperature coefficient of reactivity (Doppler coefficient) is described in UFSAR Section 4.3. In the safety analyses, the Doppler coefficient is adjusted to account for higher feedback effects in the higher power density core regions, as well as to account for uncertainties in determining the actual fuel temperature reactivity effects. Each analysis utilizes either a more negative or less negative Doppler feedback, in order to produce a more adverse result that is closer to the analytical acceptance criteria.

15.0.3.3.2 Moderator Temperature Coefficient

The Moderator Temperature Coefficient (MTC) of reactivity is described in UFSAR Section 4.3. MTC values used in the safety analyses are consistent with the limitations specified in the PVNGS Technical Specifications and the PVNGS Core Operating Limits Reports (COLRs), which vary as a function of both core power level and time in cycle, that is, Beginning-of-Cycle (BOC) to End-of-Cycle (EOC). A conservative MTC value is selected for each analysis on a case-by-case basis.

15.0.3.3.3 Shutdown CEA Reactivity

The shutdown reactivity is dependent on the CEA worth available on reactor trip, the axial power distribution, the position of the regulating CEAs, and the time in core life. Please refer to the individual event descriptions in this chapter, to determine the CEA worth that was assumed in each analysis.

Power Dependent Insertion Limits (PDILs), included in the COLR, assure adequate CEA worths are available upon reactor trip.

An example of a shutdown reactivity worth versus position curve, for an Axial Shape Index (ASI) of approximately +0.3, is shown in Figure 15.0-2.

15.0.3.3.4 Effective Delayed Neutron Fraction

The effective neutron lifetime and delayed neutron fraction are functions of fuel burnup. For each analysis, the values of the neutron lifetime and the delayed neutron fraction are selected consistent with the time in life analyzed.

15.0.3.3.5 Decay Heat Generation Rate

Analyses assume decay heat generation based upon an infinite reactor operation at the initial core power level identified for each event.

15.0.4 RADIOLOGICAL CONSEQUENCES

Some of the safety analyses presented in this chapter predict that steam or liquid will be released from the RCS or main steam system. Because radioactive material could be present in these discharges, these events are anticipated to result in radiological dose consequences for control room personnel or for the off-site general public. Appendix 15B describes an activity release model that has been used to assess the radiological consequences of certain postulated accidents presented in this chapter. Where applicable, event-specific radiological dose assessment models, which differ from those

presented in Appendix 15B, are described on a case-by-case basis in the individual event sections of this chapter.

For radiological event analyses, steam and liquid mass releases to the environment are typically derived from computer code simulations or from alternate calculations. Estimated releases are utilized in the radiological dose analyses, for the purpose of determining whole body and thyroid doses at the Exclusion Area Boundary (EAB), the outer boundary of the Low Population Zone (LPZ), the control room and other required habitable areas. Where applicable, steam and liquid leakage from plant systems, as well as analytical credits taken for automatic actuations (e.g., ESFAS functions) and manual operator actions are described in the individual event sections in this chapter.

Unless specified otherwise in the individual event sections in this chapter, the major assumptions used for calculating radiological releases to the environment are as follows:

A. The initial RCS activity level is established consistent with the PVNGS licensing basis for the event under consideration. For some events, the event methodology requires that the initial RCS activity be set to the maximum activity due to continuous full power operation with 1% failed fuel. For other events, initial conditions are based on the Technical Specification limit for RCS dose equivalent I-131 and Xe-133 specific activities.

B. The initial secondary system activity level is equal to 0.1 μCi/gm dose equivalent I-131.

C. Primary-to-secondary steam generator tube leakage is included in the calculation of activity releases to the environment from the steam generators. The leakage assumed in the safety analyses is a 1 gpm primary—to-secondary tube leak (i.e., total leakage for two steam generators), consistent with PVNGS Technical Specification 5.5.9.

D. For events that require consideration of “iodine spiking” the following are used:

1. For iodine spiking generated by the event, the iodine appearance rate is increased by a factor of 335.

2. For an abnormally high iodine concentration due to a previous iodine spike, a reactor coolant activity of 60 μCi/gm dose equivalent I-131 is assumed.

E. Breathing rate (from Table 15B-3).

F. Atmospheric dispersion factor (χ/Q) (from Table 2.3-31)

G. Dose conversion factors from ICRP-30 for radioiodines are used for thyroid inhalation dose calculations, all other dose conversion factors are obtained from Regulatory Guide 1.109.

TABLE 15.0-2

15.1 INCREASE IN HEAT REMOVAL BY THE SECONDARY SYSTEM

15.1.1 DECREASE IN FEEDWATER TEMPERATURE

15.1.1.1 Identification of Causes and Frequency Classification

A decrease in main feedwater temperature may be caused by an interruption of extraction steam to one or more feedwater heaters due to a heater drain pump malfunction, or a loss of heater drain tank or heater level control.

A decrease in main feedwater temperature event is classified as an incident of moderate frequency. A decrease in main feedwater temperature event in combination with an additional single failure is classified as an infrequent event.

15.1.1.2 Sequence of Events and System Operation

As noted in UFSAR Section 10.4.7, the main feedwater system may be operated in two different modes during normal plant power operations. In the bypass mode of operation, approximately 80% of the total feedwater flow that is delivered to the steam generators passes through two parallel trains of high pressure feedwater heaters, with the remainder of the feedwater flow bypassing these heater trains via an open bypass valve. In the turbo mode of operation, the bypass valve is closed and 100% of the total delivered feedwater flow passes through the high pressure feedwater heater trains.

In either mode of operation, the temperature of the feedwater that passes through each parallel train of three high pressure feedwater heaters is increased by approximately 100°F. Feedwater heating is provided by extraction steam from the high pressure turbine and the first and second stage reheaters,

which flows through the shell side of the feedwater heaters. Shell side condensate from each train of heaters is drained to a heater drain tank. Heater drain pumps return the condensate to the inlets of the main feedwater pumps, upstream of their respective high pressure feedwater heater trains.

If extraction steam were to be suddenly and completely lost to one train of three high pressure heaters, the temperature of the feedwater delivered to the steam generators would be reduced by approximately 40°F to 50°F, respectively, if the feedwater system were operating in the bypass or turbo mode at nominal system flow rates.

A sudden decrease in feedwater temperature would result in a decrease in reactor coolant temperature which, in the presence of a negative Moderator Temperature Coefficient (MTC), would increase core power. A sudden cooldown would likewise cause a decrease in Reactor Coolant System (RCS) and steam generator pressures. Detection of the event could therefore be accomplished by a high reactor power alarm or a steam generator low pressure alarm. If the transient were to result in an approach to Specified Acceptable Fuel Design Limits (SAFDLs), trip signals generated by the Core Protection Calculators (CPCs) would ensure that low Departure from Nucleate Boiling Ratio (DNBR) and high Local Power Density (LPD) limits are not exceeded.

15.1.1.3 Core and System Performance

A decrease in main feedwater temperature event would not challenge fuel pellet integrity. During the event, any short-term increase in reactor power, or three-dimensional shift in power generation within the core, would not be of sufficient magnitude to raise the linear heat rate above that required to cause fuel centerline melting.

A decrease in main feedwater temperature event would result in a smaller decrease in RCS temperature than an increase in main steam flow event involving the quick opening of eight Steam Bypass Control System (SBCS) valves or an inadvertent opening of a steam generator atmospheric dump valve (OSGADV) (see UFSAR Section 15.1.4). The smaller RCS cooldown would result in less of a power increase, and hence less of a decrease in the minimum hot channel DNBR during the transient. The minimum hot channel DNBR establishes whether a fuel design limit has been exceeded and therefore whether fuel cladding degradation might be anticipated.

For the decrease in main feedwater temperature event in combination with a single failure, the parameter of concern is likewise the minimum hot channel DNBR. Factors that would cause a decrease in DNBR include an increase in coolant temperature, a decrease in coolant pressure, an increase in local heat flux (including radial and axial power distribution effects), and a decrease in coolant flow rate. Evaluation of postulated single failures shows that the worst single failure for this event is a Loss of Offsite Power (LOP) following a

turbine trip, which would cause the Reactor Coolant Pumps (RCPs) to coast down and rapidly reduce the coolant flow rate. This event, however, would result in a Nuclear Steam Supply System (NSSS) response that is similar to, but less severe than, that caused by the increase in main steam flow event involving the quick opening of eight SBCS valves or an inadvertent opening of a steam generator atmospheric dump valve (OSGADV) in combination with LOP (See UFSAR Section 15.1.3 and 15.1.4). These events result in more severe RCS cooldown that in turn results in more of an increase in power, and hence more of a decrease in the minimum hot channel DNBR. Therefore, the DNBR at the moment RCPs begin to coastdown would be bounded by those events. For this reason, the infrequent decrease in the feedwater temperature event (in combination with a single failure) is bounded by the infrequent event involving the quick opening of eight SBCS valves and the inadvertent opening of steam generator atmospheric dump valve (OSGADV) (in combination with single failure) with respect to the DNBR SAFDL.

In addition, this event would result in a more benign minimum DNBR than the resulting from the limiting infrequent event that is described in the UFSAR Appendix 15.E. the event described in UFSAR Appendix 15.E establishes a limiting infrequent event, including all incidents of moderate frequency in combination with a single failure, with respect to DNBR degradation, assuming that the DNBR is already at the SAFDL when the single failure, LOP, occurs.

15.1.1.4 RCS Pressure Boundary Barrier Performance

A decrease in main feedwater temperature event is characterized by an initial cooldown of the primary and secondary systems, and decreasing RCS and steam generator pressures. If the event results in a reactor trip and Main Steam Isolation Signal (MSIS), repressurization of the RCS and steam generators would occur due to decay heat from radionuclides in the core, heat stored in the metal structures of the NSSS, and heat from any operating RCPs. Additionally, if pressurizer pressure decreases below the Safety Injection Actuation Signal (SIAS) setpoint, safety injection flow may also result in repressurization of the RCS. Eventually, however, plant operators would take action to cool down and depressurize the plant to Shutdown Cooling (SDC) entry conditions. This may be accomplished by feeding the steam generators with Auxiliary Feedwater (AFW) flow and by releasing steam through the Atmospheric Dump Valves (ADVs).

The subsequent heatup and repressurization of the NSSS would not challenge RCS pressure boundary peak pressure limits. Prior to the operators taking action to cool down the plant, the secondary system peak pressure would be limited by the Main Steam Safety Valves (MSSVs), which have sufficient capacities to relieve the steam that may be generated by NSSS heat sources. Furthermore, if the heat transfer rate from the RCS to the secondary system were degraded for any reason, as might occur when a LOP results in a loss of forced RCS coolant flow, the Pressurizer Safety Valves (PSVs) may also open to limit the

RCS peak pressure. Because the maximum allowable lift settings for the MSSVs and PSVs are well below the peak pressure regulatory limits for this event, a decrease in feedwater temperature, or a decrease in feedwater temperature in combination with a single failure, would not challenge the RCS pressure boundary through overpressurization of either the primary or secondary systems.

15.1.1.5 Containment Performance and Radiological Consequences

A decrease in feedwater temperature event in combination with an additional single failure (for example, a LOP following turbine trip) is classified as an infrequent event, which may result in limited fuel cladding degradation. Offsite radiological dose consequences are limited to a small fraction, or 10%, of 10 CFR Part 100 guideline values. Additionally, radiation exposures for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A. The offsite and control room radiological dose consequences associated with this infrequent event are bounded by those that may result from an Inadvertent Opening of a Steam Generator Atmospheric Dump Valve with a Loss of Offsite Power (IOSGADVLOP) event, (see UFSAR Section 15.1.4) and/or the limiting infrequent event (see UFSAR Appendix 15.E), and are in compliance with regulatory guidelines.

15.1.1.6 Conclusions

Evaluation of the decrease in feedwater temperature event shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- For the moderate frequency decrease in feedwater temperature event (without an additional single failure), fuel cladding integrity will be maintained.
- For the infrequent decrease in feedwater temperature event (with an additional single failure), limited fuel cladding degradation may occur. However, offsite and control room radiological dose consequences are bounded by those that may result from an IOSGADVLOP event, (see UFSAR Section 15.1.4) and/or the limiting infrequent event (see UFSAR Appendix 15.E), and are in compliance with regulatory guidelines.

15.1.2 INCREASE IN MAIN FEEDWATER FLOW

15.1.2.1 Identification of Causes and Frequency Classification

An increase in main feedwater flow to the steam generators may be caused by inadvertent equipment malfunctions in the Feedwater Control System (FWCS), resulting in the opening of feedwater control valves beyond their desired positions, or an increase in feedwater pump speed.

An increase in main feedwater flow event is classified as an incident of moderate frequency. An increase in main feedwater

flow event in combination with an additional single failure is classified as an infrequent event.

15.1.2.2 Sequence of Events and System Operation

During normal power operations, feedwater flow is automatically controlled by the FWCS through main feedwater control valves, which establish steam generator feedwater balancing in conjunction with variable-speed feedwater pump turbine drives. If a hypothetical equipment malfunction were to suddenly increase FWCS demand signals to their maximum output values, the control valves would stroke fully open and the feedwater pumps would accelerate to maximum speed. If the plant were operating at full power when this occurred, the maximum increase in feedwater flow that would result is estimated to be approximately 25% of the nominal main feedwater system flow rate.

A sudden increase in main feedwater flow to the steam generators would result in a decrease in reactor coolant temperature which, in the presence of a negative MTC, would increase core power. A sudden increase in feedwater flow would also cause an increase in steam generator water level and a decrease in RCS and steam generator pressures. Detection of the event could therefore be accomplished by a high reactor power alarm, a steam generator low pressure alarm, or a steam generator high water level alarm. If the transient were to result in an approach to SAFDLs, trip signals generated by the CPCs would ensure that low DNBR and high LPD limits were not exceeded. Likewise, if steam generator water level increased

significantly, a reactor trip and main steam isolation on high steam generator level would occur, thereby protecting the steam generators from overfilling.

15.1.2.3 Core and System Performance

An increase in main feedwater flow event would not challenge fuel pellet integrity. During the event, any short-term increase in reactor power, or three-dimensional shift in power generation within the core, would not be of sufficient magnitude to raise the linear heat rate above that required to cause fuel centerline melting.

An increase in main feedwater flow event would result in a smaller decrease in RCS temperature than an increase in main steam flow event involving the quick opening of eight SBCS valves or the inadvertent opening of a steam generator atmospheric dump valve (OSGADV) (see UFSAR Section 15.1.3 and 15.1.4). The smaller RCS cooldown would result in less of a power increase, and hence less of a decrease in the minimum hot channel DNBR during the transient. The minimum hot channel DNBR establishes whether a fuel design limit has been exceeded and therefore whether fuel cladding degradation might be anticipated.

For the increase in main feedwater flow event in combination with a single failure, the parameter of concern is likewise the minimum hot channel DNBR. Factors that would cause a decrease in DNBR include an increase in coolant temperature, a decrease in coolant pressure, an increase in local heat flux (including

radial and axial power distribution effects), and a decrease in coolant flow rate. Evaluation of postulated single failures shows that the worst single failure for this event is a LOP following a turbine trip, which would cause the RCPs to coast down and rapidly reduce the coolant flow rate. This event, however, would result in a Nuclear Steam Supply System (NSSS) response that is similar to, but less severe than, that caused by the increase in main steam flow event involving the quick opening of eight SBCS valves or an inadvertent opening of a steam generator atmospheric dump valve in combination with LOP (See UFSAR Section 15.1.3 and 15.1.4). The quick opening of eight SBCS valves results in more severe RCS cooldown that in turn results in more of an increase in power, and hence more of a decrease in the minimum hot channel DNBR. Therefore, the DNBR at the moment RCPs begin to coastdown would be bounded by those events. For this reason, the infrequent increase in the feedwater flow event (in combination with a single failure) is bounded by the infrequent event involving the quick opening of eight SBCS valves and inadvertent opening of a steam generator atmospheric dump valve (OSGADV) (in combination with single failure) with respect to the DNBR SAFDL.

In addition, this event would result in a more benign minimum DNBR than that resulting from the limiting infrequent event that is described in the UFDAR Appendix 15.E. The event described in UFSAR Appendix 15.E establishes a limiting infrequent event, including all incidents of moderate frequency in combination with a single failure, with respect to DNBR

degradation, assuming that the DNBR is already at the SAFDL when the single failure, LOP, occurs.

15.1.2.4 RCS Pressure Boundary Barrier Performance

An increase in main feedwater flow event is characterized by an initial cooldown of the primary and secondary systems, decreasing RCS and steam generator pressures, and increasing steam generator water level. If the event results in a reactor trip and MSIS, repressurization of the RCS and steam generators may occur due to decay heat from radionuclides in the core, heat stored in the metal structures of the NSSS, and heat from any operating RCPs. Additionally, if pressurizer pressure decreases below the SIAS setpoint, safety injection flow may also serve to repressurize the RCS. Eventually, however, plant operators would take action to cool down and depressurize the plant to SDC entry conditions. This may be accomplished by feeding the steam generators with AFW flow and by releasing steam through the ADVs.

The subsequent heatup and repressurization of the NSSS would not challenge RCS pressure boundary peak pressure limits. Prior to the operators taking action to cool down the plant, the secondary system peak pressure would be limited by the MSSVs, which have sufficient capacities to relieve the steam that may be generated by NSSS heat sources. Furthermore, if the heat transfer rate from the RCS to the secondary system were degraded for any reason, as might occur when a LOP results in a loss of forced RCS coolant flow, the PSVs may also open to limit the RCS peak pressure. Because the maximum allowable

lift settings for the MSSVs and PSVs are well below the peak pressure regulatory limits for this event, an increase in main feedwater flow, or an increase in main feedwater flow in combination with a single failure, would not challenge the RCS pressure boundary through overpressurization of either the primary or secondary systems.

15.1.2.5 Containment Performance and Radiological Consequences

An increase in main feedwater flow event in combination with an additional single failure (for example, a LOP following turbine trip) is classified as an infrequent event, which may result in limited fuel cladding degradation. Offsite radiological dose consequences are limited to a small fraction, or 10%, of 10 CFR Part 100 guideline values. Additionally, radiation exposures for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A. The offsite and control room radiological dose consequences associated with this infrequent event are bounded by those that may result from an IOSGADVLOP event, (see UFSAR Section 15.1.4) and/or the limiting infrequent event (see UFSAR Appendix 15.E), and are in compliance with regulatory guidelines.

15.1.2.6 Conclusions

Evaluation of the increase in main feedwater flow event shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).

- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- For the moderate frequency increase in main feedwater flow event (without an additional single failure), fuel cladding integrity will be maintained.
- For the infrequent increase in main feedwater flow event (with an additional single failure), limited fuel cladding degradation may occur. However, offsite and control room radiological dose consequences are bounded by those that may result from an IOSGADVLOP event, (see UFSAR Section 15.1.4) and/or the limiting infrequent event (see UFSAR Appendix 15.E), and are in compliance with regulatory guidelines.

15.1.3 INCREASE IN MAIN STEAM FLOW

15.1.3.1 Identification of Causes and Frequency Classification

An increase in main steam flow event may be caused by equipment malfunctions or inadvertent operator actions that result in the sudden opening of one or more Steam Bypass Control System (SBCS) valves; the opening of a turbine admission valve beyond its desired position; or the opening of an Atmospheric Dump Valve (ADV). Postulated events that involve the SBCS and turbine admission valves, which are located downstream of the Main Steam Isolation Valves (MSIVs), are addressed in this UFSAR section. Inadvertent openings of ADVs, which are located upstream of the MSIVs, are addressed in UFSAR Section 15.1.4.

An increase in main steam flow event is classified as an incident of moderate frequency. An increase in main steam flow event in combination with an additional single failure is classified as an infrequent event.

15.1.3.2 Sequence of Events and System Operation

When the plant is operating at full power, main steam flow will increase if a turbine admission valve suddenly opens beyond its desired position, or if one or more SBCS valves suddenly open. The largest possible increase in main steam flow would occur if an equipment malfunction resulted in the simultaneous quick opening of all eight SBCS valves (SBCVs). The maximum allowable capacity of each non-safety-related SBCV is 11% of the Design Steam Rate (DSR), where the DSR is based on the original licensed power level of 3800 MWt. The DSR is less than the nominal steam flow rate at the current licensed Rated Thermal Power (RTP). Given the maximum capacity of each SBCV, main steam flow would increase by less than 88% of the steam flow corresponding the current licensed RTP.

Table 15.1.3-1 provides the sequence of events for the limiting moderate frequency increase in main steam flow analysis, involving a quick opening of all eight SBCVs at 100% power. This sequence of events was obtained by simulating the event with the computer codes identified in Section 15.1.3.3. Figures 15.1.3-1 through 15.1.3-12 show the short-term response of key NSSS parameters during the portion of the event that presents the greatest challenge to SAFDLs. Specifically, Figure 15.1.3-11 shows how DNBR approaches and passes through a minimum value shortly after event initiation. Figures 15.1.3-13 through 15.1.3-15 show the long-term response of key parameters prior to the time at which operators are assumed to take control of plant (i.e., 30 minutes after event initiation).

The sudden increase in main steam flow (Figure 15.1.3-1) results in a decrease in reactor coolant temperature (Figure 15.1.3-2) which, in the presence of a negative MTC, results in an increase in reactivity (Figure 15.1.3-3), core power (Figure 15.1.3-4), and core heat flux (Figure 15.1.3-5).

INCREASE IN HEAT REMOVAL

BY THE SECONDARY SYSTEM

Table 15.1.3-1

SEQUENCE OF EVENTS FOR THE LIMITING MODERATE FREQUENCY STEAM BYPASS CONTROL SYSTEM MALFUNCTION SAFETY ANALYSIS

Time	Event
0.00	Eight SBCS valves quick-open
6.49	Steam generator pressure reaches MSIS setpoint
6.72	CPC VOPT reaches reactor trip setpoint
7.47	Reactor trip breakers open
7.72	Turbine trip occurs
8.08	CEAs begin to fall
8.50	Minimum DNBR occurs
12.10	MSIVs close. Flow through SBCS valves stops.
112.02	MSSVs open on steam generator 1[1]
112.02	MSSVs open on steam generator 2[1]
112.39	Maximum steam generator 2 pressure occurs
165.58	MSSVs close on steam generator 1[1]
165.58	MSSVs close on steam generator 2[1]
323.52	Pressurizer Pressure reaches SIAS septoint.
363.52	HPSI flow Begins
600.55	Maximum steam generator 1 pressure occurs
665.64	AFW flow delivered to steam generator 1
665.64	AFW flow delivered to steam generator 2
1009.47	AFW flow shutoff reached in steam generator 2.
1011.11	AFW flow shutoff reached in steam generator 1.
1800.00	Plant operators take control of the plant

[1]Only the first opening and closing of the MSSVs are documented.

Table 15.1.3-1 (Page 2 of 2)

SEQUENCE OF EVENTS FOR THE LIMITING MODERATE FREQUENCY STEAM BYPASS CONTROL SYSTEM MALFUNCTION SAFETY ANALYSIS

Time	Event
1000	Steam generator No. 1 water level recovers to high level AFAS setpoint. AFW flow stopped to steam generator No. 1
1073	MSSVs open on steam generator No. 2
1074	MSSVs open on steam generator No. 1
1114	MSSVs close on steam generator No. 2
1115	MSSVs close on steam generator No. 1
1269	MSSVs open on steam generator Nos. 1 and 2
1279	Steam generator No. 1 water level decreases to low level AFAS setpoint. AFW flow reinitiated to steam generator No. 1
1280	Steam generator No. 2 water level decreases to low level AFAS setpoint. AFW flow reinitiated to steam generator No. 2
1302	MSSVs open on steam generator Nos. 1 and 2
1556	Steam generator No. 2 water level recovers to high level AFAS setpoint. AFW flow stopped to steam generator No. 2
1559	Steam generator No. 1 water level recovers to high level AFAS setpoint. AFW flow stopped to steam generator No. 1
1688	MSSVs open on steam generator Nos. 1 and 2
1728	MSSVs close on steam generator No. 2
1729	MSSVs close on steam generator No. 1
1800	Plant operators take control of plant

A sudden increase in main steam flow would also cause a short-term increase in the indicated steam generator water level due to swell effects (Figure 15.1.3-6), and an almost immediate decrease in both RCS and steam generator pressures (Figures 15.1.3-7 and 15.1.3-8, respectively). Despite the short-term increase in indicated steam generator water level, the mass of liquid in both steam generators would actually decrease slightly due to increased steam flow during the early part of the transient (Figure 15.1.3-9). Detection of the event may be accomplished by a high reactor power alarm, an RCS low pressure alarm, or a steam generator low pressure alarm.

Rapid cooling of the RCS would increase coolant density and cause a temporary reduction in pressurizer level (Figure 15.1.3-10). When the colder fluid exiting the steam generator reaches the core inlet, the core power will increase, causing the core heat flux to increase, albeit with a delay of a few seconds. This increased heat flux, in conjunction with the decreased RCS pressure, would cause the DNBR to decrease (Figure 15.1.3-11).

As the event proceeds, the steam generator pressure decreases and approaches the Low Steam Generator Pressure Trip (LSGPT). At the same time, reactor power increases toward a CPC auxiliary trip, the Variable Overpower Trip (VOPT). A VOPT will occur before the LSGPT for more negative values of MTC; however, for less negative values of MTC, the power increase may not be sufficient to result in the VOPT before the steam generator pressure reaches the LSGPT. The most limiting

analysis case, which yielded the lowest DNBR value, was found to occur when the VOPT and LSGPT trips occurred at approximately the same time.

Following reactor trip, Control Element Assemblies (CEAs) would fall into the reactor core, rapidly reducing reactivity, core power, and core heat flux. As indicated in Table 15.1.3-1, minimum DNBR is predicted to occur shortly after the CEAs begin inserting into the core.

The course of the transient depends on the choice of MTC, because the LSGPT occurs in conjunction with a Main Steam Isolation Signal (MSIS). Thus, depending on which trip signal intervenes, and even how close the LSGPT is to the setpoint, the system responses for the steam system may take one of two different paths.

In the case of tripping on the LSGPT, the MSIS accompanying the trip would result in closure of the MSIVs and Main Feedwater Isolation Valves (MFIVs). Closure of these valves would stop the flow of main feedwater to the steam generators (Figure 15.1.3-12) as well as the flow of steam out of the open SBCVs. It would also stop the temperature and pressure decrease in the RCS temporarily and there would be no Safety Injection Actuation Signal (SIAS).

If the trip were to occur on the VOPT and the steam generator pressure were far enough above the MSIS setpoint to avoid an immediate MSIS, there would be a turbine trip associated with the VOPT, but the flow through the SBCVs would continue. Thus, in spite of the turbine trip, RCS pressure would continue to

decrease as heat loss through the open SBCVs exceeds the post-trip heat generation rate in the NSSS. As the RCS continued to cool down, the pressurizer would eventually empty and pressurizer pressure would decrease to the SIAS setpoint, actuating the safety injection pumps. After a brief time delay, during which the High Pressure Safety Injection (HPSI) pumps reach full speed, safety injection flow would be delivered to the RCS, provided RCS pressure was below the shutoff head of the HPSI pumps. Shortly thereafter, the decreasing steam generator pressure would reach the MSIS setpoint, thereby halting the steam flow from both steam generators and effectively stopping the cooldown.

Following the MSIS, the RCS and steam generators would begin to repressurize, due to the heat released by fission product decay, running RCPs, hot metal structures in the NSSS and, in the event of VOPT, the HPSI flow (Figures 15.1.3-13 and 13.1.3-14, respectively). The pressure in the steam generators would continue to rise until the MSSV setpoint is reached. At this point, the MSSVs would open, limiting the pressure and releasing steam generator inventory. As the steam generator pressure dropped from this release, the MSSVs would close and the steam generator pressure would begin rising again. The release of inventory associated with each lifting of the MSSVs would cause the liquid levels in the steam generators to decrease until they reach the Auxiliary Feedwater Actuation Signal (AFAS) setpoint. This would initiate the delivery of AFW flow to the steam generators, which would continue until the high level reset was reached.

After initiation of AFW flow to the steam generators, the plant would achieve quasi-steady-state conditions with heat removal provided by cycling of the MSSVs, and makeup water provided by cycling of the AFW system as water levels rise and fall in both steam generators. Pressurizer level would likewise rise and fall as the RCS periodically heats up, then temporarily cools down again with each MSSV lift (Figure 15.1.3-15).

Operator action is not credited in the safety analysis until 30 minutes following the SBCS malfunction. At that time, it is assumed that plant operators will take action to initiate a controlled plant cooldown to SDC entry conditions, for example by establishing a steaming path through the ADVs.

15.1.3.3 Core and System Performance

An event involving an increase in main steam flow would not challenge fuel pellet integrity. During the event, any short-term increase in reactor power, or three-dimensional shift in power generation within the core, would not be of sufficient magnitude to raise the linear heat rate above that required to cause fuel centerline melting.

An increase in main steam flow event results in thermal margin degradation very similar to that experienced in the IOSGADV moderate frequency event with respect to the DNBR SAFDL. The mathematical models, input parameters, initial conditions, and results of the SBCS malfunction safety analysis are described in the subsections below for this moderate frequency event.

For the infrequent increase in main steam flow event in combination with a single failure, the parameter of concern is also the minimum hot channel DNBR. Factors that would cause a decrease in DNBR include an increase in coolant temperature, a decrease in coolant pressure, an increase in local heat flux (including radial and axial power distribution effects), and a decrease in coolant flow rate. Evaluation of postulated single failures shows that the worst single failure for this event is a LOP following a turbine trip, which would cause the RCPs to coast down and rapidly reduce the coolant flow rate.

The infrequent event involving an increase in main steam flow is initiated by the quick opening of eight SBCVs combined with LOP. This event is bounded by the IOSGADVLOP event with respect to the DNBR SAFDL and dose consequences for those events involving an increase in heat removal by the secondary system.

The SBCS malfunction with a LOP is still bounded by the infrequent event described in the UFSAR Appendix 15.E, the Loss of Flow (LOF) from a SAFDL. The LOF from a SAFDL establishes a limiting infrequent event with respect to DNBR degradation for all moderate frequency events in combination with a single failure by assuming that the DNBR is already at the SAFDL when the LOF occurs. The minimum DNBR during the limiting moderate frequency event involving increased main steam flow remains above the DNBR SAFDL and, when combined with LOP following a turbine trip, would yield a minimum DNBR that is higher than that for the LOF from a SAFDL. Hence, the limiting infrequent

event for an increase in main steam flow (quick opening of eight SBCVs with a single failure) is bounded with respect to the DNBR by the IOSGADVLOP and the limiting infrequent event evaluated in UFSAR Appendix 15.E.

15.1.3.3.1 Mathematical Models

The moderate frequency event for an increase in main steam flow was analyzed with the following mathematical models:

- The CENTS computer code was used to simulate the NSSS transient response. The CENTS computer code is described in UFSAR Section 15.0.3.1.3.2 and in an NSSS vendor topical report.[(1)(2)]

- The CPC FORTRAN computer code was used to simulate CPC reactor trip functions and to predict the time at which the CPC VOPT setpoint would be reached. This time, with appropriate delays for signal processing and opening of the reactor trip breakers, was utilized in CENTS code input. The CPCs are described in UFSAR Section 7.2, and associated algorithms and simulation code are described in NSSS vendor topical reports.[(3)(4)]

- The CETOP-D computer code, which uses the CE-1 Critical Heat Flux (CHF) correlation, was used to calculate the initial and transient DNBR values. CETOP-D was also used to determine initial Power Operating Limit (POL) conditions for this event (see UFSAR Section 15.1.3.3.2 for additional information on POL conditions). The

CETOP-D computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports.[5][6][7]

15.1.3.3.2 Input Parameters and Initial Conditions

Table 15.1.3-2 summarizes the key input parameters and initial conditions utilized in the safety analysis for the limiting moderate frequency event involving an increase in main steam flow.

The following points serve to explain the selection of initial conditions as they appear in Table 15.1.3-2:

- During normal plant power operations, the Core Operating Limits Supervisory System (COLSS) monitors various parameters to assist operators in maintaining plant conditions within the Technical Specification Limiting Conditions for Operation (LCOs). When COLSS is in service, it continuously calculates the core power at which the DNBR SAFDL would be reached, based on the measured temperature, pressure, flow, radial peaking factor, and axial power distribution. This COLSS-calculated core power is then divided by a numerical value, called the Required Overpower Margin (ROPM), to yield a DNBR Power Operating Limit (POL). If the measured core power exceeds the calculated POL, a COLSS alarm would alert plant operators to take action as required by Technical Specifications. The DNBR POL therefore serves to preserve thermal margin to accommodate potential operational transients. For this

safety analysis, it was assumed that the plant would be operating at a POL condition immediately prior to the event, at the most limiting RCS flow rate. Because the event simulation was initiated from a calculated POL, additional power measurement uncertainties were not added to the initial assumed core power level. Analytical values for the initial core inlet temperature, pressurizer pressure, and RCS coolant flow rate corresponding to the POL were determined with the CETOP-D computer code, for an initial core power of 100% of RTP.

Table 15.1.3-2

INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE STEAM BYPASS CONTROL SYSTEM MALFUNCTION SAFETY ANALYSIS

Parameter	Assumed Value
Initial Core Power (% of RTP)	100%
Initial core Inlet Temperature (¡F)	566
Initial Pressurizer Pressure (psia)	2100
Initial RCS Flow Rate (% of Design Rated)	110.4
Initial Pressurizer Water Level (% Narrow Range)	24
Initial Steam Generator Water Level (% Wide Range)	80.7
Moderator Temperature Coefficient ($\Delta\rho$/¡F)	$-2.25x10^{-4}$
Doppler Fuel Temperature Coefficient	Least Negative
Delayed Neutron Kinetics	EOC
Axial Shape Index for DNBR calculation	-0.2
CEA Worth at Trip (%$\Delta\rho$)	8.0
Fuel Rod Gap Conductance (BTU/hr-ft^2-¡F)	6100
Total Number of Plugged Steam Generator Tubes	0
Single Failure	None

- DNBR degradation during the event is sensitive to the initial pressurizer water level and a minimum value was selected for the initial conditions, based on parametric evaluation.

- DNBR degradation during the event is not sensitive to the initial steam generator level unless a high steam generator level trip were credited. Since no credit is taken for that trip, it was disabled and nominal values were used for initial steam generator level. The CENTS code automatically calculates the initial steam generator pressure, given steam generator water level, reactor power, and other inputs to the computer code.

- The SBCS malfunction event causes a rapid cooldown of the RCS. Using the most negative MTC allowed by the Technical Specifications and COLR would result in the most rapid power increase and the greatest overshoot in power after the VOPT. However, because the heat flux lags behind the power, it does not necessarily produce the greatest decrease in DNBR. As the MTC is made less negative, the power excursion is slowed down. This allows the heat flux to stay closer to the power and it allows the VOPT to shift upwards a small amount. The heat flux at the time of minimum DNBR increases for this event as the MTC is made less negative and the DNBR decreases. As the MTC is made less and less negative, a point is reached at which the LSGPT and the VOPT are reached concurrently. This MTC results in the lowest

minimum DNBR. Making the MTC less negative will result in the LSGPT occurring with the power below the VOPT setpoint. This decreases the heat flux and increases the minimum DNBR. The value shown in Table 15.1.3-2 corresponds to the limiting case, for which the VOPT and LSGPT occur at approximately the same time.

- The least negative Doppler fuel temperature coefficient curve, which corresponds to Beginning of Cycle (BOC) conditions, was used. Use of the least negative values minimizes the addition of negative reactivity caused by increasing fuel temperature. This is not important for cases with intermediate values of MTC, but for the case with the most negative MTC, this choice will result in a more rapid increase in reactor core power.

- End of Cycle (EOC) values were chosen to model delayed neutron kinetics. EOC values enhance the power excursion by minimizing the effect of delayed neutrons on the rate of power increase. This is not important for cases with intermediate values of MTC, but for the case with the most negative MTC, this choice will result in a more rapid increase in reactor core power.

- If power generation is shifted toward the bottom of the core, the insertion of negative reactivity following reactor trip will be somewhat delayed until the CEAs have inserted farther into the core. The scram reactivity curve was therefore based on a positive ASI representing a bottom-peaked core. The time versus scram reactivity curve was

adjusted to account for a 0.6-second CEA holding coil time delay following opening of the reactor trip breakers, and normalized to model 90% CEA insertion at 4.0 seconds after power is removed from Control Element Drive Mechanism (CEDM) coils, (see UFSAR Section 3.9.4).

- The CEA worth at trip represents the minimum SCRAM worth for Hot Full Power (HFP) conditions at BOC, assuming the most reactive CEA remains stuck out of the core following reactor trip. This is more limiting (less negative) than the anticipated scram reactivity worth at other times during the operating cycle for HFP conditions.

- The fuel rod gap conductance value was selected in a manner that energy from the fuel would quickly reach the surface of the fuel rod clad. A large value results in a higher heat flux and greater degradation of DNBR during the initial power excursion.

- It was assumed that steam generator tubes were not plugged for this safety analysis. This enhances heat transfer from the RCS to the main steam system, which in turn enhances the initial RCS cooldown and maximizes the positive reactivity insertion due to the negative MTC. Additionally, this enhances the decrease in RCS pressure during the cooldown, which serves to degrade DNBR.

- For the moderate frequency event involving an increase in main steam flow, an additional single failure was not assumed.

For those safety-related Reactor Protective System (RPS) and Engineered Safety Features Actuation System (ESFAS) setpoints and response times that had a direct effect on acceptance criteria for this event, analytical values were chosen to be consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

15.1.3.3.3 Results

The analysis shows that the calculated minimum DNBR approaches a value of 1.41 at 8.5 seconds following event initiation. This value is greater than the DNBR SAFDL of 1.34. The linear heat rate will not present a credible challenge to fuel centerline melting. Therefore, fuel damage is not predicted to occur for this event.

15.1.3.4 RCS Pressure Boundary Barrier Performance

The increased steam flow events are characterized by a cooldown and depressurization of the primary and secondary systems in the short-term. However, this initial cooldown and depressurization is reversed after automatic halting of the steam flow following an MSIS resulting in heat-up and repressurization of primary and secondary systems. A comparison of the RCS pressures and temperatures shows that the RCS temperature and pressure decrease for the increased main steam flow event due to the opening of one SBCV is similar to that for the IOSGADV event described in UFSAR Section 15.1.4 because of the same flow capacity of an ADV and SBCV (11% of

the DSR). Opening of more SBCVs would result in a larger cooldown and depressurization of the RCS than the IOSGADV event in the short-term. Additionally, over the longer term, steam flow through the open SBCVs would be halted automatically following an MSIS and controlled heat removal would be achieved by both steam generators, while an IOSGADV event would result in dry-out of one steam generator and long-term controlled heat removal would be achieved through only one steam generator. As a result of the increased cooling from the stuck-open ADV, the RCS would be cooler for the IOSGADV for several minutes post-SCRAM. However, because the heat is being removed through only one steam generator, the RCS temperature and pressure for the IOSGADV would be significantly higher than that for the SBCS malfunction in the long term. Secondary pressures are limited by the MSSV setpoints and will be no greater for the SBCS malfunction than the intact steam generator in the IOSGADV. Based on the above, the maximum primary and secondary pressures for moderate frequency and infrequent events involving a main steam flow increase (inadvertent opening of one or more SBCVs) are bounded by those for moderate frequency and infrequent IOSGADV events, respectively.

15.1.3.5 Containment Performance and Radiological Consequences

An increase in main steam flow event in combination with an additional single failure (for example, LOP following turbine trip) is classified as an infrequent event. Offsite radiological dose consequences are limited to a small fraction, or 10%, of 10 CFR Part 100 guideline values. Additionally,

radiation exposures for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A. The offsite and control room radiological dose consequences associated with this infrequent event are bounded by those that may result from an IOSGADVLOP event, and are in compliance with regulatory guidelines (see UFSAR Section 15.1.4.5).

15.1.3.6 Conclusions

Evaluation of the increase in main steam flow event shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- For the moderate frequency increase in main steam flow event (without an additional single failure), fuel cladding integrity will be maintained.
- For the infrequent increase in main steam flow event (with an additional single failure), limited fuel cladding degradation may occur. However, offsite and control room radiological dose consequences are bounded by those that may result from an IOSGADVLOP event, and are in compliance with regulatory guidelines (see UFSAR Section 15.1.4)

15.1.4 INADVERTENT OPENING OF A STEAM GENERATOR ATMOSPHERIC DUMP VALVE

15.1.4.1 Identification of Causes and Frequency Classification

An IOSGADV is postulated to occur as a result of an inadvertent operator action or equipment malfunction in the valve control system.

An IOSGADV event is classified as an incident of moderate frequency. An IOSGADV event in combination with an additional single failure is classified as an infrequent event.

15.1.4.2 Sequence of Events and System Operation

The sequence of events and NSSS response to an IOSGADV event is similar to that described in UFSAR Section 15.1.3 for the increase in main steam flow event involving a sudden opening of the same or one or more SBCS valves. An IOSGADV event, however, would result in a smaller short-term increase in the main steam flow rate than the SBCS malfunction event which evaluates opening of one or more (up to eight) SBCS valves – each with flow capacity equal to that of an ADV. Additionally, over the longer term, steam flow through the open ADV would not be halted automatically following an MSIS, and the affected SG would continue to discharge steam to the atmosphere, eventually drying out. Therefore, the short-term NSSS response to an IOSGADV event would occur more slowly than for the SBCS malfunction event, but long-term controlled heat removal would be achieved through one rather than both steam generators.

Table 15.1.4-1 provides the sequence of events for an IOSGADV event in which a single failure involving a LOP after turbine trip has been assumed. This sequence of events was obtained by simulating the event with the computer codes identified in UFSAR Sections 15.1.4.3 and 15.1.4.4. Figures 15.1.4-1 through 15.1.4-14 depict the response of key NSSS parameters during this event.

An inadvertent opening of a steam generator ADV causes the main steam flow rate to increase (Figure 15.1.4-1), which results in a decrease in RCS hot leg, cold leg, and average coolant temperatures (Figures 15.1.4-2, 15.1.4-3, and 15.1.4-4, respectively). In the presence of a negative MTC, the decrease in RCS temperature results in an increase in reactivity (Figure 15.1.4-5), core power (Figure 15.1.4-6), and core heat flux (Figure 15.1.4-7). The increase in main steam flow rate would likewise cause a short-term increase in the indicated steam generator water level due to swell effects (Figure 15.1.4-8) and a decrease in both RCS and steam generator pressures (Figures 15.1.4-9 and 15.1.4-10, respectively). Despite the short-term increase in indicated steam generator water level, 2the mass of liquid in both

Table 15.1.4-1

SEQUENCE OF EVENTS FOR THE IOSGADVLOP SAFETY ANALYSIS

Time	Event
0.0	Inadvertent opening of an SG ADV
187.97	Steam generator pressure reaches reactor trip setpoint
187.97	Steam generator pressure reaches MSIS setpoint
187.97	Turbine trip occurs
187.97	LOP occurs
189.12	Reactor trip breakers open
189.73	CEAs begin to fall
190.64	Minimum DNBR occurs
193.58	MSIVs close. Steam flow from unaffected steam generated halted
239.67	MSSVs open, unaffected SG
255.79	Pressurizer empties
269.74	MSSVs close, unaffected SG
270.46	Pressurizer pressure reaches SIAS setpoint
310.48	HPSI pumps begin injecting into the RCS
1119.50	Affected SG dries out
1800.00	Plant operators close the open ADV on affected SG
1800.00	Plant operators take control of the plant

steam generators would not change significantly during the first few minutes of the transient (Figure 15.1.4-11).

Detection of the event may be accomplished by a high reactor power alarm, an RCS low pressure alarm, or a steam generator low pressure alarm. Reactor trip may be initiated by the CPCs on VOPT or an approach to the DNBR SAFDL, or by the RPS on a low steam generator pressure trip. As the event proceeds, the steam generator pressure decreases and approaches the Low Steam Generator Pressure Trip (LSGPT). For negative values of MTC, reactor power also increases toward a CPC auxiliary trip, the Variable Overpower Trip (VOPT). A VOPT will occur before the LSGPT for more negative values of MTC; however, for less negative values of MTC, the power increase may not be sufficient to result in the VOPT before the steam generator pressure reaches the LSGPT. The most limiting analysis case, which yielded the lowest DNBR value, was found to occur when the VOPT and LSGPT trips occurred at approximately the same time. Table 15.1.4-1 reflects a trip due to low steam generator pressure, with an MSIS occurring simultaneously at the analysis low steam generator pressure setpoint.

A turbine trip would occur following the reactor trip. The IOSGADVLOP case considers that the transmission network becomes unstable and collapses upon the sudden loss of generating capacity from the affected unit. A LOP would occur following the turbine trip. At least three seconds of offsite power is anticipated following the turbine trip (see UFSAR Section 15.0), however, the safety analysis results presented

in Table 15.1.4-1 conservatively model a simultaneous reactor trip, turbine trip, and LOP. This conservative assumption is tied to NRC acceptance of the fuel failure analysis convolution methodology. All four RCPs would then begin to coast down as a result of the LOP cutting power to the RCP motors, and the RCS would transition from forced flow to natural circulation conditions.

Short-term cooling of the RCS would increase coolant density, causing pressurizer level to decrease and the pressurizer to temporarily empty (Figure 15.1.4-12). The short-term increase in core heat flux and decrease in RCS pressure would, however, effectively reduce coolant subcooling and thereby cause the hot channel DNBR to decrease. DNBR would be degraded further in the first few seconds following the LOP, due to the rapid decrease in RCS flow rate as the RCPs coast down (Figure 15.1.4-13). CEAs will also fall into the reactor core following the reactor trip, rapidly reducing reactivity, core power, and core heat flux. As indicated in Table 15.1.4-1, minimum DNBR is predicted to occur shortly after the CEAs begin inserting into the core.

The MSIS would result in closure of the MSIVs, thereby halting the flow of steam from the unaffected or intact steam generator, which serves to maintain secondary system inventory. The MSIS would also result in closure of the MFIVs, stopping the flow of main feedwater to both steam generators (Figure 15.1.4-14). Because the RCS hot leg temperature would be higher than the temperature in the intact steam generator

following the MSIS, heat transfer from the RCS would continue to that steam generator. Eventually, the intact steam generator would heat up and repressurize to the lift setting of the first bank of MSSVs. The affected steam generator, however, would continue to blow down and depressurize because its open ADV is located upstream of the MSIVs. The affected steam generator would therefore eventually dry out.

The safety analysis predicts that AFW flow would not be automatically delivered to either steam generator. In the case of the unaffected steam generator, the safety analysis shows that closure of the MSIVs and FWIVs effectively preserves secondary system inventory, so that steam generator’s water level does not decrease to the AFAS setpoint within the first thirty minutes of the event sequence. Additionally, the analysis shows that AFW flow is not automatically delivered to the affected steam generator, even though its water level steadily decreases to the AFAS setpoint. This is due to an AFW Lockout that occurs when the affected steam generator’s pressure decreases significantly below the pressure in the unaffected steam generator. The AFW Lockout, that is based on the pressure difference between steam generators prevents addition of feedwater to the affected steam generator, and thus a loss of AFW inventory to the environment via the affected steam generator.

While blowdown continues through the open ADV on the affected steam generator, heat losses from the RCS to the secondary system would exceed the heat generation rate in the RCS which,

after a reactor trip and LOP, would be limited to decay heat from radioactive isotopes in the core and heat released by metallic components and structures in the NSSS. Pressurizer pressure would therefore decrease to the SIAS setpoint. Safety injection flow would be delivered to the RCS, however, only when RCS pressure decreases below the shutoff head of the HPSI pumps.

Following dryout of the affected steam generator, heat losses from the RCS to the secondary system would decrease sharply, and the RCS would begin to heat up. RCS repressurization would occur due to safety injection flow as well as the heat released by fission product decay and hot metal structures in the NSSS. The rate of heat transfer to the unaffected steam generator would also decrease as the temperature difference between that steam generator and its associated RCS hot leg decreased. The safety analysis shows that both the PSVs and the first bank of MSSVs would eventually lift to relieve pressure in the NSSS and to provide additional energy removal from the primary and secondary systems.

Operator action is not credited in the IOSGADVLOP safety analysis until thirty minutes following event initiation. At that time, it is assumed that plant operators will take action to manually close the ADV and to initiate a controlled plant cooldown to SDC entry conditions.

15.1.4.3 Core and System Performance

A moderate frequency IOSGADV event would result in an RCS cooldown that is similar to, but slower than, that caused by an increase in main steam flow event involving the quick opening of eight SBCS valves (see UFSAR Section 15.1.3). However, due to the more limiting MTC value chosen for this event, the reactor trip is delayed until the SGLPT occurs. The results of the IOSGADV are very close to the SBCS malfunction event, even though that event results in a greater increase in main steam flow and a faster RCS cooldown.

For the infrequent IOSGADVLOP event, the parameter of concern is likewise the minimum hot channel DNBR. Factors that would cause a decrease in DNBR include an increase in coolant temperature, a decrease in coolant pressure, an increase in local heat flux (including radial and axial power distribution effects), and a decrease in coolant flow rate. Evaluation of postulated single failures shows that the worst single failure for this event is a LOP following a turbine trip, which would cause the RCPs to coast down and rapidly reduce the coolant flow rate. This event results in a NSSS response that is similar to, that caused by the increase in main steam flow event involving the quick opening of eight SBCS valves in combination with LOP (See UFSAR Section 15.1.3). However, even though the quick opening of eight SBCS valves results in more severe RCS cooldown and higher increase in power, the IOSGADVLOP event results in a more limiting minimum hot channel DNBR than other infrequent events involving an increase in heat

removal. For this reason, the infrequent IOSGADV event (in combination with a single failure) bounds the infrequent event involving the quick opening of eight SBCS valves (in combination with single failure) with respect to the DNBR SAFDL.

15.1.4.3.1 Mathematical Model

The limiting infrequent event involving an increase in heat removal by the secondary system – an IOSGADVLOP – was analyzed with respect to RCS pressure boundary performance with the following mathematical models:

- The CENTS computer code was used to simulate the NSSS response, including the predicted time of reactor trip due to low steam generator pressure. The CENTS computer code is described in UFSAR Section 15.0.3.1.3.2 and in an NSSS vendor topical report.[1][2]

- The CETOP-D computer code, which uses the CE-1 CHF correlation, was used to determine the initial DNBR POL conditions for this event (see UFSAR Section 15.1.4.4.2 below). The CETOP-D computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports.[5][6][7]

15.1.4.3.2 Input Parameters and Initial Conditions

Table 15.1.4-2 and 15.1.4-3 summarizes the key input parameters and initial conditions utilized in the safety analysis for an IOSGADV and IOSGADVLOP event. The following points serve to

explain the selection of initial conditions as they appear in Table 15.1.4-2:

- During normal power operations, the Core Operating Limits Supervisory System (COLSS) monitors various parameters to assist operators in maintaining plant conditions within the Technical Specification LCOs. When COLSS is in-service, it continuously calculates the core power at which the DNBR SAFDL would be reached, based on the measured temperature, pressure, flow, radial peaking factor, and axial power distribution. This COLSS-calculated core power is then divided by a numerical value, called the Required Overpower Margin (ROPM), to yield a DNBR Power Operating Limit (POL). If the measured core power exceeds the calculated POL, a COLSS alarm would alert plant operators to take action as required by Technical Specifications. The DNBR POL therefore serves to preserve thermal margin to accommodate potential operational transients. For this safety analysis, it was assumed that the plant would be operating at a POL condition immediately prior to the event, at the most limiting RCS flow rate. Because the event simulation was initiated from a calculated POL, additional power measurement uncertainties were not added to the initial assumed core power level. Analytical values for the initial core inlet temperature, pressurizer pressure, and RCS coolant flow rate corresponding to the POL were determined with the CETOP-D computer code, for an initial core power of 100% of RTP.

Table 15.1.4-2
INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE
IOSGADV SAFETY ANALYSIS

Parameter	Value
Initial Core Power (% of RTP)	100%
Initial Core Inlet Temperature (°F)	566
Initial Pressurizer Pressure (psia)	2100
Initial RCS Flow Rate (% of Design Rated)	110.4
Initial Pressurizer Water Level (% Narrow Range)	24
Initial Steam Generator Water Level (% Wide Range)	86
Moderator Temperature Coefficient ($\Delta\rho$/°F)	$-0.20\text{x}10^{-4}$
Doppler Fuel Temperature Coefficient	Least Negative
Delayed Neutron Kinetics	BOC
Axial Shape Index for DNBR Calculation	-0.2
CEA Worth at Trip (%$\Delta\rho$)	8.0
Fuel Rod Gap Conductance (BTU/hr-ft^2-°F)	6100
Total Number of Plugged Steam Generator Tubes	0
Single Failure	None

INCREASE IN HEAT REMOVAL

BY THE SECONDARY SYSTEM

Table 15.1.4-3
INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE
IOSGADV SAFETY ANALYSIS

Parameter	Value
Initial Core Power (% of RTP)	100%
Initial Core Inlet Temperature (°F)	566
Initial Pressurizer Pressure (psia)	2100
Initial RCS Flow Rate (% of Design Rated)	110.4
Initial Pressurizer Water Level (% Narrow Range)	24
Initial Steam Generator Water Level (% Wide Range)	86
Moderator Temperature Coefficient ($\Delta\rho$/°F)	-0.40×10^{-4}
Doppler Fuel Temperature Coefficient	Least Negative
Delayed Neutron Kinetics	BOC
Axial Shape Index for DNBR Calculation	-0.2
CEA Worth at Trip (%$\Delta\rho$)	8.0
Fuel Rod Gap Conductance (BTU/hr-ft^2-°F)	662
Total Number of Plugged Steam Generator Tubes	0
Single Failure	LOP

- Parametric evaluation determined that the DNBR degradation during the event is sensitive to the initial pressurizer water level, and the minimum pressurizer water level was used.

- Parametric evaluation determined that the DNBR degradation during the event is sensitive to the initial steam generator water level, and the maximum initial steam generator water level was used. The CENTS code automatically calculates the initial steam generator pressure, given steam generator water level, reactor power, and other inputs to the computer code.

- The IOSGADVLOP event causes a slower cooldown of the RCS than the SBCS malfunction, but the LOP portion of the event causes a heatup of coolant in the core region as the flow rate decreases during RCP coastdown. Using the most negative MTC allowed by the Technical Specifications and COLR would result in the most rapid power increase and the greatest overshoot in power after the VOPT. However, because the heat flux lags behind the power, it does not necessarily produce the greatest decrease in DNBR. As the MTC is made less negative, the power excursion is slowed down. This allows the heat flux to stay close to the power and it allows the VOPT to shift upwards a small amount. The heat flux at the time of minimum DNBR increases for this event as the MTC is made less negative and the DNBR decreases. As the MTC is made less and less negative, a point is reached at which the

LSGPT and the VOPT are reached concurrently. This MTC results in the lowest minimum DNBR.

- The least negative Doppler fuel temperature coefficient curve, at BOC, was assumed. Least negative values minimize the addition of negative reactivity caused by increasing fuel temperature.

- BOC values were chosen to model delayed neutron kinetics, based on the parametric study described above.

- If power generation in the core is shifted toward the bottom, the insertion of negative reactivity following reactor trip will be somewhat delayed until the CEAs have inserted farther into the core. The scram reactivity curve was therefore based on a positive ASI representing a bottom-peaked core. The time versus scram reactivity curve was adjusted to account for a 0.6-second CEA holding coil time delay following opening of the reactor trip breakers, and normalized to model 90% CEA insertion at 4.0 seconds after power is removed from CEDM coils (see UFSAR Section 3.9.4). However, for DNBR calculations, having power at the top of the core would be more limiting and the ASI for the DNBR calculations was based on a negative ASI.

- The CEA worth at trip represents the minimum scram worth for HFP conditions at BOC, assuming the most reactive CEA remains stuck out of the core following reactor trip. This is more limiting (less negative) than the

anticipated scram reactivity worth at other times during the operating cycle for HFP conditions.

- For the fuel rod gas gap conductance, a high value was selected for IOSGADV and a low value was selected for IOSGADVLOP, based on the parametric study described above.
- It was assumed that steam generator tubes were not plugged for this safety analysis, based on the parametric study described above.
- For the limiting infrequent event analysis, an additional single failure involving a LOP was assumed.

For those safety-related Reactor Protective System (RPS) and Engineered Safety Features Actuation System (ESFAS) setpoints and response times that had a direct effect on acceptance criteria for this event, analytical values were chosen to be consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

15.1.4.3.3 Results

The moderate frequency IOSGADV and infrequent IOSGADVLOP events would not challenge fuel pellet integrity. During these events, any short-term increase in reactor power, or three-dimensional shift in power generation within the core, would not be of sufficient magnitude to raise the linear heat rate above that required to cause fuel centerline melting.

The analysis shows that the calculated minimum DNBR for the IOSGADV event approaches a value of 1.40 at 138 seconds following event initiation. This value is greater than the DNBR SAFDL of 1.34.

For the infrequent IOSGADVLOP event (i.e., an IOSGADV event with an additional single failure), limited fuel cladding degradation may occur. However, offsite radiological dose consequences will not exceed a small fraction, or 10%, of 10 CFR Part 100 guideline values. Likewise, control room dose consequences will not exceed the limits specified by GDC 19 of 10 CFR 50 Appendix A.

15.1.4.4 RCS Pressure Boundary Barrier Performance

The IOSGADV and IOSGADVLOP events, like the SBCS malfunction event described in UFSAR Section 15.1.3, are characterized by an initial cooldown of the primary and secondary systems, and decreasing RCS and steam generator pressures. However, because the affected steam generator would dry out even following an MSIS, heat removal after an IOSGADV or IOSGADVLOP event must be accomplished through only one intact steam generator, at least until plant operators take action to close the open ADV on the affected steam generator. Therefore, unlike the SBCS malfunction event, heat removal may not be sufficient to prevent repressurization of the RCS and the unaffected steam generators. For this reason, the IOSGADV is the limiting moderate frequency (and limiting infrequent, when combined with single failure) event involving an increase in heat removal by

the secondary system with respect to RCS pressure boundary performance.

The performance of the RCS pressure boundary is evaluated herein for the limiting infrequent event involving an increase in heat removal by the secondary system with a single failure, an IOSGADVLOP. The conclusions, however, also apply to the moderate frequency IOSGADV event, because peak pressures in the RCS and secondary systems are limited by PSV and MSSV setpoints and capacities, respectively.

15.1.4.4.1 Mathematical Model

The mathematical model is the same as described in Section 15.1.4.3.1.

15.1.4.4.2 Input Parameters and Initial Conditions

The input parameters and initial conditions are the same as described in Section 15.1.4.3.2.

15.1.4.4.3 Results

The IOSGADVLOP safety analysis shows that pressurizer pressure may increase to the maximum PSV lift setting allowed by the Technical Specifications around the end of the 30-minute simulation. Immediately prior to the PSV lift the peak RCS pressure is calculated to be less than 2560 psia, for both RTPs which is below the regulatory limit for this event (i.e., 110% of the RCS design pressure of 2500 psia, or 2750 psia).

The IOSGADVLOP safety analysis, like the SBCS malfunction analysis described in UFSAR Section 15.1.3, also shows that the peak secondary system pressure occurs when the first bank of MSSVs cycle open. The calculated peak secondary system pressure is less than 1305 psia, which is below the regulatory limit for this event (i.e., 110% of the steam generator shell side design pressure of 1270 psia, or 1397 psia).

Therefore, the peak RCS and secondary system pressures will not pose a challenge to the RCS pressure boundary, for the limiting moderate frequency and infrequent event, with respect to pressure limits, involving an increase in heat removal by the secondary system.

15.1.4.5 Containment Performance and Radiological Consequences

An inadvertent opening of a steam generator ADV in combination with an additional single failure (i.e., LOP following turbine trip) is classified as an infrequent event. Offsite radiological dose consequences are limited to a small fraction, or 10%, of 10 CFR Part 100 guideline values. Additionally, radiation exposures for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A.

Control room radiological assessments for bounding unfiltered inleakage are presented in UFSAR Section 6.4.7. The results presented in that UFSAR section for a postulated Reactor Coolant Pump (RCP) sheared shaft event with a stuck open ADV bound the anticipated control room exposure for the IOSGADVLOP event. The RCP sheared shaft event is predicted to result in a

higher percentage of fuel failure than the IOSGADVLOP event which, in combination with a stuck open ADV, would result in a correspondingly higher control room dose than the IOSGADVLOP event.

The offsite radiological dose consequences associated with the infrequent IOSGADVLOP event are evaluated in the following UFSAR subsections.

15.1.4.5.1 Mathematical Models

For the offsite radiological dose assessment, activity in the RCS is calculated on the basis of the pre-event radioiodine and noble gas activity levels (which are limited by plant Technical Specifications), to which is added the anticipated post-event increase in activity levels due to fuel pin failures. The increase in activity levels due to fuel pin failures is dependent upon the radial peaking factor, which affects the radionuclide inventory in the fuel rod gas gap, as well as the fuel failure fraction, which defines the number of pins that are assumed to release radionuclides to the RCS coolant.

Once the activity level in the RCS is determined, the amount of activity carried over to the steam generators by primary-to-secondary leakage is calculated. All of the activity that is contained in or leaked to the affected steam generator within the first 30 minutes of the event is assumed to be released to the atmosphere. At 30 minutes, analytical credit is taken for plant operators closing the open ADV on the affected steam generator, thereby halting the release of radionuclides from that steam generator to the environment.

Activity that leaks into the unaffected steam generator is assumed to mix with that steam generator's secondary inventory. The level of activity in this generator will therefore increase as the event proceeds. After the operators close the ADV on the affected steam generator, they may begin a controlled cooldown using the unaffected steam generator. The activity released from the unaffected steam generator to the environment may then be determined, based on a steaming rate that will remove decay heat and successfully cool down the NSSS to SDC entry conditions.

Based on the activity releases, the thyroid and whole body doses at the Exclusion Area Boundary (EAB) and Low Population Zone (LPZ) are calculated as a function of the product of the radial peaking factor (Fr) and fuel failure fraction (FF). The production of Fr and FF that just corresponds to the acceptance limits, that is a small fraction (10%) of 10 CFR Part 100 guideline values, is calculated from this functional relationship. As long as this calculated product for a reload does not exceed the value corresponding to the acceptance limits, the calculated doses for that reload will not exceed the acceptance limits.

15.1.4.5.2 Input Parameters and Initial Conditions

Offsite radiological dose consequences associated with the IOSGADVLOP event were analyzed under the assumptions listed in Section 15.0.4 and the following conditions:

1. Isotope inventories were based on a core power level of 4070 MWt, or 102% of the RTP of 3990 MWt.

2. Based on Technical Specification limits, the initial assumed activity in the NSSS was:

   - RCS Dose Equivalent (DEQ) I-131: 1.0 μCi/gm
   - RCS Noble Gas(DEQ) Xe-133: 550 μCi/gm
   - Secondary System DEQ I-131: 0.10 μCi/gm

3. An RCS liquid mass of 555,000 lbm of water was used in the analysis, including 45,000 lbm of water in the pressurizer. Additionally, 4,500 lbm of steam was assumed to be in the pressurizer. Although the RCS may hold more mass, these values were selected to increase the iodine concentration following postulated fuel failures, which conservatively increases offsite dose consequences.Since the PSVs lift for this event, the dose calculation conservatively takes into account the activity released to containment, even though the Reactor Drain Tank is sized to remain intact from the PSV discharge.

4. A steam generator liquid mass of 160,600 lbm per steam generator was used in the analysis. Although the steam generators may hold more mass, this value was selected to increase the iodine concentration in the affected steam generators, which conservatively increases offsite dose consequences.

5. A primary-to-secondary leak rate of 0.5 gpm (720 gallons per day) per steam generator was assumed. This is consistent with the PVNGS Technical Specification 5.5.9.

6. It was assumed that 10% of the iodine and noble gas inventories in the fuel pins were resident in the fuel rod gas gap, and available for release upon clad rupture.

7. All of the activity in the fuel rod gas gap was assumed to be released to the RCS coolant upon fuel pin failure.

8. All of the iodines associated with leakage to the affected steam generator were assumed to be released to the environment i.e. with a decontamination factor of 1.0, until the open ADV was closed at 30 minutes into the event sequence. After 30 minutes, the affected steam generator did not contribute further to radiological releases, because all subsequent steaming associated with decay heat removal and controlled plant cooldown were assumed to occur through the unaffected steam generator.

9. Iodines associated with leakage to the unaffected steam generator are released to the environment during steaming with decontamination factor of 100 since the steam generator inventory, i.e. level, is maintained.

10. It was assumed that plant operators would not initiate a controlled plant cooldown to SDC entry conditions for at least 30 minutes following event initiation. However, it should be noted that a faster RCS cooldown rate would

increase steam releases during the first two hours following the event, which would produce more severe thyroid doses at the EAB. On the other hand, a slower RCS cooldown rate would allow radionuclide concentrations to build up in the secondary system, which would produce more severe 8-hour doses at the LPZ. Therefore, radiological dose calculations were performed using two different cooldown rates:

- A maximum Technical Specification cooldown rate of 100°F/hr, initiated at 30 minutes into the event sequence.
- A slower cooldown rate of 40°F/hr, initiated at 30 minutes into the event sequence, which would bring the RCS to SDC entry conditions at approximately 8 hours following event initiation.

11. Decay heat during the 8-hour period following the event was based on the 1979 ANS decay heat curve, with a 2σ uncertainty. Use of a maximum decay heat curve increases the amount of steam released to the environment, thereby resulting in more severe dose consequences.

12. Although the LOP would cause the RCPs to coast down during an IOSGADVLOP event, it was conservatively assumed that all four RCPs would remain in operation for the radiological dose analysis. Therefore, 26 MWt of RCP heat was added to the 2-hour EAB and 8-hour LPZ dose

calculations, which conservatively increased steam releases and offsite doses during the controlled cooldown.

13. A value of 740,000 BTU/°F was used to represent the specific heat capacity of the RCS, the RCS clad, and the steam generators. Use of this value increases the amount of steam that must be released to the environment during the controlled cooldown.

14. The χ/Q atmospheric dispersion factors used in the analysis are the short-term factors shown in UFSAR Table 2.3-31.

15. Although the results of the transient simulation of IOSGADVLOP shows the DNBR remained above SAFDL and thus no fuel pin failures occurred, the radiological dose analysis conservatively assumes a fuel failure fraction of 5.5%.

16. A radial peaking factor of 1.72, corresponding to the maximum allowable radial peaking factors for PVNGS cores, was used in the analysis.

15.1.4.5.3 Results

An IOSGADV in combination with an additional single failure (a LOP following turbine trip) is classified as an infrequent event, which may result in limited fuel cladding degradation. Offsite radiological dose consequences are limited to a small fraction or 10%, of 10 CFR Part 100 guideline values. Therefore the radiological limits for the limiting infrequent increase in heat removal by the secondary system event, IOSGADVLOP are 30 Rem for the thyroid and 2.5 Rem for the whole body. Additionally, radiation exposures for control room personnel are subject to the limits specified in GDC 19 of 10 CFR 50 Appendix A.

The radiological dose analysis conservatively assumed 5.5% fuel failure in the bounding analysis for dose consequences. The results of the IOSGADVLOP radiological dose analysis for this assumed percentage of failed fuel are shown in Table 15.1.4-4.

Table 15.1.4-4
OFFSITE RADIOLOGICAL DOSES FOR IOSGADVLOP SAFETY ANALYSES

Thyroid Dose (REM)		Whole Body Dose (REM)	
0-2 Hour EAD	0-8 Hour LPZ	0-2 Hour EAB	0-8 Hour LPZ
25.1	12.6	0.7	0.7

The dose consequences remain below the acceptance criteria for the IOSGADVLOP event.

15.1.4.6 Conclusion

Evaluation of the IOSGADV event shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- For the moderate frequency IOSGADV event (without an additional single failure), fuel cladding integrity will be maintained.
- For the infrequent IOSGADVLOP event (i.e., an IOSGADV event with an additional single failure), limited fuel cladding degradation may occur. However, offsite radiological dose consequences will not exceed a small fraction, or 10%, of 10 CFR Part 100 guideline values. Likewise, control room dose consequences will not exceed the limits specified by GDC 19 of 10 CFR 50 Appendix A.

15.1.5 STEAM SYSTEM PIPING FAILURES INSIDE AND OUTSIDE CONTAINMENT – OPERATING MODES 1 AND 2

15.1.5.1 Identification of Causes and Frequency Classification

A Main Steam Line Break (MSLB) is a postulated break or rupture of a pipe in the main steam system, either inside or outside the containment building.

A MSLB is classified as a limiting fault. Protection by design is therefore provided for MSLBs, up to and including the complete severance of a Seismic Category I main steam line upstream of the containment isolation valves (i.e., Main Steam Isolation Valves).

15.1.5.2 Sequence of Events and System Operation

A MSLB is characterized as a cooldown event, because the blowdown of main steam through a pipe break would result in excessive energy removal from the NSSS and a power-to-load mismatch. Additionally, if the MSLB occurred upstream of a Main Steam Isolation Valve (MSIV), the affected steam generator would continue to blow down and dry out following a Main Steam Isolation Signal (MSIS). Long-term controlled heat removal must then be accomplished through the remaining unaffected steam generator.

The largest possible MSLB is a double-ended guillotine rupture of a main steam line upstream of an MSIV. The PVNGS steam lines, however, have integral venturi flow restrictors installed in the outlet nozzles of both steam generators. The maximum steam blowdown rate is therefore limited by the cross-sectional throat area of each flow restrictor, which is approximately 1.283 ft^2.

Two types of analyses are performed for postulated MSLBs that may occur during operating Modes 1 (Power Operation) and 2 (Startup). MSLBs are analyzed for that portion of the accident immediately prior to and during reactor trip, when CEAs begin

to fall into the core (henceforth referred to as the "pre-trip" phase), as well as for that portion of the accident following CEA insertion, when continued cooldown of the NSSS causes moderator density to increase and the reactor again approaches criticality (henceforth referred to as the "post-trip" phase). There is a greater potential for fuel damage during the pre-trip phase of a MSLB than during the post-trip phase, because post-trip fission power levels are sufficiently low to prevent a significant degradation in fuel performance. For this reason, the pre-trip analyses are performed for limiting Hot Full Power (HFP) initial conditions. The post-trip analyses, however, are performed for both HFP and Hot Zero Power (HZP) initial conditions, to assess the potential for fuel damage as a result of a Return-to-Power (R-t-P) following postulated MSLBs inside containment.

The PVNGS MSLB analyses therefore cover a wide range of initial conditions in Modes 1 and 2. These analyses, which are described in further detail below, are as follows:

A. Pre-trip analyses that maximize the potential for a short-term power excursion, a decrease in the hot channel minimum DNBR value, and radiological consequences:

   1. SLB Case – A MSLB outside containment at HFP, in combination with a stuck CEA and with offsite power available. Credit is taken for a Core Protection Calculator (CPC) auxiliary trip, the Variable Over Power Trip (VOPT). There are no credible single

failures that might occur during the pre-trip phase of the accident to enhance the power excursion or degrade thermal margin.

2. SLBLOP Case – A MSLB outside containment at HFP, in combination with a stuck CEA and a coincident Loss of Offsite Power (LOP). Credit is taken for a low RCP shaft speed trip. There are no credible single failures that might occur during the pre-trip phase of the accident to enhance the power excursion or degrade thermal margin.

B. Post-trip analyses that maximize the potential for a R-t-P:

1. SLBFP Case – A MSLB inside containment at HFP with offsite power available, in combination with a stuck CEA and a single failure of a High Pressure Safety Injection (HPSI) pump. Credit is taken for a CPC VOPT.

2. SLBFPLOP Case – A MSLB inside containment at HFP with a coincident LOP, in combination with a stuck CEA and a single failure of a HPSI pump. Credit is taken for a low RCP shaft speed trip.

3. SLBZP Case – A MSLB inside containment at HZP with offsite power available, in combination with a stuck CEA and a single failure of a HPSI pump. Credit is taken for a CPC VOPT.

4. SLBZPLOP Case – A MSLB inside containment at HZP with a coincident LOP, in combination with a stuck CEA and a single failure of a HPSI pump. Credit is taken for a low RCP shaft speed trip.

Detailed analysis of the two pre-trip cases reveals that the SLB case is the limiting pre-trip MSLB safety analysis for PVNGS. This case yields the highest peak power excursion and the lowest hot channel minimum DNBR value, before the CEAs have completed their fall into the reactor core. Likewise, detailed analysis of the four post-trip cases reveals that the SLBFPLOP case is the limiting post-trip MSLB safety analysis for PVNGS. Of the four post-trip cases, the SLBFPLOP yields both the highest post-trip reactivity value and the highest post-trip fission power.

Table 15.1.5-1

SEQUENCE OF EVENTS FOR THE
LIMITING PRE-TRIP MSLB SAFETY ANALYSIS (SLB CASE)

Time (seconds) RTP 3990 MWt	Event
0.00	Double-ended guillotine MSLB (SG#1)occurs outside containment
3.62	CPC VOPT setpoint reached
4.37	Reactor trip breakers open
4.37	Turbine trip occurs
4.98	CEAs begin to fall
5.03	Steam generator level reaches MSIS setpoint
5.37	Peak power occurs
6.00	Hot channel minimum DNBR occurs

The sequences of events for the limiting SLB (pre-trip) and SLBFPLOP (post-trip) cases are provided in Tables 15.1.5-1 and 15.1.5-2, respectively. These sequences were obtained by simulating the MSLB events with the computer codes identified in UFSAR Section 15.1.5.3.

Because the sequence of events and timing for the pre-trip SLB case is very similar to that provided in UFSAR Section 15.1.3 for the SBCS malfunction safety analysis, figures that depict the short-term response of key NSSS parameters are not provided here for the SLB analysis. However, Figures 15.1.5-1 through 15.1.5-14 are provided to depict the NSSS response for the longer-term SLBFPLOP post-trip analysis.

Like the SBCS malfunction and IOSGADV events, a MSLB causes the main steam flow rate to rapidly increase (Figure 15.1.5-1), which results in a power-to-load mismatch and a decrease in RCS temperature (Figure 15.1.5-2). In the presence of a negative MTC, the decrease in RCS temperature results in a short-term increase in reactivity (Figure 15.1.5-3), core power (Figure 15.1.5-4), and core heat flux (Figure 15.1.5-5). The rapid cooldown will also result in an initial decrease in RCS pressure (Figure 15.1.5-6). Blowdown of the affected steam generator results in an initial decrease in steam generator pressures and levels (Figure 15.1.5-7 and 15.1.5-8, respectively) although a very short-term increase in the indicated steam generator water level due to swell effects is also anticipated (Figure 15.1.5-8) which may trigger a MSIS on high steam generator level. Upon MSIS, the MSIVs would close,

halting the steam release from the unaffected steam generator. As a consequence, decrease in the pressure and inventory of the unaffected steam generator could stop, while the affected steam generator pressure and level continue to decrease.

Table 15.1.5-2
SEQUENCE OF EVENTS FOR THE
LIMITING POST-TRIP MSLB SAFETY ANALYSIS (SLBFPLOP CASE)

Time (seconds)	Event
0.00	Double-ended guillotine MSLB (SG #1) occurs inside containment
0.00	LOP occurs
0.00	RCPs begin to coast down
0.00	SG level reaches MSIS setpoint and FWIVs close
0.65	RCP shaft speed reaches CPC auxiliary trip setpoint
0.95	Reactor trip breakers open
1.55	CEAs begin to fall
5.62	MSIVs closed. Steam flow from steam generator No. 2 halted
13.72	SG Differential Pressure AFW Lockout occurs
19.80	AFW actuation and delivery to SG #2
69.97	SIAS occurs due to low pressurizer pressure
79.05	Pressurizer empties
88.23	Void begins to form in reactor vessel upper head
89.97	One HPSI pump begins injecting into the RCS
171.53	Safety injection boron reaches RCS cold legs
251.01	AFAS cutoff setpoint is reached in SG #2 and AFW flow is terminated
295.41	Maximum post-trip reactivity occurs
341.01	Time of Maximum Return to Power
341.41	MacBeth minimum DNBR occurs
360.81	Steam generator No. 1 dries out
1800	Plant operators take control of the plant

Detection of a MSLB may be accomplished by a high reactor power alarm, an RCS or steam generator low pressure alarm, recognition of a power-to-load mismatch, or a high containment pressure alarm (if the MSLB occurs inside containment).

The PVNGS MSLB safety analyses credit the CPC VOPT or the RPS Low SG Pressure Trip for the case when offsite power is available (e.g., SLB case), and a CPC low RCP shaft speed trip when a coincident LOP is postulated to occur (e.g., SLBFPLOP case). For the limiting post-trip SLBFPLOP case, the coolant flow rate through the RCS would decrease rapidly following the LOP, as the RCPs coast down and the RCS transitions from forced flow to natural circulation conditions (Figure 15.1.5-9).

As explained in UFSAR Section 15.1.5.3 below, assessment of fuel performance degradation differs between the pre-trip and post-trip MSLB safety analyses. For pre-trip cases, consideration is given to the short-term increase in core heat flux and decrease in RCS pressure, which would effectively reduce coolant subcooling and thereby cause the hot channel DNBR to decrease. Also, for pre-trip analyses, the minimum DNBR is predicted to occur as CEAs are falling into the reactor core during the reactor trip. For these pre-trip cases, the minimum DNBR which is computed using the CE-1 Critical Heat Flux (CHF) correlation is compared to the DNBR SAFDL which is based on a statistical combination of uncertainties methodology (see UFSAR Section 4.4.2.2). Table 15.1.5-1 shows that the hot channel minimum DNBR occurs very early in the limiting SLB event sequence.

For post-trip analyses, however, fuel degradation cannot be assessed in the same manner, because the applicable range of the CE-1 CHF correlation does not extend to the low RCS flow rates and low pressures that may occur following a reactor trip. Therefore, as explained in UFSAR Section 15.1.5.3, post-trip analyses utilize the Macbeth[17][18] CHF correlation to calculate a minimum DNBR value that occurs well after the CEAs have reached the bottom of the core. Table 15.1.5-2 and Figure 15.1.5-14 show that the Macbeth minimum DNBR occurs several minutes into the SLBFPLOP event sequence. Unlike DNBR values calculated with the CE-1 CHF correlation, Macbeth DNBR values are compared to a deterministic limit of 1.30 rather than a statistical one.

Although a coincident LOP and loss of forced flow through the RCS may result in higher coolant temperatures in the vicinity of the core, overall the RCS would still continue to cool down while the faulted steam generator dried out. This cooldown would increase RCS coolant density, causing the pressurizer to temporarily empty (Figure 15.1.5-10) and a void to form in the reactor vessel upper head (Figure 15.1.5-11). Pressurizer pressure would eventually decrease to the SIAS setpoint, actuating the safety injection pumps. Even if one HPSI pump failed to start on demand, sufficient safety injection flow would still be delivered to the RCS after the RCS pressure decreased below the shutoff head of the remaining operable HPSI pump (Figure 15.1.5-12). Safety injection flow into the RCS would serve not only to repressurize the system and provide inventory control, but would also deliver soluble boron that

would add negative reactivity and slow down an approach to criticality or R-t-P.

Low pressure in the affected steam generator would eventually result in an MSIS and closure of the MFIVs, stopping the flow of main feedwater to both steam generators (Figure 15.1.5-13), and in closure of the MSIVs, thereby halting the flow of steam from the unaffected steam generator, which serves to maintain secondary system inventory.

Table 15.1.5-2 indicates that MSIS occurs at time = 0.0 in the event. This is due to the choice of initial steam generator water level. Since the MSIS occurs at time = 0.0, the unaffected SG is isolated from the break and pressurizes to the MSSV setpoints early in the transient. The lockout function prevents the addition of feedwater to the affected steam generator, and thus an unwanted loss of AFW inventory to the environment through the affected steam generator. However, due to the conservative choice of AFAS setpoint, AFAS is actuated in the unaffected SG. AFW continues to supply the unaffected steam generator as needed during the transient. Following dryout of the affected steam generator, decay heat from fission products in the core, and heat released by the hot metal structures of the NSSS, would raise temperatures and repressurize both the RCS and the intact steam generator. However, due to the additional cooling provided by the auxiliary feedwater, neither the main steam system or reactor coolant system pressure boundaries are challenged later in the event sequence.

Operator action is not credited in the MSLB safety analyses until 30 minutes following event initiation. At that time, it is assumed that plant operators will take action to initiate a controlled plant cooldown to SDC entry conditions, for example by manually establishing AFW flow and a steaming path through the ADVs associated with the unaffected steam generator.

15.1.5.3 Core and System Performance

Because MSLBs result in rapid reactivity insertions and power excursions, they are evaluated with respect to degradation in fuel performance, and the potential for post-trip criticality or R-t-P.

For pre-trip MSLB safety analyses, initial conditions are chosen to obtain the most adverse power excursion and fuel performance degradation. Because the hot channel minimum DNBR value provides a measure of fuel performance degradation, pre-trip analyses consider those parameters and conditions that would cause the greatest decrease in the local or hot channel DNBR, such as an increase in local heat flux, an increase in reactor coolant temperature, a decrease in reactor coolant flow rate, and a decrease in reactor coolant pressure.

Likewise, for post-trip MSLB safety analyses, initial conditions are chosen to maximize the potential for a R-t-P, as measured by the maximum post-trip reactivity value, the timing of the reactivity insertion, the duration of the reactivity peak, and the maximum post-trip fission power which then translated into minimum local or hot channel DNBR.

15.1.5.3.1 Mathematical Models

15.1.5.3.1.1 Pre-Trip Safety Analyses

The PVNGS pre-trip MSLB safety analyses utilized the following mathematical models:

- The CENTS computer code was used to simulate the NSSS transient response. The CENTS computer code is described in UFSAR Section 15.0.3.1.3.2 and in an NSSS vendor topical report.(1)(2)

- The FORTRAN CPC computer code was used to simulate CPC reactor trip functions. Predicted times for reactor trips, with appropriate delays for signal processing and opening of the reactor trip breakers, were utilized in CENTS code input. The CPCs are described in UFSAR Section 7.2, and associated algorithms and simulation code are described in NSSS vendor topical reports.(3)(4)

- The CETOP-D computer code, which uses the CE-1 CHF correlation, was used to calculate initial and transient DNBR values. CETOP-D was also used to determine initial Power Operating Limit (POL) conditions. The CETOP-D computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports.(5)(6)(7)

- The TORC computer code, which uses the CE-1 CHF correlation, was used to calculate the minimum DNBR value at the time of minimum DNBR predicted by the CETOP-D code, if CETOP-D predicted a minimum DNBR value below the DNBR

SAFDL. Because the models in the CETOP-D code are not as detailed as those in TORC, DNBR predictions from CETOP-D are typically adjusted by penalty factors to ensure conservatism. Use of the more detailed TORC computer code reduces the need for penalty factors and provides a more accurate prediction of the DNBR value than the CETOP-D code. The TORC computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports.(10)(11)

15.1.5.3.1.2 Post-Trip Safety Analyses

The PVNGS post-trip MSLB safety analyses utilized the following mathematical models:

- The CENTS computer code was used to simulate the NSSS transient response. The CENTS computer code is described in UFSAR Section 15.0.3.1.3.2 and in an NSSS vendor topical report.(1)(2)

- The FORTRAN CPC computer code was used to simulate CPC reactor trip functions. The CPCs are described in UFSAR Section 7.2, and associated algorithms and simulation code are described in NSSS vendor topical reports.(3)(4)

- As noted above, the determination of DNBR for post-trip MSLB analyses requires methods that differ from those used for pre-trip analyses. This is because the verified range of the CE-1 CHF correlation, which is used in the CETOP-D and TORC computer codes, does not extend to lowpressures and low flow rates that may exist in the RCS following a

reactor trip. Therefore, the Macbeth correlation[17][18] is utilized to ascertain the margin to DNB during the post-trip phase. The Macbeth correlation calculates the CHF as a function of mass flux, inlet subcooling, system pressure, heated diameter, and channel length. Use of a channel heat balance allows the correlation to be converted to a “local conditions” form, thereby allowing the CHF to be determined as a function of height in the hot channel. The effect of non-uniform axial heating may be incorporated by using the method applied by Lee in Reference 19. Because the CEA of greatest reactivity worth is assumed to remain out of the core following the reactor trip, the Macbeth DNBR calculations must account for the high localized power peak that may exist in the core post-trip. The post-trip analyses therefore utilize a maximum fission power dependent core peaking factor, F_Q, that is a function of both fission power and coolant flow rate through the core. F_Q values are therefore different for forced flow cases (i.e., offsite power available) than for cases in which the RCPs coast down (i.e., a LOP occurs). The Macbeth CHF correlation is also described in the CENTS computer code topical report.[1]

15.1.5.3.2 Input Parameters and Initial Conditions

15.1.5.3.2.1 Pre-Trip Safety Analyses

Table 15.1.5-3 summarizes the key input parameters and initial conditions utilized in the limiting pre-trip MSLB safety

analyses, SLB case, which were selected to obtain the most adverse power excursion and fuel performance degradation. The following points serve to explain the selection of initial conditions as they appear in Table 15.1.5-3:

- For the SLB case, a CPC VOPT auxiliary reactor trip was credited. The initial core power was set to 95% of RTP for this case, thereby allowing the VOPT setpoint to increase as core power rises early in the simulations. This causes a slight delay in the reactor trip and enhances the initial power excursion. Because the same ROPM value is used at power levels ≥ 95% of RTP, initial thermal margin to the DNBR SAFDL is the same at 95% power as at 100% power.

- A maximum core inlet temperature was selected because it maximizes the average temperatures in the RCS coolant loops. Maximizing the initial RCS average loop temperature tends to maximize the initial steam generator pressure, and hence maximizes the cooldown rate and reactivity insertion following a MSLB. The values in Table 15.1.5-3 include instrument uncertainty.

- The pre-trip analyses are not sensitive to the initial pressurizer pressure. Therefore, a nominal value was used.

- A maximum RCS flow rate was used in the CENTS code. CENTS code output was then passed to the CETOP-D code to perform transient DNBR calculations. CETOP-D DNBR calculations

were initiated from a Power Operating Limit (POL) corresponding to the maximum RCS flow rate.

- The pre-trip analyses are not sensitive to either the initial pressurizer or steam generator water levels. Therefore, nominal values were used.
- A MSLB causes a rapid cooldown of the RCS. Therefore, the most negative MTC allowed by the Technical Specifications and COLR was used to maximize the positive reactivity insertion caused by the cooldown.
- The least negative Doppler fuel temperature coefficient curve, at Beginning of Cycle (BOC), was conservatively assumed. Least negative values minimize the addition of negative reactivity caused by increasing fuel temperature. Therefore, the reactor core may achieve a higher peak power and heat flux during the initial RCS cooldown.
- End of Cycle (EOC) values were chosen to model delayed neutron kinetics. EOC values serve to emphasize the initial power excursion by minimizing the effect of delayed neutrons on the rate of power increase.

Table 15.1.5-3

INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE LIMITING PRE-TRIP MAIN STEAM LINE BREAK (SLB CASE) SAFETY ANALYSES

Parameter	Assumed Value
	RTP 3990 MWt
Initial Core Power (% of RTP)	95
Initial Core Inlet Temperature (°F)	566
Initial Pressurizer Pressure (psia)	2250[a]
Initial RCS Flow Rate (% of Design Rated)	116
Initial Pressurizer Water Level (% Narrow Range)	52[a]
Initial Steam Generator Water Level (% Wide Range)	81[a]
Moderator Temperature Coefficient ($\Delta\rho$/°F)	-4.4×10^{-4}
Doppler Fuel Temperature Coefficient	BOC
Delayed Neutron Kinetics	EOC
Axial Shape Index for Scram Curve	+0.3
CEA Worth at Trip (%$\Delta\rho$)	-8.0
Fuel Rod Gap Conductance (BTU/hr-ft^2-°F)	6984
Number of Plugged Steam Generator Tubes (Total)	0
Break Size (ft^2)	1.283
Loss of Offsite Power	No

(a) Nominal range values are used since the event is not sensitive to these parameters.

- If power generation in the core is shifted toward the bottom, the insertion of negative reactivity during reactor trip will be delayed until the CEAs have inserted farther into the core. The scram reactivity curve was therefore based on a positive ASI representing a bottom-peaked core. The time versus scram reactivity curve was adjusted to account for a 0.6-second CEA holding coil time delay following opening of the reactor trip breakers, and normalized to model 90% CEA insertion at 4.0 seconds after power is removed from CEDM coils (see UFSAR Section 3.9.4).

- The CEA worth at trip represents the minimum scram worth for Hot Full Power (HFP) conditions at BOC, assuming the most reactive CEA remains stuck out of the core following reactor trip. This is more limiting (less negative) than the anticipated HFP scram reactivity worth at other times during the cycle, this is conservative.

- The fuel rod gas gap conductance value was selected so that energy from the fuel would quickly reach the surface of the fuel rod clad. This results in a higher heat flux which closely follows core power, and greater degradation of DNBR during the initial power excursion.

- It was assumed that steam generator tubes were not plugged for the pre-trip MSLB safety analyses. This enhances the initial rate of heat transfer from the RCS to the main steam system, which in turn enhances the initial RCS cooldown and maximizes the positive reactivity insertion

due to the negative MTC. Additionally, this enhances the decrease in RCS pressure during the cooldown, which serves to degrade DNBR.

- A large break size was assumed for the MSLB, with steam blowdown limited by the cross-sectional throat area of the flow restrictors in the outlet nozzles of both steam generators. A large break size maximizes the initial cooldown rate and resulting reactivity insertion.

- For the limiting case, a LOP was not assumed to occur, so the reactor trip would be delayed until the CPC VOPT auxiliary trip was received. There are no credible single failures (see UFSAR Table 15.0-0) that would serve to enhance the power excursion or degrade thermal margin during the first few seconds of the pre-trip MSLB simulations; therefore, an additional single failure was not postulated.

For those safety-related Reactor Protective System (RPS) and Engineered Safety Features Actuation System (ESFAS) setpoints and response times that had a direct effect on acceptance criteria for this event, analytical values were chosen to be consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

15.1.5.3.2.2 Post-Trip Safety Analyses

Table 15.1.5-4 summarizes the key input parameters and initial conditions utilized in the PVNGS post-trip MSLB safety

analyses. Because degradation in fuel performance during the post-trip phase of a MSLB can only occur if there is a R-t-P, analytical values were selected to maximize the potential for an approach to criticality or a R-T-P. As noted above, the magnitude of a R-t-P is primarily determined by the maximum post-trip reactivity value, the timing of the reactivity insertion, and the duration of the reactivity peak.

The following points serve to explain the selection of initial conditions as they appear in Table 15.1.5-4:

- A maximum initial core power, including a 2% power measurement uncertainty, was selected for the HFP cases. Use of a maximum initial core power maximizes the initial core outlet temperature as well as the initial average temperature in the RCS coolant loops. Maximizing the initial core outlet temperature maximizes the initial energy stored in the water and metal of the upper head region of the reactor vessel, and also maximizes the saturation pressure of the liquid in this region. Following a MSLB, when RCS pressure falls below the saturation pressure of the liquid in the upper head region, this stored energy will help vaporize liquid and thereby slow the rate at which the RCS pressure decreases. Selecting the RCP Seal Leakage to be 0.0 gpm also slows the rate at which the RCS pressure decreases. This in turn tends to delay and reduce the rate of safety injection, which minimizes the negative reactivity due to boron at the time of R-t-P. Furthermore, maximizing the

initial average temperature of the RCS coolant loops maximizes the initial steam generator pressure, which maximizes the blowdown and rate of energy removal following a MSLB. Increasing the rate of energy removal likewise increases the RCS core inlet temperature cooldown rate which, in the presence of a negative MTC, enhances the positive reactivity insertion due to the cooldown. Maximizing the initial RCS average temperature also causes the cooldown to occur over a more adverse portion of the moderator reactivity function, i.e., the portion having the greatest rate of change of reactivity with temperature.

- Maximum initial core inlet temperatures were selected because they maximize the average temperatures in the RCS coolant loops. As explained above, maximizing the initial RCS average loop temperature tends to maximize the initial steam generator pressure, and hence maximizes the cooldown rate and reactivity insertion following a MSLB. The values shown in Table 15.1.5-4 reflect the maximum allowed RCS cold leg temperatures including instrument uncertainty.

- A high initial pressurizer pressure and pressurizer water level was selected. This increases transient RCS pressures, thereby delaying and impeding safety injection flow and the delivery of boron to the core region.

INCREASE IN HEAT REMOVAL

BY THE SECONDARY SYSTEM

Table 15.1.5-4

INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE LIMITING POST-TRIP MAIN STEAM LINE BREAK (SLBFPLOP CASE) SAFETY ANALYSES

Parameter	Assumed Value
Initial Core Power (% of RTP)	102
Initial Core Inlet Temperature (°F)	566
Initial Pressurizer Pressure (psia)	2325
Initial RCS Flow Rate (% of Design Rated)	95
Initial Pressurizer Water Level (%)	60
Initial Steam Generator Water Level (% Narrow Range)	96
Auxiliary Feedwater Actuation Setpoint (% Wide Range)	82
Auxiliary Feedwater Cutoff Setpoint (% Wide Range)	99
Moderator Temperature Coefficient ($\Delta\rho$/°F)	$-4.4\text{x}10^{-4}$
Doppler Fuel Temperature Coefficient	EOC
Delayed Neutron Kinetics	BOC
Inverse Boron Worth (ppm/%$\Delta\rho$)	-130
Axial Shape Index for Scram Curve	+0.6
CEA Worth at Trip (%$\Delta\rho$)	-8.75
Fuel Rod Gap Conductance (BTU/hr-ft^2-°F)	656
Number of Plugged Steam Generator Tubes (Total)	2516
Break Size (ft^2)	1.283
Loss of Offsite Power	Yes
Additional Single Failure	One HPSI pump
RCP Seal Leakage (gpm)	0.0

- A minimum initial core flow rate maximizes the rate of core inlet temperature cooldown following a MSLB, which in turn maximizes the reactivity insertion in the presence of a negative MTC cooldown curve.

- A high initial steam generator water level corresponding to the high SG level alarm setpoint was selected for both steam generators based on parametric analysis. This increases the cooldown rate following a MSLB. However, it will also result in an MSIS at time = 0.0 and FWIV closure. In addition, the use of a high initial water level in the unaffected SG could prevent level from decreasing to the AFAS low level setpoint during the event.

- MTC has a significant effect on the potential for a R-t-P following a MSLB, due to the magnitude of the positive reactivity that results from the RCS cooldown. Therefore, the most negative MTC cooldown curve was used for this analysis, corresponding to End of Cycle (EOC) conditions. That is, because a loss of CEA reactivity worth may occur as the moderator becomes denser during the cooldown, reactivity is adjusted to account for the effects of changes in moderator density. Additionally, the moderator reactivity contribution to core power was based on cold-edge temperature, which is weighted to account for the colder water returning to the RCS from the faulted steam generator, rather than the core bulk or average temperature.

- An EOC (most negative) Doppler fuel temperature coefficients curve was used for the post-trip MSLB analyses. Use of a most negative curve adversely affects R-t-P by adding relatively more positive reactivity as the fuel goes from operating temperatures prior to the MSLB, to lower temperatures that occur during the post-MSLB cooldown.

- Relative to other parameters, the delayed neutron fraction has a minor effect on the potential for a R-t-P. Beginning of Cycle (BOC) values were conservatively chosen because they result in relatively more delayed neutrons, which delay the rate of decrease in core power post-trip. This in turn extends the duration of a reactivity peak or R-t-P if it occurs.

- A maximum value was selected for the inverse boron worth, to reduce the negative reactivity that is inserted as a result of boron injected by the Safety Injection (SI) system. A sweep-out volume of 60.6 cubic feet was used for the SI lines, representing the volume of water that must be displaced before safety injection boron reaches the primary system.

- The rate at which negative reactivity is added by CEAs during a reactor trip has little effect on the potential for a post-trip R-t-P. Therefore, the initial axial power distribution is of little importance for post-trip MSLB safety analyses. However, the axial power distribution that was selected was bottom-peaked to delay the full

effect of scram reactivity for as long as possible. Additionally, the time versus scram reactivity curve was adjusted to account for a 0.6-second CEA holding coil time delay following opening of the reactor trip breakers, and normalized to model 90% CEA insertion at 4.0 seconds after power is removed from CEDM coils (see UFSAR Section 3.9.4).

- The CEA worth at trip represents the minimum allowed scram worth at EOC, assuming the most reactive CEA remains stuck out of the core following the trip. The selection of EOC values is consistent with the selection of the MTC and Doppler values, i.e., they represent the same point in time in an operating cycle.

- The post-trip MSLB safety analyses utilized a fuel rod gas gap conductance value which results in a bounding core average effective fuel temperature at full power EOC conditions. A higher full power fuel temperature results in a larger reactivity addition as the core goes from HFP to HZP conditions, which results in a larger scram worth requirement to prevent return to power.

- It was assumed that steam generator tubes were plugged for the post-trip MSLB safety analyses. Although this would tend to reduce heat transfer from the RCS to the main steam system, which may reduce the initial RCS cooldown, a parametric evaluation showed that increased tube plugging has a more adverse effect during the post-trip phase. The initial RCS cooldown was maximized by conservatively

assuming that the full steam generator heat transfer area would be maintained throughout blowdown of the faulted steam generator, rather than decreasing as steam generator water mass decreased. The heat transfer area was ramped down to zero only after the mass of liquid in the steam generator decreased below 100 lbm. Tube plugging therefore had more of a direct effect on post-trip RCS temperatures and flow rates, especially under natural circulation conditions, which in turn affected post-trip DNBR values and the potential for a R-t-P.

- A large break size was assumed for each post-trip MSLB analysis, with steam blowdown limited by the cross-sectional throat area of the flow restrictors in the outlet nozzles of both steam generators. A large break size maximizes the initial cooldown rate and resulting reactivity insertion.

- For the limiting case, a LOP was assumed to occur coincident with the MSLB. This assumption results in an early RCP coastdown, which affects both the post-trip minimum DNBR value and the timing and magnitude of a R-t-P. Although a lower core flow rate tends to result in a smaller R-t-P, a lower flow rate has more of a direct effect on the minimum DNBR value than does the magnitude of the R-t-P. Therefore, a LOP coincident with a MSLB yields the greatest potential for degradation in post-trip fuel performance.

- For the post-trip MSLB analyses, an additional single failure involving the failure of a HPSI pump to start on demand was assumed (see UFSAR Table 15.0-0). This single failure served to reduce the capacity of the SI system to provide boron to the core region of the RCS, which increased the potential for a R-t-P. Other postulated singles failures, including a single failure of a Main Steam Isolation Valve (MSIV) to close, were determined to be less limiting than the single failure of a HPSI pump.

For those safety-related Reactor Protective System (RPS) and Engineered Safety Features Actuation System (ESFAS) setpoints and response times that had a direct effect on acceptance criteria for this event, analytical values were chosen to be consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

15.1.5.3.3 Results

15.1.5.3.3.1 Pre-Trip Safety Analyses

The limiting pre-trip MSLB safety analysis, for a break that occurs outside containment without a coincident LOP (i.e., the SLB case), shows that core power reached a peak around 115% - 116% of RTP, shortly after the CEAs begin to fall into the core. However, during the event, the short-term excursion in reactor power would not be of sufficient magnitude to raise the linear heat rate above that required to cause fuel centerline melting.

The limiting pre-trip MSLB safety analysis also shows that the hot channel minimum DNBR (computed with the CE-1 CHF correlation and CETOP code) was calculated to be 1.33 for 3990 MWt RTP cores. Since CETOP DNBR values are conservative relative to TORC DNBR values, cycle specific Thermal Hydraulic calculations are performed to confirm that the calculated DNBR value remains above the SAFDL. These cycle specific calculations also ensure that the radiological dose consequences presented in Section 15.1.5.5 for this event remain bounding.

15.1.5.3.3.2 Post-Trip Safety Analyses

The results of the limiting post-trip MSLB core performance safety analyses (SLBFPLOP) are summarized in Table 15.1.5-5.

The SLBFP, SLBZP, and SLBZPLOP cases were determined to be non-limiting with respect to acceptance criteria for post-trip MSLB core performance analyses. That is, Macbeth minimum DNBR values during the low flow, low pressure post-trip phase did not decrease below a deterministic limit of 1.30; post-trip fission power steadily decreased; and the maximum post-trip reactivity achieved in each case indicated that the reactor remained shut down after the CEAs had fully inserted into the core.

For the limiting SLBFPLOP case, however, post-trip fission power and reactivity initially decreased, and then began to increase again as the moderator continued to cool down. The maximum fission power and reactivity occur before the affected

SG dries out. High pressure safety injection boron ensures that the reactor remains shut down and the minimum DNBR remains above the deterministic limit of 1.30 during the post-trip period.

The core linear heat rate during the post-trip phase is dependent upon the post-trip fission power, the decay heat released by radioactive isotopes in the core, and applicable peaking factors. For the limiting SLBFPLOP case, it was determined that the linear heat rate would remain well below that required to cause fuel centerline melting.

It is therefore concluded that fuel damage will not occur during the post-trip phase of a postulated MSLB.

Table 15.1.5-5

CORE PERFORMANCE SAFETY ANALYSIS RESULTS FOR THE LIMITING POST-TRIP MAIN STEAM LINE BREAK (SLBFPLOP CASE) SAFETY ANALYSES

Parameter	Results
Macbeth Minimum DNBR	2.42
Time of Macbeth Minimum DNBR (sec)	341
Maximum Post-Trip Fission Power (% RTP)	1.385×10^{-2}
Time of Maximum Post-Trip Fission Power (sec)	341
Maximum Post-Trip Reactivity (%$\Delta\rho$)	0.02036
Time of Maximum Post-Trip Reactivity (sec)	295

15.1.5.4 RCS Pressure Boundary Barrier Performance

Postulated MSLBs during Modes 1 (Power Operation) and 2 (Startup), like the SBCS malfunction and IOSGADVLOP events described in UFSAR Sections 15.1.3 and 15.1.4, respectively, are characterized by an initial cooldown of the primary and secondary systems, and decreasing RCS and steam generator pressures. Additionally, like an IOSGADVLOP event, the affected steam generator would not be completely secured following an MSIS if the MSLB occurs upstream of an MSIV. If this were to occur, the affected steam generator would eventually dry out, and long-term heat removal would have to be accomplished through the unaffected steam generator. Therefore, for a large MSLB upstream of an MSIV, long-term heat removal via the MSSVs may not be sufficient to prevent re-pressurization of the RCS to the lift setting of the PSVs (see UFSAR Section 15.1.4).

In addition to the long term repressurization, the RCS performance is investigated in the short-term for brittle fracture criterion because of low temperature and high pressure conditions that may occur simultaneously due to the rapid cooldown and the high pressure safety injection. This investigation merely consists of comparing the conditions observed during MSLB event with the low temperature overpressurization analyses detailed in UFSAR Chapter 5.

15.1.5.4.1 Mathematical Models

The mathematical models that were used to analyze the performance of the RCS pressure boundary are the same as those described in UFSAR Section 15.1.5.3.1.

15.1.5.4.2 Input Parameters and Initial Conditions

The key input parameters and initial conditions that were used to analyze the performance of the RCS pressure boundary are the same as those described in UFSAR Section 15.1.5.3.2.

15.1.5.4.3 Results

Figure 15.1.5.6 and 15.1.5.7 shows the RCS and SG pressure response for the limiting post-trip MSLB, a SLBFPLOP. Due to the early MSIS, the unaffected SG is isolated from the break. Heat up and pressurization occurs, but is turned around by the addition of AFW to the unaffected SG. Later in the event sequence after the AFW cutoff setpoint is reached, the unaffected SG begins to heat up and repressurize again. The peak secondary pressure is limited by the MSSV setpoints, which is below the acceptable design limit (i.e., 110% of the steam generator shell side design pressure of 1270 psia, or 1397 psia). Well before the end of the post-trip MSLB simulation, RCS pressure turns around and begins to increase as a result of safety injection flow, decay heat, and heat released from the hot metal structures that comprise the NSSS. Auxiliary feedwater addition and cooling by the intact SG helps keep the RCS pressure below the PSV setpoint of 2450 psia

during the 30 minute transient. Therefore, peak RCS pressure remains below the acceptable design limit for this event (i.e., 110% of the RCS design pressure of 2500 psia, or 2750 psia).

During a MSLB event, combination of low temperature and high pressure does not challenge the RCS integrity due to the brittle fracture since the combination of temperature and pressure remain well within the reactor vessel design that is evaluated in UFSAR Chapter 5. Therefore, the peak RCS and secondary system pressures that may occur following a MSLB in Modes 1 and 2 will be maintained within acceptable design limits.

15.1.5.5 Containment Performance and Radiological Consequences

A MSLB is classified as a limiting fault, for which radiological dose consequences are subject to various regulatory limits. Specifically, if fuel failure is postulated to occur, or if the MSLB is assumed to occur following an operational transient that has raised the RCS iodine concentration to the maximum value permitted by Technical Specifications (i.e., a Preaccident Iodine Spike, or PIS case), then offsite radiological doses must not exceed 10 CFR Part 100 guideline values. That is, 2-hour doses at the Exclusion Area Boundary (EAB) and 8-hour doses at the outer boundary of the Low Population Zone (LPZ) would be limited to a thyroid dose of 300 Rem and a whole body dose of 25 Rem. However, if the reactor trip or RCS depressurization following the MSLB is assumed to create an accident-Generated Iodine Spike (GIS) without fuel failure, then offsite dose consequences must not

exceed a small fraction, or 10%, of 10 CFR Part 100 guideline values. Finally, radiation exposures for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A.

Control room radiological assessments for bounding unfiltered inleakage are presented in UFSAR Section 6.4.7. The limiting cases presented in that UFSAR section bound the anticipated control room exposures for postulated MSLB events. For example, the results presented therein for a Steam Generator Tube Rupture (SGTR) with a stuck open ADV bound a MSLB with a PIS or GIS iodine spike. Likewise, a MSLB that is limited to 1% fuel failure is bounded by the RCP sheared shaft event with a stuck open ADV, because the sheared shaft event results in a higher percentage of fuel damage.

The offsite radiological dose consequences associated with limiting fault MSLBs are evaluated in the following subsections.

15.1.5.5.1 Mathematical Models

The offsite radiological consequences of postulated MSLBs are evaluated for breaks that may occur outside the containment building.

Activity in the RCS is calculated on the basis of initial radioiodine and noble gas activity levels, which are limited by plant Technical Specifications, to which is added the increase in activity due to fuel failure or iodine spikes. For postulated fuel failure, the increase in RCS activity is

dependent upon the radial peaking factor, which affects the radionuclide inventory in the fuel rod gas gap, as well as the fuel failure fraction, which defines the number of pins that are assumed to release radionuclides to the RCS coolant. For PIS and GIS cases, the increase in RCS activity is determined by analytical iodine spiking factors.

Once the activity level in the RCS is determined, the amount of activity carried over to the secondary system by primary-to-secondary leakage is calculated. All of the activity that is contained in or leaked to the affected steam generator is assumed to be released to the environment.

Once primary and secondary activity releases to the environment are quantified, the thyroid and whole body doses at the EAB and LPZ are calculated.

15.1.5.5.2 Input Parameters and Initial Conditions

Offsite radiological dose consequences associated with MSLBs were analyzed under the assumptions listed in Section 15.0.4 and the following conditions:

1. Isotope inventories were based on a core power level of 4070 MWt, or 102% of the RTP of 3990 MWt.
2. Based on Technical Specification limits, the initial assumed activity in the NSSS was:
   - RCS Dose Equivalent (DEQ) I-131: 1.0 μCi/gm
   - RCS Noble Gas(DEQ) Xe-133: 550 μCi/gm

- Secondary System DEQ I-131: 0.10 μCi/gm

3. For PIS cases, the initial concentration of DEQ I-131 in the RCS was increased by a factor of 60. For GIS cases, an accident-generated spiking factor of 500 was used to compute the time-dependent RCS iodine concentration.

4. An RCS liquid mass of 555,000 lbm of water was used in the analysis, including 45,000 lbm of water in the pressurizer. Additionally, 4,500 lbm of steam was assumed to be in the pressurizer. Although the RCS may hold more mass, these values were selected to increase the iodine concentration following postulated fuel failures, which conservatively increases offsite dose consequences.

5. Since the PSVs may lift for this event, the dose calculation conservatively takes into account activity that might be released to containment, even though the Reactor Drain Tank is sized to remain intact from the PSV discharge.

6. Steam generator liquid masses ranging from 160,600 lbm of water (bounding low value for a transient) to 310,000 lbm of water (bounding high value for HZP) were considered in the analysis. This range of steam generator liquid masses bounds the masses that would occur during normal operation or during a transient. A minimum value of steam generator liquid mass tends to increase the releases for cases with fuel failures, thereby increasing offsite dose consequences. However, in cases without fuel failure, the releases from the affected steam generator have a much

larger contribution and a maximum steam generator, and a maximum liquid mass can increase the offsite dose consequences.

7. A primary-to-secondary leak rate of 0.5 gpm (720 gallons per day) per steam generator was assumed. This is consistent with the PVNGS Technical Specification 5.5.9 and conservative with respect to the current Technical Specification limit.

8. All of the iodines associated with the affected steam generator were assumed to be released to the environment, i.e., with a decontamination factor of 1.0.

9. Iodines associated with leakage to the unaffected steam generator are released to the environment during steaming with decontamination factor of 100 since the steam generator inventory, i.e. level, is maintained.

10. A radial peaking factor of 1.72 was used, which conservatively increased the radioisotope inventories that were predicted to reside in the fuel rods.

11. It was assumed that 10% of the iodine and noble gas inventories in the fuel pins were resident in the fuel rod gas gap, and available for release upon clad rupture.

12. All of the activity in the fuel rod gas gap was assumed to be released to the RCS coolant upon fuel pin failure which was assumed to be 1%.

13. It was assumed that plant operators would not initiate a plant cooldown to SDC entry conditions for at least

30 minutes following event initiation. However, it should be noted that a faster RCS cooldown rate would increase steam releases during the first two hours following the event, which would produce more severe thyroid doses at the EAB. On the other hand, a slower RCS cooldown rate would allow radionuclide concentrations to build up in the secondary system, which would produce more severe 8-hour doses at the LPZ. Therefore, radiological dose calculations were performed using two different cooldown rates:

- A maximum Technical Specifications cooldown rate of 100°F/hr, initiated at 30 minutes into the event sequence.
- A slower cooldown rate of 40°F/hr, initiated at 30 minutes into the event sequence, which would bring the RCS to SDC entry conditions at approximately 8 hours following event initiation.

14. Decay heat following the MSLB was based on the 1979 ANS decay heat curve, with a 2σ uncertainty. Use of a maximum decay heat curve increases the amount of steam released to the environment, thereby resulting in more severe dose consequences.

15. It was assumed that all four RCPs would remain in operation for the duration of the radiological dose analysis. Therefore, 26 MWt of RCP heat was included in the dose calculations, which conservatively increased

steam releases and offsite doses during the controlled cooldown.

16. A value of 740,000 BTU/°F was used to represent the specific heat capacity of the RCS, the RCS clad, and the steam generators. Use of this value increases the amount of steam that must be released to the environment during the controlled cooldown.

17. The χ/Q atmospheric dispersion factors used in the analysis are the short-term factors shown in UFSAR Table 2.3-31.

Table 15.1.5-8 shows that the offsite dose consequences of a MSLB outside containment with an accident-Generated Iodine Spike (GIS), will not exceed 10% of the 10 CFR Part 100 guideline values (i.e., 30 Rem thyroid and 2.5 Rem whole body). Likewise, a MSLB outside containment, with either a Preaccident Iodine Spike (PIS) or 1% fuel failure, will not exceed 10 CFR Part 100 guideline values (i.e., 300 Rem thyroid and 25 Rem whole body). The results shown in Table 15.1.5-6 are therefore in compliance with the regulatory guidelines for postulated MSLBs. These results bound the core power levels of 3990 MWt or less.

Because the potential for fuel failure is sufficiently limited (see UFSAR Section 15.1.5.3.3), it is also concluded that the core will remain in place and intact with no loss of core cooling capabilities.

15.1.5.5.3 Results

Table 15.1.5-6 presents the calculated offsite radiological dose consequences for postulated MSLBs outside containment.

Table 15.1.5-6

OFFSITE RADIOLOGICAL DOSES FOR MSLBs
OUTSIDE THE CONTAINMENT BUILDING

MSLB Case	Fuel Failure Fraction	Thyroid Dose (REM)		Whole Body Dose (REM)	
		0-2 Hour EAB	0-8 Hour LPZ	0-2 Hour EAB	0-8 Hour LPZ
PIS	0%	2.2	1.4	0.005	0.003
GIS	0%	2.5	5.2	0.02	0.04
Fuel Failure[a]	1%	17.7	19.4	0.24	0.24

a. Although fuel damage is not predicted to occur (see UFSAR Section 15.1.5.3.3) the analyses for potential radiological dose consequences assume that the maximum percentage of fuel pins allowed to fail for a MSLB with the break outside containment is 1%.

15.1.5.6 Conclusions

Evaluation of postulated MSLBs in plant operating Modes 1 (Power Operation) and 2 (Startup) shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- If a MSLB results in an accident-Generated Iodine Spike (GIS), offsite radiological dose consequences will not exceed a small fraction, or 10%, of the 10 CFR Part 100 guideline values.

- If a MSLB results in 1% failed fuel, or if it occurs with a Preaccident Iodine Spike (PIS), offsite radiological dose consequences will not exceed 10 CFR Part 100 guideline values.
- Control room dose consequences following a MSLB will not exceed the limits specified by GDC 19 of 10 CFR 50 Appendix A.

15.1.6 STEAM SYSTEM PIPING FAILURES INSIDE AND OUTSIDE CONTAINMENT - OPERATING MODE 3

15.1.6.1 Identification of Causes and Frequency Classification

A Main Steam Line Break (MSLB) is a postulated break or rupture of a pipe in the main steam system, either inside or outside the containment building.

A MSLB is classified as a limiting fault. Protection by design is therefore provided for MSLBs, up to and including the complete severance of a Seismic Category I main steam line upstream of the containment isolation valves (i.e., Main Steam Isolation Valves).

15.1.6.2 Sequence of Events and System Operation

A MSLB is characterized as a cooldown event, because the blowdown of main steam through a pipe break would result in excessive energy removal from the NSSS and a power-to-load mismatch. Additionally, if the MSLB occurred upstream of a Main Steam Isolation Valve (MSIV), the affected steam generator would continue to blow down and dry out following a Main Steam

Isolation Signal (MSIS). Long-term controlled heat removal must then be accomplished through the remaining unaffected steam generator.

The largest possible MSLB that may occur is a double-ended guillotine rupture of a main steam line upstream of an MSIV. The PVNGS steam lines, however, have integral venturi flow restrictors installed in the steam generator outlet nozzles. The maximum steam blowdown rate is therefore limited by the cross-sectional throat area of a flow restrictor, which is approximately 1.283 ft^2.

Postulated MSLBs that may occur in operating Mode 3 (Hot Standby) are analyzed with respect to fuel performance, as well as to demonstrate the adequacy of shutdown margin requirements. There are four significant differences between the MSLB analyses performed for Modes 1 and 2 (see UFSAR Section 15.1.5) and those performed for Mode 3:

- In Mode 3, reactor trip breakers may be either open or closed at the time of event initiation, and CEAs may therefore be either inserted into or withdrawn from the core.
- In Mode 3, the reactor would be subcritical at the time of event initiation, with reactivity limited to a $k_{effective}$ that is less than 0.99.
- In Mode 3, RCS cold leg temperature at the time of event initiation would be in the range of approximately 350°F (the lower limit of Operating Mode 3) to 572°F.

- In Mode 3 with the initial RCS cold leg indicated temperature ≥ 485°F, Technical Specifications require that two trains of Emergency Core Cooling System (ECCS) be operable. Below 485°F, only one train of High Pressure Safety Injection (HPSI) is required to be operable. Application of the Single Failure Criterion therefore results in a total loss of safety injection capability for Mode 3 MSLB analysis initiated at lower cold leg temperatures.

Consequently, MSLB safety analysis was performed for a wide range of Mode 3 conditions. For the analysis, initial subcriticalities were determined on the basis of Temperature-Dependent Shutdown Margin (TDSDM) requirements discussed in UFSAR Section 15.1.6.3.3.

Samples of the Mode 3 MSLB analysis are as follows:

A. An inside containment break initiated at an RCS cold leg temperature of 572°F, with a coincident LOP.

B. An inside containment break initiated at an RCS cold leg temperature of 572°F, with offsite power available.

C. An inside containment break initiated at an RCS cold leg temperature of 572°F, with LOP and Steam Generator (SG) tube plugging.

D. An inside containment break initiated at an RCS indicated cold leg temperature of 500°F, with a coincident LOP.

E. An inside containment break initiated at an RCS indicated cold leg temperature of 485°F, with a coincident LOP and no HPSI pump available.

F. An inside containment break initiated at an RCS indicated cold leg temperature of 450°F, with a coincident LOP and no HPSI pump available.

G. An inside containment break initiated at an RCS indicated cold leg temperature of 350°F, with a coincident LOP and no HPSI pump available.

This safety analysis reveals that the case initiated at an RCS cold leg temperature of 572°F with a coincident LOP and SG tube plugging yields the maximum total reactivity, maximum core power fraction, and maximum heat flux fraction for a postulated Mode 3 MSLB. This case therefore also yields the lowest Macbeth DNBR and highest linear heat rate values, making it the limiting case with respect to the potential for fuel degradation.

The sequence of events for this limiting case is provided in Table 15.1.6-1. (For breaks initiated at lower RCS cold leg temperatures, the timing of events may differ, and safety injection may not be credited in the analysis as explained above.) This sequence of events was obtained by simulating the limiting Mode 3 MSLB event with the mathematical models identified in UFSAR Section 15.1.6.3.

For this limiting case, the MSLB will initially cause the main steam flow rate to rapidly increase, then gradually decrease as

the affected steam generator blows down and depressurizes (Figure 15.1.6-1). The excess steam demand will cool the RCS, decreasing cold leg temperatures in both RCS loops (Figure 15.1.6-2) as well as the average core inlet and outlet temperatures (Figure 15.1.6-3). In the presence of a negative MTC, the decrease in RCS temperature will result in an increase in reactivity (Figure 15.1.6-4), core power (Figure 15.1.6-5), and core heat flux (Figure 15.1.6-6). Figure 15.1.6-6 shows that the core heat flux may peak twice during the event simulation. The first peak occurs during the first few seconds of the transient, as forced flow through the core rapidly decreases following the LOP, and as MSIVs are closing and slowing the rate of decrease in core inlet temperature. The second peak occurs later, as the rate of increase in moderator reactivity slows, and negative reactivity from safety injection boron effectively stops the increase in core power.

Table 15.1.6-1

SEQUENCE OF EVENTS FOR THE LIMITING
SUBCRITICAL MAIN STEAM LINE BREAK WITH LOP SAFETY ANALYSIS
(RCS T_{cold} = 572°F)

Time (seconds)	Event
0.0	Double-ended guillotine MSLB (on SG#1) occurs inside or outside containment
0.0	LOP occurs
0.0	RCPs begins to coast down
6.49	Steam generator pressure reaches MSIS setpoint
6.99	Void begins to form in reactor vessel upper head
11.58	SIAS trip setpoint reached
12.10	All MSIVs closed. Steam flow from steam generator No. 2 halted
41.58	One HPSI pump begins injecting water into the RCS
174.0	Safety injection boron reaches RCS cold legs
212.0	Maximum total reactivity occurs
291.9	Macbeth minimum DNBR occurs
292.0	Maximum core power fraction occurs
295.0	Maximum heat flux fraction occurs
1800.0	Plant operators take control of the plant

Like MSLBs that may occur in Modes 1 and 2, the rapid cooldown following a Mode 3 MSLB will also result in decreasing RCS and steam generator pressures (Figures 15.1.6-7 and 15.1.6-8, respectively). Additionally, although some secondary system inventory may initially be lost from the unaffected steam generator, closure of the MSIVs following an MSIS will serve to retain water in that generator (Figure 15.1.6-9).

Detection of a Mode 3 MSLB may be accomplished by an RCS or steam generator low pressure alarm, a steam generator low level alarm, recognition of an excess steam demand, or a high containment pressure alarm (if the MSLB occurs inside containment).

For the limiting Mode 3 MSLB, Table 15.1.6-1 does not reflect a reactor trip or CEA insertion following a trip. Although a trip is anticipated in the actual plant, it should be noted that CEAs may already be fully inserted into the core when the plant is in Mode 3. Therefore, for analytical purposes, CEA worth at trip is not explicitly modeled with a time-dependent scram curve, but rather it is accounted for in the initial assumed subcriticality. This analytical practice is utilized for Mode 3 MSLBs because the minimum DNBR and maximum linear heat rate values occur later in the event sequence, after any trippable CEAs have fallen into the core.

Table 15.1.6-1 reflects a coincident LOP in the sequence of events. Following a LOP, the coolant flow rate through the RCS would decrease rapidly, as the RCPs coast down and the RCS transitions from forced flow to natural circulation conditions

(Figure 15.1.6-10). Although a loss of forced flow may result in locally higher coolant temperatures in the core region, overall the RCS would still continue to cool down while the faulted steam generator dries out. This cooldown would increase RCS coolant density, causing the pressurizer level to drop temporarily (Figure 15.1.6-11) and a void to form in the reactor vessel upper head.

Pressurizer pressure would likewise decrease to the SIAS setpoint, actuating any operable safety injection pumps. As noted above, however, consideration of Technical Specification requirements and the Single Failure Criterion results in only one HPSI pump starting on demand, if the initial cold leg indicated temperature is greater than or equal to 485°F. At these higher temperatures, safety injection flow into the RCS would serve to deliver soluble boron and add negative reactivity, thereby counteracting the positive reactivity insertion due to the moderator cooldown and Doppler effects. At lower initial cold leg temperatures, however, the moderator reactivity insertion is less severe, and soluble boron is not required to halt the increase in reactivity and core power in the presence of adequate CEA worth at trip. For analytical purposes, no safety injection flow is credited for initial cold leg indicated temperatures that are less than or equal to 485°F.

Operator action is not credited in the Mode 3 MSLB safety analysis for 30 minutes following event initiation. At that time, however, it is assumed that plant operators would take action to stabilize the plant in a safe shutdown condition.

15.1.6.3 Core and System Performance

15.1.6.3.1 Mathematical Models

The PVNGS Mode 3 MSLB safety analysis utilized the following mathematical models:

- The CENTS computer code was used to simulate the NSSS transient response. The CENTS computer code is described in UFSAR Section 15.0.3.1.3.2 and in an NSSS vendor topical report.[1][2]

- Because the range of the CE-1 CHF correlation does not extend to low pressures and low flow rates that may exist in the RCS following a Mode 3 MSLB, the Macbeth correlation[17][18] is utilized to determine the margin to DNB. The Macbeth correlation calculates CHF as a function of mass flux, inlet subcooling, system pressure, heated diameter, and channel length. Use of a channel heat balance allows the correlation to be converted to a "local conditions" form, thereby allowing CHF to be determined as a function of height in the hot channel. The effect of non-uniform axial heating is incorporated by using the method applied by Lee in Reference 19. The Macbeth CHF correlation is also described in the CENTS computer code topical report.[1]

15.1.6.3.2 Input Parameters and Initial Conditions

Table 15.1.6-2 summarizes the key input parameters and initial conditions utilized in the PVNGS Mode 3 MSLB safety analyses.

The following points serve to explain the selection of initial conditions as they appear in Table 15.1.6-2:

- Initial core power level is established by the initial subcriticality corresponding to each RCS cold leg temperature, where the initial subcriticality is assumed to equal the minimum required TDSDM for the reactor trip breakers closed configuration case (see Figure 15.1.6-12). Evaluation of the reactor trip breakers open configuration case is discussed in Section 15.1.6.3.3.
- Initial core inlet temperatures were selected to bound the plant configurations, and TDSDM allowed by Technical Specifications in Mode 3.

Table 15.1.6-2

INPUT PARAMETERS AND INITIAL CONDITIONS
FOR THE LIMITING SUBCRITICAL MAIN STEAM LINE BREAK
SAFETY ANALYSES (RCS T_{COLD} = 572°F)

Parameter	Assumed Values
Initial Subcriticality (%Δρ)	-6.50
Initial Core Power (% of RTP)	1.54×10^{-6}
Initial Core Inlet Temperature (°F)	572
Initial Pressurizer Pressure (psia)	1340
Initial RCS Flow Rate (% of Design Rated)	95
Initial Pressurizer Water Level (% Narrow Range)	60
Initial Steam Generator Water Level (Feet)	33 (61% WR)
Moderator Temperature Coefficient (Δρ/°F)	-4.4×10^{-4}
Doppler Fuel Temperature Coefficient	EOC
Delayed Neutron Kinetics	EOC
Inverse Boron Worth (ppm/%Δρ)	-130
Fuel Rod Gap Conductance (BTU/hr-ft^2-°F)	5755
Number of Plugged Steam Generator Tubes (Total %)	10
Break Size (ft^2)	1.283
Loss of Offsite Power	Yes
Additional Single Failure	HPSI

- An initial pressurizer pressure of 1340 psia was assumed for the case of 572°F cold leg temperature. The SIAS setpoint was set at the saturation pressure of the cold leg indicated temperature. For other temperature cases, a lowest possible Pressurizer pressure and lowest SIAS setpoint (saturation pressure) are used.
- The initial assumed core flow rate affects the rate of core inlet temperature cooldown following a MSLB, which in turn affects the positive reactivity insertion in the presence of a negative MTC cooldown curve. In accordance with station operating procedures, between 2 and 4 RCPs may be in operation during Mode 3, depending upon the RCS cold leg temperature. Additionally, Technical Specifications allow for all RCPs to be de-energized for up to one hour (per 8-hour period). For comparative purposes, the safety analyses described herein assumed 4 RCPs were in operation at the time of event initiation. For those cases with a coincident LOP, all RCPs were then immediately de-energized at event initiation. For cases with offsite power available, Mode 3 MSLB analysis was performed with various RCP operating configurations. The analysis confirmed that the conclusions described herein remain valid, i.e., the limiting case with regard to fuel performance is the case initiated from an RCS cold leg temperature of 572°F with a coincident LOP, and the shutdown margin requirements for trip breakers closed configuration.

- A high Pressurizer level was selected since use of a high level tends to delay SIAS. The analysis conservatively assumes a pressurizer level corresponding to 60% of Pressurizer level control range.

- The safety analysis performs parametrics on the Pressurizer pressure and steam generator level. High steam generator level increases the stored energy, results in a more severe blowdown, a faster cooldown rate following the MSLB, and a greater reactivity insertion in the presence of a negative MTC cooldown curve. However, this also causes the Pressurizer pressure to drop much lower such that the HPSI pump is able to inject more highly borated water into the core.

- When the liquid inventory in a steam generator decreased below 5000 lbm as a result of the blowdown, the primary-to-secondary system heat transfer rate was ramped down to zero as the mass decreased to 2500 lbm.

- The most negative MTC cooldown curve was used for this analysis, corresponding to End of Cycle (EOC) conditions.

- An EOC (most negative) Doppler fuel temperature coefficients curve was used for the Mode 3 MSLB analysis. Use of EOC values is consistent with the selection of the most negative MTC cooldown curve. Use of a most negative curve adds relatively more positive reactivity as a result of a change in fuel temperature following a MSLB.

- Relative to other parameters, the delayed neutron fraction has a minor effect on core power following a Mode 3 MSLB. EOC values were chosen, consistent with the use of EOC MTC and Doppler values.

- A maximum value was selected for the inverse boron worth, to reduce the negative reactivity that would be inserted as a result of boron injected by the Safety Injection (SI) system. The sweep-out volume represents the volume of water that must be displaced before safety injection boron reaches the primary system. The Safety analysis for this event uses a more conservative (larger) sweep-out volume than the required value of 60.6 cubic feet in the SI line from the RCS. Boron injection was credited only for those cases initiated from an RCS cold leg indicated temperature of 485°F or higher (see UFSAR Section 15.1.6.2).

- The maximum fuel rod gas gap conductance value was selected so that energy from the fuel would quickly reach the surface of the fuel rod clad. This results in a heat flux that closely follows core power, and therefore more thermal margin degradation as power increases.

- Steam generator tube plugging decreases the heat transfer rate from the RCS to the secondary system and thereby decreases the initial SG pressure. A lower SG pressure promotes an earlier MSIS but delays the SIAS (due to higher pressurizer pressure). The combination effect determines the resulting limiting condition. Based on the

parameteric evaluation, it is shown that the limiting case is 10% tube plugged for 3990 MWt configuration.

- A large break size was assumed for the analysis, with steam blowdown limited by the cross-sectional throat area of the flow restrictors in the outlet nozzles of both steam generators. A large break size maximizes the cooldown rate and resulting reactivity insertion.

- For the Mode 3 MSLB analysis, an additional single failure involving the failure of one HPSI pump to start on demand was assumed (see UFSAR Table 15.0-0). For those cases initiated at an RCS cold leg indicated temperature of 485°F or higher, this single failure served to reduce the capacity of the SI system to provide boron to the RCS. For those cases initiated at lower RCS cold leg temperatures, this failure resulted in a total loss of SI capacity (see UFSAR Section 15.1.6.2). A single failure affecting SI capacity is more limiting with respect to core performance than a postulated failure of an MSIV to close following an MSIS.

15.1.6.3.3 Results

Key results for the limiting Mode 3 MSLB safety analysis are summarized in Table 15.1.6-3.

Table 15.1.6-3

RESULTS FOR THE LIMITING SUBCRITICAL MAIN STEAM LINE BREAK SAFETY ANALYSES (RCS T_{COLD} = 572°F)

Parameter	Results
Peak Linear Heat Generation Rate (KW/ft)	12.8
Maximum Core Power (% of RTP)	1.46
Maximum Total Reactivity (%$\Delta\rho$)	0.236
Minimum MacBeth DNBR	1.95

The case initiated at an RCS cold leg temperature of 572°F, with a coincident LOP and SG tube plugging, yielded the largest total reactivity, the largest core power fraction, and the largest heat flux fraction for any of the analyzed Mode 3 MSLBs. Further analysis of this case revealed that, if both the fission power and decay power components were taken into consideration, the peak transient linear heat rate would be less than that required to cause fuel centerline melting. Additionally, the calculated Macbeth DNBR remained above the deterministic limit of 1.30. Therefore, it is concluded that fuel clad degradation would not occur following a postulated MSLB in Mode 3.

As noted previously, the Mode 3 MSLB safety analysis cases were initiated from subcritical conditions, where the initial subcriticality was assumed to be equal to the minimum required TDSDM for an indicated cold leg temperature (see Table 15.1.6-2 and Figure 15.1.6-12). However, as Figure 15.1.6-12 shows, the

minimum required TDSDM differs between the trip breakers open configuration and the trip breaker closed configuration. Generally, if the reactor trip breakers are open, the minimum SDM required by the Core Operating Limits Report (COLR) is less than that required when the breakers are closed, across the entire range of cold leg temperatures allowed in Mode 3.

However, it should also be noted that the Technical Specification definition for SDM states that the single CEA of highest reactivity worth is assumed to be fully withdrawn from the core. Therefore, if the CEAs are in a confirmed inserted configuration with reactor trip breakers open, the amount of reactivity by which the plant would actually be subcritical would be the sum of the SDM and the Stuck Rod Worth (SRW). Figure 15.1.6-12 illustrates an example in which the SRW is assumed to be 2.0% $\Delta\rho$.

Figure 15.1.6-12 shows that the plant must be subcritical by a SDM of at least 4.0% $\Delta\rho$ to 6.5% $\Delta\rho$ (depending upon the value of T_{cold}) when reactor trip breakers are closed, or by a SDM of at least 1.0% $\Delta\rho$ to 5.0% $\Delta\rho$ when reactor trip breakers are open. However, for the breakers open condition, these SDM values are based on the assumption that the most reactive rod is held out of the core. In the trip breakers open configuration, this “stuck” rod is actually inserted into the core, adding another 2.0% $\Delta\rho$ of subcriticality. Therefore, for the trip breakers open configuration, the reactor would actually be subcritical by at least 3.0% $\Delta\rho$ to 7.0% $\Delta\rho$ (depending upon the value of T_{cold}).

Further comparison of the curves in Figure 15.1.6-12 shows that, for RCS cold leg temperatures greater than 450°F, the reactor would be less subcritical (i.e., at a higher initial core power level) for the trip breakers closed configuration than for the trip breakers open configuration. Therefore, the Mode 3 MSLB safety analyses described herein for the trip breakers closed configuration (above 450°F), clearly bound the trip breakers open configuration when the SRW is at least 2.0% $\Delta\rho$.

Conversely, for RCS cold leg indicated temperatures less than 450°F, the reactor would be initially less subcritical for the trip breakers open configuration than for the trip breakers closed configuration. Therefore, it is concluded that the trip breakers open configuration likewise bound the trip breakers closed configuration if the SRW is at least 2.0% $\Delta\rho$.

Therefore, verification that the SRW is at least 2.0% $\Delta\rho$ for reload core designs, ensures that the Mode 3 MSLB safety analysis described herein bounds both the trip breakers open and trip breakers closed configurations, across the full spectrum of Mode 3 cold leg temperatures.

15.1.6.4 RCS Pressure Boundary Barrier Performance

15.1.6.4.1 Mathematical Models

The mathematical models that were used to analyze the performance of the RCS pressure boundary are the same as those described in UFSAR Section 15.1.6.3.1.

15.1.6.4.2 Input Parameters and Initial Conditions

The key input parameters and initial conditions that were used to analyze the performance of the RCS pressure boundary are the same as those described in Section 15.1.6.3.2.

15.1.6.4.3 Results

The safety analysis shows that Mode 3 MSLB is primarily characterized as a cooldown event and that, following an MSIS, both RCS and steam generator pressures will tend to stabilize (see Figures 15.1.6-7 and 15.1.6-8). Because heat sources in the NSSS are not sufficient to raise pressurizer pressure to the minimum PSV lift setting specified in the Technical Specifications, the peak RCS pressure will remain below the acceptable design limit for this event (i.e., 110% of the RCS design pressure of 2500 psia, or 2750 psia). Likewise, pressure in the main steam system will remain below the minimum allowable MSSV lift settings and therefore below the acceptable design limit for this event (i.e., 110% of the steam generator shell side design pressure of 1270 psia, or 1397 psia).

15.1.6.5 Containment Performance and Radiological Consequences

The core performance safety analysis in UFSAR Section 15.1.6.3 indicates that MSLBs in Mode 3 (Hot Standby) will not result in fuel clad degradation. Hence, significant offsite and control room dose consequences are not anticipated for such events. Nonetheless, because MSLBs are classified as limiting faults, their postulated consequences include the potential to release

significant amounts of radioactive material to the environment. It is concluded that the radiological consequences of MSLBs that may occur during Mode 3 are conservatively bounded by the results presented in UFSAR Section 15.1.5.5 for MSLBs that may occur in Modes 1 (Power Operation) or 2 (Startup).

15.1.6.6 Conclusions

Evaluation of postulated MSLBs in plant operating Mode 3 (Hot Standby) shows that:

- Pressure in the RCS will be maintained below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- Pressure in the main steam system will be maintained below 110% of the steam generator shell side design value (i.e., 110% of 1270 psia, or 1397 psia).
- Offsite and control room radiological dose consequences are bounded by the results presented in UFSAR Section 15.1.5.5 for MSLBs that may occur in Modes 1 (Power Operation) or 2 (Startup).

15.2 DECREASE IN HEAT REMOVAL BY THE SECONDARY SYSTEM

15.2.1 LOSS OF EXTERNAL LOAD

15.2.1.1 Identification of Event and Causes

The loss of external load event is caused by the disconnection of the turbine generator from the transmission network.

15.2.1.2 Sequence of Events and Systems Operation

A loss of external load generates a turbine trip which results in a reduction in steam flow from the steam generators to the turbine, due to the closure of the turbine stop valves. The steam bypass control system (SBCS) and reactor power cutback system (RPCS) are both normally in the automatic mode and would be available upon turbine trip to accommodate the load rejection without necessitating reactor trip or the opening of main steam safety valves. Should a turbine trip occur with these systems in the manual mode, a complete termination of main steam flow results and reactor trip would occur on high pressurizer pressure. If no credit is taken for immediate operator action, the main steam safety valves will open to limit the secondary pressure increase and provide a heat sink for the nuclear steam supply system (NSSS). The operator can initiate a controlled system cooldown using the SBCS any time after reactor trip occurs.

15.2.1.3 Analysis of Effects and Consequences

The results of the loss of load event are no more limiting with respect to reactor coolant system (RCS) pressurization than

those of the loss of condenser vacuum (LOCV) event presented in subsection 15.2.3. The LOCV also results in a turbine trip; however, feedwater flow is assumed to terminate following LOCV whereas it is assumed to ramp down to 5% following the loss of load. This larger reduction in heat removal capability results in a higher peak RCS pressure for the LOCV.

Like the LOCV, the departure from nucleate boiling ratio (DNBR) increases during the loss of load due to the increasing pressure. Thus, the initial DNBR is also the minimum DNBR. For the loss of load, due to its similarity with the LOCV event, there are no concurrent single failures which, when combined with the loss of external load, result in consequences more severe than the LOCV event with respect to RCS pressurization. The limiting single failure with respect to fuel performance is the loss of offsite power following a turbine trip. This event with a loss of offsite power results in an event similar to the loss of flow (LOF) event discussed in subsection 15.3.1. Results of the LOF event are directly applicable to the loss of external load with loss of offsite power following a turbine trip.

15.2.1.4 Conclusions

For the loss of load event and the loss of load with a single failure, the RCS pressure remains below 2750 psia thus ensuring primary integrity, and the minimum DNBR remains above the limit thus ensuring fuel cladding integrity.

15.2.2 TURBINE TRIP

15.2.2.1 Identification of Event and Causes

A turbine trip may result from a number of conditions which cause the turbine generator control system (TGCS) to initiate a turbine trip signal. A turbine trip initiates closure of the turbine stop valves.

15.2.2.2 Sequence of Events and Systems Operation

A turbine trip results in a reduction in steam flow from the steam generators to the turbine due to the closure of the turbine stop valves. The SBCS and RPCS are both normally in the automatic mode and would be available upon turbine trip to accommodate the load rejection without necessitating reactor trip or the opening of main steam safety valves. Should a turbine trip occur with these systems in the manual mode, a complete termination of main steam flow results and reactor trip would occur on high pressurizer pressure. If no credit is taken for immediate operator action, the main steam safety valves will open to limit the secondary pressure increase and provide a heat sink for the NSSS. The operator can initiate a controlled system cooldown using the SBCS any time after reactor trip occurs.

15.2.2.3 Analysis of Effects and Consequences

The results of the turbine trip event are no more limiting with respect to RCS pressurization than those of the LOCV event presented in subsection 15.2.3. The LOCV also results in a

turbine trip; however, feedwater flow is assumed to terminate following LOCV whereas it is assumed to ramp down to 5% following the turbine trip. This larger reduction in heat removal capability results in a larger peak RCS pressure for the LOCV.

Like the LOCV, the DNBR increases during the turbine trip due to the increasing pressure. Thus, the initial DNBR is also the minimum DNBR for the loss of load. Due to its similarity with the LOCV events, there are no concurrent single failures which when combined with the turbine trip result in consequences more severe than the LOCV event with respect to RCS pressurization. The limiting single failure with respect to fuel performance is the loss of offsite power following a turbine trip. This event with a loss of offsite power results in an event similar to the loss of ac power which initiates the LOF event discussed in subsection 15.3.1. Results of the LOF event are directly applicable to the turbine trip event with a loss of offsite power.

15.2.2.4 Conclusions

For the turbine trip event and the turbine trip with a single failure, the RCS pressure remains below 2750 psia thus ensuring primary system integrity, and the minimum DNBR remains above the limit thus ensuring fuel cladding integrity.

15.2.3 LOSS OF CONDENSER VACUUM

15.2.3.1 Identification of Causes and Frequency Classification

A loss of condenser vacuum (LOCV) may occur due to, but not limited to, the failure of the circulating water system to supply cooling water to the condenser; failure of the main condenser evacuation system to remove non-condensable gases; failure of a condenser vacuum breaker; excessive in-leakage of air through a turbine gland packing; loss of power (LOP); or rupture of a condenser shell.

An LOCV is an Anticipated Operational Occurrence (AOO) and is classified as an incident of moderate frequency.

15.2.3.2 Sequence of Events and Systems Operation

The LOCV analyses are performed as separate cases for the primary and secondary peak pressure limits, since these events are not mutually conservative. The sequence of events for the moderate frequency LOCV event is presented in Table 15.2.3.1 for the primary peak pressure case and Table 15.2.3.2 for the secondary peak pressure case. The primary peak pressure case also analyzes the fuel integrity (minimum DNBR) for the LOCV event.

Condenser pressure will increase following an LOCV, causing a trip of the main turbine and closure of the Turbine Admission Valves (TAVs). The LOCV also causes the feedwater pumps to trip due to low suction pressure and disables the turbine bypass valves. The closure of the turbine stop valves and coastdown of main feedwater pumps result in a Reactor Coolant

(Primary) System (RCS) and Main Steam (Secondary) System heat up, and both system pressures increase rapidly. A reactor trip occurs on high pressurizer pressure (HPPT) occurs. The pressure increase in the primary and secondary system are limited by the primary safety valves (PSVs) and main steam safety valves (MSSVs).

If the Reactor Power Cutback System (RPCS) and the Steam Bypass Control System (SBCS) are in automatic mode of operation, a reactor power cutback may occur and the Nuclear Steam Supply System (NSSS) may continue to operate at a reduced power level. However, for the LOCV analysis, both the RPCS and SBCS are assumed to be in manual mode and credit is not taken for their functioning. Likewise, the Pressurizer Pressure Control System (PPCS) and Pressurizer Level Control System (PLCS), which may reduce over pressurization of the RCS, are assumed to be in manual mode and no credit is taken for their functioning.

A reactor trip on low steam generator level (LSGLT) could occur immediately following a LOCV, when a steam generator pressure spike causes the steam bubbles in the steam generator to collapse. However, this level trip is not credited in the analysis.

An auxiliary feedwater actuation signal (AFAS) on low steam generator level occurs as the plant begins to cooldown and depressurize. The auxiliary feedwater flow is automatically initiated after a time delay and begins to fill the steam generators until a normal level is reached.

The LOCV analysis does not credit operator action for the first thirty minutes following the event. Thirty minutes after initiation of the LOCV event, the operators commence a cooldown using the Atmospheric Dump Valves (ADVs).

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System (ESFAS) functions are consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS UFSAR delineated in UFSAR Chapter 7.

The NRC's Standard Review Plan states that an incident of moderate frequency, such as the loss of condenser vacuum event, should not generate a more serious plant condition without other faults occurring independently. In addition, the Standard Review Plan states that an incident of moderate frequency, in combination with a single active component failure or single operator error, should not result in the loss of function of any barrier other than the fuel cladding.

A LOCV event will cause a termination of feedwater and main steam flow. The analysis does not model the time dependence in detail. Instead, the LOCV is assumed to abruptly and completely terminate both main steam and feedwater flow. In considering the peak pressure criteria, the only mechanisms for mitigation of the RCS and main steam system overpressurization are the PSVs, MSSVs and RCS flow. Table 15.0-0 is used to determine credible single failures for safety analysis. This table indicates that there are no credible failures that can

degrade the PSV and MSSV capacity. Technical Specification 3.7.1 places limits on reactor power and variable overpower trip (VOPT) setpoints when one or more MSSVs are inoperable, thereby ensuring secondary system peak pressure remains within 110% of secondary system design pressure. The LOCV is one of the transients analyzed for validating Technical Specification 3.7.1. A decrease in RCS to steam generator heat transfer due to reactor coolant flow coastdown can be caused by a LOP following a turbine trip. A Reactor Coolant Pump (RCP) coastdown results in a reactor trip that is generated by the Core Protection Calculators on RCP speed. Due to the rapid reactor trip, this failure reduces the peak pressure relative to the LOCV itself. The results of the parametric study show that a LOP coinciding or following the High Pressurizer Pressure Trip (HPPT) does not make the primary and secondary side pressures more adverse. In addition, it is assumed that the most reactive control rod fails to insert on scram.

Therefore, it was concluded that there is no single failure that would make the maximum primary and secondary pressure more limiting during a LOCV event.

A decrease in RCS flow is the only parameter which can significantly reduce the minimum DNBR during a LOCV event. The LOP is the only failure that may affect RCS flow. LOCV by itself, however, produces an increasing RCS pressure which compensates for the elevated RCS temperatures such that the available thermal margin does not degrade before the onset of the LOP. Thus, the overall DNBR degradation experienced during

an LOCV event with LOP would be bounded by that of the loss of RCS flow event of UFSAR Section 15.3.1.

Table 15.2.3-1
SEQUENCE OF EVENTS FOR THE LOCV
PRIMARY SIDE PEAK PRESSURE and FUEL PERFORMANCE (DNBR) EVENT

Time (sec)	Events
0.00	LOCV, turbine trip, main FW pump trip
0.00	Minimum DNBR occurs
7.05	Pressurizer pressure reaches HPPT setpoint
7.55	Reactor trip breakers open
8.16	Scram CEAs begin falling
8.69	PSVs open
8.99	MSSV Bank 1 opens[1]
9.60	Maximum RCS pressure reached
11.08	MSSV Bank 2 opens
12.93	PSVs close
13.35	Maximum steam generator pressure occurs
13.36	MSSV Bank 3 opens
16.81	Steam generator water level reaches AFAS Analytical setpoint
19.80	MSSV Bank 3 closes
31.39	MSSV Bank 2 closes
59.98	MSSV Bank 1 closes
62.90	Auxiliary Feedwater (AFW) flow initiated
1798.50	Maximum pressurizer water volume occurs
1800.0	Operator initiates plant cooldown

[1]Bank 1 MSSVs cycle throughout the 1800 seconds. Only the initial opening and closure are listed in the table.

Table 15.2.3-2
SEQUENCE OF EVENTS FOR THE LOCV
SECONDARY SIDE PEAK PRESSURE EVENT

Time (sec)	Event
0.00	LOCV, turbine trip, main feedwater pump trip occur
0.00	Minimum DNBR occurs
4.02	MSSV bank 1 opens[2]
5.65	MSSV bank 2 opens
6.89	Pressurizer pressure reaches HPPT setpoint
7.32	MSSV bank 3 opens
7.39	Reactor trip breakers open
8.00	Scram CEAs begin falling
9.50	PSVs open
9.83	Maximum RCS pressure occurs
11.50	PSVs close
12.09	Maximum pressurizer water volume
12.56	Steam generator water level reaches AFAS analytical setpoint
13.97	Maximum steam generator pressure occurs
22.62	MSSV bank 3 closes
34.77	MSSV bank 2 closes
58.56	AFW flow initiated
60.10	Pressurizer Pressure reaches SIAS analytical setpoint
64.10	MSSV bank 1 closes
90.10	High Pressure Safety Injection flow initiated
1800.0	Operator initiates plant cooldown

[2]Bank 1 MSSVs cycle throughout the 1800 seconds. Only the initial opening and closure are listed in the table.

15.2.3.3 Core and System Performance

A. Mathematical Model

The NSSS response to a LOCV was simulated using the CENTS computer program described in UFSAR Section 15.0.3.1.3.2. Parametric studies are performed using key design inputs to maximize primary and secondary side pressures. Inputs to the CENTS code such as moderator reactivity as a function of moderator density, Doppler reactivity as a function of effective fuel temperature, and shutdown rod worth were calculated using the two-dimensional ROCS code discussed in UFSAR Section 4.3.3.1.1.2. Shutdown rod worth assumes that the most reactive control rod fails to insert on scram. Input to the CENTS code may also be calculated using the SIMULATE-3 code discussed in UFSAR Section 4.3.3.1.1.5.

The initial and transient DNBR was calculated using the CETOP computer code (see UFSAR Section 4.4 and 15.0.3.1.6), which uses the CE-1 CHF correlation described in reference 2. The LOCV event does not present a challenge to the DNBR SAFDL because the RCS overpressurization tends to increase DNBR.

Since there is no power excursion during the transient, the LOCV event does not challenge the peak fuel centerline temperature SAFDL or the limit on linear heat generation rate (21 kW/ft).

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a LOCV from full power conditions are presented in Table 15.2.3-3. The initial conditions were varied within the ranges of steady state operation configurations (i.e., specified by the Technical Specifications, plant configuration, and design specifications) to determine the set of initial conditions that produce the most adverse consequences following a LOCV.

Parameters of interest include initial core inlet temperature, core inlet flow, pressurizer pressure, steam generator level, pressurizer water level, PSV and MSSV tolerances and blowdowns, Moderator Temperature Coefficient (MTC), Fuel Temperature Coefficient (FTC), fuel rod gap conductances, kinetics parameters, LOP, function of PLCS and PPCS and SG tube plugging. Starting from a base case, one parameter at a time is changed to establish the trends for the RCS and steam generator pressure.

C. Results

The response of key core parameters as a function of time is presented in Figures 15.2.3-1 through 15.2.3-3 and 15.2.3-14 through 15.2.3-17 for this moderate frequency event for the primary peak pressure case and the secondary peak pressure case, respectively. The sudden reduction in steam flow caused by the LOCV leads to a reduction of the

primary-to-secondary heat transfer and an increase in RCS temperature. The rapid heatup and volumetric expansion of the reactor coolant results in an increase in pressurizer pressure. When the pressurizer pressure reaches the HPPT setpoint, reactor trip occurs. The CEAs drop into the core initiating the decrease in core power from full power.

Table 15.2.3-3
ASSUMED INITIAL CONDITIONS FOR LOCV
PRIMARY PEAK PRESSURE/DNBR AND SECONDARY SIDE PEAK PRESSURE CASES

Parameter	Value	
	Primary Side Peak Pressure/DNBR Case	Secondary Side Peak Pressure Case
Initial core power (% of RTP)	102	102
Initial core inlet temperature (°F)	555	566
Initial pressurizer pressure (psia)	2100	2100
Initial RCS flow (% design)	116	95
Initial pressurizer water level (%)	24	24
Initial steam generator level (% WR)	60.7	60.7
Moderator Temperature Coefficient ($\Delta\rho$/°F)	0.0	0.0
Fuel Temperature Coefficient	Least negative	Most negative
SCRAM delay time (sec)	0.5	0.5
CEA holding coil delay (sec)	0.6	0.6
CEA worth at trip - WRSO (%$\Delta\rho$)	8.0	8.0
Fuel gap conductance (Btu/hr-ft^2-°F)	500	500
Plugged tubes (per steam generator)	1258	0
AFW flow (gpm/pump)	650	650
AFW delay time (sec)	46	46
PSV setpoint tolerance	+3%	+3%
PSV blowdown	5%	5%
MSSV Setpoint Tolerance	+3%	+3%
MSSV blowdown	5%	5%
Pressurizer heaters and sprays	Off	On
Charging and letdown flows (gpm)	139.5/29	46.5/46.5
LOP	No	No

Since there is no power excursion during the transient, the LOCV event does not challenge the peak fuel centerline temperature SAFDL or the limit on linear heat generation rate (21 kW/ft).

The minimum DNBR is greater than the DNBR SAFDL value of 1.34 and meets the acceptance criteria of the Standard Review Plan (see Figure 15.2.3-14). Therefore, fuel cladding damage is not predicted for this moderate frequency event.

15.2.3.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate the RCS barrier performance for the limiting moderate frequency event are identical to those described in UFSAR Section 15.2.3.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed to evaluate the RCS barrier performance for the limiting moderate frequency event are identical to those described in UFSAR Section 15.2.3.3.B.

C. Results

The response of key RCS parameters as a function of time is presented in Figures 15.2.3-4 through 15.2.3-13 and 15.2.3-18 through 15.2.3-28 for this limiting moderate frequency event.

The PSVs open and a maximum RCS pressure of 2745 psia is reached, which is less than 110% (2750 psia) of RCS design pressure (2500 psia). For the secondary side peak pressure case, three banks of MSSVs open and the maximum secondary system pressure of 1390 psia is reached, which is less than 110% (1397 psia) of secondary system design pressure (1270 psia).

These primary and secondary side maximum pressures meet the acceptance criteria of Standard Review Plan 15.2.3.

15.2.3.5 Radiological Consequences and Containment Performance

LOCV is a moderate frequency event in which no fuel damage occurs. Therefore, radiological consequences are not calculated for this event and containment isolation is not credited.

15.2.3.6 Conclusions

For the loss of condenser vacuum event, the maximum RCS pressure remains below 110% of RCS design pressure(2750 psia), thus ensuring primary system integrity. Likewise, the maximum secondary system pressure remains below 110% of design pressure (1397 psia), thus ensuring secondary system integrity.

The minimum DNBR remains well above the SAFDL limit, thus ensuring fuel cladding integrity.

15.2.4 MAIN STEAM ISOLATION VALVE CLOSURE

15.2.4.1 Identification of Event and Causes

The main steam isolation valve closure event is initiated by the closure of all MSIVs due to a spurious closure signal.

15.2.4.2 Sequence of Events and Systems Operation

The closure of all MSIVs results in the termination of all main steam flow. The decreased heat removal results in increasing primary and secondary temperatures and pressure. Reactor trip occurs on high pressurizer pressure. The pressure increases in the primary and secondary systems are limited by the pressurizer and steam generator safety valves. The operator can initiate a controlled system cooldown using the steam bypass control system any time after reactor trip occurs.

15.2.4.3 Analysis of Effects and Consequences

The results of the MSIV closure event are no more limiting with respect to RCS pressurization than those of the LOCV event presented in subsection 15.2.3. The LOCV also results in the termination of all main steam flow. However, main steam flow is terminated more rapidly during the LOCV since the closure time for the turbine stop valves is much shorter than that for the MSIVs. The faster reduction in heat removal results in a higher peak RCS pressure for the LOCV event.

Like the LOCV, the DNBR increases during the MSIV closure event due to the increasing pressure. Thus, the initial DNBR is also the minimum DNBR for the MSIV closure event.

Due to the similarity with the LOCV event, there are no concurrent single failures which when combined with the MSIV closure event result in consequences more severe than the LOCV event with respect to RCS pressurization. The limiting single failure with respect to fuel performance is the loss of offsite power following a turbine trip. This event with a loss of offsite power results in an event similar to the loss of ac power which initiates the LOF event discussed in subsection 15.3.2. Results of the LOF event are directly applicable to the MSIV closure with loss of offsite power following a turbine trip.

15.2.4.4 Conclusions

For the MSIV closure event and the MSIV closure with a single failure, the RCS pressure remains below 2750 psia thus ensuring primary system integrity, and the minimum DNBR remains above the limit thus ensuring fuel clad integrity.

15.2.5 STEAM PRESSURE REGULATOR FAILURE

This event does not apply to the CESSAR SYSTEM 80 design and therefore is not presented.

15.2.6 LOSS OF NONEMERGENCY AC POWER TO THE STATION AUXILIARIES

15.2.6.1 Identification of Event and Causes

The loss of nonemergency ac power to the station auxiliaries (LOAC) may result from either a complete loss of power from the

transmission network or a loss of power to 13.8kV buses NAN-S01 and NAN-S02. The LOAC is presented as the initiating event for the four pump loss of flow event discussed in subsection 15.3.1.

15.2.6.2 Sequence of Events and Systems Operation

When all normal ac power is assumed to be lost to the plant, the turbine stop valves close, and it is assumed that the area of the turbine control valves is instantaneously reduced to zero. Also, the feedwater flow to both steam generators is instantaneously assumed to go to zero. The reactor coolant pumps coast down and the reactor coolant flow begins to decrease. A reactor trip will occur as a result of a low DNBR condition as the flow coastdown begins. The pressure increases in the RCS and steam generators are limited by the pressurizer and steam generator safety valves.

The loss of all normal ac power is followed by automatic startup of the standby diesel generators, the power output of which is sufficient to supply electrical power to all necessary engineered safety features systems and to provide the capability of maintaining the plant in a safe shutdown condition. Subsequent to the reactor trip, stored and fission product decay energy must be dissipated by the reactor coolant system and main steam system. In the absence of forced reactor coolant flow, convective heat transfer coolant flow occurs. Initially, residual water inventory in the steam generators is used as a heat sink, and the resultant steam is released to atmosphere by the spring-loaded steam generator safety valves.

With the availability of standby diesel power, auxiliary feedwater is automatically initiated on a low steam generator water level signal. Plant cooldown is operator controlled via the atmospheric dump valves.

15.2.6.3 Analysis of Effects and Consequences

The results of the LOAC event are identical to those of the loss of reactor coolant flow event presented in subsection 15.3.1, and are no more limiting with respect to RCS pressurization than the LOCV event discussed in subsection 15.2.3. During the LOCV event the plant experiences simultaneous losses of steam and feedwater flow and condenser availability. In addition, the plant experiences a complete loss of forced reactor coolant flow during the LOAC event. The loss of forced reactor coolant flow results in an earlier reactor trip for the LOAC event (on low RCP shaft speed) compared to the reactor trip for the LOCV event (on high pressurizer pressure). The earlier trip promotes a less severe primary-to-secondary heat imbalance and hence a lower peak RCS pressure for the LOAC event.

The fuel performance for the LOAC is no more limiting than that for the LOF event discussed in subsection 15.3.1. The LOAC is the initiating event for the LOF so the fuel performance results of the LOF event are directly applicable to the LOAC event.

15.2.6.4 Conclusions

For the LOAC event and the LOAC with a concurrent single failure, the RCS pressure remains below 2750 psia thus ensuring primary system integrity, and the minimum DNBR remains above the limit thus ensuring fuel cladding integrity.

15.2.7 LOSS OF NORMAL FEEDWATER FLOW

15.2.7.1 Identification of Event and Causes

The loss of normal feedwater flow (LFW) event may be initiated by losing one or both main feedwater pumps or by a spurious signal being generated by the feedwater control system resulting in a closure of the feedwater control valve(s).

15.2.7.2 Sequence of Events and Systems Operation

LFW results in decreasing water level and increasing pressure and temperature in the steam generators. The RCS pressure and temperature also rise until a reactor trip occurs either due to low steam generator water level or high pressurizer pressure. Assuming the SBCS is in the manual mode of operation, termination of main steam flow due to closure of the turbine stop valves following reactor trip temporarily causes steam generator and RCS pressurization. The decrease in core heat rate after insertion of the CEAs in combination with the main steam safety valves opening restores the RCS to a new steady state condition. Auxiliary feedwater flow is automatically initiated on a low steam generator water level, assuring sufficient steam generator inventory for core decay heat

removal and cooldown to shutdown cooling entrance conditions. The cooldown is operator controlled using the SBCS and the condenser.

15.2.7.3 Analysis of Effects and Consequences

The maximum RCS pressure for the LFW event is less than that for the LOCV event discussed in subsection 15.2.3. The LOCV event results in the termination of main steam flow prior to reactor trip in addition to the total loss of normal feedwater flow. This additional condition aggravates RCS pressurization by further reducing the rate of primary-to-secondary heat transfer below that of the LFW event.

Like the LOCV, the DNBR increases during the LFW event due to the increasing RCS pressure. Thus the initial DNBR is also the minimum DNBR for the LFW event.

There are no concurrent single failures which when combined with LFW result in consequences more severe than the LOCV event with respect to RCS pressurization.

The limiting single failure with respect to fuel performance is the loss of offsite power following turbine trip. For the LFW event, prior to turbine trip the DNBR increases due to the RCS pressure increase. DNBR then briefly decreases after turbine trip due to the reactor coolant flow coastdown on loss of offsite power. The DNBR decreases similar to the DNBR transient associated with the total loss of reactor coolant flow event shown in subsection 15.3.1; however, the DNBR decrease for LFW is not as severe due to the earlier reactor

trip relative to the initiation of the coolant flow coastdown. Therefore, the minimum DNBR remains above the limit.

15.2.7.4 Conclusions

For the loss of feedwater flow event and the loss of feedwater flow with a concurrent single failure the RCS pressure remains below 2750 psia thus ensuring primary system integrity, and the minimum DNBR remains above the limit ensuring fuel cladding integrity.

15.2.8 FEEDWATER SYSTEM PIPE BREAKS

Feedwater line breaks (FWLBs) may occur due to pipe failures in the main feedwater system (FWS). The pipe breaks in the FWS are evaluated to confirm that the reactor coolant system is maintained in a safe status for a range of break areas up to and including double-ended breaks of the largest feedwater line.

The FWLB transient that results from the postulated FWS line break is sensitive to the break discharge rate. Therefore, a range of break sizes are evaluated to determine the acceptance of the most limiting Nuclear Steam Supply System (NSSS) response. Depending on the break size, location, and the plant operating conditions at the time of break, the effects of the break could cause a Reactor Coolant System (RCS) heatup (due to reduced feedwater flow to the affected steam generator) or a RCS cooldown (due to excessive energy discharge through the break).

In order to discuss the possible effects, FWLBs are categorized as small if the associated discharge flow is within the capacity of the FWS, and otherwise as large. For analytical consideration, break sizes that are less than or equal to 0.2 ft^2 are considered as small breaks in FWLB analyses. Break locations are identified with respect to the feedwater line reverse flow check valves, which are located between the steam generator feedwater nozzles and the containment penetrations. Closure of these valves to reverse flow from the nearest steam generator maintains the integrity and would limit uncontrolled discharge of that generator in the presence of a break upstream of the valves.

Breaks upstream of the check valves can initiate one of the following transients. If the FWS is unavailable following the pipe failure, a total loss of normal feedwater flow (LOFW) results. With the FWS remaining in operation no reduction in feedwater flow occurs for small breaks, while large breaks impose either a partial LOFW or a total LOFW, if the break area is sufficient to discharge the entire feedwater pump flow capacity.

In addition to the possibility of partial or total LOFW events, breaks downstream of the check valves have the potential to establish reverse flow from the nearest steam generator (referred to as the "affected" generator) back through the break. Reverse flow occurs whenever the FWS is not operating subsequent to a pipe break or when the FWS is operating but without sufficient capacity to maintain pressure at the break

above the steam generator pressure. It is only these breaks developing reverse flow that are of interest in these analyses in order to maximize the transient effects.

Depending on the enthalpy of the reverse flow and the ruptured steam generator's heat transfer characteristics, the reverse flow may induce either a RCS heatup or cooldown. However, excessive heat removal through the break is not considered in this analysis, because the cooldown potential is less than that of the main steam line break events. The maximum break size is smaller for the feedwater line break events than for the Main Steam Line Break (MSLB) event. In addition, MSLBs have a greater potential for discharging high enthalpy fluid due to the location of steam piping above feedwater piping within the steam generator Furthermore, the FWLBs cause an instant reduction in feedwater flow, unlike MSLBs. Since FWLBs can cause a rapid depletion of the affected steam generator's liquid mass, reduced heat transfer capability and a rapid RCS heatup and pressurization, it is the heatup potential that is emphasized in the peak pressure analyses.

A general description of the FWLB event follows, assuming a break downstream of the check valves, unavailability of the FWS, and low enthalpy break discharge. The loss of subcooled feedwater flow to both steam generators causes increasing steam generator temperatures and decreasing liquid inventories and water levels. The rising secondary temperatures reduce the primary-to-secondary heat transfer and cause a heatup and pressurization of the RCS. The heatup becomes more severe as

the ruptured steam generator experiences a further reduction in its heat transfer capability due to insufficient liquid inventory as the break discharge continues. This initial sequence of events culminates with a reactor trip on high pressurizer pressure, low steam generator water level, or high containment pressure. RCS heatup can continue after the reactor trip due to a total loss of heat transfer in the ruptured steam generator as it empties. Eventually the decreasing core power following reactor trip reduces the core heat rate to the heat removal capacity of the unaffected steam generator.

15.2.8.1 Parametric Analysis for FWLBs

Sensitivity studies are used to establish the limiting set of initial operating and transient parameters for the FWLB events with respect to RCS pressurization, long term RCS heat removal capacity of the Auxiliary Feedwater (AFW) system and pressurizer fill using the CENTS computer code. These parameters include break size and steam generator mass interval over which heat transfer area ramps to zero ΔM, initial core power, initial RCS pressure, initial RCS flow, initial pressurizer liquid volume, pressurizer and main steam safety valve tolerance and blowdown, core physics conditions, fuel rod gap conductance, initial core inlet temperature, initial feedwater enthalpy, and initial steam generator inventory.

15.2.8.1.1 Parametrics on Key Parameters

For the parametric study on the key parameters, the FWLB with loss of offsite power (LOP) methodology that considers a coinciding High Pressurizer Pressure Trip (HPPT) and Low Steam Generator Level Trip (LSGLT) (occurring at 5500 lbm liquid mass inventory) with a constant break size is applied and the initial steam generator level is adjusted to match the trips. Selection of the parameters is based on the range specified by the Technical Specifications, plant configuration, and design specifications. Starting from a base case that is based on a set of configuration and assumptions, one parameter at a time is changed. The resulting pressures and levels shown in Figures 15.2.8-1 through 15.2.8-11 are used to establish the trends for the RCS peak pressure and the maximum pressurizer level for each parameter.

Initial pressurizer pressure affects the timing of HPPT, and is a parameter that is adjusted to result in coinciding HPPT and the LSGLT. Therefore, the effect of the initial pressurizer pressure on peak RCS and maximum pressurizer level is evaluated together with the initial steam generator inventory, the break size, and the initial temperature. The limiting initial pressurizer pressure is determined in conjunction with the determination of the limiting break size in UFSAR Section 15.2.8.1.2.

A higher initial core inlet temperature increases the initial steam generator pressure and reduces primary to secondary heat transfer. A higher temperature also results in higher RCS

energy content to be removed. Increased initial steam generator pressure due to higher temperature results in an earlier opening of the Main Steam Safety Valves (MSSVs), which increases the heat removal by the secondary system during the transient. Depending on the other conditions and time of trip, timing of these competing effects during the transient can make the peak pressure or pressurizer level more adverse or more benign. Therefore, a further study was conducted in conjunction with the break size and initial pressure in UFSAR Section 15.2.8.1.2.

15.2.8.1.2 Parametrics on Limiting Break Size and Steam Generator Heat Transfer Characteristics

In order to determine the sensitivity of the RCS pressurization to the ruptured steam generator heat transfer characteristics, the effective heat transfer area was conservatively assumed to decreased linearly (from the design value to zero) as the steam generator liquid mass decreased (from a selected value to zero). The mass interval over which the ramp down is assumed to occur is referred to as ΔM. Decreasing values of ΔM imply a more rapid loss of heat transfer in the ruptured steam generator.

After the most limiting key initial parameters are determined as described in UFSAR Section 15.2.8.1.1, the parametric study on break size and ΔM was performed. In addition to the break size and ΔM, different combinations of the initial pressurizer pressure and initial core inlet temperature are considered

since the combinations of these effect the primary to secondary heat transfer characteristics, break flow characteristics and the heat removal by Primary Safety Valves (PSVs) and MSSVs during the transient. The reactor trip is modeled to occur either on high pressurizer pressure trip or steam generator liquid mass. The trip will occur either on the LSGLT for larger break sizes since the steam generator empties faster, or on the HPPT for smaller break sizes since the RCS pressurization is steeper. Effects of initial pressurizer pressure and core inlet temperature are evaluated by starting the event at a minimum steam generator level. Results indicate that the current methodology of matching the HPPT with the LSGLT is limiting.

The limiting break size, and initial pressurizer pressure and core inlet temperatures are then evaluated for two heat transfer degradation assumptions per methodology; ΔM=0 for FWLBs with LOP, and ΔM=30,000 for small FWLBs without LOP and a single failure.

<u>ΔM =0 Case:</u>

For the instantaneous loss of heat transfer (ΔM =0), the most adverse peak pressure is obtained when the event starts from the maximum initial core inlet temperature and minimum initial pressurizer pressure (Figure 15.2.8-12). The limiting break size is the one that results in simultaneous trips on HPPT and LSGLT, which is chosen to occur when 5500 lbm liquid mass inventory is left in the steam generator.

If the LSGLT occurs much earlier than HPPT, as for larger break sizes, RCS pressure and temperature are lower at the time of trip. In addition, the larger break sizes provide additional heat removal by the energy release from the break. Thus, the complete loss of heat transfer in the affected steam generator has less severe effect for very large breaks since it is off-set by this additional energy removal through the break, resulting in lower RCS peak pressure.

If the trip on HPPT occurs much earlier than the LSGLT, as for smaller break sizes, the left over liquid inventory in the affected steam generator provides cooldown of the RCS through the break until the heat transfer is lost at low steam generator inventory. Furthermore, for smaller break sizes, additional cooling becomes available when the PSVs open. For very small break sizes, the cooldown by the PSVs become more effective than the cooldown by the break. The cooling effect of the PSVs can be seen by looking at the results for very small break sizes. Below a certain break size, the cooldown by the leftover steam generator inventory is not significant, and the peak RCS pressure is driven by the PSVs. The peak pressure occurs much earlier than the loss of heat transfer, and is not affected by the break sizes.

As illustrated in Figure 15.2.8-12, lower initial pressure results in later simultaneous trips, shifting the peak pressure vs. break size curve to the left. In other words, decreasing initial pressure (or smaller break size) results in higher peak pressure. Lower initial core inlet temperature causes

additional delay of the simultaneous trips, resulting in smaller break sizes for matching trips. However, this results in lower peak RCS pressure due to the decreased energy content of the primary system at lower inlet temperatures. Therefore, for peak pressure determination, the limiting break size is the smallest break size that would result in simultaneous trips for the event starting from highest core inlet temperature and lowest pressurizer pressure.

The effect of initial core inlet temperature and initial pressurizer pressure on maximum pressurizer level for different break sizes is shown in Figure 15.2.8-13. Simultaneous HPPT with LSGLT also produces the most adverse pressurizer level. Lower initial pressurizer pressure results in a later trip which provides more time for pressurizer inventory addition before trip. Although the parametric study for $\Delta M=0$ shows that the maximum initial core inlet temperature is more limiting, the pressurizer volume is also increased by decreasing temperatures for smaller break sizes. Since the pressurizer level is evaluated for the long term cooling scenario, the later peaks of maximum pressurizer level are more of a concern. In the long term cooling case, the primary system is cooled by the AFWS, relief from the PSVs, MSSVs, and energy release from the break following the steam generator dryout. For these cooling mechanisms, the lower temperature and smaller break combination results in less heat removal. This is because the higher core inlet temperature (or higher initial steam generator pressure) causes the MSSVs to open early, and larger breaks would discharge more energy. Also, a lower core inlet

temperature maximizes the swelling affect due to the density change in the RCS thus maximizing the pressurizer liquid volume increase in the long term. Considering these effects, it is determined that the minimum temperature and minimum break size would produce most adverse result in terms of the pressurizer level for the long term cooling case.

In conclusion, the parametrics have determined that for the ΔM=0 case, the smallest break size that would produce simultaneous HPPT and steam generator dryout combined with the lowest initial core inlet temperature and lowest initial pressurizer pressure is the most limiting case in terms of long term heat removal.

ΔM =30000 Case:

For the degradation of heat transfer over a mass range corresponding to ΔM =30,000, the most adverse peak pressure is obtained when the event starts from the maximum initial core inlet temperature and maximum initial pressurizer pressure (Figure 15.2.8-14). If the LSGLT (corresponding to 35,000 lbm) occurs much earlier than HPPT, the larger break sizes provide cooldown of the primary by the energy release from the break compensating for the heat transfer degradation. If the trip on HPPT occurs much earlier than the degradation of heat transfer, the cooldown by the PSVs and by the break is adequate enough to limit the RCS pressure prior to the heat transfer degradation. For smaller size breaks, PSVs may open earlier during the heat transfer degradation making the effect of reduced heat transfer insignificant. As illustrated in Figure 15.2.8-14, larger

break sizes result in higher peak pressure since the heat transfer degradation is faster and the PSVs open late, shifting the peak pressure vs. break size curve to the right. Competing effects of cooling by the PSVs and the heat transfer degradation can be seen by looking at the results for very small break sizes (Figure 15.2.8-15). Below a certain break size, the heat transfer degradation is not significant since it is slower than the pressure increase, and the peak RCS pressure is driven by the PSVs. The peak pressure occurs much earlier than the total loss of heat transfer. Also, for small break sizes, the maximum peak pressure occurs when the LSGLT approaches the HPPT. Therefore, the limiting break size is the largest break size that would give coinciding HPPT and LSGLT with the highest initial core inlet temperature and pressurizer pressure. The largest break size for small FWLBs is 0.2 ft^2, by definition.

Also in Figure 15.2.8-14, the effect of the initial core inlet temperature shows variation by break size. This is due to the additional cooldown provided by the opening of MSSVs. When the initial core inlet temperature is higher, the initial steam generator pressure is higher, which results in earlier opening of MSSVs.

The limiting combination of initial core inlet temperature and initial pressurizer pressure on maximum pressurizer level is the same for the $\Delta M = 0$ and the $\Delta M = 30000$ cases. The effect of lower core inlet temperature and the smaller break size is more noticeable in Figure 15.2.8-15.

15.2.8.1.3 Parametric Study on Single Failure for FWLB without LOP

The FWLB without LOP methodology assumes a single failure of one of the two fast bus transfer circuits resulting in a Failure to Fast Bus Transfer (FFBT). Normally, both fast bus transfer circuits are operable. However, there is no restriction on removing one or both circuits from service for a period of time during the normal operations. Therefore, the limiting single failure from Table 15.0-0 for the FWLB without LOP methodology was investigated. It was determined that there are no credible single failures (see Table 15.0-0) which, in combination with one or both fast bus transfer circuits blocked, would make the consequences of the event more severe. A two Reactor Coolant Pump (RCP) coastdown, assuming both fast bus transfer circuits are in service and a single failure on one of them occurs, is more limiting than either a total LOP (four RCP coastdown) or full fast bus transfer (no RCP coastdown).

15.2.8.2 Feedwater Line Break Event with Loss of Offsite Power

Analysis of the limiting FWLB event with a LOP was performed using the CENTS computer code along with several simplifying assumptions which, with respect to RCS overpressurization, conservatively model the break discharge flow and enthalpy and the ruptured steam generator water level and heat transfer.

Blowdown of the steam generator nearest the FWLB is modeled assuming frictionless critical flow as calculated by the Henry-

Fauske correlation (reference 4). Although the enthalpy of the blowdown depends on the location of the break and fluid conditions within the affected steam generator, it is assumed that saturated liquid is discharged until no liquid remains, at which time saturated steam discharge is assumed.

With respect to RCS overpressurization these assumptions result in conservatively high mass, low energy flow from the break, thereby minimizing the ruptured generator heat removal capacity.

No credit is taken for a LSGLT in the affected steam generator until the generator is emptied of liquid. This conservatively delays the time of reactor trip, prolonging the RCS heatup and overpressurization. Additionally, no credit is taken for the high containment pressure trip.

15.2.8.2.1 Identification of Causes and Frequency Classification

The FWLB event may occur due to a pipe failure in the FWS.

A FWLB with a LOP is classified as a limiting fault event.

15.2.8.2.2 Sequence of Events and Systems Operation

The sequence of events for the FWLB with LOP is presented in Table 15.2.8-1.

The FWLB event with LOP is initiated by a break with size as stated in Table 15.2.8-2, that is assumed to occur between the steam generator economizer feedwater nozzle and its associated feedwater line check valve.

An instantaneous total loss of main feedwater flow to both steam generators is assumed. Critical flow is established from the affected steam generator through the feedwater line break. In addition, it is assumed that the FWS is unavailable and that the break discharge enthalpy remains as saturated liquid until the affected steam generator empties, at which time saturated steam enthalpy is assumed. The loss of subcooled feedwater flow to both steam generators causes increasing steam generator temperatures and decreasing liquid inventories. This reduces the primary-to-secondary heat transfer rate, resulting in increased RCS temperature and pressure.

The affected steam generator is assumed to instantaneously lose all heat transfer capability due to total depletion of its liquid inventory by boil off and break discharge flow. This initiates a rapid heatup and pressurization of the RCS and depressurization of the steam generators. A reactor trip occurs on high pressurizer pressure, which is coincident with a trip signal (LSGLT) on low steam generator water level. A turbine trip on reactor trip occurs followed by a LOP and closure of the turbine admission valves (TAVs). The closing of the TAVs leaves the feedwater line break as the only steam discharge path. This results in steam generator pressurization which reduces the primary-to-secondary temperature difference and heat transfer rate, thus continuing the RCS heatup. In addition, the loss of reactor coolant flow following the LOP decreases the rate of heat removal in the steam generator tubes, resulting in a significant reduction of heat removal from the RCS.

The reduction of primary side heat removal causes RCS volumetric expansion that results in compression of the pressurizer steam volume due to insurge flow through the pressurizer surge line, which increases the pressurizer pressure above the primary safety valve (PSV) setpoint. When the pressurizer pressure reaches the PSV setpoint, the PSVs open. The maximum RCS pressure remains below 120% of design pressure. The primary side heatup rate lowers due to the decrease in core decay heat flux, which results in a decrease in RCS pressure.

The MSSVs open, limiting secondary side pressure and stabilizing the temperature. This allows a greater heat transfer rate to the unaffected steam generator. The unaffected steam generator maximum pressure, remains below 120% of design pressure.

As a result of steaming through the MSSVs, the unaffected steam generator water level decreases and initiates an auxiliary feedwater actuation signal (AFAS). During the transient, the pressurizer water volume remains below the PSV nozzle elevation.

The secondary side pressure decreases due to a cooldown attributed to auxiliary feedwater (AFW), PSV and MSSV action, and steam flow from the reverse direction through the affected steam generator and out the feedwater line break. A main steam isolation signal (MSIS) is generated on a low steam generator pressure, which closes the main steam isolation valves (MSIVs), and isolates the unaffected steam generator from the affected

steam generator. After the MSIVs close, the pressure difference between the affected and unaffected steam generators increases and reaches the AFW ΔP-lockout setpoint. At this time, the AFW is fully diverted to the unaffected steam generator, restoring its water level. The unaffected steam generator re-pressurizes, causing a reduction in heat transfer and subsequent primary system heatup and pressurization. The primary-to-secondary heat and pressure imbalance is eliminated shortly after the re-opening of the MSSVs. The NSSS enters a quasi-steady state with a gradual cooldown and depressurization due to decreasing core decay heat generation. After 1800 seconds the operators initiate a controlled cooldown to shutdown cooling entry conditions, using the atmospheric dump valves (ADVs).

The FWLB with LOP analysis conservatively assumes operator action is delayed until 30 minutes after the occurrence of the event.

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System (ESFAS) functions are consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

The NSSS is protected during this transient by the primary safety valves (PSVs) and the following trips:

- Steam Generator Low Level

- Steam Generator Low Pressure
- High Pressurizer Pressure
- Low Departure from Nucleate Boiling Ratio (DNBR)
- High Containment Pressure
- Variable Overpower Trip

Depending upon the initial conditions, any one of these trips may terminate this transient. The NSSS is also protected by MSIVs, feedwater line check valves, MSSVs, and the AFWS, all of which serve to maintain the integrity of the secondary heat sink following reactor trip.

In considering the peak pressure criteria for this event and a postulated worst single active component failure in a system required to mitigate the transient, UFSAR Table 15.0-0 was used. As a result of the evaluation method applied to this analysis, the only mechanisms for mitigation of the RCS and main steam pressurization are the PSVs, MSSVs, and RCS flow. The RCS flow and MSSVs influence the RCS-to-steam generator heat transfer rate.

There are no credible failures that can degrade the PSV or MSSV capacity. Technical Specifications place limits on reactor power and variable overpower trip (VOPT) setpoints when one or more MSSVs are inoperable, thereby ensuring primary and secondary system peak pressure remains within applicable maximum pressure limits. The FWLB event is one of the transients analyzed for validating Technical

Specification 3.7.1. A decrease in RCS-to-steam generator heat transfer due to reactor coolant flow coastdown can be caused by a FFBT following turbine trip or by a LOP following turbine trip (i.e., two RCP or four RCP coastdown, respectively). In this analysis a LOP is assumed to occur following a turbine trip, which results in a four pump coastdown. In addition, it is assumed that the most reactive control rod fails to insert on scram. Therefore, for the FWLB event with a reactor trip followed by a turbine trip and a LOP, there is no credible single failure to make the event consequences more adverse with respect to primary peak pressure.

The FWLB long term cooling event presented in UFSAR Section 15.2.8.4 evaluates the single failure of one auxiliary feedwater pump that results in reduced secondary side heat removal capacity.

Table 15.2.8-1
SEQUENCE OF EVENTS FOR THE FEEDWATER LINE BREAK EVENT WITH LOSS OF OFFSITE POWER FOR PEAK PRESSURE and FUEL PERFORMANCE

Time (sec)	Event(s)
0.0	FWLB occurs. Complete loss of normal feedwater to both steam generators occurs
36.04	High Pressurizer Pressure Trip Activated
36.18	Dryout of affected steam generator (5,000 lbm of liquid inventory). AFAS generated in affected SG[1]
36.54	Reactor trip breakers open
36.54	Turbine trip occurs
36.54	LOP occurs
36.73	Unaffected steam generator reaches Low Steam Generator Level Trip analytical setpoint
37.15	Scram CEAs begin falling
37.94	PSVs open
39.41	Maximum RCS pressure
43.98	PSVs close
44.44	MSSV bank 1 opens on unaffected steam generator
44.96	MSSV bank 1 opens on affected steam generator
45.21	Peak secondary pressure occurs
<1800	Long-term automatic plant system actions and NSSS response to this transient are similar to the long-term cooling FWLB event
1800.0	Operator initiates plant cooldown

[1] Although AFAS is assumed to occur when the steam Generator reaches dryout, no AFW flow is delivered to the steam generators during the 60 seconds of the transient analyzed because of the 46-second delay time, nor is a MSIS or AFW lockout generated. The responses of these systems are similar to Long-Term Cooling FWLB transient presented in UFSAR Section 15.2.8.4.

15.2.8.2.3 Core and System Performance

A Mathematical Model

The NSSS response to the FWLB with LOP was simulated using the CENTS computer code described in UFSAR Section 15.0.3.1.3.2. Inputs to the CENTS code such as moderator reactivity as a function of moderator density, Doppler reactivity as a function of effective fuel temperature, and shutdown rod worth were calculated using the two-dimensional ROCS code discussed in UFSAR Section 4.3.3.1.1.2. The shutdown rod worth assumes that the most reactive control rod fails to insert on scram. Input to the CENTS code may also be calculated using the SIMULATE-3 code discussed in UFSAR Section 4.3.3.1.1.5.

The DNBR for the core hot channel was calculated using the CETOP computer code (see UFSAR Sections 4.4 and 15.0.3.1.6) which uses the CE-1 critical heat flux (CHF) correlation (Reference 2). Transient dependent input to CETOP such as RCS pressure, coolant flowrate through the core, core inlet temperature, and core average heat flux are obtained from the transient response predicted by CENTS.

The methodology for FWLB with LOP applies to a whole spectrum of feedwater line breaks, occurring with a LOP resulting from a turbine trip and a limiting single failure. FWLB event with LOP and a single failure is subject to ASME Service Level C pressure limit (120% of

design pressure) due to the very low estimated frequency of occurrence.

The analysis methods address the influence of the four major controlling parameters:

- discharge enthalpy
- discharge flow
- low water level trip condition in the ruptured steam generator
- heat transfer characteristics of the ruptured steam generator.

The principal conservative assumptions and analytical methods utilized in the analysis of this event include:

- Conservative estimation of the break flow and enthalpy, i.e. discharge of saturated liquid until steam generator is dry (steam generator is considered dry when 5000 lbm or less of liquid inventory is left).
- Delay of heat transfer degradation in the affected steam generator until the liquid inventory is depleted and then assuming an instantaneous loss of heat transfer.
- Initializing key parameters such that a reactor trip occurs on high pressurizer pressure coinciding with LSGLT, which is delayed until liquid mass inventory in the affected steam generator is depleted.

- Delaying the AFAS until liquid mass inventory in the affected steam generator is depleted.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a FWLB with LOP from full power conditions are presented in Table 15.2.8-2. The input parameters and initial conditions are based on the parametric studies discussed in UFSAR Section 15.2.8.1, selected to maximize the consequences of the FWLB.

The input parameters used in this analysis include:

- Maximum initial core power - Maximum core power maximizes the heat content of the primary system and the amount of energy to be removed by the secondary system. This results in a larger heat up and pressurization of the primary and secondary systems.

- Maximum initial core inlet temperature - This maximizes the amount of energy to be removed from the primary system following a loss of heat sink, and increases the initial steam generator pressure. This results in a reduced primary to secondary heat transfer, and a higher RCS peak pressure.

- Maximum initial RCS flow - For a given core power and core inlet temperature, maximum RCS flow results in a lower hot leg temperature and thus a lower steam generator temperature. This results in decreased break flow and enthalpy. The decreased break flow and

enthalpy (i.e., decreased heat removal through the break) prior to trip increases the primary system pressurization.

- Minimum initial pressurizer pressure - Sensitivity studies show that the minimum pressurizer pressure and maximum initial core inlet temperature result in the limiting RCS pressurization.

- Minimum Initial Core Average Fuel Rod Gap Conductance - Minimum fuel rod gap conductance delays the heat transfer from the fuel to the reactor coolant. This increases the energy content of the primary system after trip, resulting in higher primary and secondary peak pressures.

- Maximum PSVs opening setpoint - This delays the pressure relief of primary system and heat removal through the PSVs, thus maximizing the peak primary pressure.

- Minimum initial pressurizer volume - This delays the HPPT due to steam cushioning effect, thereby resulting in a higher primary peak pressure.

- Minimum initial steam generator level - A lower initial steam generator inventory results in earlier degradation in heat transfer, earlier emptying of the affected and intact steam generators and a higher RCS pressure.

- Minimum initial feedwater enthalpy - This minimizes the heat removal capability of the affected steam generator, thereby contributing to primary side heatup and results in higher RCS pressure.
- Least negative (most positive) moderator temperature coefficient (MTC) - This reduces the negative reactivity insertion into the core due to coolant heat up during the event, thus resulting in a slower decrease in power and higher heat content of the primary.
- Maximum number of plugged steam generator tubes - Increasing the number of plugged steam generator tubes decreases the heat transfer from primary to secondary side due to the reduced steam generator heat transfer surface area. This contributes to RCS heatup and pressurization.
- Limiting break size - The limiting FWLB with LOP event break size is determined by parametric study discussed in UFSAR Section 15.2.8.1.2 and is stated in Table 15.2.8-2.

C. Results

The response of key core parameters as a function of time following a FWLB and LOP break are provided in Table 15.2.8-1 and Figures 15.2.8-16 through 15.2.8-18 and 15.2.8-31.

The FWLB transient DNBR values are dependent upon variations in RCS pressure, core inlet temperature, core flow and core heat flux. The immediate loss of feedwater results in increased RCS temperature and pressure. The increase in RCS temperature and pressure is initially gradual since the steam flow has not been immediately interrupted. The increasing RCS pressure tends to increase the DNBR value, however, the increasing RCS temperature tends to stabilize the DNBR and result in a rather flat trace as depicted in figure 15.2.8-31. The LOP and coastdown of the RCPs significantly reduces flow

Table 15.2.8-2
ASSUMED INITIAL CONDITIONS FOR THE FEEDWATER LINE BREAK EVENT WITH LOSS OF OFFSITE POWER PEAK PRESSURE AND FUEL PERFORMANCE EVENT

Parameter	Value
Initial core power(% of RTP)	102
Initial core inlet temperature (°F)	566
Initial pressurizer pressure, psia	2275
Initial RCS flow, (% of design)	116
Initial pressurizer level (%)	24
Initial steam generator level (% of WR)	80.7
Initial feedwater enthalpy (Btu/lbm)	426.7
Moderator Temperature Coefficient ($\Delta\rho$/°F)	-0.2 E-4
Fuel Temperature Coefficient	Least negative
SCRAM delay time (sec)	1.15
CEA holding coil delay (sec)	0.6
CEA worth of trip-WRSO (%$\Delta\rho$)	8.0
Fuel rod gap conductance (Btu/hr-ft^2-°F)	500
Plugged tubes per Steam Generator	1258
PSV setpoint tolerance	+3%
PSV Blowdown	5%
MSSV setpoint tolerance	+3%
MSSV Blowdown	5%
Single Failure	None
LOP	Yes
Feedwater pipe break area (ft^2)	0.162

to the core. This in conjunction with rising coolant temperature, positive MTC, reactivity feedbacks, and core power result in overcoming the effect of increased pressure on DNBR. The DNBR sharply decreases for a few seconds and reaches its lowest value, but remains above the Specified Acceptable Fuel Designed Limit (SAFDL) for DNBR of 1.34. The decrease in core heat flux after trip, increase in RCS pressure and stabilizing RCS temperature, results in a sharp increase in DNBR value.

Since there is no power excursion during the transient, the FWLB event does not challenge the peak fuel centerline temperature SAFDL or the limit on linear heat generation rate (21 kW/ft).

The FWLB with LOP transient minimum DNBR (see Figure 15.2.8-31) is greater than the DNBR SAFDL value of 1.34, and therefore meets the acceptance criteria documented in Reference 3. Fuel cladding damage does not occur for this limiting fault event.

15.2.8.2.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.2.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed in the computer codes to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.2.3.B.

C. Results

The response of key RCS parameters as a function of time is presented in Figures 15.2.8-19 through 15.2.8-30 for this limiting fault event.

The FWLB with LOP assumes a loss of main feedwater to both steam generators resulting in a reduction of steam generator water inventory, pressurization of the secondary side, and a resulting heatup and pressurization of the primary side. The primary side heatup causes volumetric expansion and increase in pressurizer water level and pressure. A reactor trip occurs on a HPPT followed by a concurrent LOP on turbine trip. The turbine trip causes TAV closure. This reduction in primary to secondary heat transfer causes a rapid heatup of primary side coolant and the PSVs open to limit pressure. The MSSVs open to limit secondary side pressure.

For 3990 MWt, the maximum RCS pressure reaches 2745 psia, which is less than 120% (3000 psia) of RCS design pressure (2500 psia). The maximum secondary system pressure is 1313 psia, which is less than 120% (1524 psia) of the secondary system design pressure (1270 psia).

The maximum primary and secondary system pressures for this event meet the limiting pressure acceptance criteria of the Standard Review Plan.

As explained in UFSAR Section 15.2.8, FWLB is analyzed as a heat-up transient, and the cooldown potential of a FWLB is less than that of a MSLB. Therefore, the potential of reactor vessel being subject to brittle fracture (GDC 35) is bounded by the MSLB.

15.2.8.2.5 Radiological Consequences and Containment Performance

Fuel damage is not predicted for this limiting fault event. During this event, three sources of radioactivity contribute to the site boundary dose; the initial activity in the steam generator inventory, the activity associated with primary-to-secondary leakage from the steam generator tubes and releases from the reactor drain tank. These sources are assumed to be at 0.1 μCi/gm for the initial steam generator inventory, and at 1.0 μCi/gm dose equivalent I-131 for the RCS sources, respectively. Analysis methodologies are the same as those used in UFSAR Section 15.1.5.5 for the limiting fault MSLB event. The dose analysis for FWLB with LOP uses bounding MSLB release rates, determined independently of break size. Assuming all of the radioactivity is released to the atmosphere, the offsite dose due to the feedwater line break with loss of offsite power results in no more than 3.1 REM two-hour inhalation thyroid dose at the exclusion area boundary (EAB) and 1.7 REM eight hour inhalation thyroid dose at the low

population zone (LPZ) boundary. Whole body doses do not exceed 0.1 REM for either two-hour EAB or eight-hour LPZ. Since no fuel failure is predicted, no containment isolation is credited. In addition, the control room dose is bounded by the control room dose analyzed for events in UFSAR Section 6.4.7.3.

15.2.8.2.6 Conclusions

For the FWLB with a LOP resulting from a turbine trip, the maximum RCS pressure remains below 120% (3000 psia) of design pressure, thus ensuring primary system integrity. Likewise, the maximum secondary system pressure remains below 120% (1524 psia) of design pressure.

The minimum DNBR remains above the SAFDL limit, thereby ensuring fuel cladding integrity. All dose consequences are well within the 10CFR100 guidelines.

15.2.8.3 Feedwater Line Break Event With Offsite Power Available and Limiting Single Failure

The FWLB with LOP event presented in UFSAR Section 15.2.8.2 shows that the limiting break size, when combined with the LOP, produces the maximum primary and secondary pressures below 120% of the design values. The NRC has stated (Reference 3) that 120% of design maximum pressure criterion is appropriate for FWLB combined with the LOP. However, the NRC also stated in reference 3, that it must be shown that small break loss of feedwater inventory events with the limiting single failure and offsite power available meet the maximum pressure criterion of 110% of the design value. In order to demonstrate compliance

with this criterion, a conservative analysis method was developed for the FWLB, with a break size area less than or equal to 0.2 ft^2 with offsite power available. This is also referred to as a "small" feedwater line break event because of the analysis method assumed for the steam generator heat transfer characteristics.

15.2.8.3.1 Identification of Causes and Frequency Classification

The feedwater line break with a single failure and offsite power available may occur due to a pipe failure in the FWS.

The FWLB with a limiting single failure and offsite power available is classified as a limiting fault event.

15.2.8.3.2 Sequence of Events and Systems Operation

The sequence of events presented in Table 15.2.8-3 summarizes the important plant system responses for the FWLB with a limiting single failure and offsite power available.

The FWLB with single failure and offsite power available is initiated by a break with size as stated in Table 15.2.8-4, that is assumed to occur between the steam generator economizer feedwater nozzle and its associated feedwater line check valve and results in an instantaneous total loss of main feedwater flow to both steam generators. Critical flow is established from the affected steam generator through the feedwater line break. In addition, it is assumed that the FWS is unavailable and that the break discharge enthalpy remains as saturated

liquid until the affected steam generator empties, at which time saturated vapor enthalpy is assumed. The loss of subcooled feedwater flow to both steam generators causes increasing steam generator temperatures and decreasing liquid inventories. This causes a reduction in the primary-to-secondary heat transfer rate and an increase RCS temperature and pressure.

As a result of heat transfer degradation due to insufficient water inventory in the affected steam generator a rapid heatup and pressurization of the RCS occurs, generating a HPPT signal that is coincident with a LSGLT signal. The reactor trip breakers open followed by an assumed instantaneous turbine trip and closure of TAVs. The closure of the TAVs leaves the feedwater line break as the only steam discharge path. This results in steam generator pressurization and reduction in primary-to-secondary heat transfer rate, which causes a RCS heatup. Immediately following turbine trip, a FFBT is assumed and results in the coastdown of two RCPs. The two-pump loss of reactor coolant flow decreases the rate of heat removal in the steam generator tubes resulting in a significant reduction of heat removal from the RCS.

The reduction of primary side heat removal causes RCS volumetric expansion that results in compression of the pressurizer steam volume due to insurge flow through the pressurizer surge line that increases the pressurizer pressure above the PSV setpoint. When the pressurizer pressure reaches the PSV setpoint, the PSVs open and offset the pressurization by releasing steam. The maximum RCS pressure remains below

110% of design pressure. The primary side heatup rate lowers due to the decrease in core decay heat flux, which results in a decrease in RCS pressure.

The MSSVs open, stabilizing the secondary side temperature. This allows a greater heat transfer rate to the unaffected steam generator. The maximum unaffected steam generator pressure remains below 110% of design pressure.

As a result of steaming through the MSSVs, the unaffected steam generator water level decreases and initiates an AFAS.

The secondary side pressure decreases due to a cooldown attributed to AFW, PSV and MSSV action, and steam flow from the reverse direction through the affected steam generator and out the feedwater line break. A MSIS is generated on low steam generator pressure, which closes the MSIVs, and isolates the unaffected steam generator from the affected steam generator and the feedwater line break. After the MSIVs close, the pressure difference between the affected and unaffected steam generators increases and reaches the AFW ΔP lockout setpoint. At this time, the AFW is fully diverted to the unaffected steam generator, restoring its water level. The unaffected steam generator re-pressurizes, causing a reduction of heat transfer and subsequent primary system heatup and pressurization. The primary-to-secondary heat and pressure imbalance is eliminated shortly after the re-opening of the MSSVs. The NSSS enters a quasi-steady state with a gradual cooldown and depressurization due to decreasing core decay heat generation. After

1800 seconds the operators initiate a controlled cooldown to shutdown cooling entry conditions, using the ADVs.

The analysis of the FWLB with a single failure and offsite power available conservatively assumes operator action is delayed until 30 minutes after the occurrence of the initiating event.

Analytical setpoints and response times associated with the RPS trip functions and ESFAS functions are consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

The NSSS is protected during the transient by the PSVs and the following trips:

- Steam Generator Low Level
- Steam Generator Low Pressure
- High Pressurizer Pressure
- Low Departure from Nucleate Boiling Ratio (DNBR)
- High Containment Pressure
- Variable Overpower Trip.

Depending upon the particular initial conditions, any one of these trips may terminate this transient. The NSSS is also protected by MSIVs, feedwater line check valves, MSSVs, and the AFWS which serve to maintain the integrity of the secondary heat sink following reactor trip.

In considering the peak pressure criteria for this event and a postulated active single component failure in a system required to mitigate the transient, Table 15.0-0 was used. As a result of the evaluation method applied to this analysis, the only mechanisms for mitigation of the RCS and main steam pressurization are the PSVs, MSSVs, and RCS flow. The RCS flow and MSSVs influence the RCS-to-steam generator heat transfer rate.

Table 15.0-0 indicates that there are no credible failures that can degrade the PSV or MSSV capacity. Technical specification 3.7-1 places limits on reactor power and VOPT setpoints when one or more MSSVs are inoperable, thereby ensuring primary and secondary system peak pressure remains within 110% of system design pressure. A decrease in RCS-to-steam generator heat transfer due to reactor coolant flow coastdown can be caused by a FFBT following turbine trip or LOP following turbine trip (i.e., two RCP or four RCP coastdown, respectively). Because offsite power is assumed to be available for this analysis, a fast bus transfer will occur following turbine trip if the transfer buses are available. Assuming both transfer buses are available, a FFBT is assumed following the turbine trip, which results in the coastdown of two RCPs in diagonally opposite loops. It has been determined by parametric analysis in UFSAR Section 15.2.8.1.3 that this plant configuration is limiting for the event. There is no other credible single failure, besides FFBT, to make the event consequences more adverse with respect to primary peak

pressure. In addition, it is assumed that the most reactive control rod fails to insert on scram.

The FWLB with LOP long term cooling event presented in UFSAR Section 15.2.8.4 evaluates the single failure of one AFW pump that results in reduced secondary side heat removal capacity.

15.2.8.3.3 Core and System Performance

A. Mathematical Model

The computer codes used to simulate the NSSS and core thermal-hydraulic response to the FWLB with single failure and offsite power available are the same as those described in UFSAR Section 15.2.8.2.3.A.

The methodology used in the analysis of FWLB with single failure and offsite power available, (small break loss of feedwater inventory events), is the same as that described and applied in UFSAR Section 15.2.8.2, with the exception of the treatment of steam generator heat transfer and reactor trip on steam generator low water level.

Table 15.2.8-3
SEQUENCE OF EVENTS FOR FEEDWATER LINE BREAK WITH LIMITING SINGLE FAILURE AND OFFSITE POWER AVAILABLE

Time (sec)	Event
0.0	FWLB occurs. A complete loss of normal feedwater to both steam generators occurs
27.41	Affected steam generator reaches Low Steam Generator Level Trip analytical setpoint
27.45	High Pressurizer Pressure Trip Activated
27.95	Reactor Trip breakers open
27.95	Turbine Trip occur and FFBT
28.56	Scram CEAs begin falling
30.67	PSVs open
31.21	Maximum RCS pressure occurs
31.54	MSSV bank 1 opens on unaffected steam generator
31.57	MSSV bank 1 opens on affected steam generator
34.06	PSVs close
34.69	Peak secondary pressure occurs
35.24	Affected steam generator dries out. AFAS is generated in affected steam generator[2]
48.69	MSSV bank 1 closes on affected steam generator
51.74	MSSV bank 1 closes on unaffected steam generator
< 1800	Long-term automatic plant system actions and NSSS response to this transient are similar to the long-term cooling FWLB event
1800.0	Plant cooldown is initiated

[2] Although AFAS is assumed to occur when the steam generator reaches dryout, no AFW flow is delivered to the steam generators during the 60 seconds of the transient analyzed because of the 46-second delay time, nor is a MSIS or AFW lockout generated. The responses of these systems are similar to Long-Term Cooling FWLB transient presented in UFSAR Section 15.2.8.4.

Predictions of steam generator heat transfer and level behavior are based on the model documented in references 5 through 8. As discussed below, this model is conservative when applied to the small break loss of feedwater inventory events.

Steam Generator Heat Transfer

RCS pressurization is largely a function of the rate of heat transfer decrease by the affected steam generator as its inventory is depleted. UFSAR Section 15.2.8.1.2 documents the sensitivity of RCS pressurization to steam generator heat transfer behavior. The study verified that RCS pressurization is maximized by underestimating the affected steam generator liquid mass corresponding to the initiation of heat transfer degradation (i.e., overestimating the rate of heat transfer decrease). The original methodology took a simplistic and clearly conservative approach by assuming heat transfer degradation was instantaneous upon steam generator dryout. However, this approach is modified in order to more realistically model the behavior for small breaks.

A gradual heat transfer reduction is expected as the steam generator tubes are exposed to increasing void fractions, which force the tubes from the normal nucleate boiling heat transfer regime into transition boiling and eventually into liquid deficient heat transfer. Transition boiling is anticipated when the local void fraction exceeds 0.9. Liquid deficient heat transfer

develops when local qualities approach 0.9. Under full power conditions and utilizing the steam generator model documented in references 3, 5 and 6, the onset of these heat transfer regimes corresponds to steam generator liquid inventories of approximately 70,000 lbm and 35,000 lbm, respectively, for the System 80 design. However, the referenced model conservatively ignores the transition boiling regime, thereby delaying heat transfer degradation until fluid conditions correspond to liquid deficient heat transfer. Therefore, the modified treatment of steam generator heat transfer behavior is conservative, since it underestimates the liquid mass associated with the initiation of heat transfer degradation.

Steam Generator Low Water Level Trip

As discussed in UFSAR Section 15.2.8.2, the original loss of feedwater inventory event method credited the LSGLT in the affected steam generator only after its liquid inventory had been depleted. This assured conservative treatment of low level trip even if the loss of feedwater inventory event caused rapid steam generator depressurization (i.e., large breaks) and consequent swelling of the downcomer level due to flashing of the downcomer liquid. However, for sufficiently small breaks the steam generator pressure remains constant or increases prior to reactor trip and no downcomer level swell will occur due to flashing. Therefore, in the analysis of small break loss of feedwater inventory events, the LSGLT

is modeled to occur with a larger liquid inventory remaining.

For the System 80 design steam generators, the low level trip setpoint corresponds to a downcomer liquid level of approximately 24 feet above the tube sheet and a liquid inventory of over 70,000 lbm under full power conditions (based on the reference steam generator model). However, the analysis of small break loss of feedwater inventory events conservatively delays low level trip until heat transfer degradation begins with approximately 35,000 lbm of liquid remaining in the affected steam generator.

The methodology was developed to meet the requirement that the analysis is of the FWLB with single failure and offsite power available will not result in exceeding 110% of primary and secondary system design pressures.

The method of analyses includes parametrics (sensitivity studies) to establish the limiting initial operating and transient parameters and break sizes with respect to RCS overpressurization during the small feedwater line break event (UFSAR Section 15.2.8.1).

The conservative assumptions made in this FWLB with single failure and offsite power available analysis include:

- Conservative estimation of the break flow and enthalpy by assuming discharge of saturated liquid until the steam generator is dry (steam generator is considered dry when 5000 lbm or less of liquid inventory remains).

- Conservative delay in crediting a reactor trip generated on low level by the affected steam generator. The LSGLT is delayed until the liquid mass inventory is at or below 35000 lbm.
- Conservative gradual heat transfer reduction. The affected steam generator heat transfer is gradually reduced until liquid deficient heat transfer begins at approximately 35000 lbm. This conservative treatment of steam generator heat transfer behavior effectively underestimates the liquid mass associated with the initiation of heat transfer degradation at which time the LSGLT is credited.
- The transient is initialized so that a reactor trip occurs on the HPPT simultaneously with a LSGLT signal (when 35000 lbm remains in affected steam generator).
- The AFAS is delayed until the liquid mass inventory in the affected steam generator is depleted.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a FWLB with single failure and offsite power available from full power conditions are presented in Table 15.2.8-4. The input parameters and initial conditions were selected in order to maximize the consequences of the FWLB with single failure and offsite power available.

The following input parameters used in the analysis are discussed:

- Maximum initial core power - Maximum core power maximizes the heat content of the primary system and maximizes the amount of energy to be removed by the secondary system. This results in a larger heat up and pressurization of the primary and secondary systems.
- Maximum initial core inlet temperature - This maximizes the amount of energy to be removed from the primary system following a loss of heat sink, and increases the initial steam generator pressure. This results in a reduced primary to secondary heat transfer, and a higher RCS peak pressure.
- Maximum initial RCS flow - For a given core power and core inlet temperature, maximum RCS flow results in a lower hot leg temperature and thus a lower steam generator temperature. This results in decreased break flow and enthalpy. The decreased break flow and enthalpy prior to trip (i.e., decreased heat removal through the break) increases the primary system pressurization.
- Maximum (adjusted) initial pressurizer pressure - Sensitivity studies show that the maximum pressurizer pressure and maximum initial core inlet temperature result in the maximum RCS pressurization.

- Minimum Initial Core Average fuel rod gap conductance - Minimum fuel rod gap conductance delays the heat transfer from the fuel to the reactor coolant. This increases the energy content of the primary system after trip, resulting in higher primary and secondary peak pressures.
- Maximum PSVs opening setpoint - This delays the pressure relief of primary system and heat removal through the PSVs, thus maximizing the peak primary pressure.
- Minimum initial pressurizer volume - This delays the HPPT due to steam cushioning effect, thereby resulting in a higher primary peak pressure.
- Minimum initial steam generator level - A lower initial steam generator inventory results in earlier degradation in heat transfer, earlier emptying of the affected and unaffected steam generators and a higher RCS pressure.
- Minimum initial feedwater enthalpy - This minimizes the affected steam generator's heat removal capability, thereby contributing to primary side heatup and results in higher RCS pressure.
- Least negative (most positive) MTC - This reduces the negative reactivity insertion into the core due to coolant heat up during the event, thus resulting in a

slower decrease in power and higher heat content of the primary.

- Maximum number of plugged steam generator tubes - Increasing the number of plugged steam generator tubes decreases the heat transfer from primary to secondary side due to the reduced steam generator heat transfer surface area. This contributes to RCS heatup and pressurization.

- Limiting break size - The limiting FWLB with single failure and offsite power available event break size is determined by parametric study presented in UFSAR Section 15.2.8.1 and is stated in Table 15.2.8-4.

Table 15.2.8-4
ASSUMED INITIAL CONDITIONS FOR FEEDWATER LINE BREAK
WITH LIMITING SINGLE FAILURE AND OFFSITE POWER AVAILABLE

Parameter	Value
Initial core power (% of RTP)	102
Initial core inlet temperature (°F)	566
Initial pressurizer pressure (psia)	2312
Initial RCS flow (% of design)	116
Initial pressurizer level (%)	24
Initial steam generator level (% of WR)	80.7
Initial feedwater enthalpy (Btu/lbm)	426.7
Moderator Temperature Coefficient ($\Delta\rho$/°F)	-0.2 E-4
Fuel Temperature Coefficient	Least negative
CEA worth of trip-WRSO (%$\Delta\rho$)	8.0
Fuel rod gap conductance (Btu/h-ft^2-°F)	500
Plugged tubes	1258
PSV setpoint tolerance	+3%
PSV Blowdown	5%
MSSV setpoint tolerance	+3%
MSSV Blowdown	5%
Single Failure	FFBT
LOP	No
Feedwater pipe break area, ft^2	0.199

C. Results

The response of key core parameters as a function of time following a FWLB with a limiting single failure and offsite power available are provided in table 15.2.8-3 and figures 15.2.8-32 through 15.2.8-34.

The FWLB transient DNBR and fuel centerline temperature or LHGR discussion in UFSAR Section 15.2.8.2.3.C is applicable to this event. The minimum DNBR calculated in UFSAR Section 15.2.8.2.3 for the peak pressure FWLB with LOP event that is initiated from low RCS pressure and high RCS temperature with the four pump coastdown on LOP is more limiting for degradation of DNBR. Therefore, it is concluded that fuel clad degradation would not occur following a FWLB with a single failure and offsite power available.

15.2.8.3.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.3.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed in the computer codes to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.3.3.B.

C. Results

The response of key RCS parameters as a function of time is presented in Figures 15.2.8-35 through 15.2.8-41 for this limiting fault event.

The FWLB assumes a loss of main feedwater to both steam generators resulting in a reduction of steam generator water inventory, pressurization of the secondary side, and a resulting heatup and pressurization of the primary side. The primary side heatup causes volumetric expansion and an increase in pressurizer water level and pressure. A reactor trip occurs on the HPPT along with a turbine trip and TAV closure. Following the turbine trip, the FFBT occurs and results in the coastdown of two RCPs resulting in a reduction of heat removal from the RCS. This reduction in primary to secondary heat transfer causes a rapid heatup of primary side coolant which causes the PSVs to open to limit the RCS pressure increase. The MSSVs open to limit the secondary side pressure increase.

For 3990 MWt, the maximum RCS pressure reaches 2688 psia, which is less than 110% (2750 psia) of RCS design pressure (2500 psia). The maximum secondary system pressure reaches 1353 psia, which is less than 110% (1397 psia) of the secondary system design pressure (1270 psia). The maximum primary and secondary system pressures for this event meet the limiting pressure acceptance criteria of Reference 3.

15.2.8.3.5 Radiological Consequences and Containment Performance

Fuel damage is not predicted for this limiting fault event. The dose consequences for this event are no more limiting then the dose consequence assessment presented in UFSAR Section 15.2.8.2.5.

15.2.8.3.6 Conclusions

For the FWLB with a limiting single failure and offsite power available, with a break size less than or equal to 0.2 ft^2, the maximum RCS pressure remains below 110% of design pressure (2750 psia), thus ensuring primary system integrity. Likewise, the maximum secondary system pressure remains below 110% of design pressure (1397 psia).

The minimum DNBR remains above the SAFDL limit, thereby ensuring fuel cladding integrity. All dose consequences are within the 10CFR100 guidelines.

15.2.8.4 Feedwater Line Break with LOP and Single Failure for Long Term Cooling

The FWLB with LOP and SF transient is the most limiting transient with respect to long-term RCS heat removal capability. It bounds the FWLB without LOP and SF event discussed in 15.2.8.3. The adequacy of the auxiliary feedwater (AFW) system capacity to remove decay heat from the primary side following a FWLB event when considered with a LOP and a single failure (failure of one of the two AFW pumps to start)

is demonstrated in this section. This section also demonstrates that the largest increase in pressurizer water level occurs during this transient and remains below the primary safety valve (PSV) inlet nozzles. As a result, it demonstrates that part of UFSAR Chapter 18.II.D TMI Requirements regarding PSV operability are met; since the water level in the pressurizer remains below the PSV inlet nozzles and only steam is discharged through the PSVs. PSV design requirements are discussed in UFSAR Chapter 5.

15.2.8.4.1 Identification of Causes and Frequency Classification

A decrease in heat removal by the secondary system may be caused by a feedwater line break (FWLB) in the main feedwater system (FWS). The FWLB with a single failure and loss of offsite power is classified as a limiting fault.

15.2.8.4.2 Sequence of Events and Systems Operation

The sequence of events for the FWLB with a LOP resulting from turbine trip and a single failure (the active failure of an AFW pump) is presented in Table 15.2.8-5. This sequence of events was obtained by simulating the FWLB event with the computer codes identified in Section 15.2.8.3.A.

The postulated event is initiated by a pipe break that is assumed to occur between the steam generator economizer feedwater nozzle and its associated feedwater line check valve and results in an instantaneous total loss of main feedwater flow to both steam generators. Critical flow is established

from the affected steam generator through the feedwater line break. In addition, it is assumed that the break discharge enthalpy corresponds to that of saturated liquid until the affected steam generator empties, at which time saturated vapor enthalpy is assumed. The loss of subcooled feedwater flow to both steam generators causes increasing steam generator temperatures and decreasing liquid inventories, that reduce the primary-to-secondary heat transfer rate and increase RCS temperature and pressure.

The affected steam generator is assumed to instantaneously lose all heat transfer capability due to total depletion of its liquid inventory. As a result of steaming through the break, both the affected steam generator and the unaffected steam generator water level decreases and initiates an auxiliary feedwater actuation signal (AFAS). No credit is taken for the AFAS or the low steam generator level trip until steam generator dryout occurs. A reactor trip occurs on high pressurizer pressure, which is coincident with the affected steam generator dryout. Depending on the feedwater line break size, a containment pressure high trip and a containment high-high pressure Engineered Safety Features Actuation System (ESFAS) signal may also occur for an inside containment FWLB. In order to account for the containment pressure trip condition and coincident containment isolation actuation signal (CIAS), safety injection actuation signal (SIAS) and main steam isolation signal (MSIS), it is assumed that a containment pressure trip condition and CIAS/SIAS/MSIS occur at the same time as the high pressurizer pressure trip. In addition, the

containment spray actuation signal (CSAS) is assumed to activate coincident to the reactor trip and resulting ESFAS signals. The turbine trips following reactor trip and a loss of offsite power (LOP) occurs three seconds after turbine trip (see UFSAR Section 15.0.2.4). The closing of the turbine admission valves leaves the feedwater line break as the only steam discharge path. The loss of reactor coolant flow following the LOP decreases the rate of heat transfer in the steam generator tubes, resulting in a reduction o f heat removal from the RCS. This exacerbates the heatup and pressurization of the RCS and steam generators.

The reduction of primary side heat removal causes RCS volumetric expansion that results in compression of the pressurizer steam volume due to insurge flow through the pressurizer surge line, which increases the pressurizer pressure above the pressurizer safety valve (PSV) opening setpoints. The main steam safety valves (MSSVs) also open, limiting secondary side pressure and stabilizing temperature. This increases the heat transfer rate to the unaffected steam generator, which results in a decrease in RCS pressure.

One charging pump load sequences to the diesel generator and provides full flow after LOP and SIAS (see footnote h to UFSAR Table 8.3-3). The main steam isolation valves (MSIVs) close after the MSIS, isolating the unaffected steam generator from the break. After the MSIVs close, the reduction in heat transfer causes the unaffected SG to repressurize, the primary system to heat up the repressurize and additional pressurizer insurge occurs. The opening of the PSVs also results in

additional pressurizer insurge. The pressure difference between the affected and unaffected steam generator reaches the auxiliary feedwater ΔP-lockout setpoint prior to any auxiliary feedwater flow being initiated.

The auxiliary feedwater is fully diverted to the unaffected steam generator, restoring its water level. The secondary side pressure fluctuates around the MSSV opening and closing setpoints as they cycle. The PSVs will likewise cycle to relieve RCS pressure. The maximum liquid volume attained in the pressurizer during the FWLB event remains below the volume which results in water entrainment into the PSV nozzles when they are open (the PSV nozzles are at an elevation equivalent to 99.4% level). Thus, the pressurizer does not go solid at any time and RCS pressure control is maintained. The transient is terminated at 1800 seconds, when operators initiate a controlled cooldown, such as by using ADVs, to shutdown cooling entry conditions. The operator can take action to isolate the affected steam generator and refill the unaffected steam generator by manual control of AFW any time after the reactor trip occurs. However, the FWLB with LOP and Single Failure analysis does not credit any operator action for the first 20 minutes of the transient.

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System (ESFAS) functions were chosen to be consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS Technical Specifications and UFSAR Chapter 7.

The NSSS is protected during this transient by the primary safety valves (PSVs) and the following trips:

- Steam Generator Low Level
- Steam Generator Low Pressure
- High Pressurizer Pressure
- Low Departure from Nucleate Boiling Ratio (DNBR)
- High Containment Pressure
- Variable Overpower Trip.

Depending upon the initial conditions, any one of these trips may terminate this transient. The NSSS is also protected by main steam isolation valves (MSIVs), feedwater line check valves, main steam safety valves (MSSVs), and the auxiliary feedwater system (AFWS) which serve to maintain the integrity of the secondary heat sink following reactor trip.

The peak pressure criteria for the FWLB with LOP and a postulated active single component failure (UFSAR, Table 15.0-0) in a system required to control the transient in accordance with the NRC’s Standard Review Plan (SRP) are presented in Section 15.2.8.2.2 and 15.2.8.2.3 for the FWLB with LOP and FWLB with single failure and offsite power available, respectively.

For the long term cooling aspect of the FWLB event, the mechanisms to mitigate the primary and secondary heatup and pressurization and to provide a heat sink for decay heat are the PSVs, MSSVs, RCS flow, and the AFW capacity. There is no

credible single failure that can degrade the PSV and MSSV capacity, and the rationale for the degradation of the RCS flow as a result of the LOP is the same as that discussed in Sections 15.2.8.2.2 and 15.2.8.2.3. The only active single failure that can reduce the long-term secondary side heat removal capacity is the failure of one of the two auxiliary feedwater pumps to start (Table 15.0-0).

In this analysis it is demonstrated that the FWLB with a loss of offsite power and the failure of one AFW pump to start provides adequate decay heat removal so that no loss of core cooling would result. It is further demonstrated in the analysis that the pressurizer does not go solid or pass water through the PSVs. Hence, no loss of control in the RCS pressure boundary occurs.

TABLE 15.2.8-5
SEQUENCE OF EVENTS FOR FEEDWATER LINE BREAK WITH
LOSS OF OFFSITE POWER AND SINGLE FAILURE EVENT

Time (sec.)	EVENT	Value
0	FWLB and complete LOFW to both SGs, break size (ft^2)	0.199
31.07	Pressurizer pressure reaches trip setpoint (psia). (1)	2450
31.07	HPPT signal generated. SIAS/CIAS/MSIS/CSAS signals generated	
31.15	PSVs open (psia).	2450
31.22	Dryout of affected SG (lbm of liquid inventory), AFAS generated in affected SG.	<5000
31.57	Reactor trip breakers open.	
31.57	Turbine trip occurs	
31.87	Maximum RCS pressure (psia).	2572
32.18	Scram CEAs begin falling.	
34.57	LOP occurs	
36.69	Main Steam Isolation Valves close	
37.26	MSSVs bank 1 open (psia) (2)	1303
38.77	MSSVs bank 2 open (psia)	1344
39.32	PSVs close (psia)	2102
43.19	Maximum SG Pressure (psia)	1367
43.96	AFW Lockout (psid)	270
59.64	MSSVs bank 2 close	1276
74.57	One charging pump restarts (gpm)	44
77.24	AFW initiated to SG #2 (one pump, gpm)	650
91.31	MSSVs bank 1 close (psia) (2)	1237
1200	Operator Action – Intact SG ADV opened (%)	10
1800	Maximum liquid volume of pressurizer (ft^3)	1683
1800	Operators initiate plant cool down	

Notes: 1 - The HPPT is coincident with the LSGLT.

2 - Only the first time the Bank 1 MSSV open and close is listed. The Bank 1 MSSVs continue to cycle as required to remove decay heat.

15.2.8.4.3 Core and System Performance

A. Mathematical Model

The NSSS response to the long-term heat removal FWLB with LOP and Single Failure event was simulated using the CENTS computer code described in UFSAR Section 15.0.3.

Reactivity/Physics related data were provided to the CENTS computer code via the same computer codes and methods discussed in Section 15.2.8.2.3.A.

The minimum DNBR for the core hot channel for the FWLB with LOP was calculated with the CETOP computer code (described in UFSAR Section 4.4) and is discussed in Section 15.2.8.2.3.

The method of analysis includes parametrics (sensitivity studies) used to establish the limiting initial operating and transient parameters and break sizes with respect to long term heat removal and pressurizer fill, as discussed in Section 15.2.8.1. The method of analysis is the same as the FWLB with LOP methodology discussed in Section 15.2.8.2 in addition to the following conservative assumptions:

- The single failure of one of the two safety-related auxiliary feedwater pumps.
- All auxiliary feedwater which is diverted to the affected steam generator is not credited for heat removal.

- The maximum value within the allowable range is assumed for auxiliary feedwater temperature.
- CIAS/SIAS/MSIS are initiated on high containment pressure at the time of reactor trip. This methodology does not change the timing of the reactor trip, or the methodology for matching the HPPT with dryout of the affected steam generator. Parametric analysis determined that the time of reactor trip is the most adverse time to initiate the CIAS/SIAS/MSIS. This methodology assumes that a CIAS/SIAS/MSIS occurs on high containment pressure, simultaneously with the high pressurizer pressure trip. Early MSIS (before SG low pressure occurs) is conservative with respect to pressurizer level criteria since it eliminates the unaffected SG cooldown through the break early in the transient. There is no effect on peak RCS pressure due to early MSIS, since the peak pressure occurs before the closure of the main steam isolation valves (MSIVs). A SIAS causes the charging pumps to load sequence to the diesel generator after LOP, depending on demand from the PLCS. This is a conservative assumption for pressurizer fill criteria since it adds inventory to the RCS.
- The pressurizer Level Control System is in the automatic mode with the plant operated on program Tavg at the start of the transient. This methodology provides justification for using the nominal cold leg

temperature as the initial cold leg temperature assumption for the event.

- CSAS initiated on high-high containment pressure at the time of reactor trip. This methodology does not change the timing of the reactor trip, or the methodology for matching the HPPT with dryout of the affected steam generator. It is conservative to assume that a Containment Spray Actuation Signal (CSAS) coincident with the CIAS signal. Since the containment peak pressure and temperature analysis did not explicitly analyze any feedwater line break events, [Chapter 6, Section 6.2.1.1.1.1] the exact amount of time that elapses from when the containment pressure reaches the high containment pressure trip setpoint to when it reaches the high-high containment pressure trip setpoint is unknown. Therefore it is conservative to assume that it reaches the high-high containment pressure trip setpoint at the same instant it reaches the high containment pressure trip setpoint. A review of Chapter 6, Table 6.2.4-2 determined that the activation of the CSAS isolates the CBO return to the VCT Instrument air, and nuclear cooling water penetrations into / out of containment and opens the spray header isolation valves. For this analysis the key effect is the isolating of the CBO return to VCT. This is a conservative assumption for pressurizer fill criteria since it adds inventory to the RCS.

- The PVNGS Emergency Operating Procedure (EOPs) contain explicit instructions to help the operator manage to ensure that the plant is placed in a stable, safe condition following an Excessive Steam Demand event Therefore, the analysis assumes operator action to open an ADV (on the intact steam generator) to preclude a direct challenge to the RCS Inventory Control and RCS Pressure Control Safety Functions twenty (20) minutes after the even initiation.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a FWLB with LOP and Single Failure event are summarized in Table 15.2.8-6. The parameters and conditions were selected in order to demonstrate adequacy of auxiliary feedwater capacity for primary side decay heat removal and to determine the maximum pressurizer water level for PSV operability. A full spectrum of break areas based on parametrics were considered up to a break size of the combined area of flow distribution nozzles in the feedwater ring in establishing the limiting break size.

The input parameters used in this analysis include:

- Maximum initial core power - Maximum core power maximizes the heat content of the primary system and the amount of energy to be removed by the secondary system. This results in a larger heat up and

pressurization of the primary and secondary systems and pressurizer level.

- Initial core inlet temperature – As determined by parametric analysis, a lower core inlet temperature results in a higher transient pressurizer level. However, the initial core inlet temperature is chosen based on the assumption that the plant is operated on program Tavg, corresponding to the pressurizer level control system program setpoint at hot full power conditions, at the start of the transient.

- Minimum initial RCS flow - For a given power and core inlet temperature, a lower RCS flow results in a higher core outlet temperature. This maximizes the energy stored in the RCS and the energy to be removed by the secondary system, resulting in higher pressurizer level.

- Minimum Initial Pressurizer Pressure - Parametric analysis shows that a minimum initial pressurizer pressure results in a maximum pressurizer water level during the long-term heat removal FWLB.

- Minimum Initial Core Average Gap - Minimum gap conductance delays the heat transfer from the fuel to the reactor coolant. This increases the energy content of the primary system after trip, resulting in higher primary and secondary peak pressures and higher pressurizer level.

- Least negative (most positive) moderator temperature coefficient (MTC) - This reduces the negative reactivity insertion into the core due to coolant heat up during the event, thus resulting in a slower decrease in power and higher heat content of the primary.

- Minimum Pressurizer Safety Valves (PSVs) opening setpoint - Earlier opening of the PSVs increases the surge line flow into the pressurizer, thus increasing the pressurizer level.

- Maximum initial pressurizer liquid level - Parametric study shows that initiating the transient from the maximum initial pressurizer level has no significant sensitivity. However, starting from this level results in the maximum pressurizer level during the transient.

- Minimum initial steam generator level - Parametric study shows that a minimum initial steam generator inventory results in earlier degradation in heat transfer and earlier emptying of the affected and intact steam generators. This increases the RCS pressurization and pressurizer level.

- Minimum initial feedwater enthalpy - This minimizes the heat removal capability of the affected steam generator, which results in higher RCS temperature and pressure and a greater demand on AFW decay heat removal capacity.

- Maximum number of plugged steam generator tubes - The parametric study shows that asymmetric tube plugging results in maximum pressurizer level. Increasing the number of plugged steam generator tubes decreases the heat transfer from primary to secondary side due to the reduced steam generator heat transfer surface area. This contributes to RCS heatup and pressurization and greater demand on AFW decay heat removal capacity.

- Limiting break size - The limiting FWLB long term cooling event break size is determined by parametric study discussed in Section 15.2.8.1.2.

Table 15.2.8-6
ASSUMED INITIAL CONDITIONS FOR FEEDWATER LINE BREAK WITH LOSS OF OFFSITE POWER AND SINGLE FAILURE EVENT

Parameter	Value
Initial core power (% of rated)	102
Initial average RCS temperature, Tavg (at 100% power and maximum pressurizer level) (°F)	585.6
Initial Pressurizer Pressure (psia)	2100
Initial RCS Flow (% of design)	95
Initial Pressurizer water level (ft)	23.9
Initial SG Water Level (ft)	35.8 (25% NR)
Moderator Temperature Coefficient ($x10^{-4}$ $\Delta\rho$/°F)	-0.2
Fuel Temperature Coefficient	least negative
Kinetics	Maximum β
CEA Worth of Trip-WRSO (%$\Delta\rho$)	8.0
Fuel Gap Gas conductance (Btu/hr-ft^2-°F)	500
SCRAM Delay Time (sec)	0.5
CEA Holding Coil Delay Time (sec)	0.6
Plugged SG Tubes	0%/10%
PSV Tolerance	-1%
PSV Blowdown	14.2%
MSSV Tolerance	+3%
MSSV Blowdown	5%
Single Failure	One AFW pump
LOP	Yes
FWLB Area (ft^2)	0.199
RCP seal control bleed-off flow rate (gpm/RCP)	0.0
Operator Action Time (minutes)	20.0

C. Results

The response of key core parameters as a function of time following a FWLB with a loss of offsite power and a single failure of an AFW pump is the same as those discussed in Section 15.2.8.2.3.C, since that event documents the fuel performance for the FWLB events.

The FWLB transient DNBR is discussed in Section 15.2.8.2.3.C and depicted in Figure 15.2.8-31. The FWLB transient DNBR and LHGR discussion in Section 15.2.8.2.4.C is applicable to FWLB long term cooling events. The minimum DNBR versus time as shown on this figure remains above the SAFDL throughout the transient. The minimum DNBR calculated in Section 15.2.8.2.4 for the peak pressure FWLB with LOP event that is initiated from low RCS pressure and high RCS temperature with the four pump coastdown on LOP is more limiting for degradation of DNBR. Therefore, it is concluded that fuel clad degradation would not occur following a long term FWLB with loss of offsite power and a single failure.

15.2.8.4.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.4.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed in the computer codes to evaluate RCS barrier performance for this limiting fault event are identical to those described in UFSAR Section 15.2.8.4.3.B.

C. Results

The response of key RCS parameters as a function of time is presented in Figures 15.2.8-42 through 15.2.8-51 for this limiting fault event.

The limiting peak pressure FWLB events are discussed in Sections 15.2.8.2 and 15.2.8.3.

For FWLB with LOP and a single failure, auxiliary feedwater actuation in the affected steam generator is delayed until affected steam generator dry-out. A main steam isolation signal on high containment pressure isolates the unaffected steam generator from the break early in the transient. Following the isolation, AFW delivery increases the level in the unaffected steam generator (Figure 15.2.8-48 and 50). The AFW flow provides sufficient inventory for heat removal to occur through the MSSVs such that RCS pressure control is maintained by the PSVs, and the RCS converges to a quasi steady state prior to 1200 seconds (Figure 15.2.8-44 and 46). Operator action is taken at 1200 seconds. This demonstrates the adequacy of RCS decay heat removal with the AFW system during the FWLB which satisfies SRP 10.4.9 and 15.2.8.

Throughout the transient (Figure 15.2.8-46) the pressurizer water level remains low enough so that only steam is discharged from the PSVs any time the PSVs are open, as required by UFSAR Chapter 5B and 18.II.D for meeting the NUREG-0737 Requirements.

15.2.8.4.5 Radiological Consequences and Containment Performance

Fuel damage is not predicted for this limiting fault event. The dose consequences for this event are no more limiting than the dose consequence assessment presented in section 15.2.8.2.5.

15.2.8.4.6 Conclusions

The auxiliary feedwater capacity is adequate to provide removal of the core decay heat until operator action is taken 20 minutes after event initiation.

The maximum pressurizer water level remains below the PSV inlet nozzles and only steam is discharged, thereby satisfying NUREG-0737 Requirements presented in UFSAR Chapter 5B and 18.II.D.

15.3 DECREASE IN REACTOR COOLANT FLOWRATE

15.3.1 TOTAL LOSS OF REACTOR COOLANT FLOW

15.3.1.1 Identification of Causes and Frequency Classification

A complete loss of forced reactor coolant flow (LOF) may result from the simultaneous loss of electric power to all four reactor coolant pumps (RCPs). The only limiting credible failure, which can result in a simultaneous loss of power to the four RCPs, is the complete loss of offsite power.

An LOF event is an Anticipated Operational Occurrence (AOO) and is classified as an incident of moderate frequency.

15.3.1.2 Sequence of Events and System Operation

A loss of electric power to all four reactor coolant pumps produces a reduction of coolant flow through the reactor core that causes an increase in core average coolant temperature, system pressure, and a decrease in margin to DNB. A total loss of forced reactor coolant flow will produce a minimum DNBR more adverse than any partial loss of forced reactor coolant flow event that involves the loss of electrical power to three or less RCPs. This is because the reactor will trip at the same time for both cases, however the partial loss of flow has a slower flow coastdown.

If credit is not taken for a reactor trip on turbine trip, then reactor protection is provided by a core protection calculator (CPC) generated trip initiated when any one of the four RCP shaft speeds drops to 95 percent of normal speed. The credited CPC trip ensures that the event induced minimum DNBR value will remain above the Specified Acceptable Fuel Design Limit (SAFDL) for DNBR.

The combination of loss of primary heat sink (due to loss of offsite power causing a loss of load on turbine, turbine trip and closure of turbine admission valves) with a reduction of reactor coolant flow results in an increase in RCS pressure that is limited by the primary safety valves(PSVs).

The steam bypass control system also becomes unavailable due to loss of offsite power, which results in a loss of condenser vacuum and termination of main feedwater to the steam generators. This sequence of system interactions leads to the opening of the main steam safety valves (MSSVs) which limits the secondary side pressure and removes heat stored in the core and the RCS.

The sequence of events for this moderate frequency LOF event are presented in Table 15.3.1-1. A low voltage on the 4.16 kV safety buses generates an undervoltage signal which starts the emergency diesel generators. The non-safety buses are automatically separated from the safety buses and all loads are shed (except for load centers). After each diesel generator set has attained operating voltage and frequency, its output breaker closes connecting it to its safety bus. Engineered safety feature equipment is then loaded in sequence onto this bus.

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System functions were consistent with, or conservative with respect to, numerical values delineated in UFSAR Sections 7.2 and 7.3.

Following reactor trip and total loss of forced reactor coolant flow, stored and core decay heat removal occurs by means of natural circulation through the core with the steam generators providing primary to secondary side heat transfer.

An auxiliary feedwater actuation signal (AFAS) occurs as the steam generator levels decrease due to the pressure relief and mass discharge during cycling of MSSVs. Actuation of auxiliary feedwater system (AFW) system at a specific time (46 seconds after the AFAS is generated) has no impact on the event DNBR.

Plant operators may initiate cooldown 30 minutes after the event induced reactor trip occurs by utilizing the AFWS and atmospheric dump valves (ADVs).

The Standard Review Plan (Reference 1) states that an incident of moderate frequency, such as the loss of forced coolant flow, should not generate a more serious plant condition without other faults occurring independently. Furthermore, the Standard Review Plan states that an incident of moderate frequency, in combination with a single active component failure, or single operator error, should not result in the loss of function of any barrier other than the fuel cladding.

The loss of offsite power event plus a single failure will not result in a lower DNBR than that calculated for the loss of offsite power event alone. For decreasing reactor coolant flow events, the major parameter of concern is the minimum hot channel DNBR. This parameter establishes whether a fuel design limit has been violated and thus whether fuel damage might be

anticipated. Those factors which cause a decrease in local DNBR are:

- increasing coolant temperature
- decreasing coolant pressure
- increasing local heat flux (including radial and axial power distribution effects)
- decreasing coolant flow.

For the total loss of RCS flow event, the minimum DNBR occurs during the first few seconds of the transient and the reactor is tripped by the CPCs on low RCP shaft speed. Therefore, any single failure that would result in a lower DNBR during the transient would have to effect at least one of the above parameters during the first few seconds of the event. None of the single failures listed in table 15.0-0 will have any affect on the transient minimum DNBR during this period.

Additionally, none of the single failures listed in table 15.0-0 will have any effect on the peak primary system pressure. Nor will the loss of offsite power make unavailable any systems whose failure could affect the calculated peak pressure. For example, a failure of the steam dump and bypass system to modulate or quick open and a failure of the pressurizer spray control valve to open involve systems (steam dump and bypass system and pressurizer pressure control system) assumed to be in the manual mode as a result of the loss of offsite power and, hence, unavailable for at least 30 minutes.

For the reasons stated above, the loss of offsite power event with a single failure is no more adverse than the loss of offsite power event in terms of the minimum DNBR and peak primary system pressure.

Table 15.3.1-1

TYPICAL SEQUENCE OF EVENTS FOR TOTAL LOSS OF REACTOR COOLANT FLOW

Time sec)	Event
0.00	Loss of offsite power occurs
0.00	Turbine trip, Diesel generator starting signal, RCPs coast down and main feedwater is lost
0.60	Low RCP.shaft speed trip condition
0.90	Trip.breakers open
1.50	CEAs.begin to drop
2.85	Minimum.DNBR occurs
3.80	PSVs open (first occurrence)
4.25	Maximum RCS pressure
4.90	MSSVs open (first occurrence)
6.50	PSVs close (last occurrence)
11.30	Maximum steam generator pressure[1]
652.85	Low water level AFAS setpoint reached in steam generator 1
698.85	AFW begins entering steam generators
699.95	MSSVs close (last occurrence)
1800.0	Operator initiates plant cooldown

[1]The maximum steam generator pressure timing is obtained from peak secondary pressure case.

15.3.1.3 Core and System Performance

A. Mathematical Model

Several computer codes were employed to evaluate core and system performance for this moderate frequency event. The HERMITE computer code (see reference 2 and UFSAR Appendix 15D) is used to determine the reactor core response during the postulated RCS flow coastdown. The HERMITE LOF simulation, which includes thermal hydraulic data is transferred to the CETOP computer code (which uses the CE-1 CHF correlation that is described in UFSAR Sections 4.4 and 15.0.3) in order to determine thermal hydraulic conditions at time of minimum DNBR. The thermal hydraulic conditions at time of minimum DNBR are then input to the TORC computer code which also uses the CE-1 CHF correlation to calculate the value of the minimum DNBR during the LOF transient. The thermal margin to DNB for the event is calculated using the TORC computer code.

The CENTS computer code (see UFSAR Section 15.0.3.1.3.2) is used to simulate the Nuclear Steam Supply System (NSSS) response to the total loss of reactor coolant flow event.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a total loss of RCS flow are selected to minimize DNBR during the transient and are presented in Table 15.3.1-2.

The set of initial conditions selected for the analysis presented in this section is one of a very large number of combinations within the reactor operating space of steady state operational configurations, that would provide the minimum thermal margin required by the core operating limit supervisory system (COLSS). The COLSS (described in UFSAR Section 7.7) computes a Power Operating Limit that ensures the thermal margin available in the core is greater than that required to maintain a calculated LOF event minimum DNBR value that is equal to or greater than the DNBR SAFDL.

Parameters were chosen in a manner that minimizes reactor bulk saturation, which results in less void reactivity as determined in HERMITE, since minimizing negative feedback results in more adverse consequences and therefore, presents the limiting postulated LOF event. Results of parametrics show that for any axial power distribution, the most limiting Required Overpower Margin is attributed to the following: a) a minimum gap conductance, which delays the core heat flux decrease after reactor trip and results in a later DNBR turn-around and a lower RCS flow at the time of minimum DNBR. b) a maximum RCS pressure and minimum core inlet temperature, which removes the reactor core from bulk saturation conditions and minimizes void reactivity effects. c) a maximum core flow, which removes the core from bulk saturation conditions and minimizes void feedback effects.

The four pump LOF transient is characterized by the flow coastdown curve that bounds the coastdowns observed during startup testing. The consequences following a total LOF initiated from any one of these combinations of conditions would be no more adverse than those presented herein.

A bounding number of plugged steam generator tubes was assumed in the LOF analysis. The flow coastdown associated with the plugged steam generator tubes four-Pump LOF is more conservative since it causes a more rapid decrease in the RCS flow.

As shown in Table 15.3.1-2, the control element assemblies (CEAs) begin to drop into the core after loss of electrical power to the RCPs and after a conservative delay time that includes the largest possible delay times for sensor delays, CPC response time, and control element drive mechanism (CEDM) coil decay time.

C. Results

The typical response of key parameters as a function of time is presented in Figures 15.3.1-1 to 15.3.1-15 for this moderate frequency event. The loss of offsite power causes the plant to experience a simultaneous turbine trip, loss of main feedwater, condenser nonfunctionality, and a four RCP coastdown. As a result of the RCP coastdown, the CPC generates a trip signal and the CEAs start to drop into the core after a short conservative delay time.

Since there is no power excursion during the transient, the LOF event does not challenge the linear heat generation rate limit of 21 kw/ft and, consequently, the fuel temperature remains below the SAFDL.

The minimum DNBR is greater than the DNBR SAFDL value of 1.34 (see Figure 15.3.1-14) and meets the acceptance criteria of the Standard Review Plan.

Therefore, fuel cladding damage is not predicted for this moderate frequency event.

Table 15.3.1-2
ASSUMED INITIAL CONDITIONS FOR THE
TOTAL LOSS OF REACTOR COOLANT FLOW (DNBR Case)

Parameter	Value
Core power level (% of rated)	102
Core inlet coolant temperature (°F)	548
Pressurizer pressure (psia)	2325
Core mass flow (% of design)	116
Moderator temperature coefficient ($\Delta\rho$/°F)	-0.20E-4
Fuel temperature coefficient	Least negative
CEA worth for trip-WRSO (%$\Delta\rho$)	-8.0
Minimum Radial power peaking factor[1]	1.28
Fuel rod gap conductance (Btu/hr-ft^2-°F)	500
Number of plugged SG tubes	1258
Trip Delay Times (sec) a. Time for CPCs to detect low pump speed b. CPC delay to generate trip signal c. CEA holding coil delay TOTAL	 0.60 0.30 0.60 1.50

Note: The transient is insensitive to the pressurizer and steam generator levels. Nominal values were used in the analysis.

[1] This value corresponds to the lower limit on radial peaking for the "RANGE" trip in the CPC.

15.3.1.4 RCS Pressure Boundary Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate fission product barrier performance (other than fuel cladding) for this moderate frequency event are identical to those described in UFSAR Section 15.3.1.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions relevant to barrier performance for this moderate frequency event are similar to those presented in Table 15.3.1-2 of UFSAR Section 15.3.1.3.B. The safety analysis performs parametrics on core inlet temperature, RCS mass flowrate and steam generator tube plugging for peak pressure cases. The results indicate that the maximum T-cold, maximum RCS flowrate and no SG tube plugging condition produces highest peak RCS pressure while the maximum T-cold, minimum RCS flowrate and no tube plugging condition produces highest secondary peak pressure.

The PSVs were modeled to maximize primary pressure. The maximum allowable setpoints (as allowed by Technical Specification 3.4.10) were used (2475 + 3% tolerance).

The MSSVs were also modeled to maximize pressure. The maximum allowable setpoints (as allowed by Technical Specification 3.7.1) were used (setpoint + 3% tolerance).

C. Results

The typical response of key parameters as a function of time is presented in Figures 15.3.1-1 to 15.3.1-13 for this moderate frequency event. The figures are representative of the transient.

The loss of steam flow due to closure of the turbine stop valves results in a rapid increase in the steam generator pressure. A sharp reduction in primary to secondary heat transfer follows, which, in conjunction with the loss of forced reactor coolant flow, causes a rapid heatup of the primary coolant. The primary safety valves (PSVs) open and cycle several times, and slightly later the main steam safety valves (MSSVs) open and cycle several times.

The maximum RCS pressure is 2664 psia, which is less than 2750 psia (110% of RCS system design pressure of 2500 psia). The maximum secondary-system pressure is 1363 psia, which is less than 1397 psia (110% of secondary system design pressure of 1270 psia).

These values meet the acceptance criteria of the Standard Review Plan (Reference 1).

15.3.1.5 Conclusions

The minimum DNBR remains above the SAFDL limit, thereby ensuring fuel cladding integrity. The initial margin required as a result of this analysis is preserved by the limiting condition of operation on DNBR margin.

The maximum RCS and secondary system pressures remain within 110% of their design values following the total LOF event.

Radiological consequences for this event are bounded. The consequences are the result of normal RCS releases at design source terms and are negligible. This event would not result in any releases of radioactive material above that of a normal reactor trip.

15.3.2 FLOW CONTROLLER MALFUNCTION CAUSING A FLOW COASTDOWN

This event is categorized as a boiling water reactor event in NRC Standard Review Plan 15.3.2 and will therefore not be analyzed.

15.3.3 SINGLE REACTOR COOLANT PUMP ROTOR SEIZURE WITH LOSS OF OFFSITE POWER

A single reactor coolant pump (RCP) rotor seizure can be caused by seizure of the upper or lower thrust-journal bearings. A single reactor coolant pump rotor seizure with loss of offsite power (LOP) is classified as a limiting fault.

The sequence of events, system operations and plant response for the single RCP rotor seizure are almost identical to those

of a single RCP shaft break. Both events cause a rapid drop in core flow to the three pump RCS flow configuration.

The difference is that for the rotor seizure event, the reactor is tripped by the Core Protection Calculator (CPC) on a low RCP speed condition, whereas for the shaft break event, the reactor is tripped by the Reactor Protective System (RPS) on a steam generator differential pressure low flow trip. The seized rotor, having the greater resistance to the Reactor Coolant System (RCS) flow, has a slightly faster coastdown. The RCP shaft break allows a freewheeling coastdown of the impeller with the RCP motor continuing to rotate. The RCS flow coastdown is slightly slower, but because the RCP motor and shaft continue to turn the speed signals to the CPC do not decrease. Protection for this event is delayed until the RPS trip is generated.

Both the seized rotor and sheared shaft events were assessed with the LOP and it was found that the RCP shaft break resulted in slightly more fuel failure and higher radiological dose than the seized rotor event. Therefore, the results of the single RCP sheared shaft are more limiting than the seized rotor event.

15.3.4 REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER

15.3.4.1 Identification of Causes and Frequency Classification

A single reactor coolant pump sheared shaft could be caused by mechanical failure of the pump shaft. This is assumed to

result from a manufacturing defect in the shaft. A single active failure of an Atmospheric Dump Valve (ADV) to close is assumed upon opening of the ADVs after reactor trip. This ADV is assumed to remain open for the duration of the event. Following a turbine trip, a Loss of Offsite Power (LOP) caused by instability of the transmission network, triggered by the turbine trip is assumed. See UFSAR Section 15.0.2.4 for more information regarding the potential LOP following a turbine trip.

A single RCP sheared shaft is classified as a limiting fault.

15.3.4.2 Sequence of Events and Systems Operation

The shearing of the RCP shaft causes the core flow rate to rapidly decrease to a value that would occur with three reactor coolant pumps operating. The reduction in primary coolant flow rate causes an increase in the average coolant temperature in the core, a corresponding reduction in the margin to Departure from Nucleate Boiling (DNB) that may result in some fuel pins experiencing DNB, and an increase in the primary system pressure. Reactor protection is provided by a trip generated by rapid flow reduction that causes a pressure differential (Δr) across the steam generator primary side in the affected loop to decrease to a value below the Δr trip setpoint.

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System (ESFAS) functions are consistent with, or conservative with respect to, numerical

values delineated in UFSAR Sections 7.2 (table 7.2-1) and 7.3. The RPS trip conservatively assumes the largest possible delay time for sensor delay, calculation period, Control Element Drive Mechanism (CEDM) dead time, and CEDM coil decay time. The RPS Steam Generator differential pressure trip is single failure proof.

The sequence of events for this limiting fault incident is presented for each evaluation performed. Approximately 3 seconds following turbine trip, an assumed LOP causes a loss of AC power to the onsite loads due to transmission network instability (see UFSAR Section 15.0.2.4 for more details on 3 second delay). This results in a simultaneous loss of feedwater flow, condenser unavailability, and a coastdown of all RCPs. Approximately 12 seconds after the LOP occurs, the emergency diesel generators start providing power to the two plant 4.16 kV safety buses.

The pressurizer can assist (but is not credited) in the control of the RCS pressure and volume changes during the transient by compensating for the initial expansion of the RCS fluid. The combination of loss of primary heat sink (due to LOP, which causes a loss of load on turbine and closure of turbine admission valves) with the reduction of reactor coolant flow, results in an increase in RCS pressure.

The unavailability of the steam bypass control system (SBCS) due to the LOP results in an increase in secondary pressure. If no operator action is taken to open the ADVs, the RCS pressure increase is limited by the primary safety valves

(PSVs) and the main steam safety valves (MSSVs) limit the secondary side pressure and remove heat stored in the core and the RCS.

The reactor heat removal takes place by means of natural circulation in the RCS, following the coastdown of the undamaged RCPs. The steam generators provide primary to secondary heat transfer. The water level in each of the steam generators begins decreasing immediately after the loss of main feedwater flow, and an auxiliary feedwater actuation signal (AFAS) is generated on low water level in a steam generator. The AFAS setpoint is first reached in the steam generator in the unaffected loop. This leads to the startup of the auxiliary feedwater (AFW) pumps.

For radiological evaluation it is assumed that the operators open the ADVs after reactor trip. Once the ADVs are opened, one valve is assumed to remain stuck open. This results in the eventual generation of a Main Steam Isolation Signal (MSIS) on low steam generator pressure. Once the main steam isolation valves are closed further blowdown of the unaffected steam generator is prevented. AFW is automatically terminated to the affected steam generator as a result of a high differential pressure signal between steam generators. Thirty minutes from the time of shaft shear, the operator is assumed to override the AFW lockout and divert all of the AFW flow to the affected steam generator, covering the tops of the U-tubes after 90 minutes. The operator then initiates cooldown of the RCS by using the ADVs and the AFWS on the unaffected steam generator, while maintaining the level on the affected steam generator.

The process of feeding with the AFWS and releasing steam with the ADVs continues until shutdown cooling entry conditions are reached. The operator may let the ESFAS regulate the feedwater flow by issuing and withdrawing AFAS-1 and/or AFAS-2 signals down to cold shutdown entry conditions. See UFSAR Section 10.4.9 for details of the AFW systems (interface requirements are given in UFSAR Section 5.1.4).

For the core and system performance evaluation, the major parameter of concern is the minimum hot channel Departure from Nucleate Boiling Ratio (DNBR). This parameter establishes whether fuel design limit has been violated and thus whether fuel damage could be anticipated. The factors that cause a decrease in local DNBR are:

- increasing coolant temperature
- decreasing coolant pressure
- increasing local heat flux (including radial and axial power distribution effects)
- decreasing coolant flow

For the single RCP shaft break event, the minimum DNBR occurs during the first one to four seconds. Therefore, any single failure that would result in a lower DNBR during the transient would have to affect at least one of the above parameters during the first one to four seconds of the event.

The single failures that have been postulated are listed in Table 15.0-0. Most of these failures affect the secondary system, and during the first one to four seconds they do not

affect the primary system parameters that determine the DNBR. The analysis does not credit non-safety related components for any mitigating purposes. The only failures, that could affect the RCS behavior during this interval, are:

- a loss of normal AC
- a failure of the pressurizer level control system
- a failure of the pressurizer pressure control system
- a failure of the reactor regulating system

The loss of normal AC power, which is assumed to occur three seconds after turbine trip, results in loss of power to the RCP, the condensate pumps, the circulating water pumps, the pressurizer pressure and level control systems, the reactor regulating system, and the feedwater control system.

Loss of function of the condensate and circulating water pumps and the feedwater control system initially affects only the secondary system, and thus does not affect DNBR in the first one to four seconds of the transient. Loss of power to the reactor regulating system and pressurizer level and pressure control systems renders those systems unavailable. This unavailability will have no significant impact on DNBR during the first one to four seconds. Loss of power to the RCPs is the only potentially significant failure with regard to DNBR that results from a loss of AC. However, as a result of a three second delay between the time of turbine trip and the time of loss of offsite power (see UFSAR section 15.0.2.4), there is no effect on minimum DNBR. Failure of the pressurizer

level control, pressure control, or reactor regulating systems has minimal affect on any of the four factors that determine DNBR during the first one to four seconds of the event. Thus, none of the single failures listed in Table 15.0-0 will result in a more adverse transient minimum DNBR than that predicted for the single RCP shaft break event.

For pressure boundary performance evaluations, there is no single failure in addition to the LOP which results in more limiting peak RCS or secondary side pressures.

For radiological evaluations, a single active failure of an ADV to close is assumed once the ADVs are opened and this ADV is assumed to remain open for the duration of the event. The stuck open ADV is assumed to cause all of the iodine contained in the affected steam generator to be released to the atmosphere. Thus, this failure in combination with the LOP maximizes the radiological consequences of the single RCP shaft break event. None of the other single failures listed in Table 15.0-0 in combination with a loss of AC will yield more severe radiological consequences.

15.3.4.3 Core and System Performance

A. Mathematical Model

Several computer codes were employed to evaluate core and system performance for the sheared shaft limiting fault event. The transient core response was simulated using the HERMITE computer code (Reference 2) and the CETOP computer code (described in UFSAR Section 4.4 and

15.0.3.1.6) to generate the limiting core thermal hydraulic conditions at the time of minimum DNBR. The time of occurrence and the value of the minimum DNBR were calculated by the CETOP code.

The thermal-hydraulic code, TORC (described in UFSAR Section 15.0.3.1.6), was used to calculate DNBR values at various integrated radial peaking factors (Fr) to form data pairs. TORC output was used to determine fuel failure using the statistical convolution technique (see UFSAR section 15.4.8.3.C).

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a single RCP sheared shaft are presented in Table 15.3.4-1. These initial conditions result in the most adverse core performance.

UFSAR Appendix 15D describes the RCP coastdown methodology.

The flow coastdown is shown in Figure 15.3.4-8. The flow coastdown curve was developed using the methodology in Appendix 15D.

Table 15.3.4-1
ASSUMED INITIAL CONDITIONS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP CORE AND SYSTEM PERFORMANCE

Parameter	**Value**
Core Power Level	100%
Core Average Heat Flux	Maximum
Core inlet coolant temperature deg F	548
Core inlet pressure psia	2415
Core mass flow (% of design)	116
Moderator Temperature Coefficient $\Delta\rho$/deg F	-0.20×10^{-4}
Fuel Temperature Coefficient	Least Negative
CEA worth for trip - WRSO (%$\Delta\rho$)	-8.0
Maximum radial peaking factor	2.0
Fuel rod gap conductance (Btu/hr-ft2-deg F)	Minimum
Kinetics Parameters	BOC
Axial Power Distribution	-0.3
Loss of Offsite Power	Yes

The limiting initial conditions selected for the analysis have the core as far from bulk saturation conditions as possible and yet represents reasonable initial plant conditions from an operational standpoint. The results of parametrics show that the sheared shaft event initiated from top peaked initial conditions, away from saturation conditions lead to the most conservative transient simulations. Since the minimum DNBR for this event occurs

so quickly in the transient (< 3 seconds), the analysis is rather insensitive to the system responses when compared to the initial core parameters.

That is why the core parameters are discussed in detail in this section. The following analysis initial conditions tend to maximize the calculated fuel damage:

- Maximum rated core power (from a Power Operating Limit): Maximum allowable power results in more fuel failure.
- Minimum core inlet temperature: Maximizes initial core wide subcooling.
- Maximum core inlet pressure: Maximizes initial core wide subcooling.
- Maximum RCS flow: Maximizes initial core wide subcooling.
- Full power core average heat flux: Maximum Core Average Heat Flux results in more fuel failure.
- Top peaked power distribution (most negative Axial Shape Index limit): Since minimum DNBR occurs prior to CEA insertion, top peaked power distribution results in more limiting DNBR values.
- Maximum radial peaking factor (Fr): A maximum unrodded peaking factor promotes core wide subcooling and corresponds to a more limiting pin power distribution.

An unrodded pin power distribution also results in a larger number of failed fuel pins.

- Most positive (least negative) Moderator Temperature Coefficient: Increases the positive reactivity insertion due to moderator temperature feedback during the flow coastdown.

- Least negative (most positive) Fuel Temperature Coefficient (FTC): FTC has minimal impact on the analysis due to the event being short (< 4 seconds). Any reactivity feedback from the fuel in this period has a benign effect mainly because the fuel temperature does not change significantly during the time of interest.

- Maximum delayed neutron fraction: A maximum delayed neutron fraction, β, consistent with beginning of cycle conditions delays the core power decrease after reactor trip.

- Slower CEA drop time (scram position versus time) and CEDM Coil Delay time: Delays the core power decrease after reactor trip which results in a later DNBR turnaround and a lower flow at the time of minimum DNBR.

- Minimum gap conductance: Delays the core heat flux decrease after trip: resulting in a later DNBR turnaround and a lower flow at time of minimum DNBR.

C. Sequence of Events

The Sequence of Events for the Core and System Performance Analysis is shown in Table 15.3.4-2: below.

Table 15.3.4-2
SEQUENCE OF EVENTS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP FOR CORE AND SYSTEM PERFORMANCE

Time (sec)	**Event**
0.0	Reactor Coolant Pump Shaft Break occurs
2.5	Minimum DNBR Occurs
2.5	Reactor trip on low RCS flow, based on SG $\Delta\rho$
2.5	Reactor Trip Breakers Open, Turbine Generator Trip
3.1	CEAs begin to drop into the core
5.5	Loss of Offsite Power Occurs
10.0	Event Terminated

D. Results

During the first few seconds of the transient, the combination of decreasing flow rate and increasing RCS temperature results in a decrease in the DNBR of the fuel pins. The transient minimum DNBR is below the Specified Acceptable Fuel Design Limit (SAFDL) for DNBR. Figure 15.3.4-12 shows the variation of the minimum DNBR with time. The negative CEA reactivity inserted after

reactor trip causes a rapid power and heat flux decrease, which causes DNBR to increase. The amount of predicted failed fuel is determined with the statistical convolution technique (see UFSAR Section 15.4.8.3.C). The limiting fuel failure is discussed in UFSAR Section 15.3.4.6 ("EAB/LPZ Radiological Consequences and Containment Performance") and as long as the Fr (radial peaking factor) and fuel failure combination results in a bounding (2-hour site boundary) thyroid dose of less than 260 REM, the consequences remain within 10 CFR 100 guideline values.

DNB Propagation is evaluated by verifying that the bounding fuel clad strain evaluation is still applicable. The absolute minimum time in DNB required to reach NRC imposed strain limit of 29.3% is 4.5 seconds. This minimum time is based on the following conditions:

- Fuel Rod to RCS Differential Pressure < 1200 psid
- Local Heat Flux < 0.7E6 BTU/hr-ft2
- Local Mass Flux > 1.4 E6 lbm/hr-ft2
- Local Quality > -0.1

The analysis verifies the local conditions are within the specified ranges and that the overall time in DNB is less than 4.5 seconds. Therefore, DNB propagation will not occur.

15.3.4.4 RCS Pressure Boundary Barrier Performance

A. Mathematical Model

The CENTS computer code (see UFSAR Section 15.0.3.1.3.2) was used to simulate the secondary and Nuclear Steam Supply System thermal hydraulic response to a single RCP shaft break with a LOP resulting from turbine trip

B. Input Parameters and Initial Conditions

The input parameters and initial conditions relevant to barrier performance for this limiting fault event are presented in Table 15.3.4-3.

Table 15.3.4-3
ASSUMED INITIAL CONDITIONS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP FOR PRESSURE BOUNDARY PERFORMANCE

Parameter	**Value**
Core Power Level	102%
Core inlet coolant temperature deg F	548
Pressurizer Pressure (psia)	2325
Core mass flow (% of design)	116
Moderator Temperature Coefficient $\Delta\rho$/deg F	-0.18×10^{-4}
Fuel Temperature Coefficient	Least Negative
CEA worth for trip - WRSO (%$\Delta\rho$)	-8.0
Fuel rod gap conductance (Btu/hr-ft2-deg F)	Minimum
Kinetics Parameters	BOC
AFAS Setpoint (%WR)	20%
MSSV Setpoints	Minimum
MSSV Tolerance	+3%
PSV Setpoints	Maximum
PSV Tolerance	+3%
Number of plugged SG Tubes	1258
Loss of Offsite Power	Yes
Single Failure	None

The PSVs were modeled to maximize primary pressure. The maximum allowable setpoints (as allowed by Technical Specification 3.4.10) were used (2475 + 3%).

The MSSVs were also modeled to maximize primary and secondary pressure. The maximum allowable setpoints (as allowed by Technical Specification 3.7.1) were used (setpoint + 3% tolerance).

C. Sequence of Events

The Sequence of Events for the pressure boundary performance analysis are shown in Table 15.3.4-4 below.

Table 15.3.4-4
SEQUENCE OF EVENTS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP FOR PRESSURE BOUNDARY PERFORMANCE[a]

Time (sec)	**Event**
0.0	Reactor Coolant Pump Shaft Break occurs
1.7	Main Steam Isolation Signal on low SG pressure
2.5	Reactor trip on low RCS flow, based on SG $\Delta\rho$
2.5	Reactor Trip Breakers Open, Turbine Generator Trip
3.1	CEAs begin to drop into the core
5.5	Loss of Offsite Power Occurs
6.4	PSVs open
6.6	Peak RCS Pressure occurs
7.8	PSVs close
17.2	Peak SG pressure occurs
17.2	MSSVs open first time
72.7	MSSVs close[b]
807.0	AFAS generated in SG #1
853.0	AFW flow delivered to SG #1
964.3	AFW Reset in SG #1[b]
1301.9	AFAS generated in SG #2
1301.9	AFW flow delivered to SG #2
1373.2	AFW Reset in SG #2[c]
1800	Operators begin plan cooldown. Event Terminated

a. The exact diesel generator sequencing time is not critical for this event and was not specifically modeled since the diesel generator will be available to power AFW “A” well before AFAS is reached.

b. MSSVs cycle open and closed throughout the transient.

c. AFW actuation may occur and reset more than once.

D. Results

The typical transient response of key NSSS parameters as a function of time is presented on Figures 15.3.4-1 to 15.3.4-12 for this limiting fault event.

The shearing of the RCP shaft causes a reactor trip to occur on a steam generator Δr low RCS flow trip that results in a reactor trip followed by a concurrent turbine trip, which causes turbine admission valve closure. Furthermore, a reduction of flow in the affected RCS loop is compounded by the occurrence of a LOP three seconds later. The steam bypass control system, condenser and main feedwater system become unavailable, resulting in a rapid increase in secondary side pressure and temperature. The reduction in primary-to-secondary heat transfer causes a rapid heatup of the primary side coolant. No operator action is assumed for 30 minutes. The PSVs open to limit pressure and slightly later the main steam safety valves open.

The RCS pressure reaches a maximum of 2614 psia (see Figure 15.3.4-4), which is less than 2750 psia (110% of RCS system design pressure of 2500 psia). The secondary system pressure reaches a maximum of 1303 psia (see Figures 15.3.4-9 and 15.3.4-10), which is less than 1397 psia (110% of secondary design pressure of 1270 psia).

These event primary and secondary pressure values meet the acceptance criteria of the Standard Review Plan.

15.3.4.5 NSSS Response for Control Room Dose Consequences

A NSSS response evaluation is performed to determine the time of Control Room Essential Filtration Actuation and secondary mass releases due to the MSSVs and the stuck open ADV for input into the control room dose analysis presented in UFSAR 6.4.7.3.

A. Mathematical Model

The CENTS computer code (see UFSAR Section 15.0.3.1.3.2) was used to simulate the secondary and Nuclear Steam Supply System (NSSS) thermal hydraulic response to a single RCP shaft break with a LOP resulting from turbine trip.

B. Input Parameters and Initial Conditions

Input parameters and initial conditions are established to maximize secondary side releases and delay the Safety Injection Actuation Signal, which starts the control room essential filtration. Initial conditions are shown below in Table 15.3.4-5.

Table 15.3.4-5
ASSUMED INITIAL CONDITIONS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP AND A STUCK OPEN ADV

Parameter	**Value**
Core Power Level	102%
Core inlet coolant temperature deg F	548
Pressurizer Pressure (psia)	2325
Core mass flow (% of design)	116
Moderator Temperature Coefficient $\Delta\rho$/deg F	$-4.4\text{x}10^{-4}$
CEA worth for trip - WRSO (%$\Delta\rho$)	-8.0
SIAS Setpoint (psia)	1750
Initial SG Level (%WR)	42%
MSIS Setpoint (psia)	1005
AFAS Setpoint (%WR)	20%
AFW SG DP Lockout Setpoint (psid)	130
MSSV Setpoints	Minimum
MSSV Tolerance	-3%
Loss of Offsite Power	Yes
Single Failure	Stuck Open ADV

C. Sequence of Events

The Sequence of Events for the NSSS Response for Control Room Dose are shown in Table 15.3.4-6 below.

Table 15.3.4-6

SEQUENCE OF EVENTS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP WITH A STUCK OPEN ADV

Time (sec)	**Event**
0.0	Reactor Coolant Pump Shaft Break occurs
2.5	Reactor trip on low RCS flow, based on SG $\Delta\rho$
2.5	Reactor Trip Breakers Open, Turbine Generator Trip
3.1	CEAs begin to drop into the core
5.5	Loss of Offsite Power Occurs
7.4	Main Steam Safety Valves Open
15.3	Steam Generator Water Level Reaches AFAS setpoint in SG #1
18.8	Steam Generator Water Level Reaches AFAS setpoint in SG #2
61.4	Auxiliary Feedwater Initiated to SG #1
61.4	Auxiliary Feedwater Initiated to SG #2
63.9	Main Steam Safety Valves Close
122.5	Operator initiates plant cooldown by opening one ADV on each steam generator. ADV on SG #1 instantly fails full open
152.5	MSIS actuated on low SG pressure
172.4	SG $\Delta\rho$ causes AFAS lockout on SG #1, AFW to SG #1 terminated
242.5	Operator shuts ADV on SG #2
396.9	AFAS reset on high SG level in SG #2
290.3	SIAS Setpoint reached on low pressurizer pressure
330.3	SI flow initiated
447.0	SG #1 reaches dryout conditions
1800.	Operators take manual control of AFW and begin filling SG #1. AFW in SG #2 is terminated.
5291.5	SG #1 level reaches the physical location of the top of the SG U-tubes (14% NR)
5400.4	SG #1 level reaches the top of the SG U-tubes considering EOP Uncertainties (43% NR)
5401.4	Event Terminated.

D. Results

The shearing of the RCP shaft causes a reactor trip to occur on a steam generator $\Delta\rho$, low-RCS-flow trip that results in a reactor trip followed by a concurrent turbine trip, which causes turbine admission valve closure. Furthermore, a reduction of flow in the affected RCS loop is compounded by the occurrence of a LOP three seconds later. The steam bypass control system, condenser and main feedwater system become unavailable, resulting in a rapid increase in secondary side pressure and temperature. The reduction in primary-to-secondary heat transfer causes a rapid heatup of the primary side coolant. After reactor trip the operator opens ADVs on both steam generators. Once the ADVs are opened, one valve is assumed to remain stuck open. This results in the eventual generation of a Main Steam Isolation Signal (MSIS) on low steam generator pressure. Once the main steam isolation valves are closed, further blowdown of the unaffected steam generator is prevented. AFW is automatically terminated to the affected steam generator as a result of a high differential pressure signal between steam generators. Thirty minutes from the time of shaft shear, the operator overrides the AFW lockout and diverts all of the AFW flow to the affected steam generator, covering the tops of the U-tubes after 90 minutes.

Table 15.3.4-7

TIME OF SIAS AND SECONDARY MASS RELEASES FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER AND STUCK OPEN ADV

Time of SIAS (sec)	**Total MSSV Release (lbm)**	**Total ADV Release from SG #1 (lbm)**	**ADV Release for 600 seconds from SG #1 (lbm)**
290.3	12.238×10^4	4.196×10^5	1.108×10^5

15.3.4.6 EAB/LPZ Radiological Consequences/Containment Performance

A. Physical Model and Assumptions

To evaluate the consequences of the single reactor coolant pump shaft break with a LOP event, it is assumed that the condenser is not available for the entirety of the transient. After reactor trip occurs, an MSIS is generated, the steam generators are isolated and the pressure in the steam generators rises quickly to the MSSV setpoint. Sometime after the reactor trip, the operators will open an ADV on each steam generator to stop the MSSVs from cycling. When they open the ADVs, one is assumed to cycle to a fully-opened position and stick there. At this point, the operators close the ADV on the unaffected steam generator. The exact timing of these operator actions does not affect the calculated offsite doses since the dose calculation makes the simplifying assumption that the iodine contained in the affected steam generator is

released to the atmosphere at the initiation of the event. At thirty minutes the operators divert all of the AFW flow to the affected steam generator until the tops of the U-tubes are covered and then proceeds with the controlled cooldown using the ADVs on the unaffected steam generator and the AFWS while maintaining the level in the affected steam generator.

The U-tubes for the unaffected steam generator remain covered by water throughout the event so a Decontamination Factor (DF) of 100 is used for releases from this steam generator.

Peak containment pressure is not calculated for these events and would be bounded by the LOCA and MSLB events. Containment integrity will not be challenged. In the case of the sheared shaft event, the actual time the PSV is opened is less than 3 seconds.

B. Calculational Methods and Parameters

Even for identical core average and hot channel conditions for a given transient event, the number of fuel pins that experience DNB, will vary from cycle to cycle. The calculated amount of fuel failure is sensitive to fuel loading pattern (i.e. pin power distribution). Therefore, it would be difficult to bound the calculated fuel failure of all future reloads based upon any one transient response. In order to accommodate the potential variability between cycles, the calculated dose was expressed as a function of the product of the radial

peaking factor and the fuel failure fraction. The values of this product just corresponding to the limit (i.e., thyroid dose of 260 REM) were determined.

A cycle-specific analysis ensures that the product of the failure (based upon actual core loading) and the maximum cycle radial peaking factor do not exceed these limit products. As long as the product for the cycle is less than the product corresponding to the respective limit, the doses for the cycle will be less than the limits and the radiological consequences for a 2-hour, site-boundary thyroid doses will be within 10 CFR 100 guideline values.

Since an ADV is assumed to stick open, the containment barrier is not credited. Operators take action to close all system boundary valves to minimize flow/discharge to the environment.

The major assumptions, parameters, and inputs to calculational methods used to evaluate the radiological consequences of the single RCP shaft break are presented in Table 15.3.4-8. Additional clarification is provided as follows:

1. The RCS equilibrium activity is based on long term operation at 102% of Rated Thermal Power (RTP) with a technical specification limit on primary activity, expressed in Dose Equivalent I-131 (DEQ I-131) of 1.0μCi/gm.

The RCS activity is calculated to determine the total amount of activity leaked into the secondary system during the duration of the accident due to a 0.5 gal/min primary-to-secondary leak per steam generator. The primary-to-secondary leakage of 1 gal/min is assumed to continue to the steam generators for the entire event. The activity in the fuel clad gap is 10% of the iodines and 10% of the noble gases accumulated in the fuel at the end of core life, assuming continuous full power operation. All of the activity in the fuel gap for fuel rods that are calculated to experience DNB is assumed to be uniformly mixed with the reactor coolant. This assumption is consistent with Regulatory Guide 1.77.

2. The steam generator equilibrium activity is assumed to be 0.1 μCi/gm DEQ I-131 prior to the accident. This is the technical specification limit for steam generator activity.

3. Offsite power is not available. When the operators open the ADVs following the reactor trip, one is assumed to cycle to a fully-opened position and stick there. At this point, the operators close the ADV on the unaffected steam generator. The exact opening time of the stuck open ADV does not matter for the calculated EAB or LPZ doses since the simplified dose calculation model assumes all of the iodine contained in the affected steam generator is released to the

atmosphere instantaneously at the initiation of the event. At 1800 seconds, the operators begin flooding the affected steam generator and cover the tubes by 5400 seconds. The operators control the cooldown using the ADVs and the AFWS on the unaffected steam generator, while maintaining the level in the affected steam generator.

4. For the fluid leaked from primary to secondary, iodine is assumed to be released to the atmosphere with a DF of 1.0 in the affected steam generator when the tubes are uncovered. The DF is increased to 100 when the tubes are recovered at about 90 minutes.

5. Mass releases are based on the heat that must be removed from the RCS and they include the decay heat and the stored heat in the primary coolant and in the metal masses. Table 15.3.4-9 shows the releases for this analysis.

6. No credit for radioactive decay in transit to dose point is assumed.

7. The atmospheric dispersion factor used in this analysis is listed in Table 2.3-31.

8. The mathematical model used to analyze the activity released during the course of the accident is described in UFSAR Section 15.0.4 ("Radiological Consequences").

9. Since the PSVs lift for this event, the dose calculation conservatively takes into account the activity released to containment, even though the Reactor Drain Tank is sized to remain intact from the PSV discharge.

The uncertainties and conservatisms in the assumptions used to evaluate the radiological consequences of the single RCP shaft break with a LOP are as follows:

1. A conservative primary-to-secondary leakage of 1 gpm is used. This corresponds to 1440 gallons per day (gpd). Operation with a primary-to-secondary leak of 1 gpm is not allowed. Technical Specification 3.4.14 limits primary-to-secondary leakage through any one steam generator to less than 150 gpd.
2. The meteorological conditions assumed to be present at the site during the course of the accident are based on 5% level χ/Q values. Meteorological conditions will be less severe 95% of the time. This results in conservative values of atmospheric dispersion calculated for the EAB or LPZ outer boundary. Furthermore, no credit has been taken for the transit time required for activity to travel from the point of release to the EAB or LPZ outer boundary.
3. The dose calculations conservatively use the maximum cooldown rate of 100°F/hr allowed by Technical Specifications. This approach was independent of whether the charging system could compensate for the accompanying rate of shrinkage.

4. The dose calculations use a conservatively low steam generator liquid mass constant value of 160,600 lbm for the intact steam generators. This lower value is conservative as it will increase the steam generator DEQ I-131 concentration from which releases to the site boundary evolve.

DECREASE IN REACTOR

COOLANT FLOWRATE

Table 15.3.4-8

TYPICAL PARAMETERS USED IN EVALUATING THE RADIOLOGICAL CONSEQUENCES OF A SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP
(Sheet 1 of 2)

Parameter	Value
A. Data and assumptions used to evaluate the radioactive source term	
a. Power level (% RTP)	102
b. Percent of fuel calculated to experience DNB and fail (%).	17.0 at FR=1.72[2]
c. Reactor coolant activity before event, based on Technical Specifications (μCi/gm)	1.0
d. Secondary system activity before event (μCi/gm)	0.1
e. Minimum primary system liquid inventory (excluding mass in pressurizer), lbm	510,000
f. Minimum steam generator inventory, lbm per steam generator	160,600
B. Data and assumptions used to estimate activity released from the secondary system	
a. Primary to secondary leak (gpm)	0.5 per SG
b. Total mass release through the MSSVs and ADVs based on boiling off inventory to remove decay heat and stored heat.	
• Decay heat based on	1979 ANS Standard with a 2σ uncertainty.
• Specific heat for RCS metal masses.	Maximum
C. Atmospheric dispersion factors (sec/m^3)	
• EAB (0-2 hours)	2.3×10^{-4}
• LPZ (0-8 hours)	6.4×10^{-5}

[2] These values were used in the Control Room Dose calculation and are more restrictive than those used for the EAB dose. As long as the product of the Fr and fuel failure fraction (= 29.24%) does not increase, the Control Room Dose calculations will remain bounding and the EAB dose will remain within acceptance criteria.

Xe-133	5.62×10^{4}
Xe-138	4.97×10^{4}

[3] The U-tubes in the affected steam generator are assumed to be re-covered by water after this time.

Table 15.3.4-9

TYPICAL SECONDARY SYSTEM MASS RELEASE TO THE ATMOSPHERE FOR THE SINGLE REACTOR COOLANT PUMP SHAFT BREAK WITH LOSS OF OFFSITE POWER RESULTING FROM TURBINE TRIP

Time	Integrated Primary-to-Secondary Leakage (gallons)	Secondary System Mass Release (lbm)
2 hr	120	9.54×10^5
8 hr	480	2.42×10^6

15.3.4.7 Conclusions

The maximum RCS and secondary side pressures due to a single RCP shaft break in combination with a LOP resulting from turbine trip remain less than 110% of their design values.

In the event of a single RCP shaft break or rotor seizure event, the 2-hour EAB doses will be less than 260 REM for a RTP of 3990 MWt. This exposure is within 10 CFR 100 limits. The NRC changed the acceptance criteria for this event in CESSAR SER Supplement 2 as a result of the assumptions made (LOP, ADV sticks open). The acceptance criteria were changed from the guidelines in the Standard Review Plan (Reference 1) to the limits given in 10 CFR Part 100.

15.4 REACTIVITY AND POWER DISTRIBUTION ANOMALIES

15.4.1 UNCONTROLLED CONTROL ELEMENT ASSEMBLY WITHDRAWAL FROM A SUBCRITICAL OR LOW (HOT ZERO) POWER CONDITION

15.4.1.1 Identification Cause and Frequency Classification

An uncontrolled withdrawal of control element assemblies (CEAs) is postulated to occur as a result of a single failure in the control element drive mechanism (CEDM), control element drive mechanism control system, reactor regulating system or as a result of operator error.

These initiating events are Anticipated Operational Occurrences (AOOs), as discussed in Table 3.9-1 and are classified as incidents of moderate frequency.

The uncontrolled CEA withdrawal (CEAW) from subcritical and low (hot zero) power conditions are presented in this section.

15.4.1.2 Sequence of Events and Systems Operation

The withdrawal of CEAs from subcritical or low (hot zero) power conditions adds reactivity to the reactor core, causing both the core power level and the core heat flux to increase, followed by corresponding increases in reactor coolant temperatures and reactor coolant system (RCS) pressure. The withdrawal of CEAs also produces a time-dependent redistribution of core power. These transient variations in core thermal parameters may result in the system’s approach to the specified acceptable fuel design limits (SAFDLs) and RCS and secondary system pressure limits, thereby requiring the protective action of the reactor protective system (RPS).

The reactivity insertion rate accompanying the uncontrolled CEA withdrawal is dependent primarily upon the CEA withdrawal rate and the CEA worth since, at subcritical or Hot Zero Power (HZP) conditions, the normal reactor feedback mechanisms do not occur until power generation in the core is large enough to cause changes in the fuel and moderator temperatures. The reactivity insertion rate determines the rate of approach to the fuel design limits. Based on the reactivity insertion rate and the system initial conditions, the limiting moderate frequency uncontrolled CEAW transient is terminated by a high logarithmic power level trip (HLPT) for the subcritical initial condition, or an RPS variable overpower trip (VOPT) for the HZP initial condition. Depending on the reactivity insertion rate and the system initial conditions, the CPC VOPT, CPC Low DNBR, or high LPD trips may terminate the transient, as well.

The uncontrolled CEA withdrawal from subcritical or HZP conditions causes subcritical multiplication to increase core power resulting in a reactor trip. The brief power excursion which results in a slight increase in RCS temperature, is terminated when the CEAs begin to insert. The RCS pressure remains below the pressurizer pressure safety relief valve setpoint. The secondary side pressure increases slightly following reactor trip and is limited by the steam generator safety valves. The atmospheric dump valves are used to cool the RCS to shutdown cooling entry conditions. The feedwater flow rate is operated in manual mode and is very low because it matches the steam flow rates. RCS heat is removed via the steam bypass control system until the shutdown cooling system (SCS)

is manually actuated at a time when the RCS temperature and pressure have been reduced to approximately 350°F and 400 psia. The SCS provides sufficient cooling flow to cool the RCS to cold shutdown.

The sequence of events for the limiting moderate frequency CEA withdrawal transient from subcritical and HZP conditions are presented in Table 15.4.1-1. Analytical setpoints and response times associated with the RPS trip functions are consistent with, or conservative with respect to, numerical values delineated in UFSAR Section 7.2. A conservative CEA coil decay time of 0.6 seconds was used in simulating the uncontrolled CEAW transients.

Table 15.4.1-1

SEQUENCE OF EVENTS FOR SUBCRITICAL AND HOT ZERO POWER CASES

Time (seconds)		**Event**
Subcritical	**HZP**	
0.0	0.0	CEAs begin uncontrolled withdrawal
71.86	24.89	Core power reaches RX trip setpoint (% RTP)
72.36	25.34	Trip breakers open and CEA withdrawal stops
72.96	25.94	CEAs begin to drop
72.97	25.95	Peak power reached (% RTP)
73.16	26.18	Minimum DNBR occurs
73.17	26.19	Peak heat flux reached (% RTP)
73.75	30.12	Withdrawn CEAs are assumed to be fully inserted to its original position for the Subcritical event while all the CEAs except the most Worth Rod Stuck Out (WRSO) are assumed fully inserted for HZP case

15.4.1.3 Core and System Performance

A. Mathematical Model

Several computer codes are employed to evaluate core and system performance for the limiting uncontrolled CEAW moderate frequency transients. The CENTS computer code (see UFSAR Section 15.0.3.1.3.2) is used to simulate the Nuclear Steam Supply System (NSSS) response to these events by modeling the neutronics, thermal hydraulics and plant systems during transient conditions. The CETOP computer code (see UFSAR Section 4.4 and 15.0.3.1.6), uses thermal hydraulic and heat flux data from CENTS to simulate fluid conditions within the reactor core in order to calculate the time and numerical value of the fuel pin minimum departure from nucleate boiling ratio (DNBR).

A steady state peak linear heat rate of 21 kW/ft has been established as the Limiting Safety System Setting (LSSS) to prevent fuel centerline melting during normal steady state operation. Following design basis AOOs, the transient linear heat rate may exceed 21 kW/ft provided the fuel centerline melt temperature is not exceeded. However, if the transient linear heat rate does not exceed 21 kW/ft, then the fuel centerline melt temperature is also not exceeded. The calculated transient value of Linear Heat Generation Rate (LHGR) exceeds the nominal steady state LSSS of 21 kW/ft for a short period of time during the

transient. Therefore, a hand calculation is made on the amount of energy rise and deposition in the fuel, i.e., an adiabatic deposited energy calculation is performed. This is done to ensure that the fuel temperature (i.e., fuel enthalpy) remains below the melting point and no fuel failure occurs.

B. Input Parameters and Initial Conditions

Important input parameters and initial conditions used to analyze the NSSS response to a CEA withdrawal from subcritical and HZP conditions are delineated in Table 15.4.1-2. These parameters have been determined to comprise the limiting set of conditions from which an uncontrolled CEA withdrawal could be initiated from subcritical or low HZP conditions and produce the limiting moderate frequency events. A maximum initial core gap conductance is used to minimize Doppler feedback and maximize core power.

Parametric analyses have indicated that the lowest initial power and the highest reactivity insertion rates result in the highest peak core power and the most limiting thermal and hydraulic conditions for DNBR. For the subcritical event, the initial subcritical power level that results from a conservative neutron source strength is assumed. The initial minimum power, 5E-10% RTP, is calculated based on this source strength and the subcriticality imposed by the withdrawn bank, and subcriticality

multiplication. For the low power event, the lowest initial power is determined based on the High Log Power Trip (HLPT) bypass removal setpoint.

The maximum reactivity insertion rates are based on the maximum CEA withdrawal rate of the CEA drive system, 30 inches/min. For the subcritical event, only the withdrawal of regulating CEAs are evaluated since the PVNGS Technical Specifications requires adequate shutdown margin to prevent going critical by withdrawal of shutdown CEAs, and the out-of-sequence withdrawal of CEAs would result in immediate trip by CPCs due to high penalty applied. In addition, plant startup procedures instructs sequential withdrawal of CEAs in the following order, first the shutdown CEAs, then the part strength CEAs, and finally regulating CEAs. Based on the calculated maximum CEA worths, and the maximum CEA withdrawal rate, the reactivity insertion has a maximum expected rate of 2.835E-4 delta rho/sec for a CEA withdrawal from subcritical condition. The low (HZP) power maximum reactivity insertion rate is determined by performing a parametric study on the CEA bank worth, CEA positions, and axial power shapes to establish bounding bank worth and bounding axial shape. Based on the bounding bank worth and the bounding axial shape, bounding differential rod worths are determined using the HERMITE code. The maximum reactivity insertion rate of 1.7E-4 delta rho/sec is used

corresponding to the bounding differential rod worth and the maximum withdrawal speed of 30 inches/min for a CEA withdrawal from low power conditions.

For the subcritical CEA withdrawal (CEAW), the High Log Power Trip (HLPT) occurs at a setpoint of 0.1% RTP. For the CEAW at low power conditions, the analysis RPS VOPT occurs at a setpoint of 11%. The evaluation used a 12% trip setpoint to conservatively envelope the RPS VOPT band and increase rates described in UFSAR Section 7.2.

The initial conditions that result in the most rapid approach to the fuel design limits for the subcritical and HZP events are a core inlet temperature of 572°F, based on the Technical Specification in Mode 1 and operating procedures limiting temperature in lower modes, and minimum RCS flow based on four pump operation. These yield reduced heat removal, resulting in higher fuel temperatures and lower DNBRs. A minimum pressurizer pressure was used for the subcritical and HZP event conditions to obtain a conservative minimum DNBR and to minimize the initial negative reactivity feedback margin for greater fuel enthalpy production. The most positive moderator temperature coefficient (MTC) of $+0.5 \times 10^{-4}$ $\Delta\rho$/°F is assumed for this analysis. Also, the least negative in cycle Doppler coefficient was used for both uncontrolled CEA withdrawal transients.

Table 15.4.1-2

INPUT PARAMETERS AND INITIAL CONDITIONS
FOR THE LIMITING MODERATE FREQUENCY UNCONTROLLED
CEA WITHDRAWAL ANALYSES

PARAMETER	VALUE	
	Subcritical Analysis	Low (Hot Zero) Power Analysis
Initial core power (% of RTP)	5.0×10^{-8}	1.9×10^{-5}
Initial core inlet temperature (°F)	572	572
Initial pressurizer pressure (psia)	1785	2100
Initial RCS flow[a] (lbm/sec)	43278	43278
MTC ($\Delta\rho$/°F)	0.5×10^{-4}	0.5×10^{-4}
FTC[b]	Least negative	Least negative
Maximum peaking factor (F_q)	13.8	10.5
Maximum reactivity insertion rate ($\Delta\rho$/inch)	5.67×10^{-4}	3.4×10^{-4}
CEA worth at trip[c], (%$\Delta\rho$)	-1.60	-6.5 (WRSO)
Trip Setpoint[d] (% of RTP)	0.1	11.0[e]
SCRAM delay (sec)	0.5	0.45
CEA holding coil delay (sec)	0.6	0.6
Fuel rod gap conductance (Btu/hr-ft^2-°F)	6530	6530

a. This corresponds to 95% of the original design flow of 164.0 Mlbm/hr.

b. The fuel temperature coefficients used are found in the unit- and cycle-specific analyses.

c. For Subcritical CEAW only the withdrawn CEA is reinserted whereas for the Hot Zero Power case, the withdrawn CEA along with all the other CEAs except for the Worst Rod Stuck Out (WRSO) is reinserted.

d. For the CEAW from subcritical, the trip setpoint is for the HLPT. For the CEAW from HZP, the trip setpoint is for the RPS analog VOPT.

e. Note in the computer runs this is conservatively set at 12%.

C. Results

The responses of key parameters as a function of time are presented in Figures 15.4.1-1 through 15.4.1-16, typical for the uncontrolled CEAW transient from subcritical condition and the HZP condition.

The uncontrolled CEA withdrawal from a subcritical condition resulted in a reactor trip on HLPT. The minimum DNBR calculated for this event that was initiated from the conditions of Table 15.4.1-2, was 2.24 which is greater than the design limit of 1.34.

The peak LHGR was calculated to be 56.20 kW/ft, which exceeds the LSSS but the highest fuel centerline temperature reached was 1570°F, which is less than the fuel melt temperature which is based on burnup and erbia content.

The uncontrolled CEAW from HZP conditions resulted in a reactor trip on the RPS analog VOPT. The minimum DNBR calculated for this event, initiated from the conditions of Table 15.4.1-2, was 1.67 which is greater than the design limit of 1.34.

The calculated peak LHGR was 40.52 kW/ft, which exceeds the LSSS, but the fuel centerline temperature was bounded by 2600°F, which is less than the fuel melt temperature which is based on burnup and erbia content.

Therefore, fuel and/or cladding damage is not predicted for these limiting moderate frequency events and the acceptance criteria delineated in Section 15.4.1 of the Standard Review Plan (Reference 1) are met.

15.4.1.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate fission product barrier performance for the limiting moderate frequency events are described in UFSAR Section 15.4.1.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed to evaluate fission product barrier performance for the limiting moderate frequency events are described in UFSAR Section 15.4.1.3.B.

C. Results

The response of key parameters as a function of time is presented in Figures 15.4.1-1 through 15.4.1-16 for these limiting moderate frequency events. The peak RCS pressure for the CEA withdrawal from a subcritical condition presented in Figure 15.4.1-3 is less than that of the CEA withdrawal from the HZP condition presented in Figure 15.4.1-11. The calculated peak RCS pressure was 1881 psia for the CEAW from

subcritical (see Figure 15.4.1-3) and 2225 psia for the CEAW from HZP (see Figure 15.4.1-11), both of which are less than the design limit of 2750 psia.

The calculated secondary side peak pressures were 1246 psia for the CEAW from subcritical and 1260 psia for the CEAW from HZP, both of which are less than the design limit of 1397 psia.

It should be noted that these peak pressures were obtained from the cases for which the initial and transient conditions were selected to maximize heat transfer degradation and fuel centerline temperature for demonstration of this event being not a peak pressure event because of the small amount of heat transferred to the RCS from fuel during the transient. Furthermore, the peak pressure is not a SRP review criterion for this event, however, the evaluation results are reported herein.

15.4.1.5 Radiological Consequences and Containment Performance

Fuel damage is not predicted for the limiting moderate frequency uncontrolled CEA withdrawal events, and therefore there are no radiological consequences from these events. These events would not result in any release of radioactive material above that of a normal reactor trip.

15.4.1.6 Conclusions

For the postulated events involving an uncontrolled CEA withdrawal from subcritical or HZP conditions, the PVNGS design meets the relevant requirements of Standard Review Plan (Reference 1).

15.4.2 UNCONTROLLED CONTROL ELEMENT ASSEMBLY WITHDRAWAL AT POWER

15.4.2.1 Identification of Causes and Frequency Classification

An uncontrolled CEA withdrawal (CEAW) at power is assumed to occur as a result of a single failure in the control element drive mechanism (CEDM), control element drive mechanism control system, the reactor regulating system, or as a result of operator error.

An uncontrolled CEAW from power conditions is an Anticipated Occupational Occurrence (AOO), as discussed in Table 3.9-1 and is classified as an incident of moderate frequency.

15.4.2.2 Sequence of Events and Systems Operation

The uncontrolled withdrawal of a Control Element Assembly (CEA) from full power conditions adds reactivity to the core, causing both the core power level and the core heat flux to increase, followed by corresponding increases in reactor coolant temperatures and reactor coolant system (RCS) pressure. The withdrawal of CEAs also produces a time-dependent redistribution of core power. These transient variations in core thermal parameters may result in an approach to the

specified acceptable fuel design limits (SAFDLs) on DNBR and fuel centerline melt temperature, thereby requiring the protective action of the reactor protective system (RPS).

The net reactivity insertion rate accompanying the uncontrolled CEAW is dependent upon the CEA withdrawal rate and reactivity feedback mechanisms present at the time of the CEAW from full power conditions. The net reactivity insertion rate determines the rate of approach to the fuel design limits. Depending on the reactivity insertion rate and the system initial conditions, the uncontrolled CEAW transient from full power is terminated by a Core Protection Calculator (CPC) Variable Overpower Trip (VOPT) or the High Pressurizer Pressure Trip (HPPT).

Table 15.4.2-1 gives a sequence of events from the time the CEAs start to withdraw until the operator initiates a cooldown of the Nuclear Steam Supply System (NSSS). This typical sequence of events was obtained by simulating the event with the computer codes identified in UFSAR Sections 15.4.2.3 and 15.4.2.4. Figures 15.4.2-1 through 15.4.2-11[2] depict the response of key NSSS parameters during this event. The withdrawal of CEAs causes a positive reactivity change, resulting in an increase in the core power and core heat flux (Figures 15.4.2-1 and 15.4.2-2, respectively). Following the generation of a turbine trip on reactor trip, main feedwater flow reduces to 5% of nominal, full flow. The steam bypass

[2] Figures are typical representation of the transient.

control system (SBCS) is assumed to be in manual mode with all the bypass valves closed, resulting in the main steam safety valves (MSSVs) opening (Figure 15.4.2-10) to limit secondary system pressure and remove stored heat transferred from the core and the RCS. After the reactor trip and turbine trip, there is a brief power mismatch between the primary and secondary sides of the steam generator until the MSSVs open, resulting in an increase in RCS pressure and temperature (Figures 15.4.2-3 and 15.4.2-5, respectively). The RCS pressure (Figure 15.4.2-3) remains below the PSV setpoint. The analysis does not credit the actuation of the pressurizer pressure control system and level control systems. However, for RCS control and recovery following the opening of the MSSVs, the pressurizer heaters are adjusted to maintain pressure around 2100 psia. The operator initiates cooldown 30 minutes following the initiation of the event utilizing the main feedwater and the SBCS.

Table 15.4.2-1 does not reflect the event time line beyond 1800 seconds. The cooldown proceeds with the operator reducing the main steam isolation actuation setpoint to prevent the inadvertent generation of a Main Steam Isolation Signal (MSIS). When steam pressure decreases to a point where the main feedwater pumps can no longer be used, the operator secures the main pumps. Cooldown is continued by utilizing one auxiliary feedwater pump SBCS until the shutdown cooling system is manually actuated at a time when the RCS temperature and pressure have been reduced to approximately 350°F and 400 psia.

Table 15.4.2-1

SEQUENCE OF EVENTS FOR THE
SEQUENTIAL CEA WITHDRAWAL EVENT AT FULL POWER

Time (sec)	Event
0.00	CEAs begin withdrawing
13.1	CPC's trip signal generated
13.85	Reactor trip breakers open
13.85	Turbine trip occurs
14.0	Minimum DNBR occurs
14.2	Maximum core power occurs
14.45	Scram CEAs begin to drop into the core
14.7	Maximum core average heat flux occurs
16.8	Maximum RCS pressure
21.2	Maximum secondary pressure
21.3	MSSV bank open and begins to cycle open and closed
1800	Operator initiates cooldown

Analytical setpoints and response times associated with the RPS trip functions were consistent with, or conservative with respect to, numerical values delineated in UFSAR Section 7.2. A conservative CEA coil decay time of 0.6 seconds was used in simulating the uncontrolled CEAW at power transient.

15.4.2.3 Core and System Performance

A. Mathematical Model

The NSSS response to a CEA group withdrawal at full power conditions was simulated using the CENTS computer code described in UFSAR Section 15.0.3.1.3.2. The thermal margin on DNBR in the reactor core was simulated using the CETOP computer code (described in UFSAR Sections 4.4 and 15.0.3.1.6) with the CE-1 CHF correlation that is also described in UFSAR Section 4.4. If the calculated transient value of Linear Heat Generation Rate (LHGR) exceeds the conservative, steady-state limit of 21 kW/ft for a short period of time during the transient, an additional, conservative, hand calculation is performed to confirm that the fuel temperature remains below the melting point. The SAFDL requires the calculated fuel temperature not exceed the fuel melting temperature, but states that showing the LHGR remains below 21 kW/ft guarantees no fuel melting. The fuel temperature is calculated based on the amount of energy deposited in the fuel over time. This is done to ensure that the fuel temperature (i.e., fuel

enthalpy) remains below the melting point and no fuel failure occurs.

B. Input Parameters and Initial Conditions

The assumptions and input parameters that are unique to this event analysis are discussed below and are listed in Table 15.4.2-2.

These initial conditions (i.e., radial power peak, core flow, and inlet temperature) were chosen such that a reactor trip on low DNBR is actuated prior to or at the same time as the HPPT or the VOPT would be initiated. The selection of these parameters in this manner minimizes the hot channel minimum DNBR.

The initial conditions and NSSS characteristics used in this analysis yield the minimum DNBR for any CEA group withdrawal incident. Parametric studies were performed on core inlet temperature, fuel rod gap conductance, and core flow. The studies indicated that minimum DNBR during the CEA withdrawal is most sensitive to initial core inlet temperature. Thus, the minimum allowable core inlet temperature was assumed. The minimum initial pressurizer pressure, which has a negligible impact on the event was selected to avoid a HPPT actuation. Thus, the conditions chosen yield the minimum DNBR for a CEA withdrawal at power.

Table 15.4.2-2

ASSUMPTIONS AND INITIAL CONDITIONS
FOR THE SEQUENTIAL CEA WITHDRAWAL ANALYSIS

Parameter	Value **RTP 3990 MWt**
Initial core power (% of RTP)	102
Initial core inlet temperature (°F)	548
Initial pressurizer pressure (psia)	2100
Initial RCS flow (% of design)	95
Moderator temperature coefficient ($\Delta\rho$/°F)	0.0
Doppler fuel temperature coefficient[4]	Least negative
Kinetics[5]	Minimum β
Maximum radial peaking, (Fr)	2.0
Differential reactivity insertion (%$\Delta\rho$/in)	0.008
CEA withdrawal speed (inches/min)	30.0
CEA worth at trip (%$\Delta\rho$)	8.0
Fuel rod gap conductance (Btu/hr-ft^2-°F)	6527
Number of Plugged Steam Generator Tubes	0
Single failure	None
Loss of Offsite Power (LOP)	No

[4]The fuel temperature coefficient used is found in the unit- and cycle-specific analyses.

[5]The kinetics parameters used are found in the unit- and cycle-specific analyses.

The maximum power level from which the withdrawal is initiated was assumed to be 102% of licensed power. Minimum DNBR during the CEA withdrawal is more sensitive to high initial power levels. The initial core average axial power distribution for this analysis is a shape characterized by an axial shape index equal to -0.3. This distribution is assumed because it minimizes the DNBR.

Other input parameters that are important to this analysis are moderator temperature coefficient (MTC) and fuel temperature coefficient (FTC) of reactivity. The MTC assumed in this analysis corresponds to beginning-of-life core conditions. This MTC has the smallest impact on retarding the rate of change of power, coolant temperature, and DNBR. A FTC corresponding to beginning-of-life conditions was used in the analysis, since this FTC causes the least amount of negative reactivity change for mitigating the transient increases in core power, heat flux, and the reactor coolant temperatures.

The regulating CEA position from which the CEA withdrawal is initiated corresponds to 25% insertion of the first regulating bank. This particular insertion was selected based on the calculated CEA worth and associated uncertainties to produce the worst transient. A corresponding maximum differential worth of 0.008% $\Delta\rho$ per inch of rod motion was

conservatively assumed in the present analysis. This corresponds to a maximum reactivity withdrawal rate of $0.4 \times 10^{-4}\ \Delta\rho$ per second based on the maximum CEA withdrawal speed of 30 inches per minute, including all uncertainties.

All the control systems, except the SBCS, were assumed to be in the automatic mode since these systems have no impact on the minimum DNBR obtained during the transient. The SBCS is assumed to be in manual mode because this minimizes DNBR during the transient.

C. Results

The dynamic behavior of key NSSS parameters following a CEAW at power are presented in Figures 15.4.2-1 to 15.4.2-11.

The minimum DNBR calculated by CETOP is 1.55, which is greater than the DNBR SAFDL of 1.34, and occurs at 14.0 seconds into the transient as shown in Figure 15.4.2-4.

The peak LHGR reached during this transient is less than 15 kW/ft as shown in Figure 15.4.2-7. This computed LHGR is well below that for the LSSS of 21 kW/ft and, as discussed above, the peak fuel temperatures during this transient are below that of centerline melt.

Therefore, the results of the uncontrolled CEAW from full power conditions show that for the limiting

event, the acceptance criteria for the DNBR SAFDL and fuel centerline melt temperature limit are met.

15.4.2.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate fission product barrier performance for this moderate frequency event are the same as those described in UFSAR Section 15.4.2.3.A.

B. Input parameters and Initial Conditions

The input parameters and initial conditions that were employed to evaluate fission product barrier performance for this moderate frequency event are the same as those described in UFSAR Section 15.4.2.3.B.

C. Results

The uncontrolled CEAW from full power results in an increase in RCS pressure and the secondary pressure.

The maximum RCS pressure is 2338 psia (see Figure 15.4.2-3), which is below the primary side limit of 2750 psia (110% of the design pressure of 2500 psia). The secondary side pressure reaches 1230 psia (see Figure 15.4.2-6), which is below the secondary side limit of 1397 psia (110% of the design pressure of 1270 psia).

Figure 15.4.2-10 gives the MSSVs flow versus time for the uncontrolled CEAW from full power.

15.4.2.5 Radiological Consequences and Containment Performance

Fuel cladding degradation is not predicted for this moderate frequency event, and therefore there are no calculated offsite dose radiological consequences for this event. This event would not result in any releases of radioactive material above that of a normal reactor trip.

15.4.2.6 Conclusions

Evaluation of the moderate frequency uncontrolled CEAW from full power shows that:

- The fuel cladding integrity will be maintained with the minimum DNBR remaining above the SAFDL, the maximum LHGR remaining below the value that causes peak centerline melt temperature.
- The RCS pressure remains below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- The secondary side pressure remains below 110% of its design value (i.e., 110% 0f 1270 psia, or 1397 psia).
- Fuel cladding degradation is not anticipated and there are no radiological consequences resulting from the event. This event would not result in any releases of radioactive material above that of a normal reactor trip.
- For the postulated uncontrolled CEAW from full power, the PVNGS design meets the relevant requirements of the Standard Review Plan.

15.4.3 SINGLE FULL-STRENGTH CONTROL ELEMENT ASSEMBLY DROP

The 4-finger Control Element Assembly (CEA) drops are ensured acceptable results by the initial thermal margin preserved by the Limiting Conditions of Operation (LCOs), and do not rely upon CEA position-related (i.e., power distribution) penalty factors contained within the calculations in the Core Protection Calculators (CPCs).

The CEA position-related penalty factors for downward deviations of 12-fingered CEAs are calculated such that the CPCs will provide a trip when necessary. A part-strength Power Dependent Insertion Limit (PDIL) also restricts the part-strength CEA insertion to less than 25% for power levels greater than 50%. From these initial conditions, the part-strength single or subgroup drop inserts only negative reactivity (similar to a full-strength single or subgroup drop event). For CEA subgroup drops, the CEA position-related penalty factors for downward deviations are used by the CPCs to provide a trip when necessary.

15.4.3.1 Identification of Causes and Frequency Classification

A single full-strength CEA drop (FSCEAD) results from an interruption in the electrical power to the control element drive mechanism (CEDM) holding coil of a single full-strength CEA. This interruption can be caused by a holding coil failure or loss of power to the holding coil. The limiting case is the FSCEAD that does not cause a reactor trip to occur but results

in an approach to the Specified Acceptable Fuel Design Limit (SAFDL) on the Departure from Nucleate Boiling Ratio (DNBR).

The FSCEAD event is an Anticipated Operational Occurrence (AOO) as discussed in Table 3.9-1 and is classified as an incident of moderate frequency.

15.4.3.2 Sequence of Events and Systems Operation

Table 15.4.3-1 presents a chronological list of events that occur during the FSCEAD transient, from initiation to the attainment of steady state conditions.

The transient is initiated by the release and subsequent drop of a single full-strength CEA. This initiates a reduction in core power and a primary to secondary side power to load mismatch. This mismatch results in a cooldown of the RCS due to excess heat removal by the secondary system. In the presence of a negative Moderator Temperature Coefficient (MTC), the cooldown adds positive reactivity and the core power tends to return to its pre-drop level.

The resultant increase in the hot pin radial peaking factor coupled with a return to initial power (following a temporary power depression) results in a power distribution distortion that increases with time as xenon redistributes and a minimum DNBR that remains above the DNBR SAFDL value of 1.34 at 900 seconds following the drop event.

The bounding analysis conservatively assumes that the operator begins to reduce power at 900 seconds if the CEA has not been

re-aligned. Operation at reduced power is allowed for a limited period to allow the CEA to be re-aligned.

15.4.3.3 Core and System Performance

A. Mathematical Model

Hand calculations are performed to verify acceptable results for a FSCEAD. This is acceptable since the major effect considered to degrade thermal margin comes from the radially distorted power. A maximum radial distortion factor including 15 minutes of Xenon redistribution resulting from a FSCEAD is obtained from the physics calculation. The ratio of pre- and post- drop radial distortion is converted to the equivalent power ratio (the required margin) by the quasi partial derivative of the Power Operating Limit (POL) with respect to radial distortion factor. A bounding value of the POL partial derivative within LCO parameters is used to maximize the required margin, which must be reserved by COLSS, CPCS or other LCOs. Bounding partial derivatives were developed by varying one input parameter while the remaining parameters were kept unchanged. As long as the assumptions used in the development of these derivatives remain valid, their values will remain unchanged. For the derivation of the quasi partial derivatives of the POL with respect to radial distortion factor, it is assumed that the coolant inlet temperature, core flow, Fr, and pressure are at

their initial pre-transient values. This is conservation because the decrease in DNBR in the transient caused by decreasing RCS pressure is more than offset by the decreasing coolant temperature and reduced core average power.

The same methodology is used to analyze a subgroup CEA drop when both CEA calculators (CEACs) are out of service. These margin analyses (calculation of cycle specific distortion factors to ensure they are bounded by the assumed distortion values) are performed each cycle as part of the reload analysis.

The CETOP-D computer code (see UFSAR Section 15.0.3.1.6) which uses the CE-1 critical heat flux correlation (see UFSAR Section 4.4) is used to calculate the thermal margin preserved by the TS LCOs for RCS pressure, temperature, flow and ASI.

Several computer codes are employed to create a typical sequence of events. The CENTS computer code (see UFSAR Section 15.0.3.1.3.2) is used to simulate the Nuclear Steam Supply System (NSSS) response to this event. The CETOP-D computer code (see UFSAR Section 15.0.3.1.6) which uses the CE-1 critical heat flux correlation (see UFSAR Section 4.4) is used to calculate the equivalent power change corresponding to the axial and radial power distortion when the minimum DNBR is kept unchanged at the SAFDL.

B. Input Parameters and Initial Conditions

Hand Calculation Methodology

The initial conditions are set by the thermal margin reserved in COLSS or CPCS via TS 3.2.4. Since COLSS and CPCS perform an online calculation of DNBR and use measured input values, there are infinite combinations of power, pressure, temperature, coolant flow rate, radial peaking factors, and axial power distribution for any given thermal margin requirement. However TS 3.2.4 ensures a minimum thermal margin which can be converted into a maximum allowable radial distortion which is then verified to be conservative for each core design.

Sequence of Events

For the purposes of creating a sequence of events, Table 15.4.3-2 lists the assumptions and initial conditions used for the FSCEAD event. The initial conditions of power, pressure, temperature, and coolant flow rate were typical values. The axial power distribution was a limiting shape, and the radial peaking factor was chosen such that a minimum initial thermal margin was obtained. This was done so that the DNBR would be minimized.

The negative reactivity inserted by a dropped CEA causes the power to initially decrease everywhere in the core. With no reactor trip, the coolant inlet temperature and pressure will gradually decrease.

Concurrently, the radial peaking factor will increase to an asymptotic post drop value. The decreasing coolant temperature combined with the negative doppler and moderator temperature coefficients causes a positive reactivity insertion which brings the core back to the initial power.

There is no single power level or plant configuration COLSS In Service (IS)/Out of Service (OOS) and CEACSs IS/OOS that is clearly most limiting. Rather, all conditions and power levels must be considered. To generate a typical sequence of events, the heat flux is based on the 95% power conditions and the asymptotic radial peaking factor existing at that time. This particular power was chosen based on its historically limiting condition for other events and precedence in licensing submittals.

Table 15.4.3-1

SEQUENCE OF EVENTS FOR THE
SINGLE FULL-STRENGTH CEA DROP EVENT

Time (sec)	Event
0.0	CEA begins to drop into core
4.0	CEA reaches fully inserted position
4.05	Core power level reaches minimum and begins to increase due to reactivity feedback
30.0	Minimum pressurizer pressure
50.0	Core power returns to maximum value
900.0	Minimum DNBR is reached
900.0	Operator begins a power reduction if the dropped CEA is not re-aligned[6]

[6] The effects of xenon on radial power distortion at 15 minutes (900 seconds) are conservatively assumed in the bounding analysis.

Table 15.4.3-2

TYPICAL ASSUMPTIONS AND INITIAL CONDITIONS
FOR THE SINGLE FULL-STRENGTH CEA DROP

Parameter	Value
Core thermal power (% of RTP)	95
Thermal margin	117%
Axial Shape	-2.0 ASI
Initial core inlet temperature (°F)[7]	558
Initial pressurizer pressure (psia)[8]	2250
Initial RCS flow rate, (lbm/sec)[9]	48086
MTC ($\Delta\rho$°/F)	-4.4×10^{-4}
Fuel Temperature Coefficient (FTC)[10]	Least negative
Dropped CEA worth (%$\Delta\rho$)	-0.15
Pre CEA drop radial peaking distortion factor	1.6150
Post CEA drop radial peaking distortion factor	1.8146
CEA drop radial peaking distortion factor @ 15 mins	1.8609
CEA drop time (sec)	4.0
Fuel rod gap conductance (Btu/hr-ft^2-°F)	1620
Number of plugged steam generator tubes	0
Single failure	None
Loss of offsite power	No

[7] Since the purpose of the transient analysis was to provide a representative sequence of events, the inlet temperature was set to a representative value.

[8] Since the purpose of the transient analysis was to provide a representative sequence of events, the pressure was set to a representative value.

[9] Since the purpose of the transient analysis was to provide a representative sequence of events, the RCS flow was set to a representative value. The flow represents the actual value used in the runs.

[10] The fuel temperature coefficient used is found in the unit- and cycle-specific analyses.

For this event, the choice of mode for the reactor regulating system is inconsequential because there would be no regulating bank motion if the system were in manual mode; and in the automatic mode, the CEA withdrawal prohibit, actuated on the CEAC based rod deviation, prevents the motion of any regulating bank that could cause the CPC calculated minimum DNBR to approach the DNBR SAFDL.

C. Results

Table 15.4.3-1 presents the sequence of events for the full-strength CEA drop event initiated at the conditions described in Table 15.4.3-2.

A minimum CE-1 DNBR of greater than the DNBR SAFDL is obtained at 900 seconds, as determined from the initial radial power peaking increase following CEA drop plus 15 minutes of xenon redistribution at the final coolant conditions. The operator is conservatively assumed in the bounding analysis to take action at this time to begin reducing power if the misaligned CEA has not been realigned.

The fuel centerline melt temperature is not exceeded if the transient Linear Heat Generation Rate (LHGR) does not exceed 21 kW/ft. The limiting initial power is 95%.

Based on the bounding radial peaking distortion, the maximum allowable initial LHGR that could exist as an initial linear heat condition without exceeding

21.0 kW/ft during this transient exceeds 15 kW/ft (21 kW/ft/Maximum Distortion Factor = maximum allowable initial LHGR). This amount of margin is assured because the linear heat rate LCO is based on the more limiting allowable LHGR for LOCA.

Therefore, the results of the FSCEAD analysis show that for the limiting event, the acceptance criteria for the DNBR SAFDL and peak fuel centerline temperature limit are met.

15.4.3.4 Reactor Coolant System Barrier Performance

A. Mathematical Model

CENTS and CETOP computer codes (see UFSAR Sections 15.0.3.1.3.2 and 15.0.3.1.3.6) are used to simulate the Nuclear Steam Supply System (NSSS) response to this event to create a typical sequence of events.

The computer codes that were employed to evaluate fission product barrier performance for this moderate frequency event are the same as those described in UFSAR Section 15.4.3.3.A.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions that were employed to evaluate fission product barrier performance for this moderate frequency event are the same as those described in Section 15.4.3.3.B.

C. Results

The barrier performance parameters following a FSCEAD would be less adverse than those following the CEA withdrawal events from subcritical, HZP, or at power (see UFSAR Sections 15.4.1 and 15.4.2).

This event is initiated with a nominal pressurizer pressure of 2250 psia. The RCS pressure decreases as a result of the FSCEAD and remains well below the 110% primary side design limit of 2750 psia. The secondary side pressure also remains below the 110% secondary side design limit value of 1397 psia.

The single FSCEAD event does not result in a reactor and turbine trip and therefore, there are no resultant event related steam releases to the atmosphere.

15.4.3.5 Radiological Consequences and Containment Performance

Fuel cladding degradation is not predicted for this moderate frequency event, and therefore there are no offsite dose radiological consequences for this event. This event would not result in any releases of radioactive material above that of a normal reactor trip.

15.4.3.6 Conclusions

Evaluation of the moderate frequency FSCEAD event shows that:

- The fuel cladding integrity will be maintained with the minimum DNBR remaining above the SAFDL, the maximum fuel

centerline temperature remaining below the fuel melt temperature.

- The RCS pressure remains below 110% of its design value (i.e., 110% of 2500 psia, or 2750 psia).
- The secondary side pressure remains below 110% of its design value (i.e., 110% 0f 1270 psia, or 1397 psia).
- Fuel cladding degradation is not anticipated and there are no radiological consequences resulting from the event.
  - For the postulated single full-strength CEA drop event initiated from the Technical Specification LCOs, the PVNGS design meets the relevant requirements of the Standard Review Plan (Reference 1).

15.4.4 STARTUP OF AN INACTIVE REACTOR COOLANT PUMP

15.4.4.1 Identification of Event and Causes

The startup of an inactive reactor coolant pump (SIRCP) is presented here with respect to potential loss of subcriticality. This event is also evaluated with respect to Reactor Coolant System (RCS) pressure and fuel performance criteria.

Administrative procedures govern the starting of RCPs and reduce the effects of RCP starts.

15.4.4.2 Sequence of Events and Systems Operation

SIRCP can either raise or lower core average coolant temperature. The average temperature can be lowered by

increased heat transfer to the steam generators, caused by increased core coolant flow and by colder primary system water in the steam generators being forced into the core. The core average temperature can be raised by increased heat transfer from the steam generators to the RCS, as a result of increased core coolant flow and by hotter primary system water in the steam generators being forced into the core.

The SIRCP event which lowers the core average temperature (the cooldown event), combined with a negative isothermal temperature coefficient (ITC), produces a positive reactivity insertion. The SIRCP event which increases core average temperature (the heatup event), combined with a positive ITC, produces an increase in RCS pressure and a positive reactivity insertion.

15.4.4.3 Analysis of Effects and Consequences

SIRCP can cause either a heatup or cooldown of the primary system depending on the primary to secondary ΔT.

SIRCP was examined in Modes 3 through 6, since plant operation with less than four RCPs running is only permitted in these modes.

A. Mathematical Models

The reactivity added to the core during a heatup or cooldown SIRCP event was determined using conservative isothermal temperature coefficients (ITCs) with a maximum uncertainty applied. These ITCs were used with the maximum core temperature increase or decrease

to determine the maximum reactivity inserted during SIRCP. This reactivity insertion is compared to the total amount of subcriticality.

B. Input Parameters and Initial Conditions

The initial conditions considered for this event ranged from a positive to a negative temperature difference between the secondary and primary system. Assuming primary system temperature higher than the secondary temperatures (a positive temperature difference) would result in cooling down the RCS. Assuming secondary system temperature initially higher than the primary temperature (a negative temperature difference) would result in heating up the RCS. Cooling the RCS would increase reactivity if there is a negative ITC. Heating the RCS would increase reactivity and RCS pressure if there is a positive ITC.

To conservatively calculate the reactivity added to the core during SIRCP, the most negative or positive ITCs are used with uncertainties applied in the most conservative direction. The initial core average moderator temperature during SIRCP is assumed to be at the temperature corresponding to the most positive ITC for the heatup event, or the most negative ITC for the cooldown event.

The following assumptions are made:

1. Prior to SIRCP all reactor coolant pumps are off. Normally at least one RCP must be running (or one shutdown cooling train during shutdown cooling operation). The Technical Specifications allow operation without any pumps running for up to one hour. This assumption maximizes the change in temperature during SIRCP.

2. Following SIRCP the core average temperature either (1) drops to the temperature of the coldest steam generator, for the cooldown event, or (2) increases to the temperature of the hottest steam generator, for the heatup event. This conservatively bounds the maximum change in core temperature that can occur during this event, by ignoring coolant mixing that would occur in the reactor coolant system.

15.4.4.4 Results

The results show that the maximum temperature change during SIRCP when used with the most conservative ITCs does not result in a loss of subcriticality.

When the RCS is above the conditions requiring low temperature overpressure (LTOP) protection, the SIRCP event that results in a heatup of the RCS will not result in a peak pressure greater than 110% of design pressure. While the RCS is in the LTOP mode, the shutdown cooling system (SCS) relief valves will

prevent violation of RCS integrity limits. (See section 5.2 for a general discussion of RCS integrity.)

Since subcriticality is not lost during the event, there is no increase in heat flux and therefore no decrease in minimum departure from nucleate boiling ratio (DNBR).

15.4.4.5 Conclusions

The SIRCP does not result in a loss of subcriticality. The increase in pressure during this event will not result in peak pressures above the applicable limits. There is no increase in core heat flux and therefore no decrease in minimum DNBR.

15.4.5 FLOW CONTROLLER MALFUNCTION CAUSING AN INCREASE IN BWR CORE FLOW

This event is not applicable to pressurized water reactors and, therefore, is not included in this FSAR.

15.4.6 INADVERTENT DEBORATION

15.4.6.1 Identification of Event and Causes

The Inadvertent Deboration (ID) event is presented here with respect to the time available for operator corrective action prior to the reactor achieving criticality. Fuel integrity is not challenged by this event.

The ID event may be caused by improper operator action or by a failure in the boric acid makeup flow path, which reduces the flow of borated water to the charging pump suction. Either cause can produce a boron concentration of the charging flow

which is below the concentration of the reactor coolant. The ID event is classified as an incident of moderate frequency as defined in Reference 1 of UFSAR Section 15.0.

This evaluation shows that Mode 5 (cold shutdown) with the Reactor Coolant System (RCS) drained down results in the least time available for detection and termination of an ID event. The combination of lowered RCS volume and three operating charging pumps results in a small dilution time constant and the fastest dilution rate, and therefore yields the shortest time interval between initiation of an ID event and the reactor achieving criticality.

Since RCS boron concentration is maintained under strict procedural controls, the probability of a sustained and erroneous dilution due to operator error is very low.

15.4.6.2 Sequence of Events and Systems Operation

An ID event occurs when charging flow into the RCS has a lower boron concentration than the fluid within the RCS. The resulting decrease in RCS boron concentration adds positive reactivity to the core. Assuming dilution continues at the maximum possible rate with unborated charging flow, the operator has at least 15 minutes in Modes 1 through 5, and 30 minutes in Mode 6, between the receipt of an alarm from the Boron Dilution Alarm System (BDAS) and the reactor achieving criticality. The mechanism to notify the operator of an ID event when the BDAS is inoperable is chemical surveillance of

the RCS boron concentration, in accordance with the unit-specific Core Operating Limits Report (COLR).

The success path for reactivity control is as follows: The operator is alerted to a decrease in the RCS boron concentration either through a high neutron flux alarm on the startup flux channel, sampling, reactor make-up flow rate, or boric acid flow rate. The operator turns off the charging pump(s) in order to halt further dilution. Next, the operator increases the RCS boron concentration by implementing the emergency boration procedure.

When the reactor is critical (Modes 1 and 2) an ID event will result in a slow increase in core power and RCS temperature. This event is slower than other reactivity excursions analyzed (e.g., CEA withdrawals), and the reactor will trip in time to prevent violation of any safety limit. This trip ensures a second dilution period (Mode 3 or lower with All Rods In (ARI) or in an N-1 configuration), during which the operator must be notified of any ongoing deboration at least 15 minutes before the reactor achieves criticality. Therefore, Modes 1 and 2 do not have to be analyzed further with respect to an ID event.

If the reactor is subcritical with trippable CEAs withdrawn from the core (All Rods Out (ARO) in Modes 3 through 5), the high log power trip must be active. Shutdown Margin (SDM) is assumed to be at the minimum value consistent with Technical Specification limits. If the operator is not notified of the ID event with sufficient time to prevent criticality, the high log trip will actuate and insert the withdrawn CEAs into the

core. The trip will alert the operator to the ID event and ensure a second dilution period during which the operator will have at least 15 minutes to respond before the reactor achieves criticality. Thus ARO configurations in Modes 3 through 5 do not need to be analyzed further with respect to an ID event.

If the reactor is subcritical without trippable CEAs (ARI or N-1 configuration in Modes 3 through 5), an ID event will result in degradation of SDM and an increase in subcritical multiplication. SDM is assumed to be at the minimum value consistent with Technical Specification limits. The operator must be notified of the ID event at least 15 minutes before the reactor achieves criticality, so that corrective actions may be implemented. Either the BDAS, or chemical surveillance of RCS boron concentration (when BDAS is not operable), will alert the operator to the ID event.

If the reactor is in Mode 6, an ID event will result in degradation of SDM. In this instance the operator must be notified of the ID event at least 30 minutes before complete loss of subcriticality. The mechanisms to notify the operator are the same as above for Modes 3 through 5 (BDAS or chemical sampling). In Mode 6, the CEAs may be totally removed from the core, thus the ARO configuration is the most limiting and is the only configuration analyzed.

The indications and/or alarms available to alert operators to an ID event in each of the operational modes are outlined below.

A. In Modes 1 and 2, a high power trip or, for some sets of conditions, a high pressurizer pressure trip in Mode 1 or a high log power trip in Mode 2 will provide indication of any boron dilution event. Furthermore, a high T_{AVE} alarm may also occur prior to trip.

B. In Modes 3 and 4 with CEAs withdrawn, the high logarithmic power level trip and pre-trip alarm, and a high neutron flux alarm (BDAS alarm) will provide an indication to alert the operator of an inadvertent boron dilution.

C. In Modes 3, 4, and 5 with CEAs fully inserted except the worst rod stuck out and in Mode 6, a high neutron flux alarm (BDAS alarm) will provide indication of any boron dilution event.

D. In Mode 5 with the RCS partially drained for system maintenance, the primary coolant volume available for mixing consists of only the volume of the reactor vessel up to the level of the coolant legs and the volume of the shutdown cooling system. Similarly, in Modes 4 or 5 when cooling the RCS with the shutdown cooling system, the active volume may consist of only the volume of the reactor vessel (excluding the upper head region) and the volume of the shutdown cooling system. In these conditions a high neutron flux alarm (BDAS alarm) will provide indication of any boron dilution event.

Operational procedure guidelines, in addition to these indications and/or alarms, will assure detection and termination of an ID event before the reactor achieves criticality.

15.4.6.3 Analysis of Effects and Consequences

The time interval between the onset of an ID event and the reactor achieving criticality may be calculated for each possible set of initial conditions (operating mode, mixing volume, charging flow, SDM, and, if applicable, stuck rod worth). These time intervals are conservatively translated into required boron concentration surveillance intervals in the COLR, for use when BDAS is inoperable.

A. Mathematical Model

Assuming complete mixing of boron in the RCS, the rate of change of boron concentration during dilution is described by the following equation:

$$M\left(\frac{dC}{dt}\right) = -WC \qquad (1)$$

Where:

M = RCS mass

C = RCS boron concentration

t = time

W = Charging mass flow rate of unborated water

and dC/dt is maximized by maximizing W and minimizing M.

Assuming: W = constant, equal to the maximum possible value; and

M = constant, equal to the minimum value occurring during the boron dilution incident,

the solution of equation (1) can be written

$$C(t) = C_0 e^{-t/T} \qquad (2)$$

Where: $C(t)$ = Boron concentration at time t

C_0 = Initial boron concentration at time t = 0

T = M / W = Boron dilution time constant

The time T_{crit} that is required to dilute to criticality (from the start of the ID event at time t = 0) is given by:

$$T_{crit} = T \ln\left(\frac{C_0}{C_{crit}}\right) \qquad (3)$$

Where: C_{crit} = Critical boron concentration

Furthermore, the relationship between the alarm time and the BDAS alarm setpoint (i.e., the SRM ratio, or the ratio of the source range flux signal at a

particular time to the initial source range flux signal) is given by:

$$\frac{ICRR(C_0 - C_{CRIT})}{ICRR(C_0 e^{-a/T} - C_{CRIT})} \qquad (4)$$

Where: SRM_{ratio} = BDAS alarm setpoint (limiting value of 2.2)

ICRR = Inverse count rate ratio which is an empirically determined fraction of the difference between the measured boron concentration and the calculated critical boron concentration.

B. Input Parameters and Initial Conditions

It is assumed that the ID event proceeds at the maximum possible rate. For this to occur, all charging pumps must be on, the reactor makeup water pump must be on, letdown flow must be diverted from the volume control tank, and a failure in the boric acid makeup water flow path (e.g., flow control valve FV-210Y failing in the closed position) must terminate borated water flow to the charging pump suction. Specific input parameters and initial conditions for Mode 5 with the RCS partially drained, and for Mode 6, are described in the sections below.

C. Mode 5 Drained Down Boron Dilution Event

Evaluation of ID events initiated during each of the six plant operational modes (defined in the Technical Specifications) shows that Mode 5 (cold shutdown) in the drained-down configuration results in the shortest available time for detection and termination of the event. Therefore, the initial conditions and analysis parameters are chosen for the cold shutdown operational mode to minimize the interval from initiation of dilution to the time at which criticality is reached. The following are the analysis assumptions for the Mode 5 ID event:

1. Complete mixing of boron within the RCS is assumed.

2. The event is initiated at the ARI condition with reactor trip breakers open.

3. The primary coolant volume, including only the volumes for Mode 5 drained conditions as described above, is 4500 ft^3. A conservatively low reactor coolant mass was assumed by using the cold RCS internal volume. Assuming a coolant temperature of 210°F, the Technical Specification upper limit for cold shutdown, the resulting mass is 269,461 lbm.

4. All three charging pumps are assumed to be operating at a rate of 45 gpm per pump, for a

total of 135 gpm. The corresponding mass flow rate, assuming cold liquid flow, is 18.78 lbm/sec.

5. The critical boron concentration (with ARI) and the IBW are 1150 ppm and 85.6 ppm/%$\Delta\rho$, respectively, including uncertainties for the cold shutdown conditions. For Mode 5 ARI with the RCS drained to the middle of the hot legs, a value of 3.0% $\Delta\rho$ (1.0% $\Delta\rho$ Technical Specification SDM + 2.0% $\Delta\rho$ Stuck Rod Worth) is used for initial subcriticality. The initial subcritical boron concentration is found by adding the product of the IBW and the initial subcriticality (i.e., 3.0% $\Delta\rho$) to the critical boron concentration. The resulting initial boron concentration in the Mode 5 ARI configuration is therefore 1407 ppm. Thus the change in boron concentration from 3.0% $\Delta\rho$ subcritical to a critical condition is 247 ppm.

The parameters discussed above are summarized in table 15.4.6-1.

Table 15.4.6-1

ASSUMPTIONS FOR THE MODE 5 INADVERTENT DEBORATION ANALYSIS

Parameter	Assumed Value
Cold RCS volume (excluding pressurizer and surge line), ft^3	4,500
RCS mass (excluding pressurizer and surge line), lbm	269,461
Volumetric charging rate, gpm	135
Mass charging rate, lbm/sec	18.78
Dilution time constant, T, sec	14,351
Initial boron concentration, C_o, ppm	1,407
Critical boron concentration, C_{crit}' ppm	1,150

D. Mode 6 Boron Dilution Event

If the reactor is in Mode 6 an ID will result in degradation of SDM. In this instance the operator must be notified of the ID event at least 30 minutes before the reactor achieves criticality. In Mode 6, the CEAs may be totally removed from the core. Therefore, the ARO configuration is the most limiting and is the only configuration analyzed. The following are the analysis assumptions for the ID event:

1. Complete mixing of boron within the RCS is assumed.

2. The event is initiated at the ARO condition.

3. The primary coolant volume is conservatively set to the values assumed for Mode 5 drained conditions. A coolant temperature of 135° F is assumed for Mode 6, however, with a resulting mass of 276,583 lbm.

4. All three charging pumps are assumed to be on at a rate of 45 gpm per pump, for a total of 135 gpm. The corresponding mass flow rate, assuming cold liquid flow, is 18.78 lbm/sec.

5. Initial and critical boron concentrations are conservatively established at 3000 ppm (the minimum refueling boron concentration allowed by the COLR) and 2204 ppm, respectively.

The parameters discussed above are summarized in table 15.4.6-2.

Table 15.4.6-2

ASSUMPTIONS FOR THE MODE 6 INADVERTENT DEBORATION ANALYSIS

Parameter	Assumed Value
Cold RCS volume (excluding pressurizer and surge line), ft^3	4,500
RCS mass (excluding pressurizer and surge line), lbm	276,583
Volumetric charging rate, gpm	135
Mass charging rate, lbm/sec	18.78
Dilution time constant, T, sec	14,731
Initial boron concentration, C_o, ppm	3,000
Critical boron concentration, C_{crit}' ppm	2,204

15.4.6.4 Results

Using the conservative parameters described above in equations (3) and (4), sufficient time is available to assure the detection and termination of an ID event. Numerous indications of improper operation and the high neutron flux alarm on the startup flux channel will alert the operator of an ID event with at least 15 minutes (30 minutes in mode 6) remaining before the core becomes critical.

15.4.6.5 Conclusions

The ID event will result in acceptable consequences. Sufficient time is available for the operator to detect and to terminate an ID event if it occurs. Fuel integrity is not challenged during this event.

15.4.7 INADVERTENT LOADING OF A FUEL ASSEMBLY INTO THE IMPROPER POSITION

15.4.7.1 Identification of Events and Causes

The inadvertent loading of a fuel assembly into the improper position event is initiated by interchanging two fuel assemblies. The likelihood of an error in core loading is considered to be extremely remote because of the strict procedural control used during core loading.

15.4.7.2 Sequence of Events and System Operation

The fuel enrichment within a fuel assembly is identified by a coded serial number marked on the exposed surface of the top end plate of the fuel assembly. This serial number is used as a means of positive identification for each assembly in the plant. A tag board is provided in the main control room showing a schematic representation of the reactor core and spent fuel storage area. During the period of core loading, the location of each fuel assembly, and source will be shown on this tag board by a tag carrying its identification number.

The tag board in the main control room will be constantly updated by a designated member of the reactor engineering staff whenever a fuel assembly is being moved. The reactor engineering representative will be in constant communication with each area where this is occurring. All core alterations shall be observed and directly supervised by either a licensed senior reactor operator or a senior reactor operator limited to fuel handling who has no other concurrent responsibilities

during this operation. Fuel assemblies will not be moved unless these lines of communication are available. In addition to these precautions, annual inventories of the spent fuel and new fuel storage areas will be performed in addition to post refueling reactor core mapping. These inventories will be used as the basis for setting up the tag board for use during fuel movement. At the completion of core loading, the exposed surfaces of the top end plates are inspected to verify that all assemblies are correctly located. These precautions are included in the core loading procedures which are to be reviewed by appropriate plant personnel.

15.4.7.3 Analysis of Effects and Consequences

If, in spite of the extreme precautions described above, it is postulated that a fuel assembly is misloaded, several situations may be postulated. The misloading of a fuel assembly may affect the core power distribution only slightly, for example, if assemblies of similar enrichments and reactivities are misloaded. Alternatively, the core power distribution may be affected enough so that the core performance would be affected if assemblies having different enrichments or reactivities are misloaded. In the unlikely event that two assemblies of significantly different initial reactivities would be interchanged, most misloadings would be detected using either the incore or excore neutron detectors during the power ascension physics testing. Misloadings that result in significant azimuthal tilt would be detected by the differences in signals between the four excore detectors during

routine monitoring of their signals during the initial power ascension. In addition, analysis has shown that if all the incore detectors in the vicinity of the misload are operational, then most of the misloads that may result in a significant increase in power peaking will be detected during the power ascension testing. If several of the incore detectors in the vicinity of the misloaded assembly are nonfunctional, then some of the misloads that result in substantial increase in core power peaking may not be detected during the initial power ascension physics testing. Of this small class certainly the worst case that can be envisioned is the interchange of a fresh assembly with a once-burned assembly in the interior of the core. Although this type of misload may result in high local power peaking, it may not be detectable if most of the incore detectors in the vicinity of the misload are nonfunctional since it produces essentially no core wide global power tilt during the power ascension physics testing. Figure 15.4.7-1 shows a representative power distribution at the time of maximum ROPM for a worst case misload of this type.

For PVNGS, operation with an undetectable misload may result in a potential non-conservatism of the COLSS and CPC online margin assessment due to the potential non-conservatism of the measurement of local power peaking for the misloaded core. If the CECOR measured values for the radial peaking factors are conservative then safety limits will not be exceeded even during operation with an undetectable misload, since these peaking factors are used by COLSS and CPC to calculate margin to the SAFDLs.

If all the ICIs in the vicinity of the misload are functional then most of the impact of the misload on power peaking will be accounted for. However, if some of the ICIs in the vicinity of the misload are nonfunctional, then the CECOR measurement radial peaking factor may be significantly non-conservative for a core with an undetectable misload. However, even in this case the SAFDL will not be exceeded provided that the overpower margin associated with the error in measured peaking factor does not exceed the minimum (required) overpower margin (ROPM) reserved by COLSS. Thus, the analysis of this event determines the ROPM that must be reserved by COLSS to assure that the DNB SAFDLs is not violated due to a fuel assembly misloading.

The methodology used for the assembly misloading analysis is summarized as follows:

- Several candidate worst case misloads are selected for analysis. The selection of the representative worst undetectable misload was based on the reactivities and fissile content of the assemblies as well as reactivities of other assemblies in the vicinity of the misloaded assembly.
- A determination is made as to whether the misload is detectable during the startup tests. This is done by using the 3D nuclear design code (ROCS, Reference 4.3.4-5) to calculate the signal at each of the ICI locations for the fuel symmetry verification test for each postulated assembly misloading. These signals were then used by CECOR to infer the “measured” power distribution. These

CECOR cases consider several different configurations of failed instruments in the vicinity of the high-power misloaded assembly consistent with the requirements for ICI functionality.

- If the misload is judged detectable then it is eliminated from further consideration.
- Of the misloads judged undetectable several of the worst candidates are selected for analysis under full power operating conditions. The worst candidates are defined as those having the highest CECOR decalibration factor (DF).
- For each of the assembly misloadings selected for full power analysis the power distribution was calculated by both the 3D nuclear design code and CECOR at several different burnup points. The CECOR cases consider several different configurations of failed instruments consistent with the ICI functionality criteria. The design code and CECOR core power distributions are then used to establish the maximum CECOR Decalibration Factor during full power operation.
- The power distributions calculated by the 3D nuclear design code and CECOR for the burnup point corresponding to the maximum CECOR DF is used to calculate the minimum DNBR and ROPM using the CETOP code for the worst case misload.
- The largest value of ROPM calculated for the worst undetectable misload is compared to the ROPM installed in COLSS to assure that the DNB SAFDL will not be violated under any allowed operating condition. Table 15.4.7-1

shows that if all the incore detectors in the vicinity of the misloaded assembly are operational, then the misload will be detected during power ascension physics testing since it would exceed the physics startup test acceptance criteria for the maximum power difference between any assembly and its symmetric assembly average or the maximum difference between predicted and measured assembly power. If all the incore instruments within one assembly pitch of the misload are nonfunctional, then the misload may not fail the power ascension test acceptance criteria and operation under a misloaded condition at power may occur.

Table 15.4.7-2 shows the cycle maximum power peaking factors associated with the misload. If all of the incore detectors in the vicinity of the misload are functional then the error in measured power peaking (using the CECOR code, Reference 17 of Section 4.3) due to the misload will be 11%. Since the measured power peaking is used by COLSS to determine the available overpower margin and since the minimum COLSS available overpower margin under any condition is at least 17%, including allowances for uncertainties, no fuel damage is expected. If all the incore instruments within one assembly pitch of the misload are nonfunctional, then the error in measured power peaking due to the misload will be 16%. This corresponds to an overestimate in the available COLSS overpower margin of 17% which is still less then minimum COLSS overpower margin, which is always greater than 17%. Furthermore, since it is very improbable that all the incore detectors in the immediate vicinity of the misload would be nonfunctional, it is

highly likely that the misload will be detected during power ascension or early in the cycle before a significant decrease in operating margin occurs.

Based on these results:

- If all the ICIs in the vicinity of the misload are operational, then the ROPM associated with the representative worst case undetectable misload is expected to be <11%.
- With the current TRM requirement of 1 functional ICI in every 4-by-4 array of fuel assemblies, the worst undetectable misload will not result in fuel failure under any allowed operating condition even with up to 25% failed ICIs.
- The MDNBR at nominal core conditions for the representative worst case undetectable misload including allowance for physics calculational uncertainties is significantly greater than 1.34. In addition, the peak linear heat generation rate (PLHGR) for this worst undetectable misload is also well below the LHR SAFDL for fuel centerline melt.

Table 15.4.7-1

Maximum Difference in Measured Symmetric Instrument Power For Representative Worst Case Undetectable Misload During Power Ascension Testing

Case	Maximum Difference (%)
Nominal (no misload)	~0
Measured by CECOR for Representative Worst Case Undetectable Misload assuming all ICIs in vicinity of misload are functional	13.5
Measured by CECOR assuming all ICIs within one assembly pitch of the misload are nonfunctional	9.2

Table 15.4.7-2

Maximum Power Peaking Factors Occurring For Representative Worst Case Undetectable Misload

Case	Cycle Max Radial Peaking Factor
Nominal (no misload)	1.38
Representative Worst Case Undetectable Misload	1.65
Measured by CECOR for Representative Worst Case Undetectable Misload assuming all ICIs in vicinity of misload are functional	1.49
Measured by CECOR assuming all ICIs within one assembly pitch of the misload are nonfunctional	1.42

15.4.7.4 Conclusion

The inadvertent misloading of a fuel assembly into the improper position events have been analyzed and shown to be highly improbable. The fuel handling procedures and core instrument system more than adequately assure that there is not possibility of a misloaded fuel assembly event proceeding to a

point that would fail fuel, and hence meets the 10CFR 100 requirements.

15.4.8 CONTROL ELEMENT ASSEMBLY EJECTION

15.4.8.1 Identification of Cause and Frequency Classification

A Control Element Assembly (CEA) ejection (CEAE) event is postulated to occur as a result of a mechanical failure that causes an instantaneous circumferential rupture of the control element drive mechanism (CEDM) housing or its associated nozzle. This results in the reactor coolant system pressure ejecting the CEA and drive shaft to the fully withdrawn position.

The CEDM housings are capable of withstanding throughout their design life all normal operating loads including the steady state and transient operating conditions specified for the reactor vessel. Hence, the occurrence of such a failure is considered to be incredible, and the CEAE is classified as a limiting fault event.

15.4.8.2 Sequence of Events and Systems Operation

The sequence of events that occur during the fuel performance aspect of the CEAE initiated from full power Beginning-of-Cycle (BOC) conditions is presented in Table 15.4.8-1. Likewise, the sequence of events that occur during the peak pressure aspect of the CEAE is presented in Table 15.4.8-5.

The postulated mechanical failure of the CEDM causes the ejection of a CEA which adds positive reactivity to the core

that results in a rapid increase in reactor core power for a short period of time. This power excursion is terminated by the combination of delayed neutron and Doppler feedback effects. Closely following the CEAE, reactor shutdown is initiated by a core protection calculator (CPC) and/or reactor protective system (RPS) variable overpower trip (VOPT) on high neutron power. The reactor power decreases rapidly as the shutdown CEAs drop into the reactor core.

The reactor core is therefore protected against severe fuel damage by restrictions on CEA patterns and/or power dependent insertion limits during operation; and by a reactor trip. These factors combine to limit the acceptable values for fuel enthalpy, fuel and clad temperatures, and reactor coolant system (RCS) and secondary side pressures during the transient.

The sequence of events that occurs during the CEA ejection initiated from full power BOC conditions for the peak RCS pressure event is presented in Table 15.4.8-5.

The limiting secondary steam releases for the CEAE event are based on a full-power, BOC analysis[11], with the sequence of events summarized in Table 15.4.8-1. These steam releases are applied to the CEAE event radiological consequences assessment presented in UFSAR Section 15.4.8.5. The analysis assumed that the ejected CEA results in a hole at the top of the reactor

[11] The system response for the calculation of the limiting steam releases used the CESEC computer code (see UFSAR Section 15.0.3.1.3.1).

vessel head. In the analysis, secondary side steaming was maximized by assuming a loss of offsite power (LOP) following the turbine trip. This caused a 4 pump Reactor Coolant Pump (RCP) coastdown, main feedwater pump trip, loss of condenser vacuum and loss of the steam bypass control system. This results in increased primary and secondary side pressures due to decreased heat removal by the steam generators with the subsequent opening of the primary and secondary safety valves to relieve pressure and dissipate energy. A safety injection actuation signal (SIAS) was generated, adding additional boron postulated break in the primary system, caused the RCS pressure and temperature to decrease to below that of the steam generators. The analysis also assumed that operator action was delayed until 30 minutes after event initiation. Plant cooldown was accomplished by using the Auxiliary Feedwater (AFW) system in conjunction with the atmospheric dump valves (ADVs) until shutdown cooling entry conditions were reached.

Section 15.4.8 of the Standard Review Plan (Reference 1) does not require the evaluation of the 4 pump RCP coastdown for this event with respect to fuel performance. However, Regulatory Guide 1.77, Appendix B, indicates that release of fission products from the secondary system should be evaluated with the assumption of a coincident loss of offsite power.

Table 15.4.8-1

TYPICAL SEQUENCE OF EVENTS FOR THE CEA EJECTION EVENT FROM FULL POWER CONDITIONS (FUEL ENTHALPY AND TEMPERATURE CASE)

Time (sec)	Event
0.00	Mechanical failure of CEDM causes CEA to eject
0.04	Core power reaches CPC VOPT analysis setpoint
0.05	CEA is fully ejected
0.07	Maximum core power occurs
0.79	CPC VOPT signal is generated
0.79	Trip breakers open
0.79	Turbine trip occurs
1.39	CEAs begin to drop
3.33	Maximum clad surface temperature in the hot node occurs
3.33	Maximum fuel centerline temperature in the hot node occurs
~5.57	CEAs fully inserted; core power reduced to below 10% of full power

15.4.8.3 Core and System Performance

A. Mathematical Model

The Nuclear Steam Supply System (NSSS) response to a CEAE was simulated using the method of analysis described in Reference 3. The procedure outlined in Figure 2.1 of Reference 3 was used to determine the energy deposition in the fuel rod. The number of fuel pins predicted to experience departure from nucleate boiling was calculated using the STRIKIN-II computer program described in UFSAR Section 15.0.3.1.5 with the CE-1 correlation described in UFSAR Chapter 4.4. A matrix relating the initial and ejected CEA peaking factors to a pin census edit was obtained from Step 6 of the C-E synthesis method (Reference 3) and used to calculate the number of fuel pins experiencing DNB. Further conservatism was introduced by assuming that clad failure occurs when fuel rods experience DNB.

The CENTS computer code described in UFSAR Section 15.0.3.1.3.2 was used to determine the peak RCS and secondary side pressures and the overall NSSS response to the event. The inputs to CENTS were selected so that the ejected rod power excursion that resulted, maximized the time-dependent energy deposition into the RCS.

B. Input Parameters and Initial Conditions

Important input parameters and initial conditions used to analyze the NSSS response to a CEAE are delineated in

Table 15.4.8-2. A spectrum of initial reactor states (including conditions characteristic of the beginning and end of the fuel cycle) was considered. Table 15.4.8-3 lists the initial CEA Bank configurations considered as separate initial reactor states and gives the maximum worth for a CEA ejected from the state as well as the maximum post-ejection radial peaking enhancement factor. The initial conditions for the principal process variables were varied within the reactor operating space of steady state operational configurations to determine the set of conditions that produce the most adverse consequences following a CEAE. Various combinations of initial core inlet temperature, core inlet flow rate, pressurizer pressure, and axial power distribution were considered. The initial pressurizer and steam generator water levels, as controlled within the operating space, have an insignificant effect on the consequences of the CEAE analysis.

For all cases analyzed, an axial power distribution was chosen to maximize the energy content in the hottest fuel pellet. The remaining parameters were chosen based on the results shown in Chapter 4 of Reference 3. These parameters were varied in the most adverse direction until a COLSS power operating limit was achieved.

Table 15.4.8-2

TYPICAL ASSUMPTIONS USED FOR THE CEA EJECTION ANALYSIS
FULL POWER BEGINNING OF CYCLE INITIAL CONDITIONS
(FUEL ENTHALPY AND TEMPERATURE CASE)

Parameters	Values[12]
Initial core power (% of RTP)[13]	102
Initial Core inlet temperature (°F)	569
Initial RCS flow rate (lbm/sec)[14]	43277
Initial pressurizer pressure (psia)	2100
Moderator temperature coefficient (Δρ/°F)	0.0
Maximum Ejected CEA worth (%Δρ)	0.131
Fuel Temperature Coefficient[15]	Least negative
Kinetics[16]	Minimum β
Pre-ejection 3-D fuel pin peaking factor	2.005
Post-ejection 3-D fuel pin peaking factor	3.8095
CEA worth at trip, WRSO (%Δρ)	5.5
Fuel Rod gap conductance (Btu/hr-ft^2-°F)	Minimum[17]
Postulated time to eject CEA (sec)	0.05
CEA coil delay time (sec)	0.6
Axial shape index	-0.2

[12] Values are for the bounding CEAE analysis.

[13] The case was simulated for maximizing the fuel centerline temperature.

[14] This corresponds to 95% of the original design flow.

[15] The fuel temperature coefficients used are found in the unit- and cycle-specific analyses.

[16] The kinetics parameters used are found in the unit- and cycle-specific analyses.

[17] The STRIKIN-II code, using the FATES runs, solves the 1-D, radial heat conduction equation for each axial region along the hot rod. The conduction model explicitly represents the gap region and dynamically calculates the gap conductance in each axial region. This results in the smallest gap conductance so that heat transfer to the coolant is minimized.

Table 15.4.8-3

TYPICAL INITIAL REACTOR STATES CONSIDERED
FOR THE TYPICAL CEA EJECTION EVENT

Initial Rod Configuration	Ejected Rod Worth, $\%\Delta\rho$	Ejected Radial Peaking Factor
Bank 5 inserted (95% power)	0.131	1.9
Banks 4 & 5 inserted (50% power)	0.300	2.4
Banks 3, 4 & 5 inserted (20% power)	0.404	2.7

The key input parameters and initial conditions used in analysis of the CEA ejection peak RCS pressure event is presented in UFSAR Section 15.4.8.4.B. The assumptions and initial conditions used in the analysis that determined the CEA ejection secondary side steam releases are discussed in UFSAR Section 15.4.8.5.

C. Results

A spectrum of initial reactor states, shown in Table 15.4.8-3, was analyzed to show that each case met the criteria established in Regulatory Guide 1.77. All cases resulted in a radial average fuel specific enthalpy less than 280 cal/gram at the hottest axial location of the hot fuel pin. The case that resulted in the greatest potential for offsite dose consequences (i.e., the case resulting in the largest number of postulated fuel failures) was identified as the case initiated from full power beginning of cycle (BOC) initial conditions.

The following paragraphs describe this event in detail. Table 15.4.8-1 contains the sequence of events that occur during a CEAE initiated from full power. Refer to Table 15.4.8-2 for the initial conditions and assumptions used for this analysis. Figures 15.4.8-1 through 15.4.8-5 show the reactor core power, peak core power density, core average heat flux, peak hot

channel heat flux, and clad and fuel temperatures during the significant portion of transient.

Ejection of a CEA causes the core power to increase rapidly due to the almost instantaneous addition of positive reactivity. However, the rapid increase in core power is terminated by a combination of Doppler feedback and delayed neutron effects. This increase in power results in a high power trip and the reactor power begins to decrease as the CEAs enter the core. Reactivity effects are shown in Figure 15.4.8-6.

In the hot channel, the increase in heat flux is such that DNB is calculated to occur, resulting in:

- a rapid decrease in the surface heat transfer coefficient
- a rapid decrease in heat flux
- a rapid increase in clad temperature.

The heat flux continues to decrease for the remainder of the transient.

The calculated radially averaged fuel enthalpy and fuel centerline enthalpy of the hottest fuel pellet for the limiting case remains below the criterion of 280 cal/gm and the fuel centerline temperature is less than the fuel melt temperature. These results show that the CEAE accident will not result in a radial average fuel enthalpy greater than 280 cal/gm at any

axial location in any fuel rod, and that no fuel rod exceeds fuel centerline melt temperature.

NRC Regulatory Guide 1.77 recommends that the onset of DNB be used as the basis for predicting clad failure for the postulated CEA ejection event. For PVNGS, the number of fuel rods that experience DNB is calculated with a statistical convolution technique, which is discussed in UFSAR Section 15E.3.3 and described in Reference 4. The statistical convolution technique involves the summation, over the reactor core, of the number of fuel rods with a specific DNBR value, multiplied by the probability of DNB at that DNBR value. However, to provide a conservative assessment of radiological consequences, a bounding number of fuel rods is assumed to suffer clad failure in the 3954 MWt evaluation, as shown in Table 15.4.8-6. In the 4070 MWt evaluation, the allowable clad failure percentage is a function of the product of clad failure percentage and maximum fuel radial peaking factor as discussed in Section 15.4.8.5D. This limitation on clad failure is compared to a unit cycle specific fuel pin census performed for each reload analysis using the statistical convolution technique in order to predict that the number of fuel rods that experience DNB will result in less than assumed fuel rod failure in dose calculations.

15.4.8.4 Reactor Pressure Boundary Barrier Performance

The CEAE peak RCS pressure event initiated from full power BOC conditions is presented in this section.

The reactor coolant discharged through the CEA break to containment and the steaming mass release through the MSSVs and ADVs are discussed in UFSAR Section 15.4.8.5.

A. Mathematical Model

The CENTS computer code described in UFSAR Section 15.0.3.1.3.2 was used to determine the RCS and secondary side peak pressures and the overall NSSS response to the CEAE event.

The CESEC computer code described in UFSAR Section 15.0.3.1.3.1 was used in determining the barrier performance aspect of the CEAE analysis that deals with secondary side releases to atmosphere that are used in the radiological consequence UFSAR Section 15.4.8.5.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used in determining barrier performance for the peak RCS pressure during the CEA ejection accident from full power BOC conditions are presented in Table 15.4.8-4. The following assumptions were made in the analysis:

- Initial conditions for the key process variables were varied within the ranges of steady state operational configurations including the

uncertainties to determine the set of initial conditions and input variables that would produce the most adverse consequences.

- It was conservatively assumed that there was no pressure boundary breach or leakage in the CEDM area of the reactor vessel head and no pressure reduction caused by the failure of the control element mechanism housing for the primary peak pressure case.

- Only the high pressurizer pressure trip (HPPT) was credited. Although the CPC or RPS VOPT trip may occur on high neutron power much earlier than the HPPT making the event more benign, no credit was taken for these trips.

- The CEAE was assumed to result in almost immediate Turbine Admission Valve (TAV) closure (valve closes in 0.2 seconds). In addition, main feedwater was ramped to zero flow in 1.0 seconds.

- The operator may cool the NSSS by using manual operation of the AFW system and the ADVs anytime after the trip occurs. However, no credit is taken for the operator action for the first 30 minutes of the event.

The assumptions and initial conditions used in determining the secondary side steaming releases for the CEAE event are summarized in Table 15.4.8-6.

Table 15.4.8-4

TYPICAL ASSUMPTIONS USED FOR THE CEA EJECTION ANALYSIS
FOR RCS PEAK PRESSURE EVENT FROM FULL POWER
BEGINNING OF CYCLE INITIAL CONDITIONS

Parameters	Value
	RTP 3990 MWt
Initial core power (% of RTP)	102
Initial core inlet temperature (°F)	548
Initial RCS flow (lbm/sec)[18]	52845
Initial pressurizer pressure (psia)	2100
Initial pressurizer water level (ft)	11.4
Initial steam generator water level (ft)	25.7
MTC ($\Delta\rho$/°F)	0.0
Fuel Temperature Coefficient[19]	Least negative
Kinetics[20]	Minimum β
SCRAM worth at Trip, N-2 (%$\Delta\rho$)	5.5
Fuel rod gap conductance (Btu/hr-ft^2-°F)	6984
Ejected CEA worth (%$\Delta\rho$)[21]	0.157
Postulated CEAE time (sec)	0.05
SCRAM delay time (sec)	0.75
CEA holding coil delay time (sec)	0.6
Plugged steam generator tubes	0
PSV Tolerance	+3%
MSSV Tolerance	+3%
Single Failure	None
LOP	No

[18] This corresponds to 116% of original design flow.

[19] The fuel temperature coefficient used is found in the unit- and cycle-specific analyses.

[20] The kinetics parameters used are found in the unit- and cycle-specific analyses.

[21] The ejected rod worth is limited to 0.131 %$\Delta\rho$ from the fuel enthalpy and temperature case (see Table 15.4.8-2) and use of 0.157 %$\Delta\rho$ is conservative for the peak pressure case.

C. Results

The sequence of events for CEAE peak RCS and main steam pressures for barrier performance is shown in Table 15.4.8-5. The CEAE with a postulated turbine trip and loss of main feedwater results in a peak RCS pressure of 2702 psia (see Figure 15.4.8-7) that is eventually stopped by the PSVs and by the HPPT. The reactor trip causes the closure of the turbine admission valves, which causes a rapid rise in secondary-side pressure to peak pressure of 1349 psia (see Figure 15.4.8-10). The MSSVs open to relieve secondary-side pressure and dissipate energy. Typical NSSS pressure responses to the CEAE transient are presented in Figures 15.4.8-7 through 15.4.8-11[22].

The maximum RCS pressure is less than 120% (3000 psia) of RCS design pressure (2500 psia). The maximum primary pressure for this event meets the limiting pressure acceptance criteria of the Standard Review Plan (Reference 1).

[22] Figures 15.4.8-7, 15.4.8-8 and 15.4.8-10 for RCS and Secondary pressures are from the CENTS runs using the PSV opening area of 0.021602 ft^2, which is the main purpose of this event simulation. Figures 15.4.8-9 and 15.4.8-11 are from a CENTS run at 3876 MWt using a slightly larger PSV area of 0.0301 ft^2. The figures represent typical responses for the transient simulation.

Table 15.4.8-5

TYPICAL SEQUENCE OF EVENTS FOR
CEA EJECTION PEAK RCS PRESSURE EVENT

Time (sec)	Event
RTP 3990 MWt	
0.00	Mechanical failure of CEDM causes CEA to eject
0.05	CEA fully ejected
0.07	Maximum core power
19.60	HPPT reached
20.35	HPPT reactor trip, turbine trip, main feedwater trip
20.95	Scram CEAs begin to drop
21.62	PSVs open
22.16	Peak RCS pressure occurs
24.71	PSVs close
24.81	MSSVs open
27.89	Maximum steam generator pressure occurs
32.70	Steam generator level drops to auxiliary feedwater actuation signal setpoint
< 1800	Long-term automatic plant system actions and NSSS response to this transient are similar to the control element assembly withdrawal at power
1800.0	Operator initiates cooldown

15.4.8.5 Radiological Consequences and Containment Performance

A. Mathematical Model

The number of fuel pins predicted to experience departure from nucleate boiling was calculated using the STRIKIN-II computer program described in section 15.0 with the CE-1 correlation described in chapter 4. A matrix relating the initial and ejected CEA peaking factors to a pin census edit is obtained from Step 6 of the C-E synthesis method and is used to calculate the number of fuel pins experiencing DNB. The time-dependent energy deposition in the NSSS was determined from the above analysis and input into the CESEC III computer program to determine the overall NSSS response to this event.

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used for the fuel evaluation portion of a CEA ejection analysis are delineated in UFSAR Tables 15.4.8-2, 15.4.8-3 and 15.4.8-4.

For all cases analyzed, an axial power distribution was chosen to maximize the energy content in the hottest fuel pellet. The remaining parameters were chosen based on the results shown in Chapter 4 of reference 3. These parameters were varied in the most adverse direction until a COLSS power operating limit was achieved.

C. Results

The spectrum of initial reactor states contained in table 15.4.8-3 was analyzed to show that each case met the criteria established in Regulatory Guide 1.77. All cases resulted in a radial average fuel specific enthalpy less than 280 cal/gram at the hottest axial location of the hot fuel pin. The case that resulted in the greatest potential for offsite dose consequences (i.e., the case resulting in the largest number of postulated fuel failures) was identified as the case initiated from full power (FP) beginning of cycle (BOC) initial conditions. The following paragraphs describe this event in detail. Refer to table 15.4.8-4 for the initial conditions and assumptions used for this analysis.

Figures 15.4.8-1 through 15.4.8-5 show the reactor power, heat flux, and clad and fuel temperatures during the significant portion of transient. Table 15.4.8-1 contains the sequence of events that occur during a CEA ejection initiated from full power BOC initial conditions.

Ejection of a CEA causes the core power to increase rapidly due to the almost instantaneous addition of positive reactivity. However, the rapid increase in core power is terminated by a combination of Doppler feedback and delayed neutron effects. This increase in power results in a high power trip and the reactor

power begins to decrease as the CEAs enter the core. Reactivity effects are shown in figure 15.4.8-6.

In the hot channel, the increase in heat flux is such that DNB is calculated to occur, resulting in:

- a rapid decrease in the surface heat transfer coefficient
- a rapid decrease in heat flux
- a rapid increase in clad temperature.

The transient behavior of the NSSS following a postulated CEA ejection is as follows. The steam generator pressure increases rapidly due to the closure of the turbine control valve following reactor and turbine trip. The steam bypass control system is inoperable on loss of offsite power and therefore is unavailable.

Subsequently, the reduced reactor power following the reactor trip, in addition to the postulated break in the primary system, causes the RCS pressure and temperature to decrease.

The steam generator pressure decreases slowly until the main steam safety valves close. The total mass released through the safety valves is approximately 164,160 lbm in the 3954 MWt analysis and 165,528 lbm in the 4070 MWt analysis.

NRC Regulatory Guide 1.77 recommends that the onset of DNB be used as the basis for predicting clad failure for the postulated CEA ejection event. For PVNGS, the number of fuel rods that experience DNB is calculated with a statistical convolution technique, which is discussed in UFSAR Section 15E.3.3 and described in Reference 4. The statistical convolution technique involves the summation, over the reactor core, of the number of fuel rods with a specific DNBR value, multiplied by the probability of DNB at that DNBR value. However, to provide a conservative assessment of radiological consequences, 19% of the fuel rods are assumed to suffer clad failure in the 3954 MWt analysis, as shown in Table 15.4.8-6. This assumed value is greater than the percentage of fuel rods that the statistical convolution technique predicts will experience DNB.

The activity released to the containment (through the ruptured CEDM pressure housing), is assumed to be mixed instantaneously throughout the containment and is available for leakage to the atmosphere. Activity released to the containment building is the activity in primary coolant that is discharged through the CEA break. The activity in the primary coolant consists of primary coolant concentration prior to the accident and fuel-clad gap activity from the fuel rods that experience DNB. Activity is released from the containment building through the power access purge

until the purge system release path is isolated by a Containment Isolation Actuation Signal (CIAS) due to a low pressurizer pressure for the 3954 MWt analysis and due to high radiation levels at the purge monitors for the 4070 MWt analysis. Following isolation of the containment power access purge, airborne activity in containment is released via containment structural leakage.

The activity released from the secondary system is the activity released to the atmosphere from the main steam safety valves and from the atmospheric dump valves during cooldown.

Another source of activity release to the environment is due to ESF recirculation leakage outside the containment building, which is assumed to start at 20 minutes after the event. The iodine activity concentration in the recirculating water is determined assuming that 50% of the total reactor coolant system iodine activity is diluted in a containment sump water volume composed of the combined minimum water volumes of the refueling water tank, the reactor coolant system, and the safety injection tanks. The fraction of radioactive iodine in the leakage water that becomes airborne and available for release is based on the flashing fraction.

Assumptions and parameters that were unique to the evaluation of a CEA ejection event are itemized in

table 15.4.8-6. The following paragraphs provide additional clarification to some of the items contained in the table.

Activity available for release from containment at time zero.

The activity available for leakage from containment is based on the following Regulatory Guide 1.77, Appendix B assumptions:

1. The activity in the fuel clad gap is 10% of the iodines and 10% of the noble gases accumulated in the fuel at the end of core life (infinite cycle length is assumed for short lived isotopes (i.e., all isotopes other than Kr-85) per TID 14844 methodology), assuming continuous maximum full power operation. The ORIGEN computer code was used to obtain source term activities for long-lived isotopes (such as I-129 and Kr-85) using a conservative burnup as summarized in Tables 15.4.8-6 (for the 3954 MWt analysis) and 15.4.8-6A (for the 4070 MWt analysis). All of the activity in the fuel gap for fuel rods that are calculated to experience DNB is assumed to be instantaneously available for release from containment.

G. Control room parameters[a]	
1. Control room essential HVAC	
a. Normal HVAC Isolation time (CPIAS), sec	90

[a] Refer to UFSAR Section 6.4 and Appendix 15.B for parameters related to control room volume and operation of the essential HVAC system and to UFSAR Appendix 15.B for control room dispersion coefficients, occupancy factors and breathing rate. The bounding unfiltered infiltration rate to the control room is presented in UFSAR Section 6.4.7.

2. The nuclide inventory of the fraction of fuel which reaches or exceeds the initiation temperature of fuel melting at any time during the transient is to be calculated; 100% of the noble gases and 25% of the iodines in this fraction of fuel are assumed to be instantaneously available for release from the containment.

   None of the fuel was calculated to reach or exceed initiation temperature for fuel melting.

Activity release from the secondary system.

Activity released from the secondary system is based upon the secondary activity initially in the steam generators plus primary activity resulting from a 1 gpm steam generator tube leak. A steam generator decontamination factor of 100 is applied to radioactive iodine in the 1 gpm primary to secondary leakage. Supporting documentation for applying a steam generator decontamination factor of 100 to radioactive iodine is provided in Reference 7.

Activity released in secondary system steam includes activity in steam released through the Main Steam Safety Valves (MSSVs) and the Atmospheric Dump Valves (ADVs). Main steam is released via the MSSVs for 30 minutes following accident initiation. From 30 minutes after the accident initiation until shutdown cooling is established, main steam releases are via the ADVs. The mass of steam released through

the MSSVs and the ADVs is given in Table 15.4.8-6 for the 3954 MWt analysis and Table 15.4.8-6A for the 4070 MWt analysis. The Westinghouse (Old CE) CESEC III computer code was used to determine MSSV and ADV secondary system steam releases. It is indicated in Reference 8 that the CESEC III computer code underestimates the decay heat which will cause an under prediction of the steam release. MSSV and ADV steam releases were adjusted to compensate for the CESEC III under prediction of steam release. Steam releases were also adjusted to reflect RSG and power uprate for the 4070 MWt analysis.

Reactor coolant system activity after event.

The RCS activity after the event was based on the assumptions given above. The reactor coolant activity after the event is equal to the reactor coolant activity prior to the event plus the increase in activity due to fuel clad gap activity from the fraction of the fuel that experiences DNB.

Although it is unlikely that the entire radioactivity noted in table 15.4.8-6 would be instantly released from the core and the RCS, measures have been incorporated in the PVNGS design to keep offsite doses below 10CFR100 limits should such a release take place. Credit for iodine removal by sprays has not been assumed. Leakage from recirculation components outside the containment, as well as containment leakage and containment purge releases, have been assumed.

Table 15.4.8-8 presents the estimated offsite doses at the exclusion area and low population zone boundaries.

D. Conclusions: Radiological Consequences

Table 15.4.8-8 presents offsite doses at the exclusion area and low population zone boundaries.

<u>Analyzed Core Power of 3954 MWt</u>

The EAB and LPZ radiological consequences of a CEA Ejection accident are presented in Table 15.4.8-8. Thyroid and whole body doses in Table 15.4.8-8 are representative of the parameters presented in Table 15.4.8-6 for a reactor core power level of 3954 MWt with original steam generators. Control room doses are due to a CEA Ejection accident are addressed in Section 6.4.7.3.

Analyzed Core Powe of 4070 MWt

CEA Ejection analyses for a reactor core power level of 4070 MWt with replacement steam generators determine allowable combinations of accident generated failed fuel percentage (Ff) and fuel radial peaking factor (Fr) such that the total design basis offsite dose values, presented in Table 15.4.8-8, are maintained. The limiting dose associated with a CEA Ejection accident is the control room dose. It is indicated in Section 6.4.7.3 and Table 6.4.7-1 that the CEA Ejection accident is the limiting accident for the control room dose. The limiting product of Ff and Fr for the control room accident is 0.30. Fuel cycle characteristics are controlled such that the product of Ff and Fr does not exceed 0.30 following a design basis CEA Ejection accident. This will ensure that the offsite doses are within the design basis dose values presented in Table 15.4.8-8.

Table 15.4.8-8

RADIOLOGICAL CONSEQUENCES OF A CONTROL ELEMENT ASSEMBLY EJECTION ACCIDENT[a]

Dose	Thyroid Dose[c] (rem)	Whole Body Dose (rem)

a. Assumes no credit for containment sprays or non-ESF HVAC filtration.

b. Values have been rounded up.

c. The bounding control room thyroid dose is given in Section 6.4.7.

15.4.8.6 Conclusions

The rupture of a CEDM nozzle or housing and the subsequent ejection of a CEA will not result in a radial average fuel enthalpy greater than 280 cal/gram at any axial location in any fuel rod. The fuel centerline temperature will be less than fuel melt temperature. For dose consequences, refer to UFSAR Section 15.4.8.5 for details.

The peak RCS pressure for the CEAE event is less than Service Limit C, 3000 psia (120% of the design pressure of 2500 psia), as defined in the ASME code.

For the postulated event involving a CEAE, the PVNGS design meets the relevant requirements of the Standard Review Plan (Reference 1).

15.5 INCREASE IN RCS INVENTORY

15.5.1 INADVERTENT OPERATION OF THE ECCS

15.5.1.1 Identification of Event and Causes

The inadvertent operation of the emergency core cooling system (ECCS) is assumed to actuate the two high pressure safety injection (HPSI) pumps and open the corresponding discharge valves. This operation occurs as a result of a spurious signal to the system or operator error.

15.5.1.2 Sequence of Events and Systems Operation

Inadvertent operation of the ECCS is only of consequence when it occurs below the HPSI pump shutoff head pressure. Above that pressure there will be no injection of fluid into the system. Below the HPSI pump shutoff head pressure, when the shutdown cooling system is isolated the HPSI flow will increase reactor coolant system (RCS) inventory and pressure until the pressure reaches the pump shutoff head pressure. During shutdown cooling system operation the increase in RCS inventory and pressure will be mitigated by the shutdown cooling system relief valves.

15.5.1.3 Analysis of Effects and Consequences

Plant operation above the HPSI pump shutoff head pressure will not be impacted by the inadvertent operation of the ECCS. Below the HPSI pump shutoff head pressure when the shutdown cooling system is isolated, there will be an RCS inventory and pressure increase. This increase will be terminated when the pressure rises above the shutoff head pressure. Due to the

pressure increase caused by this transient at low RCS temperatures, there is an approach to the brittle fracture limits of the RCS. Examination of the Technical Specifications RCS pressure-temperature limitations shows that the brittle fracture limits will not be violated for this transient. Should the ECCS inadvertently actuate during shutdown cooling operation, the shutdown cooling relief valves will mitigate the pressure transient so that the temperature-pressure limits are not exceeded. The shutdown cooling relief valves can be isolated when the RCS temperature is above the pressure-temperature limits for brittle fracture of the RCS (See UFSAR Section 5.2.2.11).

15.5.1.4 Conclusion

The peak pressurizer pressure reached during the inadvertent operation of the ECCS is well within 110% of design pressure. Additionally, the pressure-temperature limits for brittle fracture of the RCS are not violated by this transient. The fuel integrity is not challenged by this event.

15.5.2 CVCS MALFUNCTION-PRESSURIZER LEVEL CONTROL SYSTEM MALFUNCTION WITH LOSS OF OFFSITE POWER

15.5.2.1 Identification of Event and Causes

All events and events plus single failures which cause an increase in RCS inventory as a result of failure or misoperation of the CVCS were examined with respect to the RCS pressure and fuel cladding performance. The Pressurizer Level

Control System (PLCS) malfunction was the most limiting event and is more limiting than the UFSAR Chapter 15.5.1 event.

The failure of the PLCS is an Anticipated Operational Occurrence (AOO) and is classified as an incident of moderate frequency. In combination with a single failure, the PLCS malfunction is an infrequent event.

15.5.2.2 Sequence of Events and Systems Operation

The PLCS Malfunction analyses are performed as separate cases for the primary and secondary peak pressure limits, since these events are not mutually conservative. The sequence of events is presented in Table 15.5.2.2-1.

When in the automatic mode, the PLCS responds to changes in pressurizer level by changing charging and letdown flows to maintain the program level. Normally, one charging pump is running with two charging pumps available for automatic startup when a low level setpoint is reached. If the pressurizer level controller fails low or the level setpoint generated by the reactor regulating system fails high, a low level signal can be transmitted to the controller. In response, the controller will start all the charging pumps and close the letdown control valve to its minimum opening, resulting in the maximum mass addition to the RCS.

The event initiates at the most limiting conditions allowed per Technical Specifications. The simulated malfunction of the PLCS results in the reduction of letdown to a minimum and the increase in charging to a maximum. The mismatch in charging and letdown will result in a slow, continuous in surge of RCS

coolant into the pressurizer. The RCS liquid entering the pressurizer will displace the steam above the liquid. The steam space being compressed will result in increasing RCS pressure. With the Pressurizer Pressure Control System (PPCS) in manual, the pressurizer sprays will not open and the RCS pressure will increase. The event proceeds until a reactor trip occurs on high pressurizer pressure (HPPT).If the Steam Bypass Control System (SBCS) is in automatic mode of operation, primary and secondary peak pressures should remain below relief valve setpoints. However, for the PLCS malfunction analysis, the SBCS is assumed to be in manual mode and credit is not taken for their functioning. The pressure increase in the primary and secondary systems are limited by the Primary Safety Valves (PSVs) and the Main Steam Safety Valves (MSSVs). The maximum RCS pressure occurs in the first two to five seconds following reactor trip.

As steam and energy is relieved in the Steam Generators (S/Gs) through the MSSVs, the level in the S/Gs will drop. An auxiliary feedwater actuation signal (AFAS) on low steam generator level occurs. The auxiliary feedwater flow is automatically initiated after a time delay and supplies water from the condensate storage tank (CST) to the Steam Generators.

The PLCS malfunction analysis does not credit operator action for the first thirty minutes following the event. Thirty minutes after initiation of the event, the operators stabilize the plant by securing excess charging and/or balance letdown with charging. The operators commence a cooldown using the safety grade Atmospheric Dump Valves (ADVs) and/or non-safety grade SBCS depending on system availability.

Analytical setpoints and response times associated with the Reactor Protective System (RPS) trip functions and Engineered Safety Features Actuation System (ESFAS) functions are consistent with, or conservative with respect to, limiting numerical values that appear in the PVNGS UFSAR delineated in UFSAR Chapter 7.The NRC's Standard Review Plan states that an incident of moderate frequency, such as the PLCS malfunction event, should not generate a more serious plant condition without other faults occurring independently. In addition, the Standard Review Plan states that an incident of moderate frequency, in combination with a single active component failure or single operator error, should not result in the loss of function of any barrier other than the fuel cladding.

The PLCS malfunction with pressurizer sprays in manual or off causes a reactor trip on high pressurizer pressure. The limiting criteria[1] for this event are peak pressure and secondary pressure which occur within the first two to five seconds after the high pressure reactor trip. Therefore, any single failure which would result in a higher RCS pressure during the transient would have to have an effect during the first two to five seconds following reactor trip.

The single failures that have been postulated are listed in table 15.0-0. The failures which affect the RCS behavior during this interval are:

---

[1]Primary integrity can not be compromised (i.e., neither can the primary go solid nor the PSVs pass water

- Loss of Normal AC
- Failure of the Pressurizer Pressure Control System
- Failure of the Steam Bypass Control System
- Failure of the Reactor Regulating System
- Failure of the Feedwater Control System.

Although these non-class systems would not normally be credited, the difference is the loss of RCP flow. Decreased RCP flow has the effect of decreasing heat transfer to the secondary and therefore would by itself increase primary pressure; however, loss of power to the RCPs reduces the RCP head and has a larger effect and reduces peak RCS pressure. Computer simulation has determined that a loss of power is not limiting. The de-energizing of the RCPs has the effect of reducing peak pressure in the primary and secondary. De-energizing the RCPs reduces pump flow and pump head. The CENTS code explicitly models the RCS pressures in each node and has determined that the maximum flow with RCPs running results in higher peak primary and secondary pressure. Consequently, peak RCS pressure occurs with offsite power being available and RCPs running. Peak secondary pressure also occurs with RCPs running which maximizes the heat transfer to the secondary.

Table 15.0-0 is used to determine credible single failures for safety analysis. This table indicates that there are no credible failures that can degrade the PSV and MSSV capacity. Technical Specification 3.7.1 places limits on reactor power and variable overpower trip (VOPT) setpoints when one or more MSSVs are inoperable, thereby ensuring secondary system peak

pressure remains within 110% of secondary system design pressure. The LOCV is one of the transients analyzed for validating Technical Specification 3.7.1. A decrease in RCS to steam generator heat transfer due to reactor coolant flow coastdown can be caused by a LOP following a turbine trip. However, the results of the parametric study show that a LOP coinciding or following the High Pressurizer Pressure Trip (HPPT) does not make the primary and secondary side pressures more adverse. In addition, it is assumed that the most reactive control rod fails to insert on scram.

Other single failures were examined such as operator action or equipment failure resulting in an inadvertent dilution; however, none were identified as credible. No credible single failure has been identified that makes the consequences worse than as specified under the limiting conditions described for this event. This is similar to conclusion in UFSAR 15.2.3.2 where no credible single failure was identified.

Therefore, it was concluded that there is no single failure that would make the maximum primary and secondary pressure more limiting than the LOCV event.

Regarding the approach to the fuel design limit, the major parameter of concern is the minimum hot channel Departure from Nucleate Boiling Ratio (DNBR). The major factors which cause a decrease in local DNBR are:

- Increasing Coolant Temperature
- Decreasing Coolant Flow
- Decreasing RCS Pressure, and

- Increasing Local Heat Flux (including radial and axial power distribution effects).

A decrease in RCS flow is the only parameter which can significantly reduce the minimum DNBR during the event. The PLCS malfunction with pressurizer sprays in manual or off causes a reactor trip. The heat flux starts to drop in the first five seconds. The single failures that have been postulated are listed in table 15.0-0. The failures which affect the RCS behavior during this interval are:

- Loss of Normal AC
- Failure of the Pressurizer Pressure Control System
- Failure of the Steam Bypass Control System
- Failure of the Reactor Regulating System
- Failure of the Feedwater Control System.

The loss of normal AC power results in Loss of Power to the:

- Reactor Coolant Pump,
- Condensate Pumps,
- Circulating Water Pumps,
- Pressurizer Pressure and Level Control System,
- Reactor Regulating System,
- Feedwater Control System, and
- Steam Bypass Control System.

The effect of losing normal ac power on the PLCS malfunction is as follows. Loss of power to the condensate and circulating water pumps and the feedwater control system initially effects

only the secondary system and thus does not affect DNBR in the first five seconds of the transient. Loss of power to the reactor regulating system pressurizer level and pressure control systems renders those systems inoperable. Failure of the pressurizer pressure control system or reactor regulating system cannot appreciably affect any of the major factors which determine DNBR during the first five seconds of the event. This inoperability will have no significant impact on DNBR during the first five seconds. Thus, none of the single failures listed in table 15.0-0 will result in a lower DNBR than that predicted for the PLCS malfunction with a loss of offsite power following turbine trip. Loss of power to the reactor coolant pumps is the only significant failure with regard to DNBR which results from a loss of normal ac power.

No single failure was identified from table 15.0-0 which would have a significant effect on DNBR prior to the reactor trip.

Therefore, any single failure which would result in a lower DNBR during the transient would have to affect at least one of the above parameters during the first five seconds of the event. The LOP is the only failure that may affect RCS flow. PLCS malfunction by itself, however, produces an increasing RCS pressure which compensates for the elevated RCS temperatures such that the available thermal margin does not degrade before the onset of the LOP. Thus, the overall DNBR degradation experienced during an PLCS malfunction event with LOP would be bounded by that of the loss of RCS flow event of UFSAR Section 15.3.1.

Table 15.5.2.2-1 presents a chronological sequence of events for the peak primary case which occur during PLCS malfunction from the initial malfunction until the operator stabilizes the plant and initiates plant cooldown.

Table 15.5.2.2-1 Sequence of Events

Time (sec)	Event
0	Charging flow maximized and letdown flow minimized
296.1	Pressurizer pressure reaches reactor trip analysis setpoint[a]
296.1	High pressurizer pressure trip signal generated
296.1	Turbine trip
296.6	Trip breakers open
297.2	Control rods start inserting
299.0	PSVs open
299.4	Maximum RCS[b] pressure
300.6	MSSVs first open and continue to cycle during the event
301.1	PSVs close[c]
308	Maximum steam generator pressure
357	AFW enters the steam generators
1800	Operator initiates plant cooldown

a. The time of event initiation is highly dependent on initial conditions (e.g., initial pressurizer level) that have little impact on peak primary or secondary pressure. The relative times from reactor trip until breakers opening, control rods inserting, PSVs opening and peak pressure are reasonably invariant.

b. Maximum RCS pressure includes RCP and elevation head in addition to pressurizer pressure.

c. When and how often PSVs cycle is highly dependent on initial conditions (e.g., initial pressurizer level RCS temperature) that have little impact on peak primary or secondary pressure.

15.5.2.3 Core and System Performance

A. Mathematical Model

The nuclear steam supply system (NSSS) response to PLCS malfunction with a reactor trip and a turbine trip was simulated using the CENTS computer program described in subsection 15.0.3.

B. Input Parameters and Initial Conditions

This event was not analyzed for fuel failure. Fuel failure as a result of DNB or peak linear heat rate is not of concern for this event. Pressure is increasing in this event and no power peaking or low RCS flow would occur that would not already be bounded by loss of flow.

C. Results

Since this transient causes an increase in RCS pressure due to an increase in primary coolant inventory, the DNBR increases. Therefore, the acceptance criterion regarding fuel performance is met.

15.5.2.4 Primary and Secondary Barrier Performance

A. Mathematical Model

The nuclear steam supply system (NSSS) response to PLCS malfunction with a reactor trip and a turbine trip was simulated using the CENTS computer program described in subsection 15.0.3.

B. Input Parameters and Initial Conditions

The initial conditions are set conservatively with respect to allowable TS limits, plant design, operating procedures, and instrument uncertainties. The initial conditions were varied within the ranges of steady state operation configurations (i.e., specified by the Technical Specifications, plant configuration, and design specifications) to determine the set of initial conditions that produce the most adverse consequences.

Parameters of interest include initial core inlet temperature, core inlet flow, pressurizer pressure, pressurizer water level, steam generator level, Moderator Temperature Coefficient (MTC), Fuel Temperature Coefficient (FTC), fuel rod gap conductances, kinetics parameters, LOP, and SG tube plugging. Starting from a base case, one parameter at a time is changed to establish the trends for the RCS and steam generator pressure.

For peak primary pressure and peak secondary pressure, neither the net charging rate nor the initial level have a significant impact. Although not discussed in detail, the PLCS malfunction with the sprays in automatic was analyzed and determined to be not limiting with respect to overfilling the pressurizer.

For this scenario, total charging flow due to all three pumps is 132 gal/min. Although a conservative bleedoff of 2 gpm per pump could be credited, no credit for this bleedoff has been taken. The minimum letdown flow is 30 gal/min.

Table 15.5.2.4-1

Limiting Initial Conditions for PLCSM Peak Primary and Secondary Pressure

Parameter	Value	
	Primary Peak Pressure	Secondary Peak Pressure
Initial core power (% of RTP)	102	
Initial core inlet temperature (°F)	566[a]	
Initial pressurizer pressure (psia)	2325[b]	
Initial RCS flow (% design)	116	95
Initial pressurizer water level (%)	23.9	
Pressurizer heaters	On	
Pressurizer sprays	Off	
Charging and letdown flows (gpm)	135/30	
MTC ($\delta\rho$/°F)	-0.0002[b.]	
β	Maximum [b.]	
FTC ($\delta\rho$/°F)	Most negative [b.]	
Prompt neutron lifetime (l*)	Min [b.]	Max [b.]
Fuel gap conductance (Btu/hr-ft2-°F)	500	
SCRAM delay time (sec)	0.5	
CEA holding coil delay (sec)	0.6	
CEA worth at trip - WRSO (%$\delta\rho$)	8.0	
Plugged tubes (per steam generator)	0	
Initial steam generator level (% WR)	28.22	28.22
AFW flow (gpm/pump)	650	
AFW delay time (sec)	46	
PSV setpoint tolerance	+3%	
PSV blowdown	5%	
MSSV Setpoint Tolerance	+3%	
MSSV blowdown	5%	
LOP	No	

a. The sensitivity of this parameter from minimum to maximum on peak primary pressure is much smaller than the uncertainties.

b. The sensitivity of this parameter from minimum to maximum on peak primary and secondary pressure is much smaller than uncertainties. Use of nominal values or other changes would have a negligible effect.

Table 15.5.2.4-2

Initial Conditions with Significant Impact on Peak Primary and Secondary Pressure for PLCSM

Parameter	Value	
	Peak Pressure	
	Primary	Secondary
Initial core power (% of RTP)	102	
Initial RCS flow (% design)	116	95
Fuel gap conductance (Btu/hr-ft2-°F)	500	
β	Maximum	
SCRAM delay time (sec)	0.5	
CEA holding coil delay (sec)	0.6	
CEA worth at trip - WRSO (%δρ)	8.0	
Plugged tubes (per steam generator)	0	
PSV setpoint tolerance	+3%	
Inlet temperature (°F)		566
MSSV Setpoint Tolerance		+3%

C. Results

The dynamic behavior of NSSS parameters for a PLCS malfunction with a reactor and turbine trip turbine trip is presented in figure 15.5.2-2 to 15.5.2-11. Note that the peak secondary pressure occurs for maximum primary temperature so that the figures represent both peak and primary pressure and peak secondary transient.

Failure of the PLCS causes an increase in reactor coolant system inventory initiated by the startup of the third charging pump coupled with the decrease in letdown flow to its minimum. With the PPCS in the manual mode and the proportional sprays turned off, increase in RCS inventory results in a pressurizer pressure increase to the reactor trip analysis setpoint.

Since the SBCS is conservatively assumed in the manual mode and the rate of closure of the turbine stop valves is faster than the rate of control rod insertion, pressurizer pressure increases which opens the primary safety valves. Peak primary pressure is 2681 psia which is less than 110% of the design pressure (2500 psia) or 2750 psia.

The unavailability of the SBCS causes the steam generator pressure to increase, causing the MSSVs to open. The decreasing core power and the safety valves function to limit the peak steam generator pressure to 1382 psia which is less than 110% of the design pressure (1270 psia) or 1397 psia.

At 1800 seconds, the operator stabilizes the plant and initiates plant cooldown using ADVs or SBCS.

This event has also been evaluated for peak pressurizer level (overfill) to assess the impact on the operability of the pressurizer safety valves. However, the limiting transient is discussed in section 18.II.D in accordance with NUREG-0737.

15.5.2.5 Radiological Consequences and Containment Performance

PLCSM is a moderate frequency event in which no fuel damage occurs. As noted above, the steam is discharged by the PSVs. That steam is directed to the Reactor Drain Tank (RDT). If a second lift of the PSVs occurs, the RDT rupture disk will rupture. The steam would be released to the containment. Since fuel failure will not occur as a result of not exceeding any Specified Acceptable Fuel Design Limits (SAFDLs), the dose and effluents will be controlled to the limits specified in 10CFR20. Therefore, radiological consequences are not

calculated for this event and containment isolation is not credited.

15.5.2.6 Conclusion

For the PLCS malfunction following turbine trip event, the maximum RCS pressure remains below 110% of RCS design pressure (2750 psia), thus ensuring primary system integrity. Likewise, the maximum secondary system pressure remains below 110% of design pressure (1397 psia), thus ensuring secondary system integrity.

Since this transient causes an increase in RCS pressure due to an increase in primary coolant inventory, the DNBR increases. Therefore, the acceptance criterion regarding fuel performance is met.

15.6 DECREASE IN REACTOR COOLANT SYSTEM INVENTORY

15.6.1 INADVERTENT OPENING OF A PRESSURIZER SAFETY/RELIEF VALVE

The inadvertent opening of a pressurizer safety valve event as described in NRC Standard Review Plan 15.6.1 is evaluated in the emergency core cooling systems analyses (section 6.3).

15.6.2 DOUBLE-ENDED BREAK OF A LETDOWN LINE OUTSIDE CONTAINMENT

15.6.2.1 Identification of Causes and Frequency Classification

Direct release of reactor coolant may result from a break or leak outside containment in a letdown line, instrument line, or sample line. The double-ended break of the Chemical and Volume Control System (CVCS) letdown line outside containment upstream of the letdown line control valve (DBLLOCUS) was selected for this analysis because it is the largest line, and results in the largest release of reactor coolant outside the containment.

The single active failure of an isolation valve was not considered in the analysis because the letdown line includes two isolation valves in series situated inside the containment. Hence, failure of one isolation valve does not make the consequences of the event more severe.

A letdown line break can range from a small crack in the piping to a complete double-ended break. The cause of the event may be attributed to corrosion which forms etch pits, or to fatigue cracks resulting from vibration or inadequate welds. In order to bound all break sizes,

forms and locations, a double-ended guillotine break of the letdown line just outside containment upstream of the control valve is evaluated.

The letdown line break is classified as a limiting fault event whose occurrence is not expected, but is postulated because its consequences include the potential for release of significant amounts of radioactive material. Two cases were analyzed: in the first case, the initial conditions were selected as shown in Table 15.6.2-3 to minimize DNBR (see figure 15.6.2-16) while in the second case the initial conditions were selected as shown in Section 15.6.2.4B with the exception of conservatively setting pressurizer heaters ON to maximize the blowdown flow (see figure 15.6.2-1 to 15.6.2-15). These will be discussed below.

15.6.2.2 Sequence of Events and Systems Operation

A double-ended break of the letdown line outside containment upstream of the letdown line control valve releases primary fluid to the auxiliary building as shown in figure 15.6.2-7. This discharge rate, as shown in figure 15.6.2-8, is more than twice the maximum expected letdown flow. The event will set off a number of alarms. Table 15.6.2-1 lists the alarms that would be noted by the reactor operator in the control room.

Table 15.6.2-1
ALARMS THAT WILL BE
ACTUATED FOR THE DBLLOCUS EVENT

1. Regenerative heat exchanger high exit temperature alarm
2. Letdown line low pressure alarm
   (downstream of the break)
3. Letdown line process radiation monitor loop low flow alarms
4. Auxiliary building high radiation alarm
5. Auxiliary building high temperature alarm
6. Pressurizer level deviation alarm
7. Auxiliary building sump high level alarm
8. Pressurizer low level alarm

The first three alarms listed in table 15.6.2-1 (the regenerative heat exchanger (RHX) high exit temperature alarm, the letdown line low pressure alarm, and the low flow alarm in the process radiation monitor loop) will immediately alert the operator after the initiation of the event. The high RHX outlet temperature alarm, in addition to sounding the alarm, also initiates isolation of the letdown line by closing one of the two letdown line isolation valves inside the containment. However, no credit is taken for this isolation action in the analysis. Secondly, the high radiation and high temperature alarms in the auxiliary building are expected to be triggered within a few seconds after the event initiation. Thirdly, the pressurizer level deviation alarm is expected to alert the operator approximately one minute after the initiation of the event. Next, the auxiliary building sump high level alarm is expected to be triggered within a few minutes after the initiation of the event. Lastly, the pressurizer low level alarm will occur in approximately 10 minutes after the initiation of the event.

For most nominal starting configurations, the makeup system will be able to restore VCT level before the VCT low level alarm is actuated.

The analysis assumes that the operator isolates the letdown line 10 minutes after the first three alarms resulting from the DBLLOCUS, thereby terminating any further release of primary flow to the auxiliary building. Subsequently, the operator is assumed to take appropriate steps for a controlled reactor

shutdown. The assumption of operator action within 10 minutes after the first few alarms are triggered is based on an ANS/ANSI Standard (Reference 1). The 10 minutes is the minimum time for the letdown line break event category that shall elapse from the time of the alarm until operator actions can be considered for initiation of safety functions.

Table 15.6.2-2 presents a sequence of events which occur following a double-ended break of the letdown line until the operator takes action to terminate the primary system fluid loss 10 minutes after the initiation of the event.

Table 15.6.2-2
SEQUENCE OF EVENTS FOR THE DOUBLE-ENDED BREAK
OF A LETDOWN LINE OUTSIDE CONTAINMENT
UPSTREAM OF THE LETDOWN CONTROL VALVE

Time (sec)	Event	Setpoint/Value
0.0	Letdown Line Ruptures (Break Area, ft^2)	0.01556
0.0	Maximum Break Flow Rate (lbm/sec)	48.9
600	Maximum Break Quality	0.4064
600	Maximum Integrated Mass Release, Flashed (lbm)	11,700
600	Minimum DNBR occurs	1.47
600	Operator isolates the letdown line break and takes steps for a controlled shutdown of the reactor.	10 Minutes

The operator diagnoses the event based on alarms specified in table 15.6.2-1, and may generate a manual reactor trip after isolating the letdown line. If a trip occurs, the control element assemblies (CEAs) fall into the core to provide a negative reactivity insertion. The boron concentration is adjusted to ensure that a proper negative reactivity shutdown margin is achieved prior to cooldown by manually controlling the chemical and volume control system (CVCS).

The turbine automatically trips on the manual reactor trip. The steam bypass control system (SBCS) automatically actuates and opens the steam bypass valves to dump steam to the condenser. The main feedwater control system (FWCS) responds to the reactor trip and generates a reactor trip override signal which reduces feedwater flow to a value commensurate with the decay heat load. The plant cooldown is controlled by manual operation of the SBCS. The main feedwater pumps are manually controlled and continue to supply feedwater until the operator starts the auxiliary feedwater pump and secures the main feedwater pumps.

The shutdown cooling system (SCS) is manually actuated when reactor coolant system (RCS) temperature and pressure have been reduced to approximately 350F and 400 psia. This system provides sufficient cooling flow to cool the RCS to cold shutdown.

15.6.2.3 Core and System Performance

A. Mathematical Model

The nuclear steam supply system (NSSS) response to a DBLLOCUS was simulated with the CENTS computer program (see UFSAR Section 15.0.3). The analysis assumes critical flow through the break and accounts for letdown line and regenerative heat exchanger (RHX) losses to calculate the break discharge. The pressurizer pressure control system (PPCS) and the pressurizer level control system (PLCS) are assumed normally operating unless lack of operation would make the consequences of the event more adverse. In such cases, the PPCS and PLCS are assumed to be inoperative, or in the most adverse mode, until the time of operator action.

The CETOP-D computer code (see UFSAR Section 4.4), which uses the CE-1 CHF correlation, was used to calculate the initial conditions corresponding to the DNBR SAFDL. CETOP-D was also used to calculate transient DNBR values and thermal-hydraulic conditions at the time of the minimum DNBR.

B. Input Parameters and Initial Conditions

Table 15.6.2-3 lists the assumptions and initial conditions used for the letdown line break core performance analysis. These conditions were chosen to minimize the DNBR for DBLLOCUS, within the allowable operating range specified by the Technical Specifications, plant configuration, design specifications, and instrument uncertainties.

The break, just outside the containment penetration, is assumed to be the full cross sectional area (double-ended) of the 2-inch letdown line pipe corresponding to a break area of 0.01556 ft^2 to maximize the depressurization and thus minimize the transient DNBR. In similar manner, conservatively no credit is taken for the pressurizer heaters to slowdown the depressurization.

The break is assumed to be isolated at the end of the transient, i.e., at 600 seconds (10 minutes).

C. Results

The discharge in the primary system causes the RCS pressure to decrease around 250 psi during the 10-minute transient with depressurization rate of approximately 0.40 psi/sec.

The minimum departure from nucleate boiling ratio (DNBR) decreases solely as a result of the pressure degradation, however, remains well above the SAFDL value of 1.34 during the transient (see Figure 15.6.2-16). The core power remains constant during the transient thus the linear heat generation rate remains unaffected ensuring fuel integrity.

Therefore, no fuel failure occurs during the DBLLOCUS event.

15.6.2.4 RCS Pressure Boundary and Barriers Performance

A. Mathematical Model

The mathematical model used for evaluation of barrier performance is described in section 15.6.2.3 A.

Table 15.6.2-3

ASSUMED INPUT PARAMETERS AND INITIAL CONDITIONS FOR THE DOUBLE-ENDED BREAK OF A LETDOWN LINE OUTSIDE CONTAINMENT UPSTREAM OF THE LETDOWN CONTROL VALVE

Parameter	Value
Initial Core Power Level (% of Rated)	102
Initial Core Inlet Temperature, °F	572
Initial Pressurizer Pressure, psia	2325
Initial RCS Flow (% of design lbm/hr)	95%, $155.8x10^{6}$
Initial Pressurizer Water Level, %	59
Moderator Temperature Coefficient (MTC)	nominal
Fuel Temperature (Doppler) Coefficient	nominal
Kinetics Parameters	nominal
CEA Worth at Trip	no reactor trip
Gas Gap Conductance	nominal
Number of Plugged Tubes per SG	0
Number of Running Charging Pumps	3
Pressurizer Heaters	OFF
Break Size (double-ended), ft^2	0.01556

B. Input Parameters and Initial Conditions

The input parameters and initial conditions relevant to barrier performance for the limiting fault event are the same as those presented in table 15.6.2-3 for a letdown line break from full power conditions with the exception of conservatively setting pressurizer heaters ON.

These conditions were chosen to maximize the primary system flashed mass release into the auxiliary building atmosphere for DBLLOCUS, within the allowable operating range specified by the Technical Specifications, plant configuration, design specifications, and instrument uncertainties. This, in turn, leads to the most conservative predictions of radiological releases.

Some of the initial conditions and NSSS characteristics used in this analysis of the maximum total flashed mass release for the letdown line break were based on parametric studies. The parameters evaluated were initial core inlet temperature, initial power level, initial pressurizer pressure, initial core inlet flow rate, initial pressurizer liquid inventory, MTC, RHX heat transfer, PLCS operation, and line friction loss (K-Factor) effect.

Of these parameters, the initial core power does not directly affect the break release, however, the allowed higher core inlet temperature at lower powers increases the flashed mass release from the break. On the other hand, the RCS coolant activity may be lower at lower power levels. Thus, the maximum core power with the maximum allowable core inlet temperature

for all operating power levels are conservatively used together for bounding initial conditions. A larger initial pressurizer pressure (driving head), a higher initial pressurizer level (static head), and a lower core flow(low pressure drop in the RCS loop), increase the RCS pressure at the letdown line exit resulting in a higher break release. Similarly, a lower pressure drop in the letdown line, due to line friction loss, maximizes the break discharge. The heat transfer in the RHX reduces the letdown coolant enthalpy at the break location, thus results in a lower flashed mass release at the break. As a modeling simplification, conservatively no heat transfer in the RHX is assumed in the bounding case.

The core physics parameters including the MTC have negligible to no effect on the break release since the fuel and moderator temperature remains essentially constant during the event and no power changes throughout the core occurs.

All control systems are assumed to be in the automatic mode unless lack of automatic operation would make the consequences of the event more adverse to maximize the total primary mass releases. Since no RHX heat transfer is conservatively assumed, the PLCS operation mode has insignificant effect on the break release. The heaters conservatively left at the full-on mode to maintain high pressurizer pressure thus increase the break release, during the transient.

C. Results

The response of key parameters as a function of time are presented in Figures 15.6.2-1 to 15.6.2-15 for the DBLLOCUS.

The decrease in the primary system mass causes the pressurizer pressure to decrease around 100 psi during the 10-minute transient with depressurization rate of approximately 0.20 psi/sec. Also, during the same time period the pressurizer level decreases about 10 feet (29%) to a new level of approximately 30%.

At 10 minutes into the transient the operator isolates the letdown line, terminating the release of primary fluid outside the containment. The amount of total and flashed reactor coolant released into the Auxiliary Building is shown in Figure 15.6.2-7. The break flow rate varies between 48.9 lbm/sec and 46.9 lbm/sec, as shown in Figure 15.6.2-8. The break quality varies between 0.4060 and 0.4064 during the transient, as shown in Figure 15.6.2-9. With the total mass release of about 28,800 lbm and the maximum break flow quality of about 0.4064, the total flashed release from the break during 10-minute transient is less than 11,700 lbm.

The double-ended break of a letdown line outside containment upstream of the letdown line control valve results in gradual depressurization of the reactor coolant system thus does not challenge the RCS pressure safety limit. The secondary system pressure does not increase above its initial condition value during the transient and does not challenge the 110% of the design limit ensuring integrity of the main steam system.

15.6.2.5 Radiological Consequences and Containment Performance

A. Mathematical Model

The DBLLOCUS event is indicated by several non-Q1E alarms listed in table 15.6.2-1. The first three alarms are expected to take place immediately following initiation of the event. Ten minutes after the initiating event, the letdown line is isolated by the reactor operator.

The methodology to determine the most adverse dose results includes multiplying the amount of primary coolant released into the auxiliary building by the maximum flashing fraction. The flashing fraction is based on the enthalpy and pressure of the primary coolant at the break location. Both the mass released and enthalpy values are obtained from the CENTS code.

The mathematical model used to analyze the activity released during the course of the accident is described in section 15.0.4 (Radiological Consequences) and control room doses are discussed in section 6.4.7 (Bounding System Unfiltered Air Inleakage for Radiological Design).

B. Assumptions and Parameters

The letdown line break outside containment results in the discharge of radioactivity to the environment. Worst case or conservative assumptions are:

1. The initial activity level of the primary coolant is assumed to be 3.81 μCi/gm dose equivalent I-131(DEQ I-131) as calculated using ICRP-30 iodine dose conversion factors.

This corresponds to the maximum equilibrium value with 1% failed fuel.

2. A concurrent iodine activity spike with a spiking factor of 500 for the GIS is assumed to occur coincident with initiation of the transient.

3. The quantity of steam (coolant times maximum flashing fraction) released outside containment is maximized by assuming the most adverse initial conditions and by assuming critical flow through the break.

4. The blowdown decontamination factor (DF) is calculated to determine how much iodine contained in the released primary mass is assumed to be airborne. This is based on the fraction of primary fluid that flashes to steam in the auxiliary building, based on the enthalpy of the escaping fluid.

5. No credit is taken for the retention within the auxiliary building and filtration system.

6. No credit is taken for ground deposition of the activity that escapes the auxiliary building or of decay in transit to the exclusion area boundary.

7. The meteorological conditions assumed to be present at the site during the course of the accident are based on χ/Q values which are expected to be conservative 95% of the time. This condition results in the poorest values of atmospheric dispersion calculated for the EAB or low population zone (LPZ) outer boundary. Furthermore, no

credit has been taken for the transit time required for activity to travel from the point of release to the EAB or LPZ outer boundary. Hence, the radiological consequences evaluated under these conditions are conservative. The PVNGS site specific χ/Q value used for this analysis is discussed in section 2.3.4.

8. Parametrics performed in the dose calculation concluded that all 3 charging pumps in operation prior to initiation of the line break resulted in the highest doses. The higher assumed charging flow maximizes the Iodine source in the primary and bounds all possible modes of operation.

C. Results

The radiological consequences resulting from the occurrence of a postulated letdown line rupture have been conservatively analyzed using assumptions and models described in the preceding subsections. The thyroid inhalation dose and whole body dose have been analyzed for the two-hour dose at the exclusion area boundary. The two-hour thyroid inhalation dose and whole body dose values remain less than a small fraction of 10 CFR 100 guidelines (10% of 10 CFR 100 limits) as listed in table 15.6.2-4. The containment barrier is not challenged since no releases to containment occur during this event.

Table 15.6.2-4
RADIOLOGICAL CONSEQUENCES FOR THE DBLLOCUS

Target Organ, Evaluation Period, Location	Dose (REM)	SRP Limit (REM)
Thyroid, 0-2 hrs at EAB	10.45	30
Whole Body, 0-2 hrs at EAB	0.021	2.5

15.6.2.6 Conclusions

The double-ended break of letdown line outside containment upstream of the letdown line control valve results in gradual depressurization of the reactor coolant system. The peak secondary pressure does not increase during the transient and remains below 110% of design ensuring integrity of the main steam system. The minimum DNBR remains above the SAFDL value, thereby ensuring fuel cladding integrity. The amount of coolant assumed to be released in the dose calculation is 11,900 lbm. The event generated iodine spikes (GIS) radiological releases results in a two-hour thyroid inhalation dose and whole body dose that are a small fraction of 10 CFR 100 guidelines (10% of 10 CFR 100 limits).

For the postulated event involving a letdown line break from full power conditions, the PVNGS design conforms with the applicable requirements of 10 CFR Part 50 Appendix A, General Design Criterion 55 (Reactor Coolant Pressure Boundary Penetrating Containment), as described in the NRC Standard Review Plan (Reference 2).

15.6.3 STEAM GENERATOR TUBE RUPTURE

The Steam Generator Tube Rupture (SGTR) accident is a penetration of the barrier between the Reactor Coolant System (RCS) and the main steam system, and results from a double ended guillotine break of a steam generator U-tube.

A SGTR is classified as a limiting fault event, whose occurrence is not expected during the lifetime of the plant, however, the event is postulated because the consequences include the potential for the release of significant amounts of radioactivity to the environment (i.e., an ANSI N18.2-1973 Condition IV event). Acceptance criteria for SGTR safety analyses are established on the basis of radiological dose consequences, whose acceptance limits vary with the analytical assumptions used for the SGTR event combination under consideration (e.g., availability of offsite power, iodine spiking, single failure, etc.).

SGTR event combinations are also evaluated to ensure that Emergency Operating Procedure (EOP) mitigation strategies provide sufficient direction to plant operators to prevent the occurrence of steam generator overfill. These evaluations are performed in accordance with 10 CFR 50, Appendix B, Criterion III (Design Control) processes. Prevention of steam generator overfill is not an acceptance criterion for SGTR analyses in NRC Standard Review Plan (NUREG-0800) Section 15.6.3.

15.6.3.1 Steam Generator Tube Rupture Without a Loss of Offsite Power

The SGTR with a LOP and an additional Single Failure (SF) presented in UFSAR Section 15.6.3.2 bounds all SGTR events, including the SGTR without a LOP, with respect to offsite dose consequences. The LOP causes the plant to experience a loss of turbine load, loss of normal feedwater flow and loss of condenser vacuum that results in direct steaming to the atmosphere via stuck-open Atmospheric Dump Valve (ADV), the most limiting SF, and the Main Steam Safety Valves (MSSVs). Based on the loss of the condenser vacuum and the direct steaming through the stuck-open ADV, the SGTR with LOP and a single failure is more limiting than the SGTR with respect to radiological consequences.

Additionally, operator action in conformance with Emergency Operating Procedures (EOPs) will prevent overfilling of the steam generators following a SGTR event. Steam generator level control is afforded primarily by controlling the delivery of feedwater (or auxiliary feedwater) to the steam generators, and by releasing steam through the Steam Bypass Control System (SBCS) or the Atmospheric Dump Valves (ADVs).

However, SRP Section 15.6.3 requires that the following two criteria must be met for the SGTR with no LOP:

- For the SGTR event with a pre accident iodine spike, the calculated dose should not exceed the 10 CFR 100 limits, i.e., 300 REM for the thyroid.

- For the SGTR event with an accident generated iodine spike, the calculated dose should not exceed a small part of 10 CFR 100, i.e., 30 REM to the thyroid.

In order to evaluate the dose consequence for the SGTR event, explicit modeling of the transient is not performed. The NSSS response for the SGTR with LOP event presented in UFSAR Section 15.6.3.2 was conservatively assumed to apply for the SGTR event. The dose calculation for the loss of offsite power event was modified with the assumption that the start of the cooldown at 2081 seconds (as depicted in Table 15.6.3-1), is conducted with the Steam Bypass Control System (SBCS) to the condenser instead of the ADVs for the SGTR with LOP event. The activity released to the environment is through the condenser with a DF of 100. With the exception of the performance of radiological consequences, the details outlined below for the SGTR with LOP event including the assumptions applies for the SGTR event. Thus only the radiological consequences are reported below.

15.6.3.1.1 Radiological Consequences

A. Results

The reported values for the 2-hour EAB and the 8-hour LPZ thyroid inhalation doses for the PIS and the GIS cases are presented in Table 15.6.3-1a.

Table 15.6.3-1a
RADIOLOGICAL CONSEQUENCES FOR THE SGTR EVENT

Event Case	Evaluation Period & Location	Dose (REM)
GIS	0-2 hrs at EAB	2.9
	0-8 hrs at LPZ	0.9
PIS	0-2 hrs at EAB	6.2
	0-8 hrs at LPZ	1.8

15.6.3.1.2 Conclusions

The radiological releases calculated for the SGTR event were demonstrated to be within the SRP Section 15.6.3 guidelines. Specifically, the calculated dose for the GIS does not exceed 30 REM (small part of 10 CFR 100 limit) for the thyroid.

15.6.3.2 Steam Generator Tube Rupture With a Loss of Offsite Power and a Single Failure

15.6.3.2.1 Identification of Causes and Frequency Classification

The SGTR with a LOP and a SF event is initiated by the rupture of a steam generator tube, resulting in a failure of the barrier between the RCS and the main steam system. It employs the conservative assumptions of the Standard Review Plan as described in Reference 2 (e.g., loss of offsite power, accident meteorology, iodine spiking, etc.). However, it also assumes that the challenge to the plant is enhanced by actions and failures beyond those postulated by Part 15.6.3 of the Standard Review Plan (Reference 9), as described below.

The analysis of the event postulates that the operators open the ADVs on both steam generators, at which time the ADV on affected steam generator runs to the full open position and sticks full open for the duration of the transient. This ADV is presumed to remain full open despite the availability of control systems that would close the ADV as well as a hand wheel which could be used by the operators to manually close the ADV.

A SGTRLOPSF is classified as a limiting fault event, whose occurrence is not expected during the lifetime of the plant, however, the event is postulated because the consequences include the potential for the release of significant amounts of radioactive materials. These releases cannot result in radiological doses that exceed the 10 CFR 100 limits.

15.6.3.2.2 Sequence of Events and Systems Operation

Integrity of the barrier between the RCS and main steam system is significant from a radiological release standpoint. The radioactivity from the leaking steam generator tube mixes with the shell-side water in the affected steam generator. Prior to turbine trip, the radioactive water is transported through the turbine to the condenser as steam, where the non-condensable radioactive materials are released via the condenser air removal pumps. Following the reactor trip and turbine trip followed by the postulated LOP, the condenser is unavailable. As a result, the radioactive fluid is released through the MSSVs or ADVs.

Table 15.6.3-1 provides a sequence of events for the SGTRLOPSF, from the initiation of the break to the attainment of SDC entry conditions.

The double-ended break of a steam generator tube results in a primary-to-secondary leak rate that exceeds the capacity of the charging pumps. The automatic operation of the PLCS reduces the letdown flow to a minimum value less than a minute into the event.

As a result of the inventory loss, pressurizer level (See Figure 15.6.3-5) and RCS mass gradually decreases from its initial value (See Figure 15.6.3-7). The RCS pressure also decreases (See Figure 15.6.3-2). The backup heaters are energized by the action of the PPCS to mitigate against further depressurization and the PLCS starts the third charging pump.

Following the rupture of the steam generator tube, coolant begins leaking from the RCS into the steam generators (See Figure 15.6.3-10) and the RCS continues to depressurize (See Figure 15.6.3-2). The decrease in RCS pressure typically results in a CPC trip on margin to hot-leg saturation. The auxiliary trip in the CPC (Primary Pressure out of Analyzed Range - Low) and the Low Pressurizer Pressure Trip in the Plant Protection System could also occur. Sensitivity studies for trip times showed an early trip produces more adverse radiological consequences, principally because the early trip results in the ADVs being opened sooner by the operators. A manual trip at 100 seconds was assumed in order to bound

automatic trip time, estimated to occur somewhat later in the transient.

The reactor trip causes the power to drop rapidly (See Figure 15.6.3-1). It also causes the turbine to trip and the main feedwater flow to drop rapidly to zero. When the reactor and turbine trips occur, with the SBCS in manual mode, the secondary system begins to pressurize (See Figure 15.6.3-8) until the MSSVs open[1], mitigating further secondary system pressure increases and releasing steam directly to the atmosphere. The LOP occurs three seconds after the turbine trip and the plant loses the turbine load, normal feedwater flow, forced reactor coolant flow, condenser vacuum and steam generator blowdown capability. Heat removal is initially achieved by steaming directly to atmosphere through the MSSVs and ADVs (See Figure 15.6.3-14) and AFW flow (See Figure 15.6.3-9), which is automatically initiated to both steam generators. Non-condensable material released from the condenser and the steam releases directly to the atmosphere from the MSSVs contribute to the dose consequences.

[1] Figure 15.6.3-8 does not display the peaks of the secondary pressure spikes just after the LOP that result in the opening of the MSSVs. This is a result of a lower frequency of data recording (50 second interval) for plot files for the long-term response and the fact that these pressure spikes are only about 20 seconds long.

Based on the standard post-trip procedure for PVNGS, as the pressure in the steam generators rises above the allowable range, the operator opens one ADV in each steam generator after the trip to minimize cycling of the MSSVs. Earlier opening of the ADVs results in more adverse dose consequences since it increases the release to the atmosphere. The time between the trip and operator action to open the ADVs is assumed to be 2 minutes to bound operating experience and simulator scenarios. The ADV on the affected steam generator is assumed to go to a full open position, causing an increased blowdown of the affected steam generator.

The continued decrease in RCS and pressurizer pressure results in a SIAS, and HPSI flow to the RCS begins. The pressurizer empties due to the primary-to-secondary leakage and post-trip RCS liquid shrinkage. Decreasing steam generator pressure due to flow through the ADVs results in a MSIS on low steam generator pressure being generated. The MSIS results in the closure of the MSIVs, causing a pressure differential to grow between the two steam generators as the flow through the fully-open ADV on the affected steam generator drives its pressure down faster than that of the unaffected steam generator due to the lower flow through the partially-open ADV on that steam generator. As the pressure differential increases between the two steam generators, the AFW to the affected steam generator is terminated by the ΔP lockout.

The LOP and the RCS flow coastdown result in the reduction of flow to the reactor vessel upper head region. This region

becomes thermal-hydraulically de-coupled from the rest of the RCS, and due to flashing caused by the depressurization and boil off from the metal structure-to-coolant heat transfer, voids begin to form in this region (See Figure 15.6.3-6) as the saturation pressure falls below the fluid temperature (See Figure 15.6.3-4). HPSI flow delivery to the RCS halts further RCS shrinkage and depressurization and the voids eventually collapse.

The remainder of the transient is determined by the diagnostic and mitigating operator actions, which are based on the EOP instructions for SGTR and the Functional Recovery Procedures. Timing those operator actions is consistent with or conservative to the times described in ANSI/ANS-N58.8-1984 (Reference 3).

The operator first diagnoses the excessive steam demand and closes the ADVs to prevent excessive cooldown. It is assumed that the ADV on the affected steam generator sticks open while the ADV on the unaffected steam generator closes. Diagnosis of a SGTR with Excess Steam Flow is facilitated by any or all of the following monitors and alarms:

- Rise in Condenser Off-Gas Monitor or alarm
- Rise in Steam Generator Blowdown Monitor or alarm
- Rise in Main Steam Line Monitor or alarm
- Rise in Main Steam Line N-16 Monitor or alarm
- Rise in activity in Steam Generator liquid sample

- Mismatch between feed flow and steam flow

The major post-trip EOP operator actions considered are discussed below in detail.

A. Manual Reactor Trip

Although the reactor trip by CPCs on margin to hot-leg saturation or on low pressure, or by RPS on low pressurizer pressure, is expected due to RCS depressurization during a SGTR event, an operator action to manually trip the reactor at an earlier time is assumed in order to bound the timing of automatic reactor trips, which are estimated to occur later in the transient. This is an adverse operation action, principally because the earlier trip results in the ADVs being opened sooner by the operators.

B. Opening of ADVs

In order to preclude a direct challenge to the MSSVs, the operators open the ADVs (on both steam generators) after the reactor trip, as instructed in the procedures, to relieve the pressure on the steam generators since, because of the LOP, the SBCS is not available. This is also an adverse action since an earlier opening of the ADVs results in increased release to the atmosphere, and thus, more adverse dose consequences. A bounding value of 2 minutes for the time after trip to manually open the ADVs is assumed based on operating experience and simulator scenarios.

C. Diagnose the Event and Stabilize the Plant

The operators first diagnose the Excess Steam Demand (ESD) and take action to close the ADVs to prevent excessive cooldown. This action is assumed to occur approximately seven minutes after the reactor trip and is consistent with expected operator action to ensure adequate RCS heat removal. The analysis assumes that a diagnosis of a SGTR with a continued ESD caused by the stuck-open ADV, will take approximately 15 minutes after indication of double ended guillotine break of a steam generator tube by any of the alarms and monitors listed above, after which operator actions follow guidance from the appropriate PVNGS procedure.

D. Functional Recovery Strategy

At 15 minutes post-trip, the operators are assumed to override the AFAS on the affected steam generator, which has blocked flow to the affected steam generator based on the pressure difference between the two steam generators, and establish dedicated flow from both AFW pumps to the affected steam generator until the steam generator level recovers above 40% NR. This action is consistent with the procedural strategy in response to indications of a SGTR with an ESD (due to uncontrolled steaming to atmosphere from the affected steam generator). The total AFW flow specified in the EOP for a SGTR with an ESD is between 1360 and 1600 gpm. The lower value was used to delay covering the steam generator tubes thereby maximizing the radiological releases when AFW is in manual.

E. Post-Tube Covering Strategy

After the affected steam generator level is above 40% NR, the operators are assumed to initiate a conservatively low AFW flow of 500 gpm to the unaffected steam generator. In accordance with the EOPs, the operator maintains the affected steam generator level between 40% and 60% NR, thus covering the U-tubes, for the remainder of the event by adjusting AFW flow as necessary. The operator is assumed to shift the control of heat removal to the unaffected steam generator when the affected steam generator U-tubes are covered.

F. Cooldown and Depressurize RCS to SDC Entry Conditions

The cooldown and depressurization of the RCS is predominantly due to the stuck-open ADV. However, the analysis assumes operator actions to minimize the cooldown and depressurization to remain within the restriction of EOP guidelines. Specifically, adequate SCM is maintained by utilization of HPSI pumps and pressurizer class back-up heaters.

In addition to maintaining adequate subcooling, the operator is simultaneously responsible for assuring adequate RCS inventory is maintained. Specifically, the EOPs require the operator to retain specified levels in the pressurizer and the upper head before throttling back the HPSI flow. Accordingly, the pressurizer level and the SCM (See Figure 15.6.3-15) in the analysis are maintained above the level required by the EOPs.

Table 15.6.3-1
SEQUENCE OF EVENTS FOR THE LIMITING SGTRLOP SINGLE FAILURE EVENT (3990 MWt RTP with RSG) (Page 1 of 2)

Time (sec)	Event
0	SGTR occurs
43	Letdown control valve throttled to minimum
79	Backup pressurizer heaters energized
100	Manual reactor trip
100	Reactor trip breakers open
100	Turbine trip occurs
100.6	SCRAM CEAs begin falling
102	MSSVs open
104	LOP occurs
105	Maximum steam generator pressure
109	Steam generator level reaches AFAS setpoint in unaffected steam generator
110	Steam generator level reaches AFAS setpoint in affected steam generator
155	AFW initiated to unaffected steam generator
156	AFW initiated to affected steam generator
162	MSSVs close
220	Operator initiates plant cooldown by opening one ADV on each steam generator. The ADV on one steam generator (affected) instantaneously opens fully
245	Pressurizer pressure reaches SIAS setpoint
245	SI flow initiated with no delay
251	MSIS actuation, secondary pressure

Table 15.6.3-1
SEQUENCE OF EVENTS FOR THE LIMITING SGTRLOP SINGLE FAILURE EVENT (3990 MWt RTP with RSG) (Page 2 of 2)

Time (sec)	Event
268	AFAS 1 lockout on high ΔP
317	Voids begin to form in the upper head
520	Operator shuts ADV on the unaffected steam generator to prevent excessive cooldown
608	AFAS 2 reset on high steam generator level
847	Voids collapsed in the upper head
1000	Operator overrides the ΔP lockout and initiates dedicated AFW flow of 1360 gpm to affected steam generator
1900	Operator opens pressurizer head vent
2716	HPSI flow throttled to maintain SCM less than the limit
2779	With level in the affected steam generator above the top of U-tubes, the operator secures AFW flow to affected steam generator and initiates AFW to unaffected steam generator
12610	Class back-up heaters energized to maintain target harsh SCM criteria
26014	ADV opened in the unaffected steam generator in preparation of approaching SDC entry conditions
26260	SDC entry conditions reached in the affected loop
28800	Operator activates SDC system

Although SDC entry conditions may be reached in less than 8 hours, the event was simulated for 8 hours to maximize the dose consequences.

15.6.3.2.3 Core and System Performance

A. Mathematical Model

The thermal-hydraulic response of the NSSS to the SGTRLOPSF was simulated using the CENTS computer code (described in UFSAR Section 15.0.3.1.3.2). The features incorporated in the analytical model include the following:

- secondary releases from both the MSSVs and ADVs
- early operator action for manual trip
- early operator action to open the ADVs
- a series of operator actions to cover the steam generator tubes
- time delays for operator functional recovery actions
- delay in reaching shutdown cooling (chosen to maximize 8-hour steam release)

B. Input Parameters and Initial Conditions

The input parameters and initial conditions used to analyze the NSSS response to a SGTRLOPSF are listed in Table 15.6.3-2. The initial conditions for several process variables were varied parametrically in order to determine the values or assumptions that would produce the most adverse radiological consequences. The initial condition choices that would contribute to a higher

calculated radiological release to atmosphere are discussed below.

- Maximum rated core power - Maximizes the initial heat content of the primary system and maximizes the energy removed from the secondary system. This leads to an increased heat up and pressurization of the primary and secondary systems, which increases the secondary system releases.

- Maximum core inlet temperature - Maximizes the initial secondary system pressure, which increases the steaming through the MSSVs, and maximizes the amount of heat that must be removed during the 2- and 8-hour cooldown intervals by steam releases.

- Minimum RCS flow rate - Maximizes the temperature differential across the core, which maximizes the energy that must be removed by steaming through the steam generators. This increases the activity releases through the MSSVs and ADVs.

- Maximum pressurizer pressure - Maximum initial pressurizer pressure increases the leak rate from the RCS to the affected steam generator, which increases the releases from the secondary system.

- Initial steam generator mass - Low initial steam generator water mass contributes to more adverse radiological consequences by allowing the specific activity in the

steam generators to increase more rapidly because of the leak.

- Minimum scram worth at hot full power – Minimizes the rate of decreasing core power after the reactor trip and therefore increases the heat load to be removed by secondary system releases.

- Safety Injection – Maximizing the HPSI flow will result in higher RCS pressures and increased leakage to the affected steam generator. The SIAS setpoint was set high to provide an early delivery of HPSI flow. No delay time was applied to this signal. In addition, two HPSI pumps were assumed to be available, thus maximizing the flow delivered to the RCS upon SIAS signal.

The SGTRLOPSF transient is not sensitive to the values of MTC and FTC, with regards to radiological consequences, as there are no changes in the fuel or moderator temperatures prior to reactor trip. The most negative MTC and the least FTC were used.

The major assumptions regarding systems operation during the event are summarized below.

- After reactor trip, the main feedwater flow is ramped down to zero in one second.

- Subsequent beneficial operator actions are delayed by times that are also consistent with the ANSI Standard (Reference 3).

- MSSV setpoints are set at their lowest lift pressure in order to make the MSSVs open and release steam to the atmosphere early.
- After the LOP and RCPs coast down, charging pumps are de-energized, letdown is isolated and heaters and sprays are lost.
- The LOP also causes loss of condenser vacuum, loss of steam bypass control valves, and loss of forced flow (RCP coastdown).
- When the ADVs are opened on both steam generators, one of the ADVs is assumed to fail wide open. Most of the cooldown comes about by steaming from the affected steam generator, with the unaffected steam generator being used to control cooldown to SDC entry conditions.
- The AFW system is activated at 20% level wide range and shuts off at 30% level wide range prior to operator action.
- Two AFW pumps are assumed to be available to supply feedwater to either steam generator. No credit is taken for the third 1E-powered AFW train.
- Two HPSI pumps are assumed to be available subsequent to the generation of a SIAS. The SIAS comes from a low pressurizer pressure signal and has no time delay, so that it results in maximum HPSI flow.

Table 15.6.3-2

PARAMETERS USED FOR THE LIMITING SGTRLOP SINGLE FAILURE EVENT
(3990 MWt RTP with RSG Case)

PARAMETER	Value
Initial core power (% of RTP)	102
Initial core inlet temp (°F)	568
Initial pressurizer pressure (psia)	2325
Initial RCS flow (% of design)	95
Initial pressurizer level (%)	53
Initial steam generator level (% WR)	41
MTC ($\Delta\rho$/°F)	-4.0×10^{-4}
FTC	Least negative
Kinetics	Minimum β
CEA worth at trip - WRSO (%$\Delta\rho$)	-8.0
Fuel rod gap conductance (Btu/hr-ft^2-°F)	518
Plugged steam generator tubes	0
SGTR break location	at the tube sheet
Single failure	Stuck-Open ADV (at full open position)
LOP	Yes

- The pressurizer 250 kW class 1E backup heaters are cycled as necessary to maintain adequate SCM.
- The pressurizer head vent system is manually controlled by the operators, as necessary, to depressurize the RCS during the event.
- The SBCS is assumed to be in the manual mode initially.

The event is simulated so that the SDC entry conditions are reached at about 8 hours after initiation of the double-ended rupture of the steam generator U-tube.

C. Results

Table 15.6.3-1 presents a typical sequence of events for the SGTRLOPSF event. Typical transient response of key NSSS parameters as a function of time is presented in Figures 15.6.3-1 to 15.6.3-15 for this limiting fault event.

The calculated transient minimum DNBR is greater than the DNBR SAFDL value of 1.34. Therefore, fuel cladding damage is not predicted for the limiting fault SGTRLOPSF event.

15.6.3.2.4 RCS Pressure Boundary Barrier Performance

A. Mathematical Model

The computer codes that were employed to evaluate fission product barrier performance (other than fuel cladding) for this limiting fault event are identical to those described in UFSAR Section 15.6.3.2.3.

B. Input Parameters and Initial Conditions

The input parameters and initial condition relevant to barrier performance for this limiting fault event are the same as those presented in Table 15.6.3-2 of UFSAR Section 15.6.3.2.3.

C. Results

Due to depressurization of the primary system, the RCS pressures during the event do not exceed the initial pressure

which is less than 110% (2,750 psia) of RCS system design pressure (2,500 psia). The secondary pressures reach maxima around 1300 psia just after the turbine trip and opening of the MSSVs. Thus, the maximum pressure is less than 110% (1,397 psia) of secondary design pressure (1,270 psia).

Steam generator overfill does not occur because of the single failure of the stuck open ADV on the affected steam generator, and manual control of the ADV on the unaffected steam generator.

15.6.3.2.5 Containment Performance and Radiological Consequences

A SGTRLOPSF is classified as a limiting fault. Offsite radiological dose consequences are limited to 10 CFR Part 100 guideline values. Additionally, radiation exposure for control room personnel are subject to the limits specified in General Design Criterion (GDC) 19 of 10 CFR 50 Appendix A.

Control room radiological assessments for bounding unfiltered in-leakage are presented in UFSAR Section 6.4.7. The evaluation of offsite radiological dose consequences associated with the SGTRLOPSF event is discussed below.

Peak containment pressure is not calculated for this event and would be bounded by the Design Basis Accidents, Loss-of-Coolant Accident and the Main Steam Line Break events (see UFSAR Section 6.2). Since this event results in the depressurization of the primary system, the pressurizer safety valves do not lift. The impact of the releases by the pressurizer vent

system to the containment is small enough that the impact of the radiological release from the containment to the atmosphere has negligible impact on the EAB, LPZ or Control Room doses.

A. Mathematical Model

The mathematical model employed in the evaluation of the radiological consequences resulting from the SGTRLOPSF is based on the general modeling in UFSAR Section 15.0.4 and is described below.

The SGTRLOPSF predicts that steam or liquid will be released from the RCS or main steam system and radioactive material will be present in these discharges. As a result, the SGTRLOPSF is anticipated to result in radiological dose consequences for the off-site general public. Appendix 15B describes a generic activity release model for assessing the radiological consequences of postulated accidents.

To analyze the radiological consequences of the SGTRLOPSF, the steam releases to the environment are extracted from the CENTS simulations of the event. Estimated releases are utilized in the radiological dose analyses, for the purpose of determining thyroid doses at the EAB and at the outer boundary of the LPZ.

The evaluation of the radiological consequences of the SGTRLOPSF assumes a double-ended, guillotine break at the hot side tube sheet of a steam generator U-tube while the reactor is operating at full power. Occurrence of the accident leads to an increase in contamination of the secondary system due to reactor coolant leakage through the ruptured tube. An early

reactor trip is assumed, which causes the turbine to trip and leads to a LOP three seconds after the turbine trip. Prior to LOP, the activity is released to the environment through the condenser. Following the closure of turbine admission valves, the steam generator pressure increases rapidly, resulting in opening of MSSVs and steam discharge as well as activity release through the MSSVs. Venting from the affected steam generator by the MSSVs continues until the closure of MSSVs when the secondary system pressure drops below the MSSV blowdown setpoint. Two minutes after the trip, the operator partially opens one ADV on each steam generator to minimize further challenges to the MSSVs and to stabilize RCS temperature. At this point, one of the ADVs (on affected steam generator) is assumed to open fully and remain open for the remainder of the transient.

For most of the event, the heat extraction occurs through the affected steam generator while the unaffected steam generator releases very little steam. The open ADV dumps the inventory of the affected steam generator and the leakage from the primary loop flashes and is released directly. When operator action to divert all AFW to the affected steam generator is taken, the inventory begins to increase until the U-tubes are eventually covered by liquid. At this point the release rate drops dramatically as the iodine is “scrubbed” by the water. Boil-off of the inventory in the affected steam generator, which is maintained by the operators, and controlled cooling by feeding and bleeding of the unaffected steam generator provides the cooling for the event.

The tube leak in the affected steam generator is minimized when primary-to-secondary pressure differential is reduced with a target of keeping it within 50 psid, in accordance with EOP guidance. For this event, the SDC entry conditions are reached in the affected loop prior to 8 hours. However, the transient is simulated for 8 hours in order to maximize dose consequences.

The analysis of the radiological consequences of a SGTRLOPSF considers the most severe release of secondary activity as well as primary system activity leaked from the tube break. The inventory of iodine and noble gas fission product activity available for release to the environment is a function of primary-to-secondary coolant leakage rate, the iodine spiking factor, the initial condition of the fuel in the core and the mass of steam discharged to the environment. Conservative assumptions are made for all these parameters.

B. Input Parameters and Initial Conditions

The assumptions and parameters used to determine the activity releases and offsite doses for a SGTRLOPSF are discussed below.

1. Accident doses are calculated for two different iodine spiking assumptions: (a) an event-Generated Iodine Spike (GIS) coincident with the initiation of the event and (b) a Pre-accident Iodine Spike (PIS).

2. Technical Specification limits for the initial primary system (1.0 μCi/gm) and secondary system activity (0.1 μCi/gm) concentrations are assumed. Transient

primary system specific activity is calculated using the dilution from HPSI flow.

3. A spiking factor of 335 is employed for the GIS at the time of event initiation.

4. A CVCS purification efficiency of 100% is assumed based on the bounding purification flow rate of 150 gpm.

5. The I-131 decay constant is 9.97×10^{-7} sec^{-1}.

6. For the PIS condition, a PIS factor of 60 for the primary system activity concentration is employed.

7. Total allowable primary-to-secondary leakage of 1 gpm is conservatively assumed to be in the unaffected steam generator for the duration of the transient, instead of 0.5 gpm per steam generator.

8. In the unaffected steam generator, the primary-to-secondary is released to the atmosphere with the Decontamination Factor (DF) of 100.

9. In the affected steam generator, the portion of the leaking primary fluid that flashes to steam upon entering to the steam generators is assumed to be released to the atmosphere with a DF of 1.0, while unflashed portion is assumed to mix with the steam generator inventory and released to the atmosphere with a DF of 100.

10. The portion of the leaking primary fluid that flashes to steam is calculated based on the enthalpy of the leak

(See Figure 15.6.3-12). During periods of U-tube uncovery, the flashing fraction is set to 1.0.

11. The atmosphere dispersion factors employed in the analyses are 2.3 x 10^{-4} sec/m^3 for the EAB and 6.4 x 10^{-5} sec/m^3 for the LPZ.
12. The Dose Conversion Factors (DCFs) for dose equivalent Iodine are derived from ICRP-30 (Reference 4).
13. The primary-to-secondary leakage through the tube rupture (See Figure 15.6.3-11), secondary mass inventory (See Figure 15.6.3-13), and secondary system releases from ADVs (See Figure 15.6.3-14) and MSSVs are calculated from the transient simulation of the event.
14. Prior to LOP, the activity is released to the environment through the condenser with a DF of 100.

C. Results

The reported values for the 2-hour EAB and the 8-hour LPZ thyroid inhalation doses for the PIS and the GIS cases are presented in Table 15.6.3-3. The calculated EAB and LPZ doses are within the values of 10 CFR 100. These results bound PVNGS Units operating at a RTP of 3990 MWt or less.

Table 15.6.3-3

RADIOLOGICAL CONSEQUENCES FOR THE LIMITING SGTRLOPSF EVENT

Event Case	Evaluation Period & Location	Dose (REM)
GIS	0-2 hrs at EAB	124
	0-8 hrs at LPZ	84
PIS	0-2 hrs at EAB	294
	0-8 hrs at LPZ	91

15.6.3.2.6 Conclusions

The dynamic behavior of important NSSS parameters during a typical event was presented in Figures 15.6.3-1 through 15.6.3-15. The radiological releases calculated for the limiting SGTR event (SGTR with a loss of offsite power and a fully stuck open ADV) were demonstrated to be within the 10 CFR 100 guidelines.

The RCS and secondary system pressures were shown to be below 110% of the design pressure limits, thus assuring the integrity of these systems.

Additionally, it was demonstrated that there would be no violation of the fuel thermal limits, since the minimum DNBR remains above the DNBR SAFDL value throughout the duration of the event.

15.6.4 RADIOLOGICAL CONSEQUENCES OF MAIN STEAM LINE FAILURE OUTSIDE CONTAINMENT (BWR)

Not applicable.

15.6.5 LOSS-OF-COOLANT ACCIDENTS

Refer to subsection 6.3.3 and paragraphs 6.2.1.5, 6.3.3.2.1, and 6.3.3.3 for loss-of-coolant accident (LOCA) performance evaluations of reactivity control, reactor heat removal, primary system integrity, and secondary system integrity. Also refer to the above sections for LOCA analysis of effects and consequences as they pertain to releases from the primary, secondary, and safety injection systems.

The auxiliary feedwater system is described in subsection 10.4.9. A SIAS will actuate control room and fuel building essential ventilation systems. See sections 6.4 and 9.4 for details and sections 18.II.E.1.1 and 18.II.E.1.2 for reevaluation of the auxiliary feedwater system with respect to TMI lessons learned. A CIAS or CPIAS will terminate the containment power access purge, as described in section 9.4.

15.6.5.1 Identification of Event and Causes - Small Break LOCA

Refer to subsection 6.3.3.

15.6.5.2 Sequence of Events and Systems Operation - Small Break LOCA

Seven breaks were analyzed to characterize the radiological consequences. The spectrum of seven SBLOCA break sizes

included span of the limiting break size for ECCS (0.05 ft^2) with most limiting peak cladding temperature, to break size with no core uncovery (0.01 ft^2 or less), to a 1 inch diameter break (0.005 ft^2). These analyses are specifically done for radiological assessment of SBLOCA and include the effect of ZIRLO fuel, which is bounding for both ZIRLO and Zircaloy-4 clad fuel.

15.6.5.2.1 Evaluation Model

The C-E computer codes CEFLASH - 4AS for primary coolant system thermal hydraulics, CONTRANS2 for containment pressure evaluation, and Bechtel computer code LOCADOSE for dose assessment are used for this Evaluation Model.

15.6.5.2.2 Release Pathways

The release of radioisotopes is postulated through the following pathways.

- Through containment leakage which results from release of primary coolant to the containment from the ruptured pipe. This pathway includes:
    - unfiltered discharge through the power access purge lines until such time as the valves are closed due to generation of CIAS or CPIAS,
    - Leakage through the containment structure at Technical Specification leak rates.

- Release of contaminated steam from the secondary system. This pathway includes:
    - Release of steam contaminated by leakage of primary coolant to the secondary side. The primary-to-secondary leakage is assumed to be at a rate of 1 gpm, and
    - Release from the secondary system inventory [feedwater] at Technical Specification concentration of 0.1 uCi/gm Dose Equivalent I-131.
    - Release of contaminated sump inventory from leakage of ESF components outside containment during recirculation phase.

15.6.5.2.3 Description of Results

The results of these analyses show that all SBLOCA transients achieved containment isolation and containment spray actuation before core uncovery, that is before the possibility of large radioactive release resulting from fuel cladding damage that core uncovery may cause. The 0.03 ft^2 break was determined to be the smallest size break that would exhibit cladding rupture behavior. Table 15.6.5-1 sheet one provides a summary of calculated times to core uncovery, CIAS, CSAS and core recovery. This information is used in the dose assessment evaluation to determine the magnitude of source term and

duration of release from containment power access purge prior to containment isolation.

The following are assumptions used to evaluate the RCS and containment behavior during SBLOCA:

- ALL breaks are in RCS cold leg; potential hot leg breaks are less limiting.
- Loss of offsite power at time of reactor trip.
- Isolation of Main Steam and Main feed at time of reactor trip.
- RCP trip on loss of offsite power.
- SIAS on low pressurizer pressure.
- Single failure: Loss of one diesel
- Auxiliary feedwater actuation to maintain RCS heat removal.
- Containment power purge is operating at start of this event and these valves would be isolated at initiation of CIAS (for hydraulic analysis).
- SI spillage from broken cold leg is assumed to have insignificant effect on containment responses.
- No operator action has been assumed.

Radiological consequences associated with a spectrum of small break LOCAs have been evaluated using computer code LOCADOSE in accordance with the guidelines of Regulatory Guide 1.4, Regulatory Guide 1.77, and SRP Section 15.6.5. This evaluation

is partitioned in to two groups: break sizes that would result in core uncovery and breaks that would not result in core uncovery. The limiting break's thyroid dose due to inhalation and whole-body gamma dose due to immersion are presented in table 15.6.5-1. Two break sizes were evaluated 0.03 ft^2 and 0.005 ft^2 Fuel-clad failure was postulated for the first case, fuel-clad rupture was not predicted for the 0.005 ft^2 break. Doses are calculated using ICRP-30 iodine inhalation dose conversion factors and regulatory guide 1.109 dose conversion factors for all other path ways and isotopes.

The following are a list of assumptions used to evaluate the consequences of the spectrum of SBLOCA,

- Core power was set at an elevated level of 102% of uprated licensed power (3990 MWt).
- The core activity level was based on the "bounding" source term using TID-14844 methodology.
- The initial primary system activity level was based on the maximum activity in the reactor coolant due to continuous full power operation with 1% failed fuel, with iodine at a pre-existing iodine spike level of 60 uCi/gm DEQ I-131.
- Fuel-clad failure was assumed for the case where core uncovering was observed [0.03 ft^2 break].
- For the case where fuel failure was postulated [0.03 ft^2 break]; all gaseous constituents in the fuel-clad gap were released into the primary coolant. The amount of activity

accumulated in the fuel-clad gap was assumed to be 10% of the core iodine and noble gases [Reg. Guide 1.77].

- The offsite [EAB & LPZ] and the control room atmospheric dispersion parameters [X/Qs] were based on the updated site specific meteorological data [refer to section 2.3-31],
- The containment power access purge closed within 8 seconds (8 seconds includes: instrument response time, ESF loop delay time and valve closure time) upon receipt of a containment isolation actuation signal (CIAS) or CPIAS. Time to generate an isolation signal is conservatively set to the elapsed time from the initiating event to time for containment pressure to reach 5 PSIG.
- Control room essential filtration system was activated within 50 seconds upon receipt of a SIAS.
- Spray water was delivered to the containment atmosphere in 92 seconds upon receipt of a containment spray actuation signal (CSAS). The time for the containment pressure to reach a CSAS setpoint ranged from 282 to 10,000 seconds depending upon the size of the break.
- Containment leakage rate was set at value of 0.1 vol% per day for the first 24 hours, and at half of that rate thereafter per regulatory guide 1.4.
- Primary-to-secondary leakage rate was set at value of 1.0 gpm (total). Duration of 3 hours was assumed for the break size

of 0.03 ft^2. For 0.005 ft^2 break a value of 8 hours was assumed based on natural circulation cooldown.

- ESF component leakage rate during recirculation phase was conservatively set at a constant rate of 3,000 ml/hr. This pathway only applies to the fuel-clad failure case because the smaller break does not result in sump recirculation.

15.6.5.3 Analysis of Effects and Consequences

For the break for which fuel cladding failure was postulated (0.03 ft^2), the main dose contributor was the primary fluid that leaked to the secondary side, following the release of 100 percent of the gas gap activity into the primary.

For a 0.005 ft^2 break, fuel-clad rupture was not predicted. Although the source term was based on design RCS activity level, with pre-existing iodine spike, a relatively higher thyroid dose for control room was noted which was due to extended release through the mini-purge and a fairly long isolation time for the control room.

For all cases analyzed (refer to table 15.6.5-1), the offsite doses remained bounded by the large break LOCA doses that are presented in table 15.6.5-2 and the control room doses were below GDC 19 exposure limits.

Table 15.6.5-1
RADIOLOGICAL CONSEQUENCES OF A SMALL BREAK LOCA
Summary of Calculated Time[1] vs. Break Size

a. Whole body doses do not included contribution from direct/ scatter shine (containment, outside cloud and piping/filter dose). SBLOCA direct and scatter doses are bounded by Large LOCA see table 15.6.5-2.

b. The bounding leakage and thyroid dose is given in section 6.4.7.

15.6.5.4 Identification of Event and Causes - Large Break LOCA

Refer to subsection 6.3.3.

15.6.5.5 Sequence of Events and Systems Operation - Large Break LOCA Dose Calculation

Containment power access purge through an 8-inch penetration will be terminated within 12 seconds after generation of CIAS CPIAS as described in subsection 6.5.3.1.

A SIAS will initiate a switch to the filtered recirculation and filtered makeup mode of control room ventilation as discussed in section 6.4. A SIAS will initiate filtered ventilation of the lower region (below 100-foot elevation) of the auxiliary building as discussed in section 9.4. Since recirculation loop equipment and piping for safety injection and containment sprays in the auxiliary building is located below the 100-foot elevation, leakage from active recirculation equipment is filtered prior to release to the environment.

For the limiting large break LOCA, the reactor trip will result in a turbine trip, and a subsequent loss of offsite power will result in the loss of main feedwater flow. As result of the loss of feedwater and due to fast depressurization of RCS as result of the initiating event, high containment pressure would generate a CIAS and then MSIS actuation. At this time the primary coolant and containment environment would be at lower pressure than the secondary side of the steam generators and the secondary would become a heat source for the primary system. The steam generators would then quickly depressurize

due to containment spray system and possible use of ADVs. During this time the leakage would change direction from the primary coolant to the secondary side of the steam generators. This would result in a leakage path from containment to the environment.

15.6.5.6 Analysis of Effects and Consequences - Large Break LOCA Dose Calculation

It is assumed that there is a preexisting RCS iodine spike of 60 μCi/cc dose equivalent I-131 since there will not be any fuel cladding rupture within the 20 seconds after initiation of the large break LOCA. This activity is instantaneously mixed with the containment atmosphere and available for release via the power access purge. The containment airborne radioactivity inventory will be affected by four factors: leakage, radioactive decay, plateout and sprays. No credit has been taken for spray removal of organic iodine. Refer to section 6.5 for a discussion of spray effectiveness. It is assumed that the containment leaks at the maximum rates allowed by the Technical Specifications, i.e., 0.1 vol %/d for the first 24 hours and half of that rate thereafter. This leakage, when combined with initial releases, will result in potential doses offsite and in the control room. Contribution from the containment leakage through the steam generators is evaluated. The offsite and control room doses are calculated with a single failure of a GDC 57 valve or a stuck open ADV. The leakage from containment environment through the primary system to the secondary system is conservatively assumed to be containment

atmosphere at post large break LOCA conditions. The flowrate is calculated as that produced by leaking through a steam generator tube fault equivalent in size to that which would allow the 1 gpm RCS liquid at normal operating plant conditions. This rate is used for the first 24 hours. The leakage rate is assumed to be half that for the duration of the analysis. The analysis does not take any credit for iodine partition factors or operator action to flood the steam generator. The doses are listed in table 15.6.5-2.

Additionally, there will be exposure offsite and in the control room from the filtered release of recirculation leakage. The calculated leakage is based on the containment sump inventory as per table 15.6.5-2. The doses from recirculation releases are listed in table 15.6.5-2. The total combined doses to an individual offsite and to control room operators following a postulated large break LOCA are also presented in table 15.6.5-2.

The release of radioisotopes, due to LOCA, is postulated through the following pathways:

1- The containment leakage which results from the release of primary coolant to the containment from the postulated break. This pathway includes: (1) unfiltered discharge through the power access [mini-purge] intake and exhaust lines until such time the valves are closed due to generation of a CIAS, (2) leakage through the containment structure at Technical Specification leak rates, and (3)

release of containment air through depressurized secondary system.

2- release of contaminated sump inventory due to leakage from ESF systems outside containment during the recirculation phase. This pathway includes: (1) ESF component leakage outside containment, and (2) back-leakage of recirculating sump water to refueling water storage tank during long term cooling, post RAS due to check valve CH-V-305 and CH-V-306 leakage or any other SI system leakage to the refueling water storage tank [IN 91-56].

In addition to the above contributors, control room doses are evaluated for radiological exposure due to direct dose from containment, ESF piping, shine from outside cloud and dose due to accumulation iodine on essential control room HVAC filtration filters. Table 15.6.5-2 provides detailed information on key parameters used to evaluate the consequences of LOCA and a summary of integrated doses at different locations.

15.6.5.7 Conclusions

Based on use of very conservative assumptions regarding spray effectiveness, containment ventilation, and leakage, as well as conservative fuel failure models, the offsite doses presented in table 15.6.5-2 for LOCA are substantially below 10CFR100 limits.

15.7 RADIOACTIVE MATERIAL RELEASE FROM A SUBSYSTEM OR COMPONENT

15.7.1 WASTE GAS SYSTEM FAILURE

15.7.1.1 Identification of Event and Causes

The most limiting waste gas system accident is defined as an uncontrolled release to the atmosphere of the contents of one waste gas decay tank. The gaseous radwaste system is described in section 11.3.

This accident is considered a limiting fault and is analyzed to define the worst consequences of a gaseous release that could result from any malfunction in the gaseous radwaste system. The accident as described assumes a combined failure of the waste gas decay tank and of the normal (non-ESF) radwaste building ventilation (filtration) system described in section 9.4.

15.7.1.2 Sequence of Events and System Operation

A sequence of events diagram for this accident is provided as figure 15.7.1-1. The event is characterized as a rapid release of the contents of a single waste gas decay tank to the environment (Puff model). It is postulated that the tank contains its maximum inventory and that no action is taken to mitigate the consequences of the event.

15.7.1.3 Analysis of Effects and Consequences

The instantaneous release of the waste gas decay tank inventory will result in the radiological consequences shown in table 15.7.1-1. No credit has been taken for control room essential HVAC System.

15.7.1.4 Conclusions

As noted in table 15.7.1-1, the radiological consequences are less than 1% of 10CFR100 limits even assuming coincident failure of the normal (non-ESF) radwaste building ventilation system.

15.7.2 RADIOACTIVE LIQUID WASTE SYSTEM LEAK OR FAILURE (RELEASE TO ATMOSPHERE)

The most limiting liquid waste system leak or failure would be the failure of the representative outside liquid storage tank. Refer to subsection 15.7.3.

15.7.3 POSTULATED RADIOACTIVE RELEASES DUE TO LIQUID-CONTAINING TANK FAILURES

15.7.3.1 Identification of Event and Causes

The most limiting radioactive liquid tank failure would be the uncontrolled release of liquid from a representative outside liquid storage tank. The representative outside liquid storage tank is a hypothetical tank that bounds all possible outside liquid storage tank ruptures under the absolute worst case conditions. The tank is assumed to contain the Technical Specification maximum allowable curie content, with the mixture of isotopes representative of the isotopic mixture present in RCS fluid at 600 EFPD, no gas stripping, and with 1% failed fuel. The use of the RCS source terms are intended to remove any uncertainty based on operational considerations in the liquid processing systems that feed the outside liquid storage tanks that are part of the chemical and volume control system (CVCS) as described in subsection 9.3.4, or are part of the liquid radwaste system (LRS) as described in section 11.2. In addition to use of the RCS isotopic inventory mixture, noble gases are included in the representative outside liquid storage tank inventory and are available for release. This

conservative practice will bound all possible outside liquid storage tank ruptures under the worst case conditions.

A nonmechanistic failure that instantaneously releases 100% of the tank's contents to the environment is postulated.

15.7.3.2 Sequence of Events and System Operation

A sequence of events diagram for this accident is provided as figure 15.7.3-1. The event is characterized as a rapid release of the representative outside liquid storage tank contents to the environment. It is postulated that no action is taken to mitigate the consequences of the event. Dose modeling methodology is described in subsection 15B.6.5.

15.7.3.3 Analysis of Effects and Consequences

The radiological consequences of the representative liquid storage tank rupture are described in table 15.7.3-1. The instantaneous release of the representative liquid storage tank gaseous inventory will result in radiological consequences less than waste gas system failure as described section 15.7.1.3.

Table 15.7.3-1

RADIOLOGICAL CONSEQUENCES OF A REPRESENTATIVE LIQUID STORAGE TANK FAILURE

Parameter	Value
Results	Rem
EAB (0 - 2 hr) Thyroid	1.184E-02
EAB (0 - 2 hr) Whole Body	4.594E-03
LPZ (0 - 8 hr) Thyroid	3.293E-03
LPZ (0 - 8 hr) Whole Body	1.278E-03

15.7.3.4 Conclusions

As noted in table 15.7.3-1 the radiological consequences of gaseous release from a Representative Liquid Storage Tank are less than 1% of 10CFR100 limits even though nonmechanistic instantaneous failure of the tank was postulated.

15.7.4 RADIOLOGICAL CONSEQUENCES OF FUEL HANDLING ACCIDENTS

The fuel handling accident is considered to occur at two locations at PVNGS: outside the containment building in the fuel building, and inside the containment. The events at each location are independent of each other. The failure modes for fuel handling equipment inside and outside containment are non-mechanistic and therefore the initiating events in the two buildings are independent. The analyses described herein are based on movement of only one fuel assembly.

15.7.4.1 Fuel Handling Accident Outside Containment

15.7.4.1.1 Identification of Event and Causes

The fuel handling accident that is considered results from the dropping of a single fuel assembly during fuel handling.

15.7.4.1.2 Sequence of Events and Systems Operation

A sequence of events diagram for this accident is provided as figure 15.7.4-1. The radiation monitoring system (RMS), described in section 11.5, will provide prompt notification of high airborne radiation levels in the fuel building which may develop as a result of a fuel handling accident. Additionally,

the safety-related monitors of the RMS will initiate generation of the fuel building essential ventilation actuation signal (FBEVAS). Engineered safety features equipment functions following a FBEVAS are described in section 9.4. The FBEVAS logic is described in section 7.3.

By reducing building exhaust rates and initiating exhaust filtration, ESF actions will substantially reduce potential offsite radiological exposures in the event of a fuel handling accident.

15.7.4.1.3 Analysis of Effects and Consequences

If a dropped assembly were damaged to the extent that one or more fuel rods were broken, the accumulated fission gases and iodines in the fuel rod gaps would be released to the surrounding water. Release of the solid fission products in the fuel would be negligible because of the low fuel temperature during refueling. The fuel assemblies are stored within the spent fuel racks resting on the bottom of the spent fuel pool. The tops of the racks extend above the tops of the stored fuel assemblies. A dropped fuel assembly could not strike more than one fuel assembly in the storage rack. [1] Impact could occur only between the ends of the

---

1. In Unit 2 Spent Fuel Pool Storage Location A38, Element P2F003 and surrounding support apparatus are undergoing long term storage. Due to structural damage and additional height provided by the support apparatus, Element P2F003 protrudes 2.59 inches above the upper surface of the storage rack. This condition makes it possible for an element dropped near vertically to strike one element seated in storage location and then rotate to strike the top of Element P2F003.

involved fuel assemblies, with the lower end fitting of the dropped fuel assembly impacting against the upper end fitting of the stored fuel assembly.

A. Vertical Fuel Assembly Drop

Analytical methods used to calculate the impact velocity and the resulting impact stress in Zircaloy-4 and ZIRLO fuel rod cladding for the vertical drop are described below.

The analysis of the fuel assembly vertical drop employed a summation of the forces acting on the fuel assembly in the vertical direction to determine the equation of motion of the fuel assembly. The resulting equation of motion is given below:

$$F_{vert} = M \times a = F_d + F_b - F_w$$

where:

M = mass of a fuel assembly

a = acceleration

F_d = drag force of a fuel assembly (drag coefficient x (velocity)^2)

F_b = buoyant force of a fuel assembly

F_w = weight (dry) of a fuel assembly

The analysis assumed the fuel assembly drop distance was sufficient for the fuel assembly to reach its terminal velocity (acceleration equals zero in the above equation), thus making the results conservative or applicable for any drop height. For this worst

case, the terminal velocity, and therefore the assumed impact velocity of the fuel assembly, is 254.4 and 240 inches per second for Zircaloy-4 and ZIRLO fuel, respectively, and the resulting stress in the fuel rod cladding is 24,000 psi for Zircaloy-4 and 22,320 psi for ZIRLO.

The equation employed in calculating the above impact stress in the fuel rod clad is as follows:

$$S_i = V_i \sqrt{(E/\upsilon)}$$

where:

S_i = impact stress

V_i = impact velocity

E = modulus of elasticity

υ = specific volume

The yield stress of the fuel rod cladding is 49,000 psi for Zircaloy-4 and 81,785 psi for ZIRLO. This is the minimum yield stress value for unirradiated fuel and is conservative for irradiated fuel. Thus, for the fuel assembly vertical drop, the impact stresses which result from absorbing the kinetic energy of the drop are below the yield stress of the clad for both the Zircaloy-4 and ZIRLO fuel assembly, and no fuel rod failures will occur.

B. Horizontal Fuel Assembly Drop

Horizontal impact of a fuel assembly could result from a dropped fuel assembly falling in the horizontal

position, or from a vertical fuel assembly rotating to the horizontal position. This event assumes that all fuel rods in the dropped fuel assembly fail, which is consistent with Regulatory Guide 1.25 assumptions. Thus, the dose analysis is bounding for the Zircaloy-4 and ZIRLO fuel assembly horizontal drop analyses.

C. Input Parameters and Initial Conditions for the Radiological Analysis

For the radiological consequences of a fuel handling accident evaluation, cladding failure was assumed to occur for all fuel rods in an assembly. The reactor was assumed to operate at a power level of 3990 MWt, and the earliest time at which a spent fuel assembly can be moved is considered to be 72 hours after shutdown.

Assumptions and parameters used in evaluating the fuel handling accident are listed in table 15.7.4-1. The calculational methods and assumptions described in Regulatory Guide 1.25 apply since the dropped fuel assembly meets all of the requirements of Regulatory Guide 1.25, except as discussed below.

Based on the plant specific fuel cycle design and core, the maximum fuel rod discharge pressure would exceed the Regulatory Guide 1.25 limit of 1200 psig. Therefore, a site specific methodology for addressing fuel rod pressure has been developed and is implemented herein with prior NRC approval. This

methodology (Reference 3) determines the peak assembly average fuel pin pressure rather than the maximum fuel pin pressure and demonstrates that it is less than the Regulatory Guide 1.25 limit of 1200 psig.

The peak assembly average fuel pin pressure is determined by first determining the maximum fuel rod pressure based on worst case fuel cycle parameters using computer code FATES 3B. The fuel pin internal gas pressure is based on the FATES 3B analysis for the hot rod in the hot assembly and is performed and verified for each core reload. Pressure in a fuel rod in the spent fuel pool or the refueling pool is obtained by adjusting the FATES 3B results for the temperature of the water in the spent fuel pool. This methodology is independent of individual fuel rods (or fuel assembly since all rods in an assembly are assumed to be at maximum pressure) and fuel rod core location and results in a peak rod internal pressure for the fuel type analyzed by FATES 3B.

Each type of fuel is analyzed in the same manner. Then the maximum peak assembly average fuel pin pressure is calculated by averaging the pressure for the different types of fuel pins in an assembly.

$$\text{Average Pin Pressure} = \frac{\text{Sum of Individual Pin Pressures}}{\text{Number of Pins in Assembly}}$$

$$<1200 \text{ psig}$$

Table 15.7.4-1
PARAMETERS USED IN EVALUATING THE RADIOLOGICAL
CONSEQUENCES OF A FUEL HANDLING ACCIDENT

Parameter	Reg. Guide 1.25 Assumptions	Calculational Assumption
Fuel Assy. Data: [1] Radial peaking factor Burnup, MWD/MTU Max. fuel pin pressure, psig (average pressure for 236 fuel rods in peak assembly)	1.65 25,000 1,200	1.7 70,000 Peak assembly average fuel pin pressure is < 1200 when fuel is being moved[2]
Decay time, hours	None	72
Number of failed pins	All fuel rods in an assembly	All fuel rods in assembly (236)
Fraction of fission product gases contained in the gap region of fuel rods, % Kr-85 Xe-133 Other noble gases Iodine	 30 10 10 10	 30[3] 16[3] 15[3] 15[3]
Iodine gap chemical composition, % Organic iodine compounds Inorganic iodine compounds	 0.25 99.75	 0.25 99.75
Percentage of gap activity released to pool	100	100
Peak assembly shutdown gap activity, for key isotopes (Ci):	Not quantified beyond 100% of gap inventory	I-131 ---------- 1.08E+05 Xe-131m -------- 1.12E+03 Xe-133 --------- 2.58E+05 Kr-85 ---------- 3.78E+03
Minimum water depth, Fuel Pool surface to top of damaged fuel rods, feet	23	22.5
Fuel Building filter efficiencies, % Filter eff., organic iodine Filter eff., inorganic iodine	 70 90	 70 90
Pool decontamination factors: Iodine Noble gases	 100 1	 100 1

RADIOACTIVE MATERIAL RELEASE

FROM A SUBSYSTEM OR COMPONENT

Parameter	Reg. Guide 1.25 Assumptions	Calculational Assumption
Composition of iodine in atmosphere above pool, %: Organic iodine compounds Inorganic iodine compounds	 25 75	 25 75
Time for radioactive material to escape from fuel bldg., hours	99.9% in 2 hours	>99.9% in 2 hours
Filter system effluent dilution factor	Typically none; direct passage to exhaust system. (Evaluated on individual basis.)	All activity escaping the water surface in Fuel Bld./Cont. immediately & homogeneously mixed throughout building volume of 7.36E+05 ft^3
Atmospheric diffusion factors --Inside Containment --Outside Containment	Interim factors provided until site meteorological data obtained; licensee directed to use site specific data when available	 See Table 15B-5 2.24E-04 sec/m^3

1) Fuel data valid only for oxide fuels with:

a) Highest power assy. peak linear power density no greater than 20.5 kW/ft.;

b) Highest power assy. center-line operating temp. <4,500 F.

2) FATES 3B computer code.

3) Methodology conservatively assumed to be bounding for Zircaloy-4 and ZIRLO fuel; exceeds values calculated by ANSI/ANS 5.4-1982.

The releases from the spent fuel pool are calculated in accordance with Regulatory Guide 1.25. The top of the highest damaged fuel rod would be at elevation 115 feet.[2] The spent fuel pool low water level alarm and high water level alarm setpoints are at elevations 137 feet 6 inches and 138 feet 2 inches, respectively. As such, there is a nominal 23 feet of water over the damaged fuel pins. Even if the pool water level were at the low level alarm point, there would be a minimum of 22 feet 6 inches of water over the damaged fuel pins.

Gap activities at reactor shutdown in the fuel assembly damaged as a result of a fuel handling accident in accordance with Regulatory Guide 1.25 are given in table 15.7.4-1. This activity is assumed to be instantaneously released to the fuel building subsequent to evolution from the spent fuel pool.

---

2 In Unit 2 Spent Fuel Pool Storage Location A38, Element P2F003 and surrounding support apparatus are undergoing long term storage. Due to structural damage and additional height provided by the support apparatus, Element P2F003 protrudes 2.59 inches above the upper surface of the storage rack. In the most conservative case of an element falling onto and being supported by this Element P2F003, the highest point on the supported element would be at elevation 115' 5.18". An administratively controlled minimum Spent Fuel Pool water level of 138' ensures at least 22'6" of water coverage of all parts of the dropped element. This is only required during fuel movement within the administrative restricted area surrounding fuel element P2F003.

The fuel building essential ventilation system will actuate on high radiation, which would minimize the releases to the environment.

The offsite doses at the exclusion area boundary and low population zones for a fuel handling accident outside containment are presented in table 15.7.4-3.

15.7.4.1.4 Conclusions

As noted in table 15.7.4-3, the radiological consequences of a fuel handling accident outside containment are within SRP limits and well within (25%) 10CFR100 limits, and are in all cases bounded by the postulated fuel handling accident inside containment doses. Control room doses are discussed in Section 6.4.7.3. The operator doses are within the limits set by 10CFR50 Appendix A GDC 19.

Table 15.7.4-3

RADIOLOGICAL CONSEQUENCES OF A FUEL HANDLING ACCIDENT OUTSIDE CONTAINMENT

	Dose (rem)	
	Thyroid	Whole Body
2-hour exclusion area boundary	25.1	2.88×10^{-1}
30-day low population zone	7.9	1.11×10^{-1}

15.7.4.2 Fuel Handling Accident Inside Containment

15.7.4.2.1 Identification of Event and Causes

Refer to paragraph 15.7.4.1.1.

15.7.4.2.2 Sequence of Events and Systems Operation

A sequence of events diagram for this accident is provided as figure 15.7.4-2. The RMS, described in section 11.5, will provide prompt notification of high airborne radiation levels in the containment which may develop as a result of a fuel handling accident.

15.7.4.2.3 Analysis of Effects and Consequences

The analysis presented in paragraph 15.7.4.1.3 for a fuel handling accident outside containment is also applicable to this section and as paragraph 15.7.4.1.3 assumes acceleration is zero at the terminal velocity. Thus, the consequences of a fuel handling accident in the containment are no more severe in terms of activity released from the fuel element than a fuel handling accident outside containment.

The releases from the refueling pool are calculated in accordance with the assumptions of Regulatory Guide 1.25.

It is also assumed that, for the postulated accident, this activity is instantaneously released to the containment and released to the outside atmosphere within two hours.

The 2-hour doses at the exclusion area boundary and 30 day low population zone doses are presented in table 15.7.4-5.

15.7.4.2.4 Conclusions

As shown in the results of the analyses in table 15.7.4-5, the radiological consequences of a fuel handling accident inside containment are within SRP limits and well within (25%) 10CFR100 limits. Control room doses are discussed in Section 6.4.7.3. The operator doses are within the limits set by 10CFR50 Appendix A GDC 19.

Table 15.7.4-5

RADIOLOGICAL CONSEQUENCES OF A FUEL HANDLING ACCIDENT INSIDE CONTAINMENT (WITHOUT REFUELING PURGE ISOLATION)

	Dose (rem)	
	Thyroid	Whole Body
2-hour exclusion area boundary	74.7	4.16×10^{-1}
30-day low population zone	20.8	1.16×10^{-1}

15.7.5 SPENT FUEL CASK DROP ACCIDENT

The probability of fuel handling accidents in the fuel building that result from dropping either a TSC/TFR containing spent fuel or other heavy load from the single failure proof Cask Handling Crane is sufficiently small that they are not credible events, and therefore do not require analysis. The Cask Handling Crane, the TSC, the TFR, and the associated lifting

devices used for dry fuel storage handling in the fuel building meet the applicable criteria of NUREG-0612 Section 5.1.6 (Single-Failure-Proof Handling Systems). Transport of loaded casks to the ISFSI storage location is performed within the bounds of the NAC-UMS Certificate of Compliance (CoC) (Docket no, 72-1015) and the NAC-UMS® FSAR. Refer to the NAC-UMS® and the ISFSI 72.212 Evaluation Report for details of fuel handling accidents during these operations. Interlocks and procedural and administrative controls involved in fuel handling are described in subsection 9.1.4.

APPENDIX 15A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

CONTENTS (cont)

CONTENTS (Cont)

TABLES

FIGURES

FIGURES (Cont)

QUESTION 15A.1 DELETED

QUESTION 15A.2 (NRC Question 450.10) (15.6.2)

In evaluating the double-ended break of the letdown line outside containment, provide the following:

(1) summary of primary system's iodine activity, including the potential increase in iodine release rate (iodine spiking) above the equilibrium value during the accident and its effect on the accident doses; and

(2) valve closure time and maximum permissible leakage rate of the letdown line isolation valve.

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 15A.3 (NRC No. 450.11) (15.7.3)

In evaluating the radioactive liquid waste system leak or failure, provide data, assumptions and methodology used in analyzing the radiological consequences of fission gases released to the atmosphere.

RESPONSE: The response is provided in revised paragraph 15.7.3.2.

QUESTION 15A.4 (NRC Question 460.19) (15.7)

We are currently evaluating the liquid radwaste tank failure accident for Palo Verde Nuclear Generating Station (PVNGS) Units 1, 2, and 3. Based on our evaluation, we have concluded that the tank most likely to result in the highest levels of concentrations in the release in the event of tank failure is

the concentrate monitor tank which is located in the radwaste building at elevation 100 feet (on grade) and has a capacity of 4000 gallons when filled to 80% of its capacity (see engineering drawing 13-P-OOB-003, FSAR, PVNGS for location). Our calculations show that either a dilution factor of 3 x 10^8 or a transit time of approximately 718 years will be required in order to ensure that the radionuclide concentrations at the applicable location are well below the 10CFR Part 20 limits. Please indicate whether such values can be expected at the applicable location for PVNGS and if not what dilution factor and transit time can be expected at the applicable location.

RESPONSE: The concentrate monitor tanks are located inside the radwaste building. In the event of tank failure, all leakage would be contained by curbs and floor drains and pumped (by sump pumps) for holdup and/or processing. Accordingly, no ground contamination would occur.

The concentrate monitor tank gaseous inventory is expected to be very small (refer to table 12.2-5). Thus, radiological impact due to concentrate tank failure is projected to be less than that of the refueling water tank (RWT) as noted in subsections 15.7.2 and 15.7.3. The RWT has the highest liquid and gaseous inventories and concentrations of any outside tank. Dilution factors and transit times for the perched water and regional aquifer for failure of the RWT are presented in paragraph 2.14.13.3.

<u>QUESTION 15A.5</u> (NRC Question 450.13) (15.6.3)

The radiological consequences of the steam generator tube rupture accident are presented in CESSAR Section 15.6.3 for only the exclusion area boundary. This does not fully comply with the guidelines of 10CFR Part 100 which requires a radiological consequence evaluation be performed at a low population zone for the duration of the accident. It is the staff position that CE provide the assumed LPZ envelope and provide the estimated radiological consequences at the assumed LPZ boundary for the duration of the accident.

RESPONSE: The response will be provided on the CESSAR docket.

<u>QUESTION 15A.6</u> (NRC Question 450.14) (15.6.3)

The amount of steam released from the affected and unaffected steam generators presented in FSAR subsection 15.6.3 are based upon the assumption of recovery of offsite power and condenser during the accident. This is contrary to the staff position of assuming that offsite power is lost for the duration of the accident and therefore the condenser is never available for steam dump. Because the staff uses the applicant's values or curves of the steam release estimates in its radiological consequence calculations, it is not possible to complete our review until appropriate steam release values are received. Provide the estimates of steam release to the environment assuming that the condenser is not available for the accident duration.

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 15A.7 (NRC Question 450.15) (15.6.3)

The analysis of the radiological consequences presented in FSAR subsection 15.6.3 does not appear to consider the steam release pathway occurring from the steam jet air ejectors (SJAEs) to the environment prior to assumed loss of the condenser. Because the condenser is available for a significant period prior to condenser trip and the primary to secondary leakage is greatest prior to the loss of the condenser, it is the staff position that the steam release pathway through the SJAEs to the environment needs to be considered in the radiological consequence analysis. Provide the amount of steam released through the SJAEs to the environment prior to the loss of the condenser.

RESPONSE: The PVNGS design does not include SJAEs. Air is removed via the condenser air removal system. This pathway is monitored for radioactivity prior to release and is filtered by charcoal and HEPA filters in the event of high effluent radioactivity. (Refer also to CESSAR Section 15.6.3)

QUESTION 15A.8 (NRC Question 450.16) (15.6.3)

The radiological consequence evaluation provided in CESSAR Section 15.6.3 are based upon assumptions which vary greatly from previous staff practice in the following areas:

1) The evaluations were performed using values which are less than the proposed technical specification limits for normal operation.

   This is not acceptable to the staff because the technical specifications define the operating envelope under which the plant can operate without restriction. Analyses using values less than the Technical Specifications do not verify that at the Technical Specification limits the plant would operate safely and that the radiological consequences would not exceed the staff acceptance criteria on radiological exposures.

2) The radiological consequence analysis of a steam generator tube rupture makes no mention of iodine spiking in the CESSAR document, and the Palo Verde docket uses a spiking factor of only 100.

   The staff position on an acceptable spiking factor is provided in SRP Section 15.6.3. This section states that a spiking factor of 500 times the normal release rate of iodine from the fuel should be used.

3) The iodine transport in the steam generator is determined using CENPD-180 and its supplement.

   The staff position on iodine transport in the steam generator is defined in SRP Section 15.6.3 and is that the iodine transport should be determined using the methods and models described in NUREG-0409. The CESSAR and Palo Verde dockets do not discuss the

differences in the methods used to those proposed in NUREG-0409.

Based upon the above discussion, the staff position is that the applicant provide an analysis of the radiological consequences of the steam generator tube rupture which assumes operation at the proposed technical specification values and describes the differences between the models used and those presented in the staff Standard Review Plan.

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 15A.9 (NRC Question 450.17) (15.6.2)

In the evaluation of the double-ended break of the letdown line outside containment-upstream of the letdown line control valve (CESSAR Section 15.6.2), the staff has calculated the dose in accordance with SRP 15.6.2. The result shows the EAB, 0-2 hours, thyroid dose to be 85 rems. This value is more than twice the acceptable limit of 30 rems as defined in SRP 15.6.2. The staff position is that the maximum equilibrium fission product concentration given in the technical specification be reduced from 4.7 μci/cc to the standard 1 μci/cc. This measure will correspondingly reduce the dose to within acceptable levels. State your intent regarding compliance with our position.

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 15A.10 (NRC Question 450.19) (15.7.4)

In order to complete our evaluation of the fuel handling accident analysis we request that you provide the following information:

(1) Location of RMS detector used to isolate containment refueling purge system and air flow transit time between detector and valve based on normal flowrates.

(2) Specify if the RMS detector used to isolate containment refueling purge system is ESF grade and redundant and, if so, include location of redundant detector.

(3) Location of RMS detector used to isolate fuel handling building in the event of a fuel handling accident and air flow transit line between detector and damper based on normal flowrates.

(4) Specify if RMS detector used to isolate fuel handling building, in the event of a fuel handling accident, is ESF grade and redundant and, if so, include location of redundant detector.

RESPONSE: As noted in paragraphs 15.7.4.1 and 15.7.4.2, offsite doses due to fuel handling accidents will be a small fraction of 10CFR100 limits even without isolation or filtration of containment or fuel building exhausts. Protective action is not required. The design, however, does include radiation monitors to sense the occurrence of an accident and initiate protective action.

1) The PAPA area radiation monitors isolate the containment refueling purge upon high radiation. They are located just outside the containment between the refueling purge exhaust ducting and the power access purge ducting as shown on engineering drawing 13-N-RAR-004. Air flow transit time is less than 1/4 second.

2) There are two redundant, ESF-grade monitors, 13-J-SQA-RU-37 and 13-J-SQB-RU-38. Refer to section 11.5.

3) Area radiation monitor 13-J-SQA-RU-31 is located on the east wall of the fuel building adjacent to the spent fuel pool. The detector will register the evolution of airborne radioactivity from the pool within 1/4 second.

4) 13-J-SQA-RU-31 is ESF grade. The redundant ESF monitor has two channels, low range and high range (13-J-SQB-RU-145 and 13-J-SQB-RU-146). It is located just below the roof level and samples the exhaust downstream of the dampers. The sample transit time is less than 10 seconds between duct and monitor.

QUESTION 15A.11 (NRC Question 440.32) (15.0)

Expand table 15.0-6, the list of single failure considered in transient and accident analyses, to include the following:

1. One primary safety valve stuck closed

2. One secondary safety valve fail to open or fail to close

3. Loss of offsite power

4. failure of one diesel to operate (for the events with loss of offsite power being treated as a consequential result of the event).

5. failure to achieve fast transfer

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

NOTE: Subsequent to the docketed response, it was determined that the single failure of a fast bus transfer was no longer a limiting single failure for any of the UFSAR Chapter 15 accident analyses. As noted in UFSAR Section 15.0.2.4, this single failure is bounded by the postulated loss of offsite power following a turbine trip.

QUESTION 15A.12 (NRC Question 440.33) (15.0)

For all analyses of transients with concurrent single failures, provide a reference to the sensitivity study which shows that the failure selected is the worst case single failure.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.13 (NRC Question 440.34) (15.0)

Confirm that during the preoperational or startup test phase you intend to verify the valve discharge rates and response times (such as opening and closing times for main feedwater, auxiliary feedwater, turbine and main steam isolation valves, and steam generator and pressurizer relief and safety valves)

to show that they have been conservatively modeled in the chapter 15 analyses.

RESPONSE: PVNGS intends to verify response times during a preoperational test to show that they have been conservatively modeled in chapter 15 analyses as described in CESSAR chapter 14 for valves within the CESSAR scope, and in PVNGS FSAR chapter 14 for valves outside the CESSAR scope.

<u>QUESTION 15A.14</u> (NRC Question 440.35) (15.0)

The method that you have used for calculating the amount of failed fuel after an accident has not been approved. It is our position that fuel failures be recalculated using the criteria that any fuel rod which has a CE-1 DNBR less than the minimum DNBR value determined in section 4.4 fails. Radiological consequences should be calculated accordingly.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

<u>QUESTION 15A.15</u> (NRC Question 440.36) (15.0)

Verify that for each transient analyzed in chapter 15, if operator action is not discussed then no operator action is required. In particular, consider events in which the ECCS is actuated or RCP trip would be required based on present procedures.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.16 (NRC Question 440.37) (15.0)

For each accident, discuss nonsafety grade equipment which was assumed to operate and could result in the transient becoming more severe or verify that no nonsafety grade equipment operating would produce a more severe transient. For example, the pressurizer heaters being energized for a transient resulting in high RCS pressures could tend to worsen the effects of the transient. Likewise, pressurizer spray could be detrimental for a transient resulting in low RCS pressure.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.17 DELETED

QUESTION 15A.18 (NRC Question 440.39) (15.0)

One of the key parameters in LOCA analyses is peak clad temperature. For non-LOCA transients, minimum DNBR (departure from nucleate boiling ratio) is of primary importance. For those transients analyzed in chapter 15 of the FSAR, provide graphical output of the DNBR as a function of time.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.19 (NRC Question 440.40) (15.0)

As part of the CESEC review, the NRC intends to perform audit evaluations of feedwater line breaks, steam line breaks, and large- and small-break LOCAs (as part of the FSAR and TMI Action Plan Item II.K.3.30 and II.K.3.31 reviews). In order to

perform these audits, we require the following data, as outlined in the "PWR Information Request Package."

RESPONSE: The response will be provided on the CESSAR docket.

QUESTION 15A.20 (NRC Question 440.41) (15.0)

The current CESEC model does not properly account for steam formation in the reactor vessel. Therefore, for all events in which (a) the pressurizer is calculated to drain into the hot leg, or (b) the system pressure drops to the saturation pressure of the hottest fluid in the system during normal operation, we require the applicant to reanalyze these events with an acceptable model or otherwise justify the acceptability of Palo Verde chapter 15 analyses conclusions performed with CESEC.

RESPONSE: The response was provided in CESSAR Amendment 6.

QUESTION 15A.21 (NRC Question 440.42) (15B)

Figure 15B-19 shows the primary system pressure exceeding 110% of the design pressure. This figure also indicates a substantial pressure differential between the pressurizer and reactor vessel. The standard review plans typically limit the pressurization of the RCS to 110% of the design pressure. However, the ASME pressure vessel code permits exceeding the 110% limit to approximately 120% for very low probability events. The NRC will accept the limiting pressurization transient (i.e., feedwater line break) as calculated for System 80 if we can be assured that the analysis performed is

conservative and that a small break in the feedwater line is a very low probability event.

As such, we request the following information be provided:

(1) Verification of CESEC to predict pressurization transients. This should include the developed pressure differential across the pressurizer surge line.

(2) Demonstrate that the probability of a small break in the feedwater system is not significantly more probable than the large break. Include the consideration of ancillary line breaks.

(3) Section 15B.3 references a sensitivity study for RCS overpressurization transient to plant initial conditions. Provide the results to this study in graphical form. Specifically, include DNBR and pressure as a function of time.

(4) It is expected that increasing the break area for a feedwater line break would increase the degree of primary system pressurization. A larger break area should result in an earlier loss of heat sink and corresponding higher decay heat for system pressurization. Figure 15B-1 indicates that the limiting feedwater line break is not a double-ended guillotine break (1.4 square feet), but a 0.2-square foot break. Provide greater details as to why this occurs. Is this behavior considered realistic or a consequence of a modeling assumption? Provide additional graphical explanations, including heat transfer coefficient, heat flow, secondary side inventory, all secondary side flow rates, and any additional data

required to demonstrate the reasons for the 0.2-square foot break begin the limiting break size.

(5) Figure 15B-10 provides the relationship between the maximum RCS pressure to initial steam generator inventory. Provide additional information which explains in detail functional behavior of this curve.

Page 15B-5 states: "...the initial RCS pressure can be adjusted to provide simultaneous reactor trip signals from high pressurizer pressure and low water level in the intact steam generator and hence the plateau of maximum RCS pressure." Provide greater details of the analyses and assumptions made in order to achieve coincident trip signals from the pressurizer and SG.

(6) For figure 15B-11 (and page 15B-6), how does raising the degree of feedwater subcooling increase the maximum RCS pressure? It would appear that raising the degree of subcooling would result in a larger heat sink, and, therefore, a lower peak pressure.

(7) What decay heat model does CESEC use? Does this model assume infinite irradiation?

(8) Provide details of the core and steam generator heat transfer models used in CESEC.

(9) Utilizing a one-node representation of the steam generator secondary side, how is the low liquid level trip analyzed?

(10) Provide verification of the CESEC <u>pressurizer</u> model for pressurization transients (resulting in the opening of a safety valve or PORT) with data from experiments and

operating plant transients. Of interest is level and pressure as a function of time. Document the assumptions made in analyzing these tests.

(11) Document the sensitivity of a feedwater line break with and without loss of offsite power.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions and CESSAR Amendment 6.

QUESTION 15A.22 (NRC Question 440.43) (15B)

For the feedwater line break analysis, provide the pressurizer liquid and mixture level as a function of time.

Provide detailed plots for the following parameters during the initial 50 seconds of the transient:

1. Pressurizer pressure
2. Surge line flow
3. Pressurizer mixture level
4. Pressurizer safety valve flow and quality

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.23 (NRC Question 440.44) (15.0)

We require additional information regarding the steam generator behavior during a feedwater line break. Provide the steam generator secondary side coolant inventory, mixture level, heat transfer coefficients, energy removed by each steam generator (Btu) and secondary side flow as a function of time.

It is our understanding that the limiting heat transfer modeling technique utilized in CESEC assumes an approximately constant heat transfer coefficient between the primary and secondary systems until all the liquid mass in the secondary system is depleted (i.e., WM = 0). It is not clear why the limiting modeling technique was not the case where the heat transfer was degraded as the secondary side inventory began uncovering the tubes. Please explain.

Discuss differences in the steam generator secondary heat transfer modeling between a feedwater line break and a steam line break.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.24 DELETED

QUESTION 15A.25 (NRC Question 440.46) (15.0)

Accidents resulting in containment isolation also isolate the component cooling water to the reactor coolant pumps. This can potentially lead to RCP seal damage which may result in a LOCA. Address the time available for the operators to restore the coolant to the seals. Has consideration been given to not isolating component cooling water to the RCP seals on containment isolation? If pump seal integrity cannot be maintained, evaluate the consequential failure of the pump seals for the limiting accident.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.26 DELETED

QUESTION 15A.27 (NRC Question 440.48) (15.0)

Provide a list of transients which result in opening of the pressurizer safety valves.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.28 (NRC Question 440.49) (15.0)

The staff has been informed that the CESEC-III computer program is best suited to analyze transients which void the upper head of the reactor vessel. As such, we request that the following information be provided:

(1) Documentation of the CESEC-III code. As part of the documentation, address the differences between the different versions of CESEC (I, II, and III).

(2) Provide comparative analyses with the different versions of the CESEC programs (used for licensing) to demonstrate the adequacy of previous analyses.

(3) Provide verification of CESEC-III against plant and experimental data for pressurization and depressurization transients (such as the AN0-2 experiments and the St. Lucie I cooldown experience).

(4) For those transients which result in primary system voiding, provide graphical output of the upper head mixture level as a function of time. Discuss operator actions/guidelines for detecting and mitigating primary system void formation.

(5) Show, by analysis or otherwise, that the allowable cooling rate (for cold shutdown conditions) will not result in primary system voiding.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.29 DELETED

QUESTION 15A.30 DELETED

QUESTION 15A.31 DELETED

QUESTION 15A.32 DELETED

QUESTION 15A.33 DELETED

QUESTION 15A.34 (NRC Question 440.55) (15.6)

For small-break LOCAs, containment isolation may occur. It is our understanding that component cooling water to the RCP seals will be isolated upon containment isolation. Demonstrate that the RCP seals will remain intact and maintain the pressure boundary for the duration of the accident. Address expected RCP operation. If seal integrity cannot be maintained, seal failure must be assumed. Discuss the maximum seal leakage rates based on operating experience. If the consequences of seal failure are assumed to be covered by the analyzed break spectrum, justify the differences in the break locations from the locations analyzed.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.35 DELETED

QUESTION 15A.36 (NRC Question 440.58) (15.6.3)

The analysis for a steam generator tube rupture does not address tube leakage in the unaffected steam generator. Provide an interface requirement for the allowable steam generator tube leakage and reference the technical specification limit. Confirm the analyses were performed using this allowable limit or provide justification why this leakage term can be excluded from the analyses.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.37 (NRC Question 440.59) (15.6.3)

The analysis for a steam generator tube rupture is for a double-ended rupture. Provide the analyses used to determine that this is the limiting ease. If a partial area break is considered, such that the steam generator relief valves open at a longer time into the transient is more primary coolant leaked to the secondary and out the SRVs, resulting in an increased dose rate.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.38 (NRC Question 440.60) (15.6.3)

SRP 15.6.3 acceptance criteria requires that this event be analyzed with a concurrent loss of offsite power. Provide an analysis for the limiting case which includes a concurrent loss of offsite power.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.39 (NRC Question 440.61) (15.6.3)

For the SGTR event, what prevents steam from the affected steam generator being used to drive the steam-driven auxiliary feedwater pump and exhausted to the environment? If operator action is required, confirm that no credit for operator action was given for 30 minutes, consider with your assumption for isolation of the affected steam generator. If credit was given for operator action in less than 30 minutes, provide justification why this credit can be given, or reanalyze the event assuming steam from the faulted steam generator is used to drive the steam-driven AFW pump and is exhausted to the environment.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.40 (NRC Question 440.62) (15.6.3)

Provide a description of the CESEC model used to model the CVCS from the reactor coolant system to the break point. Include a description of the environmental conditions at the break point (pressure, enthalpy, break flow model used).

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.41 (NRC Question 440.63) (15.6.3)

Discuss the single failure assumed for these analyses. What analyses/evaluations were performed to justify that the single failures chosen were the most limiting?

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.42 (NRC Question 440.64) (15.0)

In this section, you have selected the turbine trip without a single failure as the limiting reactor coolant system pressure and the limiting radiological release event for the moderate frequent event category in the decreased heat removal by secondary system group. However, these limiting cases were not selected by a qualitative comparison of similar initiating events specified in SRP 15.2.1 through SRP 15.2.7 (e.g., loss of external load, turbine trip, loss of condenser vacuum, steam pressure regulator failure, loss of normal AC power and loss of normal feedwater flow). Provide a qualitative analysis in the FSAR for each of the initiating events in the same group per the SRP, and identify the limiting cases for the group. Provide a detail quantitative analysis for each of the limiting cases including the limiting RCS pressure, limiting fuel performance, and the limiting radiological release.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

<u>QUESTION 15A.43</u> (NRC Question 440.65) (15.2)

In this section, you have provided the loss of condenser vacuum with a fast transfer failure and technical specification steam generator tube leakage as the limiting RCS pressure and the limiting radiological release event for the limiting fault event category in the decreased heat removal by secondary system group. Although, these limiting cases may be the candidates for the limiting cases for the infrequent event category in the group, they were not selected by a qualitative comparison of similar initiating events plus a single failure specified in SRP 15.2.1 through 15.2.7. Provide a qualitative analysis in the FSAR for each of the initiating event plus a single failure in the same group per the SRP, and identify the limiting cases for the group. Provide a detailed quantitative analysis for each of the limiting cases including the limiting RCS pressure, limiting fuel performance, and the limiting radiological release. Confirm that the results of the analyses meet the acceptance criteria for these events per SRP 15.2.1.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

NOTE: Subsequent to the docketed response, it was determined that the single failure of a fast bus transfer was no longer a limiting single failure for any of the UFSAR Chapter 15 accident analyses. As noted in UFSAR Section 15.0.2.4, this single failure is bounded by the postulated loss of offsite power following a turbine trip.

QUESTION 15A.44 (NRC Question 440.66) (15A)

Provide tabulations of the sequence of events, disposition of normally operating systems, utilization of safety systems, and a transient curve of primary system pressure for the total loss of primary coolant flow event. Also provide an analysis of the total loss of primary coolant flow with a single failure event. Confirm that the results of these analyses meet the acceptance criteria for these events per SRP 15.3.1.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.45 (NRC Question 440.67) (15.3)

In subsection 15.3.5 you have provided the single reactor coolant pump shaft seizure with loss of offsite power following turbine trip and with technical specification tube leakage as the limiting RCS pressure and radiological release event for the limited fault event category. This postulated event is classified as an infrequent event per SRP 15.3.3. Confirm that the results of the analysis meet the acceptance criteria for these events per SRP 15.3.3, using the criteria stated in Question 440.35 to calculate the amount of failed fuel in this event. State the amount of failed fuel in the results of the analysis. Radiological consequences should be calculated accordingly.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions and CESSAR Amendment 6.

<u>QUESTION 15A.46</u> (NRC Question 440.68) (15.0)

Provide results of an analysis of the reactor coolant pump shaft break as required by SRP 15.3.4 for staff review. The event should consider loss of offsite power following turbine trip and with technical specification steam generator tube leakage. The criteria stated in Question 440.35 should be used for the calculation of the amount of failed fuel for this event. State the amount of failed fuel in the results of the analysis. Radiological consequences should be calculated accordingly. Confirm that the results of the analysis meet the acceptance criteria for these events per SRP 15.3.4 which classifies this event as an infrequent event.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

<u>QUESTION 15A.47</u> (NRC Question 440.69) (15.5)

In this section, you have provided the pressurizer level control system malfunction (PLCSM) with a fast transfer failure and the PLCSM with a loss of offsite power at turbine trip with Technical Specification steam generator tube leakage as the limiting RCS pressure and radiological release event for the limiting fault event category in the increase in reactor coolant system inventory group. However these limiting cases were not selected by a qualitative comparison of similar initiating events plus a single failure specified in SRP 15.5.1 (e.g., inadvertent operation of high pressure ECCS or a malfunction of the CVCS). Provide a qualitative analysis in the FSAR for each of the initiating events (with and without a single active failure) in the same group per the SRP, and

identify the limiting cases for the group. Provide a detailed quantitative analysis for each of the limiting cases including the limiting RCS pressure, limiting fuel performance, and the limiting radiological release. Confirm that the results of the analyses meet the acceptance criteria for these events per SRP 15.5.1.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions

NOTE: Subsequent to the docketed response, it was determined that the single failure of a fast bus transfer was no longer a limiting single failure for any of the UFSAR Chapter 15 accident analyses. As noted in UFSAR Section 15.0.2.4, this single failure is bounded by the postulated loss of offsite power following a turbine trip.

QUESTION 15A.48 (NRC Question 440.70) (15.0)

Provide tabulations of the sequence of events, disposition of normally operating systems, utilization of safety systems, and all necessary transient curves for the startup of an inactive reactor coolant pump event. The comparison to peak RCS pressure acceptance criteria should be included in the analysis. Also provide the results of an analysis of this event with a single failure. Confirm that the results of these analyses meet the acceptance criteria for these events per SRP 15.4.4.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.49 (NRC Question 440.71) (15D)

You have provided, in CESSAR Appendix 15D, the results of an inadvertent boron dilution event without a single failure under plant cold shutdown conditions. This information is not sufficient. You should provide results of analyses for all possible boron dilution events under various plant operational modes (e.g., refueling, startup, power operation, hot standby and cold shutdown). Also provide the results of analyses of these events with a single failure. Confirm that the results of these analyses meet the acceptance criteria for these events per SRP 15.5.1. In particular, the available times per operator action between time of alarm and time of loss of shutdown margin should be shown to meet the SRP guidelines. The results of the analyses should be presented in the FSAR including tabulations of sequence of events, disposition of normally operating systems, utilization of safety systems, and all necessary transient curves for the events.

In your analysis, indicate for all modes of operation what alarms would identify to the operators that a boron dilution event was occurring. Consider the failure of the first alarm. Provide the time interval from this alarm to when the core would go critical. If a second alarm is not provided, show that the consequences of the most limiting unmitigated boron dilution event meet the staff criteria and are acceptable.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.50 DELETED

QUESTION 15A.51 (NRC Question 440.73) (15D)

Several recent LERs indicate there has been a deficiency in the inadvertent boron dilution analysis at some plants. Provide an analysis of the dilution event when the RCS is drained to the hot leg.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.52 (NRC Question 440.74) (15D)

Recently, an operating PWR experienced a boron dilution incident due to inadvertent injection of NaOH into the reactor coolant system while the reactor was in a cold shutdown condition. Discuss the potential for a boron dilution incident caused by dilution sources other than the CVCS.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

QUESTION 15A.53 (NRC Question 440.75) (15.6)

Discuss the transient resulting from a break of an ECCS injection line. In particular, describe the flow splitting which will occur in the event of a single failure and verify that the amount of flow actually reaching the core is consistent with the assumptions used in the analysis.

RESPONSE: The response was provided on the CESSAR docket. See CESSAR FSAR Responses to NRC Questions.

<u>QUESTION 15A.54</u> (NRC Question 440.76) (15.8)

The NRC is currently considering what actions may be necessary to reduce the probability and consequences of anticipated transients without scram (ATWS). Until such time as the Commission determines what plant modifications are necessary, we have generally concluded that pressurized water plants can continue to operate because the risk from anticipated transient without scram events in a limited time period is acceptably small. However, in order to further reduce the risk from anticipated transient without scram events during the interim period before completing the plant modifications determined by the Commission to be necessary, we have required that the following actions be taken:

1. Develop emergency procedures to train operators to recognize anticipated transient without scram events, including consideration of scram indicators, rod position indicators, flux monitors, pressurizer level and pressure indicators, pressurizer relief valve and safety valve indicators, and any other alarms annunciated in the control room with emphasis on alarms not processed through the electrical portion of the reactor scram system.

2. Train operators to take actions in the event of an anticipated transient without scram, including consideration of manually scramming the reactor by using the manual scram button, prompt actuation of the auxiliary feedwater system to assure delivery to the full capacity of this system, and initiation of turbine trip. The operator should also be trained to initiate boration by

actuation of the high pressure safety injection system to bring the facility to a safe shutdown condition.

Describe how you will meet the above requirements, and provide a schedule for submittal of the ATWS procedures for staff review.

RESPONSE: Procedures will be developed to cover emergencies and off-normal events. These procedures will provide sufficient guidance to ensure that correct action is taken by the operator. ATWS events will be covered in these procedures. PVNGS will provide training on ATWS events and emergency and off-normal procedures. Sufficient information will be provided so that the operator can determine if his actions are effective. Should the operator's actions not be effective, the procedure will contain additional action that can be taken by the operator to ensure the parameter and/or condition is restored to acceptable values.

Procedures will be available for NRC review at least 60 days prior to fuel load.

<u>QUESTION 15A.55</u> (NRC Question 440.82) (15.0)

Section 15D.2.2.2 of the CESSAR System 80 FSAR states that the loss of instrument air event impact on the plant systems and components will be addressed in the applicant's FSAR. Discuss the loss of instrument air for Palo Verde showing that it meets the appropriate acceptance criteria for a moderate frequency event. Causes and potential systems interactions should be addressed and the loss of instrument air should be considered

during all phases of reactor operation. Also, present your plans and capability for preoperational or startup tests to substantiate the analyses.

RESPONSE: The nitrogen supply system will support the required ESF air-supplied components normally supplied from instrument air system for one hour on loss of instrument air. This is accomplished by providing an automatic control valve connecting the nitrogen system to the instrument air system. Depletion of the nitrogen system will not affect any safety-related systems.

The following list shows the systems which would be affected on loss of instrument air and depletion of the nitrogen supply. Also shown is the position of the air (or nitrogen supply valve upon depletion of the nitrogen supply.

SYSTEM	VALVE POSITION
RCP Seal Injection	Open
RCS Letdown	Closed
CVCS Charging	Closed
Boric Acid Concentrator	Closed
Suction to RDPs	Closed
Gas Stripper	Closed
Pressurizer Sprays	Closed
Steam Bypass to Condenser	Closed
Main Steam Line Drains	Closed
Nitrogen Charging to SITs	Closed
Sulfuric Acid to ESPs	Closed

Letdown Hx Cooling Water	Closed
Turbine Cooling Water	Open
Normal Chilled Water	Closed
Auxiliary Steam System	Closed

Instrument air loss would not incapacitate any safety-related systems or equipment needed for safe shutdown. It would affect the above systems by fail-safe closing or opening (as indicated) of air-operated valves upon air failure and depletion of nitrogen supply.

QUESTION 15A.56 (SGTR Question 1)[a] (15.6.3)

In the SGTR analysis for Palo Verde units submitted by your letter dated January 27, 1984, the acceptability of the radiological consequences is heavily dependent on the operator's action on controlling the cooldown rate. It is assumed in the analysis that the operator has to open one ADV in each steam generator at a 10.5% opening position to ensure a maximum cooldown rate of 75F. The staff notes that the ADVs have no device to limit their opening to the assumed 10.5%, and other calculations have shown that an opening of slightly less than 12% would result in exceeding the 10CFR Part 100 guideline values. Also, there are no specific limits in either the technical specifications or procedures to restrict opening of the ADV to less than the 10.5% assumed. There is only the

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated April 27, 1984.

maximum cooldown rate limit of 75F/hr, a value that we believe is difficult for the operator to determine during a complicated event like the SGTR. Discuss what positive measures will be taken to ensure that the assumed ADV opening position and cooldown rate will not be exceeded.

RESPONSE: The January 27, 1984, analysis of the SGTR with the loss of offsite power and the failure of the stuck open ADV event assumed that, once the operator identified and pursued isolating the affected steam generator, all auxiliary feedwater flow ceased to that generator. This approach was chosen to maximize radiological consequences pursuant to direction from the Regulatory Staff. This arbitrary restriction results in the hypothetical radiological consequences being very sensitive to valve opening position because of the subsequent tube uncovery.

Further review of this nondesign basis accident calculation has indicated that it is unnecessarily conservative to assume tube uncovery. Accordingly, the PVNGS Emergency Operating Procedures will include direction to feed the affected steam generator in order to keep the tubes covered and maintain the iodine partition coefficient. This is not a deviation from the CE Emergency Procedure Guidelines (CEN-152). Rather, it is an additional consideration to be used to mitigate the consequences of a SGTR, and provides substantial benefits for the instances where the ruptured steam generator cannot be isolated from the atmosphere (e.g., stuck open ADV). This multiple failure event, SGTR and a fully stuck

open ADV, was not contemplated by CEN-152, just as it is not considered by the NRC's Standard Review Plan.

This modification to the PVNGS Procedure will be incorporated before fuel load of PVNGS Unit 1. Training of the operators will commence soon after approval of the procedure modification, and will require approximately 3 months to train all of the Unit 1 shifts. This training should be complete by initial criticality. Training will include simulator time and will emphasize the reduction of offsite releases and the potential for overfill of the affected steam generator.

Including this additional procedure into the analysis leads to a revised 0 to 2 hour thyroid dose of 200 rem including a fully (100%) open atmospheric dump valve and a preexisting iodine spike. This is the highest dose (refer to table 15A-1 for the complete dose results) and is well within Part 100 criteria.

It should be noted that a stuck, fully open ADV is not considered a credible event as there is no single failure that can cause the valve to run full open and stay there. Refer also to the response provided for Question 15A.58.

Table 15A-1

RADIOLOGICAL CONSEQUENCES OF THE STEAM GENERATOR TUBE RUPTURE WITH A LOSS OF OFFSITE POWER AND FULLY STUCK OPEN ADV

Location	Offsite Doses, Rem	
	GIS	PIS
1. Exclusion area boundary 0-2 hours thyroid	40	200
2. Low population zone outer boundary 0-8 hours thyroid	20	41

QUESTION 15A.57 (SGTR Question 2)[a] (15.6.3)

The SGTR analysis also assumes a cooldown rate of 30F per hour at 30 minutes after the attempted closing of the affected steam generator ADV. Describe how the operator monitors the plant conditions to prevent the cooldown rate exceeding 30F/hr during this time period.

RESPONSE: The long-term cooldown rate of 30F per hour was chosen for the January 27, 1984, analysis so that shutdown cooling conditions were reached 8 hours after the event. This maximized the 0-8 hour dose. A more rapid, or a slower, cooldown would release less steam from the ruptured steam generator.

This assumption is not used in the revised analysis presented in the response to Question 15A.56.

QUESTION 15A.58 (SGTR Question 3)[a] (15.6.3)

Since the ADVs at Palo Verde do not have upstream block valves, there would be virtually no way of isolating a stuck open ADV. The staff believes from an overall plant safety standpoint, Palo Verde should install block valves upsteam of the ADVs, per the interface requirement stated in the CESSAR System 80 FSAR. Discuss your technical justification for a lack of the block valves, especially in light of industry experience suggesting that stuck open steam system valves are not an uncommon occurrence.

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated April 27, 1984.

Additionally, the Palo Verde SGTR analysis should either assume an ADV stuck in the full open position, or the applicant should provide positive assurance that the ADV cannot be opened beyond the assumed 10.5%.

RESPONSE: The analysis presented in the response to Question 15A.56 assumes an ADV stuck in the full open position. Nevertheless, this is not considered a credible single failure.

The PVNGS ADVs are air-operated hydraulic valves. The valves are spring loaded to fail closed on loss of air. Additionally, they may be closed by air or by an integral handwheel, if necessary. In order for the valve to open, an air supply must be provided. Two parallel sets of fail closed, three-way solenoid valves (four total) provide the air supply. In the closed position, the valves isolate the air supply and bleed air off of the ADV. The solenoid valves are powered by two channels of essential dc power. Each set of solenoid valves is controllable from the Control Room. Closure of any one set of valves is sufficient to terminate the air supply and close the ADV. The control schematic is provided as figure 15A-1.

Should all four solenoid valves fail by remaining energized, the operator can regulate the air supply by using the valve positioner and controller. These will also be able to close the ADV. In short, for the ADV to open and remain open, there must be six failures involving two channels of dc power. This is considered an incredible event.

Mechanical binding of the valve was also considered. In order to remain open, the valve would need to seize up so firmly that neither air pressure, spring nor manual handwheel operation would be able to close the valve. This would result in the valve sticking at the operating range. As noted in the January 27, 1984, analysis, offsite dose exposure is less than 150 rem even with the tubes uncovered. Under the revised analysis of Question 15A.56, with the tubes covered, the dose is 41 rem (table 15A-1).
The analysis of the steam generator tube rupture with a loss of offsite power and a fully stuck open atmospheric dump valve (ADV) follows:

Identification of Event and Causes

This transient is similar to that described in CESSAR Appendix 15D. It assumes that the plant is challenged by a steam generator tube rupture that includes additional events and failures beyond those postulated by the NRC Standard Review Plan 15.6.3. In addition to the conservative assumptions of the SRP (loss of offsite power, accident meteorology, iodine spiking, etc.), this analysis postulates that the operators open an ADV on the affected steam generator and that it both runs to the full open position and that it sticks full open for the duration of the transient. The ADV is presumed to remain open despite the availability of two redundant and independent safety grade valve control systems and a manual handwheel to close the ADV.

<u>Sequence of Events and Systems Operation</u>

Table 15A-2 presents a chronological list of events that are assumed to occur during the steam generator tube rupture event with a loss of offsite power from the time of the double-ended rupture of a steam generator U-tube to the attainment of shutdown cooling entry conditions.

The C-E Emergency Procedure Guidelines, CEN-152, contain guidance to the operator for controlling a steam generator tube rupture. Recognizing that the coincident occurrence of the limiting (conservative) assumptions of the SRP is unlikely, CEN-152 proposes that, should offsite power and the steam bypass control system be unavailable, the operator opens an ADV on each steam generator (ruptured or not) in order to preclude a challenge to the main steam safety valves (MSSVs). This action presupposes that the ADVs are reliable and can be closed after the RCS is cooled to a temperature which precludes a challenge to the MSSVs. It also presupposes that the MSSVs have not opened. However, due to the coincident conservative assumptions of the SRP, the MSSVs open early in the transient. Furthermore, Palo Verde procedures are oriented towards diagnosing the event and stabilizing the plant prior to initiating cooldown.

Because of the PVNGS emphasis on proper diagnosis prior to operator action, it is unlikely that the operator would open the ADV once the diagnosis indicated an SGTR.

Nevertheless, this scenario assumes that once an operator diagnoses a SGTR, he opens an ADV (as suggested in

CEN-152). To recover from this scenario, the plant specific Palo Verde Steam Generator Tube Rupture Procedure includes direction to the operator to maintain steam generator level such that the steam generator tubes are covered.

Table 15A-2

SEQUENCE OF EVENTS FOR A STEAM GENERATOR TUBE RUPTURE WITH A LOSS OF OFFSITE POWER AND FULLY STUCK OPEN ADV (Sheet 1 of 4)

Time (Sec)	Event	Setpoint or Value	Success Path or Comment
0.0	Tube rupture occurs	--	--
40	Third charging pump started, feet below program level	-0.75	Primary system integrity
40	Letdown control valve throttled back to minimum flow, feet below prgram level	-0.75	Primary system integrity

28,800	Shutdown cooling entry conditions are reached RCS pressure, psia/ temperature, F	400/350	--
28,800	Operator activates shutdown cooling system	--	--

As is evident, the multiple failure scenario being postulated is not internally consistent. However, for analytical purposes, the sequence of events described in table 15A-2 serves to bound the scenario by projecting the adverse operator action (full opening of the ADV on the ruptured generator) and the nonmechanistic ADV failure to occur at the earliest possible time consistent with ANSI Standard N660. Subsequent beneficial operator actions are delayed by times that are also consistent with the ANSI standard.

Accordingly, an analytical model was developed from the bounding assumptions. The model features include:

- secondary releases from both the MSSVs and ADVs
- early operator action to open the ADVs
- one potential series of operator actions to cover the S/G tubes
- time delays for operator recovery action
- delay in reaching shutdown cooling (chosen to maximize 8-hour steam release)

The disposition of normally operating systems for the SGTR event are the same as those presented in Table 15D-2 of CESSAR. The utilization of safety systems during the event is the same as that presented in Table 15D-3 of CESSAR.

The major assumptions regarding systems operation during the event are summarized below.

1) The auxiliary feedwater system (AFWS) is activated at 25% level wide range and shuts off at 30% level wide range prior to operator action.

2) Two AFW pumps are assumed to be available to supply feedwater to either steam generator. No credit is taken or the third 1E powered AFW train. An AFW flowrate of 650 gallons per minute per pump is assumed to be delivered to the steam generators at a SG pressure of 1270 psia.

3) The response times of ADVs, MSIVs, AFW control valves, and AFW flow isolation valves are assumed to be instantaneous.

4) After the loss of offsite power subsequent to reactor trip, no credit is taken for charging. One charging pump is assumed available for auxiliary spray in the pressurizer.

5) Two high pressure safety injection (HPSI) pumps are assumed to be available subsequent to the generation of a safety injection actuation signal.

RADIOLOGICAL CONSEQUENCES

The physical model is the same as that discussed in CESSAR Section 15D.3.2 except that the ADV of the affected steam generator opens fully. In order to reduce the radiological releases, the operator takes appropriate actions to recover the U-tubes of the affected steam generator. Actions assumed in this analysis included overriding the automatic isolation of AFW flow to the

affected steam generator and diverting the flow of both AFW pumps of the affected steam generator.

The assumptions and conditions employed for the evaluation of radiological releases are the same as those discussed in CESSAR Section 15D.3.2.B with the exceptions of assumptions 7, 9, and 10. They are:

7. During the period when the water level in the affected steam generator is above the top of the U-tubes, that portion of the leaking primary fluid which flashes to steam upon entering the steam generator is assumed to be released to the atmosphere with a decontamination factor (DF) of 1.0. The portion of the leaked fluid that does not flash, mixes with the liquid in the steam generator and is released to the atmosphere with a DF of 100. During the period when the water level is below the top of the U-tubes, it is assumed that all the leaking primary fluid escapes to the atmosphere with a DF of 1.0. No credit is taken for the presence of steam separators and dryers which would retain a part of the escaping primary liquid in the steam generator.

9. The 0-2 hour and 2-8 hour primary-to-secondary leakage through the rupture are 285,400 lbm and 516,700 lbm, respectively.

10. The atmospheric dispersion factors employed in the analyses are: 3.1×10^{-4} sec/m^3 for the exclusion area boundary and 5.1×10^{-5} sec/m^3 for the low population zone.

The mathematical model is as described in CESSAR Section 15D.3.2.C.

The 2-hour exclusion area boundary (EAB) and the 8-hour low population zone (LPZ) boundary inhalation doses for both the GIS and the PIS are presented in table 15A-1. The calculated EAB and LPZ doses are well within the acceptance criteria.

CONCLUSIONS

The dynamic behavior of important NSSS parameters during the event is presented in figures 15A-2 through 15A-15.

The radiological releases calculated for the SGTR event with a loss of offsite power and a fully stuck open ADV are well within the 10CFR100 guidelines. The RCS and secondary system pressures are well below the 110% of the design pressure limits, thus assuring the integrity of these systems. Additionally, no violation of the fuel thermal limits occurs, since the minimum DNBR remains above the 1.19 value throughout the duration of the event.

QUESTION 15A.59 (SGTR Question 1)[a] (15.6.3)

In the response to Question 15A.56, it states that feeding the affected steam generator is not a deviation from CEN-152. Our position is that since the Palo Verde SG isolation strategy is different from the approved generic CEN-152 strategy, this is a deviation which should be justified.

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated November 28, 1984.

RESPONSE: The PVNGS procedure for mitigating a steam generator tube rupture (SGTR) has been augmented to include direction to the operator to feed the affected steam generator in order to keep the tubes covered and maintain the iodine partition coefficient. APS acknowledges that this is a deviation from CEN-152, and our justification is provided below.

By directing the operator to feed the affected steam generator, to cover the tubes, the iodine partition coefficient is maintained. By maintaining the iodine partition co-efficient, offsite doses will be reduced. With this new procedural consideration, offsite doses will be reduced for any postulated SGTR. That is, a reduction in offsite doses would be realized for those scenarios which do not include a full open atmospheric dump valve failure.

This modification to the PVNGS procedure will be incorporated before fuel load of PVNGS Unit 1. Training of the operators will commence soon after approval of the procedure modification, and will require approximately 3 months to train all of the Unit 1 shifts. This training should be complete by initial criticality. Training will include simulator time and will emphasize the reduction of offsite releases and the potential for overfill of the affected steam generator.

We believe this justifies the deviation from CEN-152, for the PVNGS SGTR procedure.

As shown in figure 15A-4, the operator action to feed the affected steam generator in combination with the stuck open ADV may result in a primary system cooldown rate in excess of the Technical Specification maximum cooldown rate of 100F per hour. Although this operator action may result in exceeding a Technical Specification requirement, the action is justified by the need to maintain offsite doses as low as possible during a SGTR event.

<u>QUESTION 15A.60</u> (SGTR Question 2)[a] (15.6.3)

For a steam generator tube rupture, initially the secondary side of the affected steam generator will be fed by both the primary-to-secondary side leak and feedwater. This influx of water creates the potential for overfilling the steam generator. Discuss the information available to the operator to prevent overfilling the steam generator and the sensitivity of the time period from the start of the accident to the time when there could be an overfill problem, assuming the operator does not take any action to prevent overfilling. Alternately, show that the consequences of SG overfill are not significant.

RESPONSE: For a SGTR with loss of offsite power and a fully stuck open ADV, the steaming rate through the stuck open ADV is significantly higher than the primary-to-secondary side leak during the entire reported period of the transient. Therefore, the influx of leak flow from the primary system

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated November 28, 1984.

alone will not create the potential for overfilling the steam generator. The operator, after taking manual control of the auxiliary feedwater system, first raises the affected SG level above the top of the U-tubes. Thereafter, the auxiliary feedwater flow is throttled to maintain the level above the top of the SG U-tubes at about 71.5% wide range. This level prevents any overfilling of the affected steam generator. The operator will continuously rely on the SG level measurements (12 Class 1E indicators per SG) for information all through the transient to keep the level below the acceptable limit of about 90% wide range in both generators. There are audio and visual alarms that actuate when it appears that the SG is being overfilled. It is these alarms and MSIS actuation which would provide overfill protection assuming no operator action. If at anytime there is a concern regarding SG overfill, the auxiliary feedwater to the affected steam generator will be temporarily terminated.

Combustion Engineering Emergency Procedure Guidelines (CEN-152) provides suggestions regarding steam generator overfill during a SGTR event mitigation. These suggestions include draining to radwaste system and steaming the generator.

<u>QUESTION 15A.61</u> (SGTR Question 3)[a] (15.6.3)

Evaluate the sensitivity of the time period the SG tubes could be uncovered to the increase in radiological consequences.

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated November 28, 1984.

Relate this study to the amount of tube uncovery without credit for manual SG level control.

RESPONSE: In the analysis of a SGTR with loss of offsite power and a fully stuck open ADV, the first operator action taken to recover the level in the affected SG was assumed to occur 2 minutes after isolation of the auxiliary feedwater flow to the affected SG. The action consisted of overriding the auxiliary feedwater isolation signal in order to start feeding the affected steam generator again. Two minutes subsequent to this action the operator takes manual control of the auxiliary feedwater system and starts feeding the affected steam generator with both auxiliary feedwater pumps. The actions were taken to raise the level in the affected SG above the top of the U-tubes as quickly as allowed by the emergency operating procedure since the magnitude of the offsite radiation dose is sensitive to the duration of SG tube uncovery.

In order to limit the doses within acceptable limits the operator needs to take timely actions. The current analysis assumed the operator takes manual control of the auxiliary feedwater system approximately 5 minutes after opening the ADV on each SG or 2 minutes after overriding the auxiliary feedwater system isolation signal. Calculations performed indicate that to limit the offsite doses to 10CFR100 guidelines, the operator will need to take manual control of the auxiliary feedwater system no later than approximately 12 minutes after opening of the ADV on each generator. The time interval between overriding the auxiliary feedwater isolation signal and taking manual control of the system is

again 2 minutes. Therefore, within the constraints and conservatisms inherent in the current model, the operator can delay taking manual control of the SG level by approximately 12 minutes after the opening of the ADVs, and still limit the offsite doses to 10CFR100 guidelines.

QUESTION 15A.62 (SGTR Question 4)[a] (15.6.3)

In your discussion of the steam generator tube rupture (Appendix); it states that 460 seconds (about 7-1/2 minutes) is the earliest possible time that the operator can take an adverse action. The bases for this statement was given as reference to ANSI Standard N660. Since the purpose of ANSI Standard N660 is not to determine the earliest time for operator to take "adverse" actions, our position is that inadequate bases have been provided to justify that the operator could not have opened the ADV earlier than 460 seconds. Therefore, determine the radiological consequences of the steam generator tube rupture with loss of offsite power assuming the operator opens an ADV on each steam generator at the earliest time possible that would result in the maximum radiological consequences.

RESPONSE: The largest contribution of the offsite dose during the event occurs in the time period between the opening of the ADVs and the time of recovery of the affected SG level above the U-tubes. This time period is greatly influenced by the inventory in the affected steam generator at the time that the ADVs are opened. In the current

a. Letter from G. W. Knighton, NRC, to E. E. Van Brunt, Jr., APS, dated November 28, 1984.

analysis the auxiliary feedwater flow to the affected SG is actuated on low SG level at about 177 seconds. Thereafter, the level is maintained in the narrow band between 25 and 30% wide range by the automatic operation of the auxiliary feedwater system. The SG level in the affected generator will be higher than 25% wide range prior to the auxiliary feedwater system actuation. Hence, opening of the ADVs at a prior time (that is, before 177 seconds) results in the inventory in the affected steam generator being higher than that calculated for the current analysis at the time the ADVs were opened. This means quicker recovery of the level in the affected steam generator since the inventory will be less depleted than for the current analysis.

Opening the ADV at an earlier time, when primary system pressure is higher, also causes increased primary-to-secondary flow through the postulated tube rupture. This offsets the level effects described above. Therefore, the overall impact on offsite doses is expected to be minimal. Analysis has verified that the most limiting offsite dose (preexisting iodine spike) is increased by less than 5%. For the offsite dose with an event generated iodine spike, analysis has verified an increase of approximately 8%. This assumes that the sequence of events between the opening of the ADVs and the operator taking manual control of the auxiliary feedwater system is the same for both cases. Therefore, even if the operator was to open the ADVs at a time prior to that assumed in the analysis, resulting offsite doses would still be within 10CFR100 guidelines.

APPENDIX 15B

DOSE MODELS USED TO EVALUATE THE ENVIRONMENTAL CONSEQUENCES OF ACCIDENTS

15B.1 INTRODUCTION

This appendix identifies the models used to calculate control room and offsite radiological doses, not calculated in CESSAR, that would result from releases of radioactivity due to various postulated accidents.

15B.2 ASSUMPTIONS

The following assumptions are basic to the model for the whole-body dose due to immersion in a cloud of radioactivity and to the model for the thyroid dose due to inhalation of radioactivity:

A. All radioactive releases are treated as ground level releases regardless of the point of discharge.

B. The dose receptor is a standard man, as defined by the International Commission on Radiological Protection (ICRP), (reference 1).

C. No credit is taken for cloud depletion by ground deposition and radioactive decay during transport to the exclusion area boundary (EAB) or the outer boundary of the low population zone (LPZ).

D. Radionuclide data, including decay constants and decay energies presented in table 15B-1, are taken from references 2 through 6.

APPENDIX 15B

Table 15B-1

RADIONUCLIDE PARAMETERS

Nuclide	Decay Constant (sec-1)	MeV/Disintegration (gamma)	Average MeV/Disintegration (beta)

Xe-138	8.15E-4	1.183	0.606

15B.3 WHOLE-BODY GAMMA AND BETA SKIN DOSE

The whole-body gamma dose delivered to an offsite dose receptor is calculated by assuming the receptor to be immersed in a hemispherical radioactive cloud that is infinite in all directions above the ground plane; i.e., a semi-infinite cloud. The concentration of radioactive material within this cloud is

uniform and equal to the maximum centerline ground level concentration that would exist in the cloud at the appropriate distance from the point of release.

The gamma dose to an offsite receptor due to gamma radiation for a given time period is:

$$D_{wb} = \chi / Q \bullet \sum_{i} DCF_{wbi} \bullet Q_i \qquad (1)$$

where:

D_{wb} = whole-body dose to an offsite receptor from gamma radiation, (rem)

χ / Q = site atmospheric dispersion factor effective during the time period at the point of exposure, (s/m^3)

DCF_{wbi} = whole body dose conversion factor for the semi-infinite cloud model for nuclide i, ($rem\text{-}m^3/Ci\text{-}s$). (See table 15B-2)

Q_i = total activity of nuclide i released during the time period, (Ci)

The gamma dose to the control room personnel is calculated assuming a finite hemispherical cloud model. The gamma dose due to gamma radiation in the control room for a given time period is:

$$D_{wb} = \frac{(CRVOL)^{0.338}}{1173} \sum_{i} DCF_{wbi} \frac{(IQ_i)\ (3600)\ (CRO)}{(CRVOL)\ (0.02832)} \qquad (2)$$

where:

D_{wb} = whole-body gamma dose to control room personnel from gamma radiation, (rem)

CRO = the control room occupancy factor ≤1

APPENDIX 15B

Table 15B-2

WHOLE-BODY GAMMA AND BETA SKIN IMMERSION DOSE CONVERSION FACTORS

Radionuclide	Beta Skin DCF (rem – m^3/Ci – sec)	Whole-Body Gamma DCF (rem – m^3/Ci – s)
I-131	3.17E-2	8.72E-2
I-132	1.32E-1	5.13E-1
I-133	7.35E-2	1.55E-1
I-134	9.23E-2	5.32E-1
I-135	1.29E-1	4.21E-1
Kr-83m	0	2.40E-6
Kr-85	4.24E-2	5.102E-4
Kr-85m	4.62E-2	3.7E-2
Kr-87	3.08E-1	1.88-1
Kr-88	7.51E-2	4.65E-1
Kr-89	3.2E-1	5.26E-1
Xe-131m	1.508E-2	2.89E-3
Xe-133m	3.15E-2	7.95E-3
Xe-133	9.69E-3	9.32E-3
Xe-135m	2.25E-2	9.89E-2
Xe-135	5.89E-2	5.74E-2
Xe-137	3.86E-1	4.50E-2
Xe-138	1.31E-1	2.80E-1

3600 = conversion factor, s/h

0.02832 = conversion factor, ft^3/m^3

CRVOL = control room volume, ft^3

IQ_i = total integrated activity for nuclide i in control room for the time period, (Ci-hr)

DCF_{wbi} = the semi-infinite cloud whole-body gamma dose conversion factor for nuclide i, (rem-m^3/Ci-s). (See table 15B-2)

The expression $\frac{(\mathrm{CRVOL})^{0.338}}{1173}$ is a geometrical correction factor to ratio a finite cloud to infinite cloud[7].

The beta skin dose to control room personnel is calculated assuming a tissue depth of 7 mg/cm^2. The beta skin dose to control room personnel for a given time period is:

$$D_{\beta s} = \frac{\mathrm{CRO}}{(\mathrm{CRVOL})\,(0.02832)} \sum_i D_{\beta si} \bullet IQ_i \qquad (3)$$

where:

$D_{\beta si}$ = the beta skin dose conversion factor for nuclide i, (rem-m^3/Ci-h). (See table 15B-2 for factor)

and all other parameters are as previously defined.

15B.4 THYROID INHALATION DOSE

The thyroid dose to an offsite receptor for a given time period is obtained from the following expression:

$$D = x / Q \bullet B_i \bullet \sum (Q_i \bullet DCF_i) \qquad (4)$$

where:

D = thyroid inhalation dose, (rem)

x/Q = site atmospheric dispersion factor during the time period, (s/m^3)

B = breathing rate during the time period, (m^3/s). (See table 15B-3)

Q_i = total activity of nuclide i released during time period, (Ci)

DCF_i = thyroid dose conversion factor for nuclide i, (rem/Ci inhaled). (See table 15B-4)

The radionuclide data are given in table 15B-1. The atmospheric dispersion factors used in the analysis of the environmental consequences of accidents are given in section 2.3.

Breathing rates and dose conversion factors for radioactive iodines required for computing thyroid inhalation doses are tabulated in Tables 15B-3 and 15B-4, respectively.

15B.5 CONTROL ROOM DOSE

During the course of an accident, control room personnel may receive doses from the following sources:

A. Direct whole-body gamma dose from the radioactivity present in the containment building

B. Direct whole-body gamma dose from the radioactive cloud surrounding the control room

C. Whole-body gamma, thyroid inhalation, and beta skin doses from the airborne radioactivity present in the control room.

In calculating the exposure to control room personnel, occupancy factors were obtained from reference 7 as follows:

0 to 24 hours: occupancy factor = 1

1 to 4 days: occupancy factor = 0.6

4 to 30 days: occupancy factor = 0.4

The dose model for each of the radiation sources is discussed below:

A. Direct whole-body gamma dose from the radioactivity present in the containment building (direct containment dose).

Time integrated (0 to 30 days) radionuclide concentrations in the containment are calculated. For conservatism, no credit is taken for reduction of the containment activity by means other than radioactive decay. The containment is modeled by an equivalent volume cylindrical source having a diameter of 146

feet and a height of 155 feet. The radioactivity present in the containment is assumed to be uniformly distributed in the cylindrical source. Shielding is provided by the 4-foot concrete containment walls, 120 feet of air separating the containment building from the control building, and 2-foot thick control room walls.

No credit is taken for any shielding that would be provided by the auxiliary building.

B. Direct whole-body gamma dose from the radioactive cloud surrounding the control room (outside cloud dose). Leakage from the containment building, or any building, will result in the formation of a radioactive plume. For conservatism it is assumed that this plume forms a cloud surrounding the control room. Gamma radiation from this cloud, although attenuated, can penetrate the control room roof and walls resulting in a whole-body gamma dose to control room personnel. The radius of the cloud is computed using a mass balance of the radioactivity released due to leakage and the volume of the cloud; therefore, the radioactive cloud is time variant and expands for the duration of the accident.

Radioactivity concentration (Ci/m^3) in the radio-active cloud surrounding the control room is the product of the building leak rate (Ci/s) and the control room atmospheric dispersion factor, χ/Q (s / m^3. Exclusion area boundary and low population zone χ/Q's are

presented in section 2.3. A tabulation of control room χ/Q's is presented in table 15B-5.

Credit is taken for concrete shielding provided by the control room walls and ceiling.

Table 15B-5

ATMOSPHERIC DISPERSION FACTORS

(1986 – 1991)

Time Period	Control Room χ/Q (s/m^3)
0 to 8 hours	1.56(-3)
8 to 24 hours	1.08(-3)
1 to 4 days	4.15(-4)
4 to 30 days	1.03(-4)

C. Dose from the airborne radioactivity present in the control room (occupancy dose).

Airborne radioactivity will be drawn into the control room due to the intake of outside air required to maintain a positive pressure in the control room. This contributes to the whole-body gamma, thyroid inhalation, and beta skin doses. The major parameters of the control room ventilation system are presented in table 15B-6.

The whole-body gamma dose is computed using a finite cloud model. The calculational model is an equivalent volume hemisphere of 42-foot radius.

A thyroid inhalation dose results from the radioactive iodine present in the control room. The control room

habitability system, designed to remove iodine from the air, is described in table 15B-6.

15B.6 ACTIVITY RELEASE MODELS

15B.6.1 GENERAL EQUATION

The activity released from a postulated accident is calculated by using the following matrix equation for each isotope and each species of iodine:

$$\frac{d\bar{A}}{dt} + \bar{C}\ \bar{A} = \bar{S}\text{; Initial Condition } \bar{A}(t_o) = \bar{A}_o \qquad (5)$$

$$\bar{Q} = \bar{L} \times \overline{AI}$$

where:

$\bar{A}(T)$ = ${}_i(a\ (t))$

a_i = the activity in the ith node, (Ci)

$\bar{C}$ = (C_{ij}) matrix

C_{ij} = the transfer rate from the ith node to the jth node, (s^{-1})

$\bar{S}$ = (S_i) vector

S_i = the production rate in the ith node (Ci/sec)

$\bar{Q}$ = the activity released to the environment over the time period t_o to t_i, (Ci)

$\bar{L}$ = (ℓ_i) matrix

ℓ_i = the leak rate from the ith node to environment (/sec)

$\overline{AI}$ = $\int_{t_o}^{t_1} \bar{A}(t)\ dt$ (Ci-sec)

APPENDIX 15B

Table 15B-6

CONTROL ROOM ESSENTIAL VENTILATION SYSTEM PARAMETERS[(a)]

Parameter	Assumption
Number of emergency ventilation systems operating	1
Maximum filtered intake rate, (SCFM)	1,000
Unfiltered intake rate, (SCFM)	0
Unfiltered intake for egress/ingress (SCFM)	See Section 6.4.7
Intake clean filter efficiency	
Iodine, elemental,%	95
Iodine, organic,%	95
Iodine, particulate%	99
Minimum Recirculation rate, standard ft3/min	25,740
Recirculation cleanup filter efficiency	
Iodine, elemental, %	95
Iodine, organic. %	95
Iodine, particulate %	99
Leak rate, standard ft3/min (out leakage)	1,010
Control room volume, standard ft3	161,000

a. There are two completely redundant emergency control room ventilation systems.

For a more detailed description of this system, refer to subsection 9.4.2. The dose model employed in this analysis is consistent with the thyroid inhalation model discussed in section 15B.4.

The beta skin dose model is consistent with the "infinite hemispherical cloud" model described in section 15B.3.

Each node represents a volume where activity can be accumulated. The environment and the control room are each represented by a node. To ensure that the system of differential equations has constant coefficients, the time scale is broken up into time intervals over which all parameters are constant. Thus, all coefficients and sources are assumed to be representable by step functions.

The matrix equation is solved using matrix techniques. The particular solution is obtained by Gaussian elimination. The homogenous solution is obtained by solving for the eigenvectors and the eigenvalues of the coefficient matrix C. They are determined by using QR transformation techniques.

The following sections describe how the coefficient matrix and the source vector are calculated for the different accident calculations.

15B.6.2 THE MODEL FOR CONTAINMENT LEAKAGE

The model for LOCA containment leakage is shown in figure 15B-1. The system of differential equations for estimating the released activity is as follows:

$$\frac{dA_1}{dt} + \lambda_d A_1 - L_{21}A_2 - L_{31}A_3 - L_{41}A_4 = 0 \qquad (6a)$$

$$\frac{dA_2}{dt} + (\lambda_d + \lambda_s + L_{21} + L_{24})\ A_2 - L_{42}A_4 = 0 \qquad (6b)$$

$$\frac{dA_3}{dt} + (\lambda_d + \lambda_s + L_{31} + L_{34})A_3 - L_{43}A_4 = 0 \qquad (6c)$$

$$\frac{dA_4}{dt} - L_{24}A_2 - L_{34}A_3 + (\lambda_d + L_{41} + L_{42} + L_{43})A_4 = 0 \qquad (6d)$$

$$\frac{dA_5}{dt} - \frac{X}{Q}\left(L_u+(1-f_L)L_f\right) L_{21}A_2 - \frac{X}{Q}\left(L_u+(1-f_L)L_f\right)L_{31}$$

$$-\frac{X}{Q}\left(L_u+(1-f_L)L_f\right) L_{41}A_4 + \left(L_f + L_u + f_rR_c + \lambda_d\right) A_5 = 0 \qquad (6e)$$

$$Q = \int_{t_0}^{t_1} \left(L_{21}A_2 + L_{31}A_3 + L_{41}A_4\right) dt \qquad (7)$$

where:

$A_1(t)$ = activity in the environment, (Ci)

$A_2(t)$ = activity in the sprayed main region of the containment, (Ci)

$A_3(t)$ = activity in the auxiliary sprayed region of the containment (Ci)

$A_4(t)$ = activity in the unsprayed region of the containment, (Ci)

$A_5(t)$ = activity in the control room, (Ci)

λ_d = radioactive decay constant, (s^{-1})

$L_{21} = \dfrac{T_{21}}{(100)(24)(3600)}$, (s^{-1})

T_{21} = leak rate from the main sprayed volume to the environment, (%/day)

$L_{31} = \dfrac{T_{31}}{(100)(24)(3600)}$, (s^{-1})

T_{31} = leak rate from the auxiliary sprayed volume to the environment, (%/day)

$L_{41} = \dfrac{T_{41}}{(100)(24)(3600)}$, (s^{-1})

T_{41} = leak rate from the unsprayed volume to the environment (%/day)

λ_s = the spray removal constant, (s^{-1})

$L_{24} = \frac{T_{24}}{(V_2)(60)}$, ($s^{-1}$)

T_{24} = transfer rate from the main sprayed region to the unsprayed region, (ft^3/min)

V_2 = volume of the main sprayed region, (ft^3)

$L_{42} = \frac{T_{42}}{(V_4)(60)}$, ($s^{-1}$)

T_{42} = transfer rate from the unsprayed region to the sprayed region, (ft^3/min)

V_4 = volume of the unsprayed region, (ft^3)

$L_{34} = \frac{T_{34}}{(V_3)(60)}$, ($s^{-1}$)

T_{34} = transfer rate from the auxiliary sprayed region to the unsprayed region (ft^3/min)

V_3 = volume of the auxiliary sprayed region (ft^3)

$L_{43} = \frac{T_{43}}{(V_4)(60)}$, ($s^{-1}$)

T_{43} = transfer rate from the unsprayed region to the auxiliary sprayed region, (ft^3/min)

$L_u = \frac{T_u \cdot (0.3048)^3}{60}$, ($m^3$/s)

Tu = unfiltered inleakage into the control room, ft^3/min)

L_f = $\frac{T_f\ (0.3048)^3}{60}$, ($m^3$/s)

f = filtered air intake rate into the control room, (ft^3/min)

f_L = filter efficiency of the filters on the intake units

x/Q = atmospheric dispersion factor for the control room, (s/m^3)

R_c = $\frac{T_r}{(V_c)\ (60)}$, (s^{-1})

T_R = filtered recirculation rate in the control room, (ft^3/min)

V_c = control room free volume, (ft^3)

f_R = filter efficiency of the filter on the recirculation unit

Q = activity released to the environment, (Ci)

The coefficient matrix is:

$\bar{C}$ =

$$\begin{bmatrix} \lambda_d & -L_{21} & -L_{31} & -L_{41} & 0 \\ 0 & \lambda_d+\lambda_s+L_{21}+L_{24} & 0 & -L_{42} & 0 \\ 0 & 0 & \lambda_d+\lambda_s+L_{31}+L_{34} & -L_{43} & 0 \\ 0 & -L_{24} & -L_{34} & \lambda_d+L_{41}+L_{42}+L_{43} & 0 \\ 0 & -x/Q(L_u+(1-f_L)L_f)L_{21} & -x/Q(L_u+(1-f_L)L_f)L_{31} & -x/Q(L_u+(1-f_L)L_f)L_{41} & L_f+L_u+f_rR_c+\lambda_d \end{bmatrix}$$

After solving for A(t), the integrated activity in each node can then be calculated. From the integrated activity, the offsite doses and the doses to the operators in the control room can be calculated using the dose models given in sections 15B.3 and 15B.4.

15B.6.3 THE MODEL FOR RECIRCULATION LOOP LEAKAGE

The model for LOCA leakage in recirculation loops outside containment is shown in figure 15.B-2. The activity released due to the operational leakage of the engineered safety feature (ESF) components during the recirculation mode of the postulated LOCA is calculated from the following equations:

$$\frac{dA_1}{dt} + \lambda_d A_1 - (1-f)L_{21}\ A_2 = 0 \qquad (8a)$$

$$\frac{dA_2}{dt} + (+\lambda_d+L_{21})\ A_2 = S_2 \qquad (8b)$$

$$Q = \int_{t_o}^{t_1} (1-f)\ L_{21}\ A_2\ dt \qquad (9)$$

where:

A_1 = the activity in the environment, (Ci)

A_2 = the activity in the ESF component rooms, (Ci)

λ_d = decay constant, (s^{-1})

L_{21} = filtered leak rate to the environment, (ESF room vol/s)

f = filter efficiency of the filters on the ESF room purge units

$$S_2 = P \bullet \frac{A_o T_s}{V_s}$$

A_o = activity in the recirculation water, (Ci)

P = iodine partition factor

T_s = twice the maximum operational leak rate, (cm^3/s)

V_s = total volume of recirculation water, (cm^3)

Q = activity released to the environment, (Ci)

The coefficient matrix is:

$$\bar{C} = \begin{bmatrix} \lambda_d & -(1-f)L_{21} \\ O & (\lambda_d + L_{21}) \end{bmatrix}$$

The source vector is

$$\bar{S} = \begin{bmatrix} O \\ \\ S_2 \end{bmatrix}$$

15B.6.4 THE MODEL FOR THE FUEL HANDLING ACCIDENT IN THE FUEL BUILDING WITH ESF SAFEGUARDS ACTUATION

The model for the release of activity from the fuel building during a postulated fuel handling accident is shown in figure 15B-3. The activity released to the environment is estimated from the following equations:

$$\frac{dA_1}{dt} + \lambda_d A_1 - (1-f)L_{21}A_2 = 0 \qquad (10a)$$

$$\frac{dA_2}{dt} + (\lambda_d + L_{21})A_2 = 0 \qquad (10b)$$

$$Q = \int_{t_o}^{t_1} L_{21}A_2 dt \qquad (11)$$

where:

A_1 = activity in the environment, (Ci)

A_2 = activity in the fuel building atmosphere, (Ci)

λ_d = decay constant, (s^{-1})

L_{21} = purge rate to the environment, (s^{-1})

f = filter efficiency of the filters on the ventilation unit

Q = activity released to the environment, (Ci)

The resultant coefficient matrix is:

$$\bar{C} = \begin{bmatrix} \lambda_d & -(1-f)L_{21} \\ 0 & (\lambda_d + L_{21}) \end{bmatrix}$$

15B.6.5 OTHER ACCIDENT MODELS

Other accidents can be conservatively modeled as simulated instantaneous releases to the environment. This is simulated as a large transfer rate to the environment. The model is shown in figure 15B-3. The system of differential equations is:

$$\frac{dA_1}{dt} + \lambda_d A_1 - L_{21} A_2 = 0 \tag{12a}$$

$$\frac{dA_2}{dt} + (\lambda_d + L_{21}) A_2 = 0 \tag{12b}$$

$$Q = \int_{t_o}^{t_1} L_{21} A_2 \, dt \tag{13}$$

where:

A_1 = activity in the environment, (Ci)

A_2 = activity to be released to the environment, (Ci)

λ_d = decay constant, (s^{-1})

L_{21} = very large transfer rate to the environment, (s^{-1})

Q = activity released to the environment, (Ci)

The resultant coefficient matrix is:

$$\bar{C} = \begin{bmatrix} \lambda_d & -L_{21} \\ & \\ O & (\lambda_d + L_{21}) \end{bmatrix}$$

ANALYSIS METHODS FOR LOSS OF PRIMARY COOLANT FLOW

CONTENTS

FIGURES

APPENDIX 15D
ANALYSIS METHODS FOR LOSS OF PRIMARY COOLANT FLOW

15D.1 INTRODUCTION

This appendix provides a description of methods used in the analysis of the nuclear steam supply system (NSSS) response to a loss of primary coolant flow (LOF) event. An LOF could occur as a result of a loss of electrical power to the four reactor coolant pumps (RCPs). The conclusions and results presented in subsection 15.3.1 were obtained using the methods described here. This method will hereafter be referred to as Space-Time Kinetics LOF (ST-LOF).

The computer codes used in the ST-LOF method are described in section 15D.2. The principal time-dependent parameters calculated are the primary coolant flow rate, reactor core power, hot bundle heat flux, and limiting channel departure from nucleate boiling ratio (DNBR). A comparison of present analysis methods with previous methods is given in section 15D.3. The analysis assumptions are listed in section 15D.4.

15D.2 COMPUTER CODES

15D.2.1 DATA TRANSFER

Given the postulated initiating event, the COAST code is used to compute the core inlet volumetric flow rate as a function of time. These data are then input to the CESEC or CENTS code which predicts the overall system response. CESEC or CENTS calculates plant protection system responses and valve actuations for assessing the long term consequences of the LOF.

CESEC or CENTS also computes the time-dependent core inlet mass flux, core inlet coolant temperature, and reactor coolant system (RCS) pressure (note that no credit is taken for pressure increases when computing the DNBR transient effects). These parameters can later be used as input to the HERMITE code. For those cases where a reactor trip occurs so rapidly that only the coolant flow rate changes, CESEC or CENTS is bypassed and the flow coastdown is input directly to HERMITE.

HERMITE is used to predict the reactor core response during a LOF. HERMITE calculates the transient core power, core average heat flux, and hot bundle heat flux. The time-dependent core average heat flux along with the core inlet coolant mass flux, core inlet coolant temperature, and RCS pressure are input to the CETOP code. This code computes the limiting channel coolant conditions and the limiting channel DNBR. Figure 15D-1 depicts the transfer of data between the computer codes used.

The entire data transfer highlighted in figure 15D-1 is not repeated for each cycle reload since nothing in the early steps changes from cycle to cycle. The later steps (specifically, HERMITE and CETOP executions) are repeated with each cycle because of changes in fuel parameters (e.g., core average heat flux and hot bundle heat flux).

15D.2.2 COAST

The COAST code is used in the same manner as described in CENPD-183.[1] COAST analyzes reactor coolant flow under any combination of active and inactive pumps in a two-loop, four pump plant. The equation of conservation of momentum is written for each of the flow paths of the COAST model assuming

unsteady one-dimensional flow of an incompressible fluid. The equation of conservation of mass is written for the appropriate nodal points. Pressure losses due to friction, bends, and shock losses are assumed proportional to the flow velocity squared. Pump dynamics are modeled using a head flow curve for a pump at full speed and using four quadrant curves, which are parametric diagrams of pump head and torque on coordinates of speed versus flow, for a pump at other than full speed.

The COAST code has been verified by comparison to measurements taken during the initial startup test program of the PVNGS units. A further description of COAST is contained in CENPD 98.[2]

15D.2.3 CESEC III OR CENTS

The CESEC III or CENTS code is used to determine the long term response of the NSSS to primary coolant flow reductions resulting from postulated LOF events. The CESEC III or CENTS code may also be used to predict the change in core inlet coolant temperature if this parameter changes before the time of minimum DNBR.

CESEC III or CENTS computes key system parameters during a transient including core heat flux, pressures, temperatures, and valve actions. A partial list of the dynamic functions included in this NSSS simulation includes:

- point kinetics neutron behavior
- Doppler and moderator reactivity feedback
- boron and control element assembly (CEA) reactivity effects

- multi-node average channel reactor core thermal hydraulics
- reactor coolant pressurization and mass transport
- RCS safety valve behavior
- steam generation
- steam generator water level
- main steam bypass
- secondary safety and turbine valve behavior
- alarm, control, protection, and engineered safety feature system actions.

Initial steam generator feedwater enthalpy and flow rate are typically set to match the initial power for transient simulations. For a further description of CESEC III or CENTS, see section 15.0.

15D.2.4 HERMITE

One application of the HERMITE code is to determine the reactor core response during postulated LOF events. HERMITE can accept as input the transient boundary conditions of coolant flow rate, inlet coolant temperature, RCS pressure, and CEA position. In this application, HERMITE solves the few-group, space- and time-dependent neutron diffusion equation including feedback effects of fuel temperature, coolant temperature,

coolant density, and control element motion for a one dimensional average fuel bundle. The fuel temperature model explicitly represents the pellet, gap, and clad regions of an average fuel pin and representative hot bundle fuel pin. The

hot bundle fuel pin power density is related to the average fuel pin power density by time-dependent planar radial power peaking factors. For the calculation of heat flux, heat conduction equations are solved by a finite difference method. Continuity and energy conservation equations are solved in order to determine the coolant temperature and density for the average and hot bundles. A further description of HERMITE is given in CENPD-188-A.[3]

The hot bundle fuel pin power density is equal to the core average fuel pin power density multiplied by the planar radial power peaking factor, $F_{(xy)}(z)$. For times prior to the insertion of CEAs, and for regions of the core that the CEAs have not entered, the $F_{(xy)}(z)$ is equal to a conservatively chosen initial value. As the CEAs pass a plane of the core, the radial power peaking factor of that plane is increased as a function of time from the initial value. The increase in $F_{(xy)}(z)$ calculated by HERMITE is limited so that the power at a hot spot within a given plane of the core will not rise faster than for the average of that plane. If the power in the average channel of the plane has fallen since the last time step, the $F_{(xy)}(z)$ increase is limited so that the power in the hot spot for that plane does not increase.

The synthesis of the axial power distribution and the planar radial power peaking factors provides a conservative representation of the hottest fuel assembly during the LOF transient, including maximum three dimensional power peaking effects. This technique yields a conservative prediction of the minimum DNBR which can occur as a result of the LOF transient.

15D.2.5 CETOP

The CETOP code uses the CE-1 critical heat flux correlation described in CENPD-162-P[4] to calculate the limiting channel DNBR transient. CETOP receives the core average fuel bundle heat flux, core inlet coolant mass flux, core inlet coolant temperature, and RCS pressure at selected times during the LOF transient. The code is used to perform static calculations of the axial coolant enthalpy distribution and DNBR at these times. No credit is taken for RCS pressure increases in calculating the DNBR. The CETOP code is also discussed in section 15.0.

15D.3 COMPARISON WITH PREVIOUS METHODS

CENPD-183, Appendix A[3] describes the methodology used to predict the consequences of postulated LOF events for many previous Combustion Engineering NSSS designs. This section summarizes the fundamental differences between the ST-LOF method and that described in CENPD-183.

The primary difference between these methods is in the calculation of the core power. The CENPD-183 method uses the QUIX code to compute reactivity as a function of CEA position assuming the neutron flux and delayed neutron precursors are in equilibrium. Combining CEA position versus time data with the reactivity versus CEA position data produces the time-dependent reactivity function which is input to the CESEC or CENTS point kinetics equations.

The ST-LOF method uses HERMITE to calculate the core power directly from CEA position versus time. HERMITE calculates the

time-dependent neutron flux in one dimension (axially) with the few group diffusion equation explicitly accounting for fission, absorption, and transport cross-section variations.

Other differences exist in the calculation of the hot channel heat flux. In the CENPD-183 methodology, it is assumed that the hot channel normalized heat flux decay is equivalent to the core average normalized heat flux decay for computing the time of minimum DNBR. Furthermore, it is assumed that the axial heat flux distribution is constant in time. The minimum DNBR value calculated with the CENPD-183 methodology assumes no decay of the hot channel heat flux.

In the ST-LOF method it is assumed that the hot bundle normalized power decay is equivalent to the core average normalized power decay prior to the insertion of the CEAs. As the CEAs are inserted in the core, the planar radial peaking factors are increased so that the hot channel power decreases less rapidly than core average power for the rodded planes. The hot bundle and core average axial heat flux distributions are each time-dependent. The minimum DNBR value calculated with the ST-LOF method is based on the decay heat flux calculated by HERMITE at the time of minimum DNBR.

CENPD-183 describes both static and dynamic methods for computing the DNBR. The ST-LOF method uses the static method for calculating the DNBR as described in CENPD-183, Appendix A except that CETOP is used in place of COSMO.

15D.4 ANALYSIS ASSUMPTIONS

A number of conservative assumptions are made in the LOF analysis. These assumptions are:

- RCS pressure increase during the transient is not credited for in DNBR calculations
- a conservative (most positive) moderator temperature coefficient (MTC) is assumed
- a conservative time of the pump speed trip is assumed
- a conservative (minimum) scram bank reactivity rod worth is assumed.

APPENDIX 15E

LIMITING INFREQUENT EVENT

APPENDIX 15E

CONTENTS

APPENDIX 15E

TABLES

APPENDIX 15E

FIGURES

APPENDIX 15E

LIMITING INFREQUENT EVENTS

15E.1 IDENTIFICATION OF CAUSES AND FREQUENCY CLASSIFICATION

This event is a composite event that is evaluated to bound all infrequent events, including Anticipated Operational Occurrences (AOOs) in combination with a single active failure, with respect to the degradation in the Departure from Nucleate Boiling Ratio (DNBR). In general, all combinations of infrequent events including AOOs with single active failures need to be evaluated. To avoid evaluating all the potential AOOs as initiating events and single failures, the composite event assumes that an unspecified initiating event degrades all the thermal margin preserved by the COLSS and brings the core conditions to the DNBR SAFDL. Therefore, this event is initiated by any AOO (moderate frequency events). The composite event, by definition, is an infrequent event and includes moderate frequency events in combination with an active single failure.

Note that this composite event bounds all infrequent events including AOOs with single failure with respect to the DNBR degradation. The limiting AOO with respect to Fuel Centerline Melt Temperature (or Peak Linear Heat Rate) is CEA Bank Withdrawal event that is evaluated in UFSAR Chapter 15.4.

15E.2 SEQUENCE OF EVENTS AND SYSTEM OPERATIONS

The composite event assumes that an unspecified initiating event degrades all the thermal margin preserved and brings the

core conditions to the DNBR SAFDL. This assumption is conservative since the AOOs are specifically analyzed to ensure that the SAFDLs are not violated and the necessary thermal margin is preserved by the LCOs. The active single failure is assumed to further aggravate the DNBR degradation. The most limiting active single failure for DNBR degradation is determined to be LOP, which in turn, result in the coastdown of all four RCPs. Therefore, the most limiting infrequent event with respect to the DNBR degradation can be described as The Loss of Flow (LOF) from the SAFDL.

The composite event then is simply modeled as a LOF, using the LOF methodology (References 1 and 2), with the conditions at the beginning of the flow coastdown corresponding to SAFDL conditions. Starting from SAFDL conditions, the LOP results in an RCP coastdown that leads almost immediately to a reactor trip by the Core Protection Calculator (CPC) DNBR function, as the reduction in Reactor Coolant System (RCS) flow degrades DNBR below the initial SAFDL conditions. Within ~3.5 seconds of event initiation (~3 seconds after reactor trip), the local and average core heat fluxes have decreased sufficiently so that no pins remain in DNB. Hence, DNB propagation is not predicted to occur. Figure 15E-1 provides the transient DNBR response for the event.

15E.3 CORE AND SYSTEM PERFORMANCE

A set of initial conditions corresponding to the DNBR SAFDL was calculated with the CETOP-D code. This is a bounding assumption, since the CPC DNBR trip will provide a trip prior to the core conditions reaching the DNBR SAFDL conditions with

a very high probability. The SAFDL conditions include an assumed, pre-existing power of 116%, representing the undefined limiting AOO. The LOF methodology models only the core average and the hot channel using the HERMITE computer code (Reference 3). The core average and hot channel response to the LOF event from these initial conditions was simulated using the 1-D HERMITE code. The transient DNBR values were calculated using the CETOP-D code, which uses the CE-1 CHF correlation. Input parameters and initial conditions were selected to maximize the DNBR degradation. Using the conditions at the time of minimum DNBR, a more accurate DNBR is calculated using the more detailed TORC code for several different values of radial peaking.

Although a LOP would not occur for at least three seconds following a turbine trip, this evaluation conservatively assumes a coincident turbine trip and LOP. The RCP coastdown leads to a CPC DNBR reactor trip. RCS flow coastdown degrades DNBR below the initial SAFDL conditions. DNBR degradation is terminated when the mitigating effects of the SCRAM Control Element Assembly (CEA) insertion dominate the flow coastdown.

15E.3.1 Mathematical Models

The Limiting Infrequent Event was analyzed with respect to core performance with the following mathematical models:

- The one-dimensional HERMITE space-time computer code was used to calculate the core average and hot channel response to a LOF event from the DNBR SAFDL. The HERMITE computer code is described in UFSAR Section 4.3 and in an

NSSS vendor topical report (Reference 3). HERMITE was also used to determine the boron concentration at the Moderator Temperature Coefficient (MTC) value selected for this analysis.

- The CETOP-D computer code, which uses the CE-1 Critical Heat Flux correlation, was used to calculate the initial and transient DNBR values. The CETOP-D computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports (References 4, 5, and 6). CETOP-D was also used to determine initial Power Operating Limit (POL) conditions for this event (see UFSAR Section 15.1.3.3.2 for additional information on POL conditions).

- The TORC computer code, which uses the CE-1 CHF correlation, was used to calculate the minimum DNBR value using the conditions corresponding to the time minimum DNBR was predicted by the CETOP-D code. The TORC computer code is described in UFSAR Section 4.4 and in NSSS vendor topical reports (References 8 and 9).

- Because the models in the CETOP-D code are not as detailed as those in TORC, DNBR predictions from CETOP-D are typically adjusted by penalty factors to ensure conservatism. Use of the more detailed TORC computer code removes the requirement for penalty factors and provides a more accurate prediction of the DNBR value than the CETOP-D code.

- Fuel failure calculations use a statistical convolution technique that is described in Reference 1. This technique involves the summation, over the reactor core,

of the number of fuel pins at a specific DNBR value, multiplied by the probability of DNB occurring at that DNBR value.

15E.3.2 Input Parameters and Initial Conditions

Table 15E-1 summarizes the key input parameters and initial conditions utilized in the core performance safety analysis for the limiting infrequent event. Since the average NSSS response is not applicable for this event, the parameters that are not input to the HERMITE or CETOP/TORC are not listed in the table.

The following assumptions are made in this analysis:

- The Rated Thermal Power (RTP) was set to the maximum, 3990 MWt.
- The most limiting event would occur from full power operation. The initial power level used in the core performance safety analysis was increased to 116% of RTP (to represent the ROPM for an unspecified limiting AOO).
- The initial core inlet temperature, and pressurizer pressure are selected to maximize the DNBR degradation, and RCS flow rate was determined with the CETOP-D code, corresponding to DNBR SAFDL conditions at the assumed initial core power. For the purpose of computing SAFDL conditions, the radial peaking factor, F_R, was set to a maximum value when obtaining the SAFDL conditions.
- The LOF involves a reduction in reactor coolant flow rate, which decreases the coolant mass flux and increases the coolant temperature in the core region. Use of a negative

MTC value during this heatup would add negative reactivity, which in turn would tend to reduce reactor power and core heat flux. Therefore, for conservatism, the least negative MTC allowed by the Technical Specifications at Hot Full Power (HFP) was used in the analysis.

- The least negative Doppler fuel temperature coefficient curve, at Beginning of Cycle (BOC), was assumed. Least negative values minimize the addition of negative reactivity caused by increasing fuel temperature.

- BOC values were chosen to model delayed neutron kinetics. The delayed fraction is larger at BOC values and results in a slower power response. This delays the decrease in core power during the flow coastdown and following the reactor trip causing the heat flux decreasing more slowly and causes a later turn-around of DNBR. Since the flow is decreasing with time, delaying the heat flux results in a lower flow rate at the time of minimum DNBR.

- If power generation in the core is shifted toward the bottom, the insertion of negative reactivity following reactor trip will be somewhat delayed until the CEAs have inserted farther into the core. The scram reactivity curve was therefore based on a positive ASI representing a bottom-peaked core. The time versus scram reactivity curve was adjusted to account for a 0.6-second CEA holding coil time delay following opening of the reactor trip breakers, and normalized to model 90% CEA insertion at 4.0 seconds after power is removed from the Control Element

Drive Mechanism (CEDM) coils (see UFSAR Section 3.9.4). In addition, the insertion of reactivity was delayed to account for the response time of the Reactor Protective System (RPS). This delay accounts for the time interval between when the CPCs would detect a low DNBR condition to the time at which electrical power to the CEDM coils would be interrupted.

- The CEA worth at trip represents the minimum scram worth for HFP conditions at BOC, assuming the most reactive CEA remains stuck out of the core following reactor trip. This is more limiting (less scram worth) than the anticipated scram reactivity worth at other times during the operating cycle for HFP conditions.
- Parametric studies with the HERMITE code for a LOF event show that, for any given axial power distribution, the most limiting ROPM occurs with lower core inlet temperatures, higher pressures, higher core flow rates and lower fuel rod pellet-to-clad gap conductance. A low value for gap conductance, which delays the decay of the heat flux, was therefore selected for this analysis, corresponding to the maximum core average linear heat rate.
- For the limiting infrequent event, an additional single active component failure involving a LOP was modeled for the core performance safety analysis.
- There was no operator action for the first 30 minutes of the event.

APPENDIX 15E

TABLE 15.E-1

PARAMETERS USED FOR THE LIMITING INFREQUENT EVENT

PARAMETER	Value
Rated Thermal Power (MWt)	3990
Initial core power (% of RTP)	116
Initial core inlet temp (°F)	548
Initial pressurizer pressure (psia)	2325
Initial RCS flow (% of design)	108.8
MTC ($\Delta\rho$/°F)	-0.2E-4
FTC	Least negative
Kinetics	Maximum β
CEA worth at trip - WRSO (%$\Delta\rho$)	-8.0
Fuel rod gap conductance (Btu/hr-ft^2-°F)	Minimum Local
Plugged SG tubes	N/A
Single failure	None
LOP	Yes

NOTE 1: The Local Minimum Fuel Rod Gap conductance (Hgap) is determined using the FATES code and is documented in a reload analyses calculation.

15E.3.3 Results

The Standard Review Plan provides a specific acceptance criterion for all AOOs with a single failure as:

> An incident of moderate frequency in combination with any single active component failure, or single operator error, should not result in loss of function of any barrier other than the fuel cladding. A limited number of fuel rod cladding perforations are acceptable.

The safety analysis shows that the calculated minimum DNBR would approach a value of 1.17 at approximately 2.1 seconds following the LOP, which is well below the DNBR SAFDL of 1.34. Figure 15E-1 depicts a representative hot channel DNBR transient for this limiting event. Within ~3.5 seconds, local and average core heat flux has decreased enough such that no pins experiencing DNB remain. Hence, DNB propagation is not predicted to occur.

The radial peaking factor used to calculate the minimum DNBR was 1.9243 for this limiting case. This corresponds to an initial peaking of 1.91 and reflects the peaking increase in the heat fluxes caused primarily by the coolant heat-up during the flow coast-down. Additional TORC cases were run to assess the sensitivity of the minimum DNBR value to changes in the radial peaking factor. The results of these additional cases, all of which used the same thermal-hydraulic conditions at the time of minimum DNBR predicted by CETOP-D, are shown in Table 15E-2.

APPENDIX 15E

Table 15E-2

TYPICAL MINIMUM DNBR VERSUS RADIAL PEAKING FACTOR FOR THE LIMITING INFREQUENT EVENT CORE PERFORMANCE SAFETY ANALYSIS

Radial Peaking Factor, F_R, at the Time of Minimum DNBR	Minimum DNBR
1.9243	1.17
1.7	1.44
1.5	1.74
1.3	2.11

Minimum DNBR versus F_R data pairs similar to Table 15E-2 are calculated in cycle-specific reload analyses to provide a prediction of the DNBR propagation and amount of fuel failure for any proposed reload core design pin census (i.e., the distribution of power generation among fuel pins in a core). Such fuel failure calculations use a statistical convolution technique that is described in Reference 2. This technique involves the grouping of fuel rods with respect to radial peaking factors; calculating the minimum DNBR in each radial pealing group; and then determining the probability of experiencing DNB corresponding to each minimum DNBR value. The number of fuel rods damaged within a radial peaking group is given by the number of fuel rods in that group, multiplied by the probability of experiencing DNB at that group's minimum DNBR value. Finally, summing up the damaged fuel rods in all radial peaking groups yields the total number of fuel rods damaged in the core.

NRC approval is based upon the use of conservative analytical assumptions, including a hot channel flow factor that does not exceed 73% of the core average assembly inlet flow. A hot channel flow factor of 70%, which includes additional voluntary conservatism beyond that required by the PVNGS licensing basis, was utilized to obtain the minimum DNBR versus F_r data pairs in Table 15E-2.

15E.4 RCS PRESSURE BOUNDARY BARRIER PERFORMANCE

The purpose of the analysis of this event is to bound DNBR degradation for infrequent events, including AOOs with active single failure. Thus, it does not address the reactor pressure boundary performance. Reactor pressure boundary barrier performance for infrequent events and AOOs with or without a single failure is addressed in their respective UFSAR sections.

15E.5 CONTAINMENT PERFORMANCE AND RADIOLOGICAL CONSEQUENCES

Offsite radiological consequences for limiting infrequent event were calculated for 2 hours at the Exclusion Area Boundary (EAB) and for 8 hours for the Low Population Zone (LPZ). The offsite dose calculation assumed 10% fuel failure to bound future fuel cycles.

The release path for iodine and noble gas activity consisted of releases by the MSSVs and controlled steaming through the Atmospheric Dump Valves (ADVs) on both steam generators during the cooldown. Due to a LOP, the condenser was unavailable and MSSVs and ADVs were employed to remove decay heat and cool down the RCS.

It was assumed that plant operators would not initiate a plant cooldown to SDC entry conditions for at least 30 minutes following event initiation.

Since this is an infrequent event, offsite radiological dose consequences are limited to a small fraction, or 10%, of 10 CFR Part 100 guideline values. Additionally, radiation exposures for control room personnel are subject to the limits specified in General Design Criterion 19 of 10 CFR 50 Appendix A.

Control room radiological assessments for bounding unfiltered in-leakage are presented in UFSAR Section 6.4.7. The results presented in that UFSAR section for a postulated RCP Sheared Shaft event with a stuck open ADV bound the anticipated control room exposure for the limiting infrequent event including AOOs with an active single failure. The RCP Sheared Shaft event was predicted to result in a higher percentage of fuel failure than the limiting infrequent event and, in combination with a stuck open ADV, the RCP Sheared Shaft event would result in a correspondingly higher control room dose than the limiting infrequent event.

The offsite radiological dose consequences associated with the limiting infrequent event are evaluated below.

15E.5.1 Mathematical Models

For the offsite radiological dose assessment, activity in the RCS was calculated on the basis of the pre-event radioiodine and noble gas activity levels (which are limited by Plant Technical Specifications), to which was added the anticipated post-event increase in activity levels due to fuel pin

failures. The increase in activity levels due to fuel pin failures is dependent upon the radial peaking factor, which affected the radionuclide inventory in the fuel rod gap, as well as the fuel failure fraction, which defined the number of pins that release radionuclides to the RCS coolant.

Once the activity level in the RCS was determined, the amount of activity carried over to the steam generators by primary-to-secondary leakage was calculated. Activity that leaks into the steam generators was assumed to mix with that steam generators' secondary inventory. The level of activity in the generator increased as the event proceeded. The activity released from the steam generators to the environment was determined, based on a steaming rate that removed decay heat and the stored heat in the plant to successfully cool down the NSSS to SDC entry conditions. Once activity releases were quantified, the thyroid and whole body doses at the Exclusion Area Boundary (EAB) and Low Population Zone (LPZ) were calculated as a function of the radial peaking factors and fuel failure fraction.

15E.5.2 Input Parameters and Initial Conditions

Offsite radiological dose consequences associated with the limiting infrequent event were analyzed under the assumptions listed in Section 15.0.4 and the following conditions:

1. Isotope inventories were based on a core power level of 102% of RTP.

2. Based on Technical Specification limits, the initial assumed contamination in the NSSS was:

- RCS Dose Equivalent (DEQ) I-131 1.0 µCi/gm
- RCS Noble Gas (DEQ) Xe-133 550 µCi/gm
- Secondary System DEQ I-131 0.10 µCi/gm

3. A RCS liquid mass of 555,000 lbm of water was used in the analysis, including 45,000 lbm of water in the pressurizer. Additionally, 4,500 lbm of steam was assumed to be in the pressurizer. Although the RCS may hold more mass, these values were selected to increase the iodine concentration following postulated fuel failures, which conservatively increases offsite dose consequences.

4. A steam generator liquid mass of 160,600 lbm per steam generator was used in the analysis. Although the steam generators can hold more mass, this value was selected to increase the iodine concentration in the unaffected steam generator, which conservatively increases offsite dose consequences.

5. A primary-to-secondary leak rate of 0.5 gpm (720 gallons per day) per steam generator was assumed. This is consistent with the PVNGS Technical Specification 5.5.9.

6. It was assumed that 10% of the iodine and noble gas inventories in the fuel pins were resident in the fuel rod pellet-to-clad gap, and available for release upon clad rupture.

7. All of the activity in the fuel rod gap was assumed to be released to the RCS coolant upon fuel pin failure.

8. Iodines associated with leakage to the steam generators were assumed to be released to the environment during steaming with a Decontamination Factor (DF) of 100.

9. It was assumed that plant operators would not initiate a plant cooldown to SDC entry conditions for at least 30 minutes following event initiation. However, it should be noted that a faster RCS cooldown rate would increase steam releases during the first two hours following the event, which would produce more severe thyroid doses at the EAB. On the other hand, a slower RCS cooldown rate would allow radionuclide concentrations to build up in the secondary system, which would produce more severe 8-hour doses at the LPZ. Therefore, radiological dose calculations were performed using two different cooldown rates:

   - A maximum Technical Specification cooldown rate of 100°F/hr, initiated at 30 minutes into the event sequence.
   - A slower cooldown rate of 40°F/hr, initiated at 30 minutes into the event sequence, which would bring the RCS to SDC entry conditions at approximately 8 hours following event initiation.

10. Decay heat during the 8-hour period following the event was based on a 1979 ANS decay heat curve increased by an amount corresponding to the 2σ of the uncertainty.

11. A value of 740,000 BTU/°F was used to represent the specific heat capacity of the RCS, the RCS clad and the

steam generators. Use of a large value increases the amount of steam that must be released to the environment during the cooldown.

12. The χ/Q atmospheric dispersion factors used in the analysis are the short-term factors shown in Table 2.3-31.

13. Since the PSVs lift for this event, the dose calculation conservatively takes into account the activity released to containment, even though the Reactor Drain Tank is sized to remain intact from the PSV discharge.

15E.5.3 Results

The results of the limiting infrequent event radiological dose analysis are shown in Table 15E-3 for radial peaking of 1.72 and a fuel failure fraction of 10.0%. These results bound RTP of 3990 MWt or less.

Table 15E-3

RADIOLOGICAL CONSEQUENCE OF LIMITING INFREQUENT EVENT RADIOLOGICAL ANALYSIS (F_R = 1.72, 10% FUEL FAILURE)

Thyroid Dose (REM)		Whole Body Dose (REM)	
2 Hour EAB	8 Hour LPZ	2 Hour EAB	8 Hour LPZ
4.5	11.7	0.96	1.11

15E.6 CONCLUSIONS

The limiting infrequent event (i.e., AOO with active single failure) results in a limited number of fuel pins predicted to be in DNB for a few seconds. DNB propagation is not predicted to occur. Offsite doses remained below the acceptance criteria for this category of event. Specifically, a small fraction of

10 CFR Part 100 guidelines (i.e., 30 REM thyroid, 2.5 REM whole body).

17. QUALITY ASSURANCE

17.1 QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION (HISTORICAL)

NOTE: Construction is complete for the three units of the Palo Verde Nuclear Generating Station (PVNGS). Sections 17.1 through 17.1C describe quality assurance during the design and construction (project phase) and will not be updated. This information is maintained as a historical reference only.

This section describes the quality assurance (QA) program which has been established by the applicant, Arizona Public Service Company (APS), to provide assurance that the engineering, design, procurement and construction of the Palo Verde Nuclear Generating Station (PVNGS) conforms with applicable regulatory requirements and with the design bases specified in the license application. The QA program described in section 17.1 is applicable to each unit during the design and construction phases. The QA program for the startup and operational phase activities of PVNGS is described in section 17.2, and will be implemented for each unit in turn as described in paragraph 17.2.2.4.

The APS QA program for the engineering design, procurement, and construction of PVNGS is described in section 17.1A of this chapter. APS shall be responsible for the implementation of this QA program. Certain work, however, has been and will be delegated to other organizations for the engineering design, procurement, and construction of the PVNGS. The major participating organizations are the Bechtel Power Corporation, Los Angeles Power Division, (Bechtel), and Combustion

Engineering, Inc. (C-E). The QA programs for Bechtel and C-E are described in sections 17.1B and 17.1C of this chapter, respectively.

The APS QA program, as well as the QA programs of Bechtel, C-E, and other suppliers, comply with the requirements of NRC Regulation 10CFR Part 50, Appendix B, Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants (10CFR50, Appendix B).

Changes to the QA program description included or referenced in sections 17.1A, 17.1B, and 17.1C of this chapter shall be submitted to the NRC in accordance with 10CFR50.55(f). Changes that do not reduce the commitments in the program are submitted within 90 days after implementation. Changes that do reduce the commitments shall be submitted to the appropriate NRC Regional Office, to the Resident Inspector, and to the Document Control Desk, U.S. NRC for approval prior to implementation.

17.1A APS QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

The APS QA program is documented by written policies and directives contained in the APS QA Manual for the Design, Procurement and Construction of PVNGS (hereafter referred to as the "APS QA Manual").

The APS QA program complies with the requirements of NRC Regulation 10CFR Part 50, Appendix B, Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants. In addition, the APS QA program is structured in accordance with the NRC Regulatory Guides listed in paragraph 17.1A.2.6.

Definitions used are in accordance with ANSI N45.2.10, Quality Assurance Terms and Definitions, as endorsed by Regulatory Guide 1.74. Exceptions and additional terms and definitions applicable to matters relating to PVNGS are included in the APS QA Manual.

17.1A.1 ORGANIZATION

17.1A.1.1 General

Arizona Public Service Company, as the applicant, is solely responsible for the establishment and execution of the APS QA program. Bechtel, acting as the agent for APS, has been delegated the responsibility for establishing and executing major portions of the APS QA program as described in this chapter. Combustion Engineering (C-E) is responsible for nuclear steam supply system as defined in chapter 17 and maintains QA responsibility for this work. APS, however, recognizes and acknowledges the ultimate responsibility for the

APS QA program and provides QA surveillance and audits activities to assure that the requirements of the APS QA program are satisfied. An interface organization chart is given in figure 17.1A-1.

17.1A.1.2 Responsibility and Authority

Figures 13.1-1 and 13.1-2 show the organizational structure and relationships to corporate management of individuals and groups within APS with project management responsibility and responsibility for management of the APS QA program during design and construction. The authority and specific responsibilities of individuals within APS who perform QA functions are established and delineated in writing in the APS QA Manual. These authorities and responsibilities are described in the following paragraphs.

17.1A.1.2.1 President and Chief Operating Officer

As shown in figure 17.1A-1, the president and chief operating officer of APS has the overall responsibility for the engineering, design, procurement, construction, and operation of PVNGS. Execution of these responsibilities is delegated to the vice president, nuclear production, through the executive vice president, Arizona Nuclear Power Project (ANPP). The responsibilities for establishing the policies and practices set forth in the APS QA Manual and assuring conformance with the requirements of the APS QA program are delegated to the director, Corporate QA/QC, through the executive vice president, ANPP. The president and chief operating officer

shall retain the responsibility, however, for assuring the independence of the director, Corporate QA/QC, from schedules and costs and for providing the director, Corporate QA/QC, the authority to direct and control the APS QA program, to assure conformance to the quality requirements of that program.

17.1A.1.2.2 Executive Vice President, Arizona Nuclear Power Project

The executive vice president, ANPP, reports directly to the president and chief operating officer and has the responsibility for establishing and maintaining the APS QA program for the PVNGS. Day-to-day responsibilities for design and construction have been delegated to the vice president, nuclear production. The responsibilities for developing the policies and practices set forth in the APS QA Manual and assuring conformance with the requirements of the APS QA program are delegated to the director, Corporate QA/QC. The executive vice president, ANPP, reserves the authority to conduct, or order, the auditing of any activity at any time to determine the effectiveness of the policies and requirements set forth in the APS QA Manual and to determine compliance with the provisions of the APS QA Manual. The executive vice president, ANPP, is responsible for instituting a formal review of the APS QA program at least annually.

17.1A.1.2.3 Vice President, Nuclear Production, ANPP Project Director

The vice president, nuclear production, through the executive vice president, ANPP, has been designated by the president and chief operating officer of APS as the responsible corporate officer, for implementation of APS QA program requirements during the performance of activities relating to the engineering, design, procurement, and construction of PVNGS. The vice president, nuclear production's responsibilities for implementing the QA program are delegated to the director, technical services. The vice president, nuclear production, was the focal point for all formal communications pertaining to PVNGS during the design and construction phase. When PVNGS Unit 1 entered the operations phase, director/manager level personnel were made responsible for formal communication within their respective areas of responsibility.

17.1A.1.2.4 Director, Corporate QA/QC

The director, Corporate QA/QC, is responsible for managing the APS QA program. The director, Corporate QA/QC, reports directly to the executive vice president, ANPP. He is responsible for the implementation of the APS QA program and for advising the executive vice president, ANPP; the president and chief operating officer; and the chairman and chief executive officer of the program's effectiveness. The director, Corporate QA/QC, has been given the authority by the president and chief operating officer to have stopped, by established procedures, unsatisfactory work or further

processing of unsatisfactory material which is not in conformance with specified quality requirements and/or the provisions of the APS QA program.

The director, Corporate QA/QC, is responsible for assuring the adequacy of the APS QA program and the QA programs of those contractors assigned the obligation of establishing and implementing portions of the APS QA program. This responsibility will be exercised through periodic surveillance and audits of the QA programs of those organizations performing the work.

The director, Corporate QA/QC, has the authority and organizational freedom to identify quality problems. He may initiate, recommend, or provide solutions to the director, technical services. He verifies implementation of solutions.

Specific duties and responsibilities of the director, Corporate QA/QC, include the following:

A. Develop and implement the APS QA program.

B. Prepare and control the APS QA Manual including revisions and its distribution.

C. Formulate QA policies for use by APS.

D. Review QA programs of Bechtel and C-E for compliance with regulatory requirements and use his delegated authority to ensure that deficiencies in their QA programs are corrected. Changes made to C-E's QA program for editorial or administrative purposes only do not require review.

E. Perform audits and surveillances of Bechtel's and C-E's QA programs, advise management of the status of program implementation and take corrective action as deemed necessary.

F. Review specifications, drawings, and procedures for conformance to APS quality requirements, applicable industry standards, and regulatory requirements.

G. Manage the QA staff in the performance of their activities and responsibilities.

H. Have audited the permanent QA records.

I. Establish liaison with the PVNGS plant manager; director, technical services; manager, transition; and the nuclear safety manager and maintain a current status of quality-related and other activities as they pertain to the PVNGS.

J. Maintain communication with the QA organizations of Bechtel and C-E with respect to QA activities.

K. Review correspondence from the NRC Office of Inspection and Enforcement and direct the preparation of inspection report responses.

L. Inform APS management of QA activities through distribution of audit reports and other quality-related information.

M. Report potential significant quality-related matters both verbally and in writing to the vice president, nuclear production.

N. Assist in preparation of significant deficiency reports to the NRC in accordance with the provisions of 10CFR50.55(e) and 10CFR Part 21.

O. Assist the assistant vice president, nuclear production; the PVNGS plant manager; the director, technical services; the transition manager; and the nuclear safety manager in preparation of quality-related procedures controlling the activities of ANPP personnel.

17.1A.1.2.5 APS Corporate QA Department

The APS Corporate QA Department is under the supervision and direction of the director, Corporate QA/QC, for the execution of the QA program. Their specific responsibilities include the following:

A. Maintain surveillance of QA requirements, practices, and experiences throughout the nuclear power industry.

B. Develop procedures that employ recent data and developments from the nuclear power industry, which are used to assure quality in engineering, design, procurement, and construction of the PVNGS.

C. Audit Bechtel's and C-E's QA programs to provide assurance that they are maintained current with new standards, criteria, and codes.

D. Review the project "Q" list of components (see table 3.2-1), equipment, structures, and systems to ascertain that the list is kept current.

E. Review drawings, procurement documents, and procedures to provide assurance that QA requirements are being incorporated.

F. Audit the design, manufacturing, testing, and construction activities of Bechtel and C-E and their subcontractors to provide assurance that quality practices are being maintained.

G. Utilize the assistance of technical services personnel in review and audit activities.

H. Review changes to Bechtel's prequalified bidders' list and provide concurrence as deemed appropriate.

The APS Corporate QA Department is organized into departments as shown in the organization chart in figure 17.2-1.

Responsibilities of the APS Corporate QA Department include QA functions relating to engineering, design, procurement, and construction of PVNGS. Therefore, these APS Corporate QA Departments are described below.

17.1A.1.2.5.1 Quality Systems and Engineering. The Quality Systems and Engineering Department, through the quality systems and engineering manager, has the responsibility to assist the director, Corporate QA/QC, in the implementation of the APS QA program. The quality systems and engineering manager reports

directly to the director, Corporate QA/QC. He is responsible to:

A. Develop, maintain, issue, review, and/or control programs and procedures required for the implementation of the APS QA program, including the Operations Quality Assurance Criteria Manual, and the APS QA Manual.

B. Review quality documents as necessary for incorporation and adequacy of quality requirements.

17.1A.1.2.5.2 Procurement Quality Department. The Procurement Quality Department, through the procurement quality manager, has the responsibility to assist the director, Corporate QA/QC, in the implementation of the APS QA program by monitoring the procurement activities of Bechtel and C-E. The procurement quality manager reports directly to the director, Corporate QA/QC. The responsibilities of the procurement quality manager include monitoring or auditing procurement, receiving, inspection, and storage activities.

17.1A.1.2.5.3 Quality Audits and Monitoring Department. The Quality Audits and Monitoring Department, through the quality audits and monitoring manager, has the responsibility to assist the director, Corporate QA/QC, in the implementation of the APS QA program for home office and site construction activities. He is also responsible for auditing and/or monitoring the implementation of the APS QA program by the APS technical services departments; and the implementation of the Bechtel

quality program for construction activities; as well as design and engineering activities by Bechtel and C-E. The quality audits and monitoring manager reports directly to the director, Corporate QA/QC.

17.1A.1.2.6 Director, Technical Services

The director, technical services, has the responsibility for engineering, construction, records management, nuclear fuels management, and licensing, and for proper implementation of the APS QA program for these functions. The director, technical services, has the assistance of technical units as shown in figure 13.1-7.

The director, technical services, has the authority to stop Technical Services Department activities that are not accomplished in compliance with applicable regulatory or QA requirements. The director, technical services, reports directly to the vice president, nuclear production.

17.1A.1.2.6.1 Nuclear Engineering (NE) Manager. The nuclear engineering manager, through the director, technical services, has been delegated responsibility for engineering, design, and procurement of the PVNGS. The nuclear engineering manager has the assistance of technical units as shown in figure 13.1-8 in fulfilling his responsibilities. The nuclear engineering manager has overall control of work performed on the project including:

A. The right to review and comment on all documents including drawings, specifications, analyses,

computations, and procurement documents prepared by contractors in performance of all work

B. The acceptance or rejection of all plans which govern the conduct of work, the assignment of responsibilities among and the coordination of activities of Bechtel, C-E, the nuclear engineering staff, suppliers, subcontractors, and consultants employed by Bechtel or APS

C. The right to inspect either directly or through his designated representative all work performed by contractors. The nuclear engineering manager shall have the responsibility and the authority to reject any material or workmanship that does not meet the requirements specified in agreements with contractors

D. The authority to accept all work performed by Bechtel subject to the concurrence of the Corporate QA manager indicating that the provisions of the APS QA program have been satisfied.

The nuclear engineering manager shall be responsible for the preparation of the nuclear engineering department procedures and instructions which shall delineate the responsibilities of the technical groups in the Nuclear Engineering Department organization and the administrative procedures and controls over the work performed by Nuclear Engineering Department personnel during the engineering design and procurement of the PVNGS.

For a complete description of the Nuclear Engineering Department including personnel qualifications, refer to subsection 13.1.1.

17.1A.1.2.6.2 Nuclear Construction Manager. The nuclear construction manager through the director, technical services, has the delegated responsibility for the construction of PVNGS. He has the assistance of several technical groups in fulfilling his responsibilities. The nuclear construction manager directs the APS field construction engineering personnel at the power plant site to ensure that the project contractors and subcontractors comply with all applicable construction codes, standards, procedures, and specifications.

The nuclear construction manager has overall control of work performed by contractors at the site including:

A. The right to evaluate the specification and purchase order of field-purchased equipment and services

B. The acceptance or rejection of all construction plans which govern the conduct of work, the assignment of responsibilities among and the coordination of activities of BPC, C-E, contractors, and consultants employed by BPC or APS.

C. The right to inspect either directly or through his designated representative all work performed by contractors. The nuclear construction manager shall have the responsibility and authority to reject any material or workmanship which does not meet the

requirements specified in agreements with contractors.

17.1A.1.2.6.3 Nuclear Records Management Manager. The nuclear records management manager, through the director, technical services, has the delegated responsibility for the receipt, microfilming, indexing, storage, control, and retrieval of records for PVNGS. The nuclear records management manager directs the technical and administrative activities within the Nuclear Records Management Department which is comprised of five units as follows: NPRM administration, RMS computer system, PVNGS drawing and document control, drawing and document control (offsite), and micrographics (onsite and offsite).

The Nuclear Records Management Department provides onsite and offsite support for design, engineering, construction, startup, and operation in the areas of documentation, drawing control, and associated reference informational material by the means of hard copy, micromedia, and/or computer-assisted retrieval.

17.1A.1.2.7 Bechtel Power Corporation

Bechtel is responsible to perform engineering, design, construction, cost engineering, procurement, QA, assistance in startup and preoperational testing, and project management coordination work requisite to the construction of three separate and complete nuclear power electric generating units. The organizational structure for QA which will direct Bechtel is described in section 17.1B.

17.1A.1.2.8 Combustion Engineering, Inc.

Combustion Engineering is responsible to APS for the engineering, design, and procurement of the nuclear steam supply system (NSSS). The organizational structure for QA within C-E and the responsibilities of individuals and groups within that organization are described in section 17.1C.

17.1A.1.3 Project Quality Assurance Interface Control

Arizona Public Service Company has overall responsibility for interface control as it applies to the engineering, design, procurement, construction, and testing of the PVNGS. This responsibility rests primarily with the vice president, nuclear production and the APS director, Corporate QA/QC. Additional responsibilities for controlling project interfaces rest with Bechtel and C-E. The responsibilities and methods used by these organizations for maintaining effective lines of communication between their QA organizations and the organizations of contractors performing work under their control are described in sections 17.1B and 17.1C, respectively. A primary responsibility of the APS director, Corporate QA/QC, is the verification of compliance with these interface measures as well as their effectiveness for controlling project interfaces.

Lines of communication between APS and its contractors shall be primarily through Bechtel. In this regard, the primary communication line between Bechtel and APS has been between the Bechtel project manager and the vice president, nuclear production. Upon issuance of the operating license for PVNGS

Unit 1, formal interfaces were established between director/manager APS personnel, and Bechtel and C-E, in areas where the individual director/manager had responsibility. The APS director, Corporate QA/QC, shall have direct access to the QA organizations within Bechtel and contractors. In general, however, this access has been through the Bechtel project QA manager.

17.1A.1.4 Personnel Qualifications

The director, Corporate QA/QC, is responsible for managing and directing the APS QA program. The director, Corporate QA/QC, shall satisfy the following minimum qualification requirements:

A. Graduate of a 4-year accredited engineering or science college or university.

B. Minimum of 5 years' experience in quality assurance, including testing or inspection (or both) of equivalent manufacturing, construction, and installation activities. At least 2 years of this experience should be associated with nuclear facilities; or if not, the individual shall have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

C. In lieu of a degree, a high school graduate plus 10 years of experience in general QA or engineering of equivalent manufacturing, construction, and installation activities. Five years of this experience is required in QA, including testing or

inspection (or both) of equivalent manufacturing, construction, and installation activities. At least 2 years of this experience should be associated with nuclear facilities; or if not, the individual shall have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

The director, Corporate QA/QC, shall have broad experience and formal training in the performance of QA and quality control activities, including inspection and testing. He must be capable of planning and providing supervision to QA personnel who will be engaged in inspecting, testing, reviewing, evaluating, and auditing the adequacy of activities to accomplish QA objectives.

The director, Corporate QA/QC, shall be responsible for having reviewed the qualifications of Bechtel, C-E, and their subcontractor personnel, and for the review of indoctrination and training programs established by those contractors for personnel who perform activities affecting quality.

17.1A.2 QUALITY ASSURANCE PROGRAM

17.1A.2.1 General

Arizona Public Service Company is responsible under the ANPP Participation Agreement to manage the construction, operation, and maintenance of PVNGS in accordance with the rules and regulations of the NRC, the construction permits, operating licenses, and SNM licenses issued for the PVNGS units by the NRC, and the applications for such permits and licenses, and in

such a manner as to provide for the protection of the health and safety of the public. The importance of QA in contributing to this safety, as well as contributing to station reliability, is also recognized.

In accordance with this philosophy, the APS QA program has been developed and establishes the policies and practices for quality assurance for the engineering, design, procurement, and construction of PVNGS. Disagreements or differences of opinion in QA matters that originate with or are brought to the attention of the director, Corporate QA/QC, are expected to be resolved jointly by him and the director, technical services, as appropriate. Where such resolution is not achieved within a reasonable period of time, unresolved differences shall be referred to the vice president, nuclear production, or executive vice president, ANPP, as appropriate.

It is the policy of APS to utilize qualified and trained personnel in all responsible project positions and job assignments. Personnel shall receive formal indoctrination in QA, including basic principles; 10CFR Part 50, Appendix B; and the contents of the APS QA Manual.

17.1A.2.2 Program Description

The APS QA program consists of three elements, which are described below. The first element is a documented system of administrative controls over activities affecting quality. The second element is quality verification, and the third element is QA.

17.1A.2.2.1 Administrative Controls

The APS QA program requires preparation of appropriate documents, including procedures, drawings, and specifications, which prescribe the measures that have been established to control all activities affecting quality. Compliance with this requirement is the responsibility of each and every organization or group with responsibility for the engineering, design, procurement, and construction of the PVNGS. The measures which are established to control work must be detailed to the extent necessary to ensure that adequate controls have been incorporated. This establishes a documented system of controls which will guarantee confidence in the acceptability or quality of the work activities governed by those documents.

17.1A.2.2.2 Quality Verification

Quality is achieved through the use of skilled personnel, adequate planning, use of suitable tools and procedures, proper definition of job requirements, and appropriate supervision and technical direction. Quality is verified through surveillance, inspection, testing, checking, and review of work activities and documentation. Quality verification is the basic responsibility of the organization or group performing the activity. Quality verification is performed, however, by individuals other than those who did the work.

17.1A.2.2.3 Quality Assurance

The QA function consists of review, surveillance, and audit. Auditing is assigned to the APS Corporate QA Department, which

is independent of the organizations responsible for the work. The APS Corporate QA Department is responsible for formulating or reviewing general quality policies; review of QA and control activities; monitoring and auditing program activities to assure compliance with established controls and requirements; and for measuring the overall effectiveness of those controls.

17.1A.2.3 Responsibilities

The organization and responsibilities of the principal parties involved in the engineering, design, procurement, and construction of the PVNGS are described in subsection 17.1A.1. The responsibilities of these organizations with respect to the elements of the APS QA program are described below.

17.1A.2.3.1 Arizona Public Service Company

Arizona Public Service Company has overall responsibility for the QA program. Responsibility for establishing and implementing a system of administrative controls over quality affecting activities rests with the director, technical services, and the director, Corporate QA/QC. These controls are described in the ANPP Administrative Policies and Procedures Manual, the corresponding ANPP department instruction manuals, and the APS QA Manual. These manuals contain the administrative procedures which control the activities of the Nuclear Engineering Department personnel, Nuclear Construction Department personnel, and Nuclear Records Management Department personnel.

The APS Corporate QA Department is primarily responsible for QA audit activities which are described in subsection 17.1A.18. The audit responsibility of the APS Corporate QA Department includes audits of contractors and the compliance of nuclear engineering, nuclear construction, and nuclear records management personnel with the provisions of the administrative procedures which control their activities.

17.1A.2.3.2 Bechtel Power Corporation

Bechtel is responsible for complying with the requirements of the APS QA program. The procedures, instructions, manuals, and other documents which delineate activities carried out by Bechtel engineering, procurement, construction, scheduling, and QA are described in section 17.1B. Bechtel is responsible to APS for the engineering, design, procurement, and construction of PVNGS. Consistent with this delegated responsibility, Bechtel is responsible for both quality verification and QA activities with respect to suppliers of equipment, material, and services including C-E.

17.1A.2.3.3 Suppliers

Arizona Public Service Company requires that suppliers of equipment, materials, and services that could affect the quality of safety-related structures, systems, and components establish and implement QA programs. These programs shall include provisions that are consistent with the APS QA program. Arizona Public Service Company responsibilities with respect to these programs will be exercised through surveillance and audit

by the APS Corporate QA Department either in conjunction with or independent of Bechtel QA. Bechtel is responsible for performing quality verification for Bechtel activities and QA for Bechtel and supplier activities.

17.1A.2.4 Program Documentation

Arizona Public Service Company QA program policies and practices are contained in the APS QA Manual and the ANPP Administrative Policies and Procedures Manual. The APS QA Manual consists of QADs, listed in table 17.1A-1, which are approved by the director, Corporate QA/QC. Requirements for preparation, review, approval, revision, and issuance and distribution of QADs are delineated in the APS QA Manual. Table 17.1A-1 includes a cross-reference of the requirements of 10CFR Part 50, Appendix B, to the QADs contained in the APS QA Manual. More detailed cross-references to implementing procedures of APS nuclear projects, Bechtel, and C-E are incorporated into various QADs in the APS QA Manual. Other documents that include instructions, procedures, and manuals delineating activities to be performed by APS, Bechtel and CE are identified in the APS QA Manual, including the ANPP Administrative Policies and Procedures.

The director, Corporate QA/QC, and the director, technical services, have the right to review and comment on all documents, including QA manuals and procedures, drawings, specifications, analyses, computations, and procurement documents prepared by Bechtel.

The document control procedures for Bechtel and C-E are identified in sections 17.1B and 17.1C, respectively.

17.1A.2.5 Management Reviews

The executive vice president, ANPP, reviews the status and adequacy of the APS QA program at least annually. The executive vice president, ANPP, requires the director, Corporate QA/QC, to make formal recommendations with regard to the adequacy of the policies and practices contained in the APS QA Manual and the compliance with those policies and practices. The recommendations become the formal record of effectiveness of the APS QA program.

The intent of the management review is to assess the scope, implementation, and effectiveness of the QA program to assure that the program effectively complies with APS policy and the requirements of 10CFR50, Appendix B. The review includes results of audits of quality affecting activities to maintain an overall awareness of the effectiveness of the APS QA program and the implementation of APS policy directives.

Additionally, and on a routine basis, the executive vice president, ANPP, reviews appropriate QA records, including but not limited to reports of audits and corrective action, and other QA summary reports.

17.1A.2.6 Applicability of Codes, Standards, and Regulatory Guides

The APS QA program has been developed, to the extent practical, in accordance with approved NRC regulatory guides and ANSI

standards. Bechtel is responsible to APS for maintaining control over the list of codes, standards, and regulatory guides which are applicable to the engineering, design, procurement, and construction of the PVNGS. This list is included in the Project Design Criteria Manual for the PVNGS, which is maintained by Bechtel. All changes to this list are reviewed by the APS director, Corporate QA/QC, and the director, technical services, prior to implementation in procurement documents.

The director, technical services, has overall responsibility for determining the applicability of codes, standards, and regulatory guides and for implementing the provisions of those requirements. The director, Corporate QA/QC, is responsible for verifying that codes, standards and regulatory guides accepted for use during the design, procurement, and construction of the PVNGS are implemented. The director, Corporate QA/QC, will coordinate this effort with the Bechtel project QA manager as necessary to take full advantage of the codes and standards reviews conducted by Bechtel.

The APS QA program is structured in accordance with the following regulatory guides with the exceptions as described in section 1.8:

A. Regulatory Guide 1.28: Quality Assurance Program Requirements (Design and Construction)

B. Regulatory Guide 1.37: Quality Assurance Requirements for Cleaning of Fluid Systems and

Associated Components of Water-Cooled Nuclear Power Plants

C. Regulatory Guide 1.38: Quality Assurance Requirements for Packaging, Shipping, Receiving, Storage and Handling of Items for Water-Cooled Nuclear Power Plants

D. Regulatory Guide 1.39: Housekeeping Requirements for Water-Cooled Nuclear Power Plants

E. Regulatory Guide 1.30: Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electrical Equipment

F. Regulatory Guide 1.94: Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants

G. Regulatory Guide 1.58: Qualification of Nuclear Power Plant Inspection, Examination and Testing Personnel

H. Regulatory Guide 1.116: Quality Assurance Requirements for Installation, Inspection and Testing of Mechanical Equipment and Systems

I. Regulatory Guide 1.88: Collection, Storage and Maintenance of Nuclear Power Plant Quality Assurance Records

J. Regulatory Guide 1.64: Quality Assurance Requirements for the Design of Nuclear Power Plants

K. Regulatory Guide 1.144: Auditing of Quality Assurance Programs for Nuclear Power Plants

L. Regulatory Guide 1.123: Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants

M. Regulatory Guide 1.146: Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants

17.1A.2.7 Safety-Related Structures, Systems, and Components Controlled by the Program

Table 3.2-1 identifies the structures, systems, and components to which the APS QA program applies and is called the Q-list. It is a tabulation of safety-related items; i.e., those items that contribute to the prevention or mitigation of the consequences of postulated accidents which could cause undue risk to the health and safety of the general public; generally, QA-related functions performed on Q-list items during the engineering, design, procurement, inspection, and testing phases are the responsibility of the organization (Bechtel or C-E) primarily responsible to supply the item.

17.1A.2.8 Personnel Indoctrination and Training

Arizona Public Service Company QA program provides for the indoctrination and training of personnel performing activities affecting quality as necessary to assure that suitable proficiency is achieved and maintained. The APS QA Manual identifies the procedures that have been established by APS for

indoctrination and training, as well as the personnel qualification requirements. Personnel indoctrination and training procedures assure that:

A. Personnel responsible for performing quality activities are instructed as to the purpose, scope, and implementation of the quality-related manuals, instructions, and procedures.

B. Personnel performing quality-related activities are trained and qualified in the principles and techniques of the activity being performed.

It is the responsibility of managers to assure that their personnel are aware of QA requirements. This is achieved through a planned training program.

Personnel designated to participate in audits shall have or will be given training and orientation in methods for performing audits. One or more of the following methods will be employed in developing personnel:

A. Training to provide personnel with working knowledge and understanding of both ANSI N45.2, Quality Assurance Program Requirements for Nuclear Power Plants, and
ANSI N45.2.12, Requirements for Auditing of Quality Assurance Programs for Nuclear Power Plants.

B. Training programs designed to provide general and specialized training in audit performance. General training will include fundamentals, objectives,

characteristics, organization, performance, and results of quality auditing. Specialized training will include methods of examining, questioning, evaluating, and documenting specific audit items, methods of identifying and following up on corrective items, and methods of closing out audit findings.

C. On-the-job training, guidance, and counseling under the direct supervision of an experienced, qualified auditor. Such training will include planning, performing, reporting, and followup action involved in conducting audits.

D. Orientation of technical specialists by the audit team leader. Such orientation will include familiarization with audit principles and procedures.

Auditors' proficiency may be maintained through one or more of the following methods:

A. Regular, active participation in the audit process.

B. Review and study of codes, standards, procedures, and instructions related to QA programs and program auditing.

C. Participation in training or orientation programs.

Training requirements and procedures for Bechtel and C-E project personnel whose work activities affect quality are delineated in sections 17.1B and 17.1C, respectively.

17.1A.3 DESIGN CONTROL

17.1A.3.1 General

The design of structures, systems, equipment, and components is controlled by the various contractor organizations to assure safe and reliable performance of products and services provided to APS. The control processes are documented by procedures and checklists which establish the responsibilities and interfaces of each contractor that has an assigned design responsibility. The procedures and checklists include means to assure that quality requirements and standards are specified in design and procurement documents; that suitable materials, parts, components, and processes are applied; and that the designs are verified for adequacy by persons other than those performing the original design. Design changes are controlled to the same level as was applied to the original design, including review and approval by the same organization that performed the original review and approval, unless otherwise designated by Bechtel with concurrence by APS. Design documents and revisions thereto shall be distributed to responsible individuals in a timely manner and controlled to prevent inadvertent use of superseded material. Errors and deficiencies in design that adversely affect safety-related structures, systems, and components are documented and appropriate corrective action is taken in accordance with subsections 17.1A.15 and 17.1A.16.

Bechtel has been delegated the responsibility for the engineering design, procurement, and construction of PVNGS. They have responsibility for the QA audit of the design control

measures and their implementation by the NSSS and other contractors performing design work. Bechtel's design control procedures are described in section 17.1B.

Combustion Engineering has responsibility for performing the design of the NSSS and/or review and approval of work performed by their subcontractors. Combustion Engineering's design control procedures are described in section 17.1C.

Arizona Public Service Company has overall responsibility for the control of the design of PVNGS. Arizona Public Service Company will review documents submitted by Bechtel, C-E, and their subcontractors. This review, in conjunction with QA audits, will provide assurance that contractor's design control measures are in conformance with the requirements of the APS QA Manual.

17.1A.3.2 Design Control Procedures

Bechtel and C-E design organizations have established and implemented design control procedures that delineate the responsibilities, authority, reporting, and methods of communication of the design organization. These procedures include provisions for the following:

A. Design Process Control

The implementation of design process control methods has been delegated to Bechtel and C-E subject to review by APS technical services and audit by Corporate QA. Design process control methods shall be applied to: analyses, such as thermal, hydraulic,

stress, and accident; core physics and design; material selection and compatibility; accessibility for both maintenance and repair and inservice inspection; and delineation of acceptance criteria for tests (construction and preoperational) and inspections.

B. Design Standards

Design documents and specifications developed for Quality Class Q structures, systems, equipment, and components shall be prepared and reviewed by Bechtel and C-E to ascertain inclusion of the following:

1. Engineering requirements
2. NRC design criteria
3. NRC QA criteria
4. NRC regulatory guide conformance or applicability
5. Applicability of industry codes and standards, i.e., ASME, IEEE, ANS, and ANSI
6. Conformance with the Safety Analysis Report
7. Interface requirements including internal interfaces.

C. Design Interface Control

Bechtel QA reviews interface control procedures to verify that implementing procedures are being properly used with design documents prepared by

Bechtel. Bechtel's design interface control is described in section 17.1B. Bechtel maintains interface control with the subcontractors and with APS. The APS Corporate QA Department will perform audits to verify that interface controls are maintained between APS and Bechtel and between Bechtel and their subcontractors, including C-E.

D. Design Verification

Bechtel and C-E are responsible for developing and implementing a design verification or checking method prior to issuance of Bechtel and C-E design, engineering, and specification documents. This will include design review, alternate calculations where applicable, and qualification testing.

Bechtel and C-E will document significant deficiencies which may adversely affect safety-related structures, equipment, systems, or components in the design process and shall take appropriate corrective action and document same. When a test program is specified to verify adequacy of the design, qualification testing of a prototype unit subjected to the most adverse design conditions shall be used. Materials, parts, equipment, and components which are considered "off-the-shelf" shall be reviewed and selected based on their suitability of application when such items are employed or related to Quality Class Q systems, structures, equipment, or components.

E. Design Change Control

Bechtel and C-E have developed and implemented design change control procedures which are commensurate with those used for the original design. Final results, upon incorporation of all design changes, are documented in final as-built drawings and specifications.

F. Field Change Control

Upon receipt of material, equipment, and components, and during the construction and preoperational test phase, field changes may be required.

Field changes shall be approved by the project engineer and shall be subject to the same design change control procedures described in paragraph 17.1A.3.2, listing C.

Field changes shall be documented and subject to design control procedures implemented by Bechtel.

Arizona Public Service Company shall be notified of each change and may review proposed changes as deemed necessary. Bechtel/C-E shall submit supporting documentation for all changes. The field changes shall be reflected in the appropriate drawings and specifications.

G. Control of Significant Deficiencies

Significant deficiencies that are safety-related shall be reported in accordance with the NRC Code of Federal Regulations -- 10CFR50.55(e).

H. Design Records

Bechtel and C-E contractors are responsible for the collection, storage, distribution, maintenance, and subsequent turnover to APS of design documents, design reviews, records, and changes thereto. The system shall be maintained in a systematic and controlled manner subject to audit by APS.

17.1A.4 PROCUREMENT DOCUMENT CONTROL

As the PVNGS units enter the operations phase, APS may directly procure material, equipment, and services in accordance with the applicable provisions of section 17.2. Material, equipment, and services so obtained may be utilized for corresponding construction phase applications. In such cases, procurement document control measures shall be established and implemented in accordance with subsection 17.2.4, in lieu of this section.

Bechtel is responsible for the preparation and submittal of procurement documents, in compliance with the QA requirements, to APS for review and comment. This review is coordinated by the director, technical services. The awarding of contracts is by APS. Contracts will be managed by Bechtel.

Combustion Engineering is responsible for procurement of NSSS components. Bechtel audits C-E procurement activities for compliance with C-E QA requirements.

Procedures established and implemented by both Bechtel and C-E delineate the preparation and the review of procurement documents by cognizant and qualified personnel, to assure that applicable regulatory requirements, design bases, and quality requirements are properly included or referenced; that these requirements can be inspected or controlled; that there are adequate acceptance/rejection criteria; and that all of these QA requirements have been complied with by the procurement documents.

The procurement documents identify the requirements for the QA program to be implemented by vendors and contractors. The QA requirements are in accordance with the Q-list, table 3.2-1. The procurement documents document the supplier's or contractor's acceptance of obligation to implement the QA program in accordance with 10CFR50, Appendix B.

Procurement documents include or reference, as applicable, basic technical requirements including regulatory requirements, component and material identifications, drawings, specifications, codes and industrial standards with applicable revision dates, tests and inspection requirements, and special process instructions and requirements for such activities as designing, fabrication, cleaning, erecting, packaging, handling, shipping, field storage, and inspecting.

Procurement documents include provisions for right of access to vendors facilities and records for source inspection and audit by Bechtel, C-E, APS, and/or regulatory agencies.

Procurement documents include, as appropriate, documentation requirements, identifying the documents to be prepared, maintained, submitted, or made available for review and comment, such as: drawings, specifications, procedures, procurement documents, manufacturing and inspection plans, inspection and test records, personnel and procedure qualifications, as well as material, chemical, and physical test results. Instructions on record retention and disposition are provided.

Changes made to procurement documents shall be subject to the same degree of control as was used in the preparation of the original documents, consistent with the requirements of ANSI N45.2.11, Paragraph 7.2. Minor changes, such as inconsequential editorial corrections or changes to commercial terms and conditions, may not require that the revised document receive the same review and approval as the original documents.

Procurement documents for spare parts or replacement parts comply with all of the foregoing requirements.

Procurement documents include provisions for extending applicable requirements of the procurement documents to the suppliers lower tier suppliers, including right of access if necessary to facilities and records by Bechtel, C-E, APS, and/or regulatory agencies.

APS has overall responsibility for the control of the procurement of PVNGS items and services. This control is exercised through reviews of procurement document control measures conducted by technical services and APS Corporate QA Departments. Audits are conducted by the APS Corporate QA Department to verify that the measures have been established and implemented.

Descriptions of Bechtel's and C-E's procurement document control measures are discussed in sections 17.1B and 17.1C, respectively.

17.1A.5 INSTRUCTIONS, PROCEDURES, AND DRAWINGS

The APS QA program requires that activities affecting quality be prescribed by documented instructions, procedures, or drawings of a type appropriate to the circumstances, and accomplished in accordance with such documents. These documents include appropriate quantitative and qualitative criteria for determining whether or not an activity has been satisfactorily accomplished.

A contractor, or supplier, responsible for an activity affecting quality is required to provide the necessary instructions, procedures, or drawings to appropriately prescribe the activity. These documents must be reviewed and approved by responsible personnel prior to accomplishing the activity.

Bechtel, and/or APS, may require the submittal of such documents for review and acceptance, prior to the undertaking

of an activity. Such a requirement shall be identified in procurement documents.

The APS Corporate QA Department verifies that activities affecting quality have been performed in accordance with instructions, procedures, or drawings and that required documentation exists for verification.

The APS QA Manual contains an identification of the controlled procedures, instructions, manuals, and other documents which delineate activities carried out by APS.

These documents form the basis for control over the activities which could affect the quality of Quality Class Q structures, systems, and components of the PVNGS during engineering, design, procurement, and construction.

The APS QA Manual identifies the originating authority; the responsibility for document review for APS QA policy compliance; the responsibility for review, comment, and acceptance within APS; and the responsibility for approval for the controlled documents used by APS. The APS Corporate QA Department will perform audits to verify that these documents are being utilized in the proper manner. Bechtel and C-E documents are identified in sections 17.1B and 17.1C, respectively.

17.1A.6 DOCUMENT CONTROL

The APS QA program requires that organizations with responsibility for documents which prescribe activities affecting quality establish and implement document control

measures. The procedures which have been established by APS to implement the requirements for document control are identified in the APS QA Manual. These procedures identify the format and content requirements for documents; the responsibilities for preparation, review, approval, and revision to documents; the document identification systems used by APS; the measures to control issuance and distribution, receipt, filing and storage, use, and disposition. Documents include drawings, design specifications, calculations, engineering studies, vendor data, test procedures, design criteria, Q-list, PSAR/FSAR, and QA programs and procedures.

The procedures which have been established by Bechtel and C-E to implement the requirements for document control are described in sections 17.1B and 17.1C.

The director, Corporate QA/QC, is responsible for the maintenance, issuance, and control of the APS QA Manual. The director, Corporate QA/QC, is also responsible for the issuance of instructions which delineate the performance of activities by APS Corporate QA personnel.

The director, technical services, is responsible for the preparation of document control procedures for the Technical Services Departments, where there is responsibility for the issuance, review, and/or acceptance of documents. Such activities include review and comment on design documents issued by Bechtel; review and comment on procurement documents prepared by Bechtel; review and comment on field design and procurement documents; review of acceptance and qualification test procedures; review and comment on construction plans; and

review and comment on changes to previously accepted documents. These document control procedures identify the individuals or groups responsible for each activity.

Bechtel has the responsibility for engineering, design, procurement, and construction document control for the project. Bechtel is responsible for the issuance of design documents to the site prior to commencement of work; the coordination and control of interface documents with various suppliers and contractors; the control of changes to design documents; coordination of documents with APS; the review and acceptance of procedures submitted by suppliers; project QA program documents; and distribution and control of design documents released for construction. Document control procedures require that only proper and current documents are provided and are used by contractors performing an activity; that superseded documents are properly controlled; that current and updated distribution lists are established; and that supervision monitors for compliance with document control requirements.

Suppliers and contractors are responsible for maintaining prescribed document control procedures as part of their own QA program. The document control measures which are adopted by an organization must be designed to assure that only currently approved documents are used by those performing an activity; that there are means for determining the status of a document; that the use of outdated or inappropriate documents is precluded; and that changes are included in all documents affected by the change.

The document control procedures require that an organization prescribe measures to preclude inadvertent use of outdated or superseded documents.

Bechtel is responsible to APS for a comprehensive system of planned and documented audits to verify compliance with all aspects of the APS QA program for document control. These audits shall be performed by personnel not having direct responsibilities in the areas being audited.

Bechtel shall conduct internal and external audits to assure that both its document control program and the programs of other organizations are being implemented and are satisfactory. Arizona Public Service Company shall ensure the adequacy of suppliers' document control measures by evaluating their QA programs as required per subsections 17.2.4 and 17.2.7.

The APS director, Corporate QA/QC, is responsible for having conducted surveys and audits to verify compliance with the requirements for the control of documentation. This includes the audit of the audit programs carried out by each organization as necessary to determine their effectiveness. The director, Corporate QA/QC, is responsible to ensure Bechtel audit schedules and results are reviewed on a routine basis to verify that appropriate corrective action and timely followup action, including reaudit of deficient areas, is taken where indicated by the audit findings.

17.1A.7 CONTROL OF PURCHASED MATERIAL, EQUIPMENT, AND SERVICES

As the PVNGS units enter the operations phase, APS may directly procure material, equipment, and services in accordance with the applicable provisions of section 17.2. Material, equipment, and services so obtained may be utilized for corresponding construction phase applications. In such cases, control of purchased material, equipment, and services shall be in accordance with subsection 17.2.7, in lieu of this section.

The APS QA program requires that procedures be implemented that delineate the methods and responsibilities for assuring that material, equipment, and services, procured by Bechtel or other suppliers and contractors, conform to the requirements of the procurement documents.

The procurement procedures of Bechtel, its suppliers, and contractors require that quotations to furnish material, equipment, and services be solicited only from a prequalified bidders' list, which is prepared by Bechtel. Criteria for prequalification are delineated in the procedures, and take into consideration previous experience with the bidder including the bidder's reputation and experience with utilities and the nuclear industry, his QA capability, and other factors. Arizona Public Service Company reviews changes to the Bechtel prequalified bidders' list.

Addition of bidders to the prequalified bidders' list requires a detailed and documented evaluation by qualified personnel, which includes assessment of bidders' management capabilities, financial resources, plant facilities, technical capabilities,

and QA programs. Visits to suppliers or contractors' facilities are made, to assist in the evaluation process.

Bechtel QA is responsible for approving the acceptance criteria for the bidders' QA program. Bechtel Procurement Supplier Quality Department is responsible for evaluating and accepting bidders' programs and manuals.

Procurement documents delineate the documentation which a successful bidder is required to furnish as evidence of compliance with the procurement document requirements.

Suppliers are required to furnish Bechtel with information concerning their manufacturing and inspection plans in order that Bechtel may plan and implement a source surveillance plan. Bechtel QA coordinates the establishment of surveillance plans with APS to permit APS participation in supplier surveillance. The surveillance plan includes inspection of items, witnessing of processes or tests, and audits of the suppliers' QA programs.

Prior to release for shipment, material and equipment requiring source inspection must be inspected for conformance to procurement document requirements by C-E representatives, and/or Bechtel procurement supplier quality representatives. Verification is made that quality documentation exists and is complete. Documentation of this verification will constitute acceptable evidence of compliance with all procurement requirements. A copy of this verification document is sent to the Bechtel field quality control engineer.

Items that have been source-inspected are examined, upon receipt, for shipping damage, correctness of identification, and proper quality documentation. Inspection status is described in subsection 17.1A.14. Documentary evidence showing that Q-list items or materials conform to procurement requirements shall be available at the site prior to installation of such items or use of such material, except as discussed in subsections 17.1A.15 and 17.1A.17. Items found by receiving inspection to be nonconforming shall be segregated and/or controlled as described in subsection 17.1A.15.

Documentary evidence is sufficient to identify the specific requirements, such as codes, standards, and specifications met by the procured item. This requirement can be satisfied by having available at the site copies of the purchase specification, purchase order and any changes, and written certification of conformance to procurement requirements. These documents shall be maintained by the project field quality control engineer. Bechtel QA shall verify by audit the validity of the certifications of conformance.

The procedures which have been established by APS to implement the requirements for procurement control are identified in the APS QA Manual. These requirements are based on Appendix B to 10CFR Part 50. The procedures which have been established by Bechtel and C-E to implement the requirements for procurement control are described in sections 17.1B and 17.1C.

The APS director, Corporate QA/QC, is responsible for having audits conducted to verify compliance with all aspects of the requirements described in the referenced procedures and QA

manuals. This includes the audit of the audit programs carried out by each involved organization. The director, Corporate QA/QC, is responsible for having reviews of Bechtel's audit schedules and results on a routine basis and for verifying that corrective action and followup action, including reaudit of deficient areas, are taken.

17.1A.8 IDENTIFICATION AND CONTROL OF MATERIALS, PARTS, AND COMPONENTS

The APS QA program requires that vendors and contractors establish and implement procedures for the identification and control of materials, parts, and components (including partially fabricated subassemblies) to assure the use or installation of only accepted items.

Bechtel is responsible for assuring that onsite procedures exist and are being implemented for the identification and control of materials, parts, and components.

Bechtel and C-E shall require in their procurement documents that equipment be identified at the source, prior to shipping, in accordance with the established plant identification system. In addition, traceability of materials, parts, or components to the supplier's quality documentation is specified in the procurement documents.

Source and receiving inspection planning shall include the verification of the correct identification of items and their records and shall note these as a condition for acceptance.

Physical identification shall be used, to the maximum extent possible, for relating an item at any stage of work to an applicable drawing, specification, and/or other pertinent technical document. Where physical identification is impractical or would affect the function or quality of the item, physical separation, procedural control, or other means shall be employed.

Material storage areas at supplier's shops and at the site shall be controlled to assure identification of materials.

The APS director, Corporate QA/QC, is responsible for having audits conducted to verify compliance with the procedures and measures for identification and control of materials, parts, and components. Audits conducted by the Corporate QA Department will evaluate the effectiveness of the controls which Bechtel is exercising over suppliers.

17.1A.9 CONTROL OF SPECIAL PROCESSES

Special processes are defined as those metallurgical, chemical, or other processes where assurance of the process quality is dependent largely on the inherent skill of the operator, and on the control of process parameters. It cannot be assured by direct inspection of work alone. These include, but are not limited to, welding, heat-treating, chemical cleaning, and nondestructive examination (NDE).

The APS QA program requires that contractors and suppliers identify, in their submittals, the special processes they intend to employ. Contractors and suppliers must assure that

in performing these processes, qualified procedures, equipment, and personnel are used under controlled conditions and in accordance with the requirements of applicable codes and standards.

Personnel, equipment, and procedures utilized in the performance, control, and inspection of special processes shall be qualified prior to use, in accordance with applicable codes and standards. Special processes shall be performed under controlled conditions by qualified personnel in accordance with written process sheets, shop procedures, checklists, travelers, or equivalent. Evidence of verification shall be documented.

For special processes not covered by existing codes or standards, or where quality requirements exceed the requirements of established codes and standards, the procedures for qualifying personnel, procedures, or equipment shall be defined in the procurement documents and shall be submitted for review prior to use.

Documentation of procedures and personnel qualification shall be kept current by the contractor or supplier. The documentation shall be subject to APS or Bechtel QA audit. Audits of special processes shall include verification that qualified personnel and procedures are used, and that there is compliance with the requirements of applicable codes and standards.

The APS director, Corporate QA/QC, shall have audits conducted which evaluate the effectiveness of the control over special processes exercised by Bechtel's QA organization. The specific

measures for control over special processes shall be identified prior to commencement of any activities by Bechtel or other contractors or suppliers performing special processes.

17.1A.10 INSPECTION

The APS QA program requires that suppliers establish, prior to manufacture, a specific inspection program for activities affecting quality, which is designed to verify compliance with the quality requirements identified in the procurement documents.

Bechtel is responsible for establishing and implementing an inspection program which meets the requirements of 10CFR50, Appendix B.

Bechtel QA has responsibility for the audit of the Bechtel inspection program and its implementation by Bechtel personnel, and other contractors and suppliers' inspection programs relative to Q-list items. Arizona Public Service Company is responsible to perform similar audits of suppliers.

Audits may be conducted by the APS Corporate QA Department to verify that inspection plans, instructions, and procedures have been established, are acceptable, and are being implemented. These audits supplement those audits conducted by Bechtel and C-E QA personnel.

Inspections shall be performed by individuals other than those who performed the activity and who are qualified. They should be from a group independent of those having direct responsibility for manufacture. If such independent inspection

personnel are not available, additional inspection shall be provided by Bechtel or other independent contractors.

The supplier shall maintain integrated manufacturing and inspection plans that clearly identify the items and activities to be inspected. The plans must include the specific inspections required by the procurement documents or those in the referenced codes and standards.

Inspections shall include the monitoring of processes and personnel when inspection of the finished product is impractical or inconclusive; inspection and process monitoring shall be utilized for adequate control.

Inspections shall be performed in accordance with procedures, instructions, and/or checklists, which shall contain the following as applicable:

A. Identification of quality characteristics to be inspected

B. Identification of those individuals or the organization responsible for performing the inspection operation

C. Acceptance/rejection criteria

D. Calibration requirements

E. A description of the methods of inspection

F. Evidence of completion and certification of inspection operation

G. Record of the results of the inspection operation

H. Record of reinspection results.

The supplier inspection plans shall include the following as applicable:

A. Identification of materials

B. Dimensional checks

C. Material test reports

D. Fitup of parts

E. Assembly of components

F. Process parameters

G. Examination of work

H. Cleanliness of parts and work area

I. Use of correct documentation

J. Monitoring of processes

K. Handling, cleaning, packaging, and storage procedures

L. Documenting of activities.

Inspections shall be satisfactorily completed and documented prior to releasing equipment for shipment, or special control established over a part or subassembly which has not completed satisfactory inspection.

Arizona Public Service Company shall review the integrated manufacturing and inspection plans of suppliers, establish a set of mandatory inspection holdpoints. Required mandatory holdpoints, beyond which work may not proceed without APS approval, shall be included in the supplier's inspection plans,

or otherwise controlled to ensure that work does not proceed without acceptance. Arizona Public Service Company shall monitor supplier's activities in accordance with paragraph 17.2.7.

Combustion Engineering and other suppliers who procure equipment from subsuppliers shall be responsible for assuring that their suppliers establish and implement a satisfactory inspection program. They shall determine that there is compliance with the quality requirements specified in the procurement documents.

Contractors at the site shall be required to establish and implement inspection programs that are in accordance with contract requirements and the applicable codes and standards. These programs are subject to review and acceptance by Bechtel.

A contractor's planned inspections shall be performed by inspection personnel, independent from the individual or group performing the activity being inspected. Bechtel shall review the contractors' inspection plans and establish notification points for their witness. Mandatory holdpoints may be established beyond which work may not proceed without Bechtel release; mandatory holdpoints shall be identified in the contractors' inspection plans.

The work of contractors who do not have inspection responsibility shall be inspected by APS or Bechtel. Inspection plans shall be based on design document requirements, the applicable codes and standards, and the work procedures adopted by the contractor. They shall provide the

contractor with the inspection program to coordinate the scheduled inspection activities. Inspections shall be documented by checklists or reports.

The inspection activities of Bechtel, and all suppliers and contractors, are subject to auditing by the APS Corporate QA Department to verify compliance with specified requirements.

17.1A.11 TEST CONTROL

The APS QA program requires that a documented test program be implemented to assure that required testing be identified and properly performed to demonstrate that Q-listed structures, systems, and components will perform satisfactorily in service. Identification of the required testing shall be based on design considerations and regulatory requirements. Testing will be in accordance with written test procedures which incorporate the requirements and acceptance limits contained in applicable design and procurement documents.

Proof and performance testing of components shall be performed and documented by suppliers as required in procurement documents. Suppliers may also be required to perform prototype qualification tests. The performance of supplier testing may be witnessed by Bechtel and/or APS. Notification and mandatory holdpoints shall be incorporated in the suppliers' manufacturing and test plans.

The procedures which have been established by Bechtel and C-E to implement the requirements for test control are described in sections 17.1B and 17.1C.

The director, Corporate QA/QC, shall have audits of Bechtel and C-E conducted to verify that documents specify the applicable tests to demonstrate that structures, systems, and components perform satisfactorily in service. Audits of the Bechtel QA program to ensure that suppliers are satisfactorily performing tests in accordance with design requirements will also be conducted.

The program for testing of structures, systems, and components, to demonstrate their satisfactory performance in service, is described in chapter 14.

17.1A.12 CONTROL OF MEASURING AND TEST EQUIPMENT

The APS QA program requires that procedures be implemented for the control, calibration, and periodic adjustment of tools, gauges, instruments, and other measuring and test equipment used to obtain and/or verify conformance to established quality requirements.

Suppliers and contractors, as part of their QA program, shall implement written procedures for the control and calibration of tools and measuring and testing equipment. Contractors shall maintain documentation of the calibration status and records of tools and gauges utilized. Assurance of supplier and contractor performance shall be obtained by evaluating their procedures, and during periodic in-process audits of records by both Bechtel and APS Corporate QA Department.

Inspection, test, and work procedures shall include provisions assuring that tools, gauges, instruments, and other inspection,

measuring, and testing equipment, and devices used in activities affecting quality, are of the proper range, type, and accuracy. To assure its accuracy, inspection, measuring, and test equipment shall be calibrated, adjusted, and maintained, prior to first use and at prescribed intervals thereafter, with calibration performed against equipment certified to have known valid relationships to nationally recognized standards or performed on some other documented basis. The acceptance criteria for principal contractor's calibrating procedures will include the requirement that the degree of uncertainty of the calibrating standards shall be less than the error of the equipment being calibrated. Control measures shall prevent the use by unauthorized personnel of calibrated tools, gauges, instruments, and other measuring and test equipment. Special calibration and control measures are not required for devices when normal commercial practices provide adequate accuracy.

The calibration status, date of calibration, and recalibration date shall be displayed prominently on each device, whenever possible, or on records traceable to the device. The records shall contain all elements necessary for control and verification of past calibration activities.

Inspection, test, and work procedures shall include the requirement that, whenever inspection, test, or measuring equipment is found to be out of calibration, the acceptability of all items inspected, tested, or measured since the last documented calibration must be evaluated.

The APS director, Corporate QA/QC, shall be responsible for having audits conducted to verify compliance with the procedures and measures for controlling measuring and test equipment. These measures shall be identified prior to commencement of any activities by suppliers or contractors which require the use of measuring and test equipment.

17.1A.13 HANDLING, STORAGE, AND SHIPPING

The APS QA program requires that procedures be established and implemented to control the handling, storage, and shipping (including cleaning, packaging, and preservation of material and equipment) to assure the maintenance of quality from source through installation or use.

Arizona Public Service Company or Bechtel shall review procurement documents to assure that they either provide, or require that suppliers provide, instructions on handling, storage, shipping, cleaning, and preservation for the product supplied. Instructions shall be provided for marking, labeling, packaging, shipping, and storing of items. Marking shall identify the shipment and special handling or storage requirements, including indications of the presence of special environments, or the need for special control.

Arizona Public Service Company shall establish a surveillance plan to assess and document onsite compliance with handling, storage, cleaning, and preservation procedures.

Combustion Engineering is responsible for verifying that requirements of procurement documents are satisfied, prior to release of an NSSS component for shipment to the site.

Bechtel shall review C-E's requirements and procedures for handling, storage, and shipping.

Bechtel has responsibility for handling, storing, and preserving materials and equipment at the site. The responsibility may be delegated to a responsible contractor, e.g., electrical equipment and materials to the electrical contractor.

Special coverings, equipment, and protective environments (such as inert gas atmosphere), specific moisture content levels, and temperature levels shall be provided and maintained for given materials and components as specified in manufacturers' instructions, supplemented by additional requirements as specified by Bechtel.

Special handling tools and equipment necessary to assure safe and adequate handling of critical, sensitive, or perishable items shall be provided and controlled. Special handling tools and equipment shall be inspected and tested by qualified personnel in accordance with written procedures, at specified times, to verify that the tools and equipment are maintained and suitable for the intended task.

Cleaning of components or systems at the site shall be performed in accordance with procedures prepared by the supplier of the equipment. The procedures shall be reviewed by APS or Bechtel. Cleaning operations may be monitored by APS or

Bechtel. The APS Corporate QA Department will conduct audits to verify that handling, storage, and shipping procedures are being implemented. These audits may be conducted through Bechtel's QA Department.

17.1A.14 INSPECTION, TEST, AND OPERATING STATUS

The APS QA program requires that written procedures be prepared and implemented which delineate the requirements, methods, and responsibilities for:

A. Indicating the status of inspections and tests performed on individual items during the procurement and construction phases of the project, to preclude inadvertent bypassing of such inspections and testing.

B. Indicating the operating status of installed structures, systems, and components during the construction testing phase, to prevent inadvertent operation of equipment or hazard to plant personnel.

These procedures shall be provided and implemented by suppliers or contractors who fabricate or assemble materials or equipment in their shops, by site contractors having responsibility for inspection of their work, and by Bechtel for onsite indication of inspection and test status of the items they inspect.

Prior to the start of preoperational testing, APS shall establish procedures, based on current practices, for the control of test and operating status indicators, including the

authority for application and removal of tags, markings, labels, and stamps.

The inspection and test status of items shall be indicated by the use of markings such as stamps, tags, labels, routing cards, or other suitable means, and shall be noted in records traceable to the item. The procedures shall delineate the authority for application and removal of status markings.

The operating status of installed structures, systems, and components shall be indicated by the operating panel readouts or equivalent. When such readouts are incomplete or inoperable and for systems and components not having such readouts, operating status shall be indicated by such means as tagging of valves and switches.

During construction testing, written procedures shall be implemented for controlling abnormal electrical or mechanical arrangements such as bypassed interlocks, installed jumpers, and piping bypasses.

Identification of abnormal operating status shall always include placing such identification at control locations where the system or component can be actuated, started, or controlled. Items whose status is nonconforming, inoperative, or malfunctioning shall be so indicated, as required by subsection 17.1A.15.

Bechtel is responsible for audits which assure that the foregoing requirements are complied with by all responsible organizations. The APS Corporate QA Department is responsible

for audits of delegated activities, and for internal audits for compliance by APS groups participating in acceptance testing.

17.1A.15 NONCONFORMING MATERIALS, PARTS, OR COMPONENTS

The APS QA program requires that procedures be prepared and implemented which describe the methods of controlling material, parts, or components that do not conform to defined requirements, to prevent their inadvertent use or installation.

All suppliers, contractors, and subcontractors who furnish, fabricate, erect, or install materials or equipment shall implement, as part of their QA program, acceptable procedures for the control of nonconforming items. These procedures shall include methods for identification, segregation, documentation, evaluation, and disposition of items that do not conform to the requirements of the design or procurement documents, including the pertinent QA programs.

Upon identification of a nonconformance, the supplier or contractor shall suspend the affected work until the nonconformance has been evaluated if:

A. The continuance of the work would conceal the nonconformance and make corrective action difficult or impossible.

B. The nonconformance is due to the work procedure and continuing its use would increase the extent or severity of the nonconformance.

Nonconforming items, where practical, shall be segregated from acceptable material in a controlled access location; when this

is not possible, control shall be maintained by tagging, marking, or other clear means of identification. Installation of nonconforming items into plant systems will be permitted only when established procedures are implemented which assure that the component or system will not be operated unsafely. As a general rule, nonconforming items are not to be used or installed. However, this requirement will not preclude reasonable exceptions such as those situations where nonconforming conditions relate only to the need for minor repairs or replacement of easily accessible parts, or lack of actual documentation at the site, and where the nonconformance can be readily resolved. In such cases, the decision to proceed on installation of nonconforming items must be supported by appropriate engineering evaluations.

Justification for use and installation of a nonconforming item will be generally limited to avoidance of unreasonable schedule delays or prevention of equipment or component placement which would otherwise seriously block access to placement areas.

Nonconformance reports justifying installation or use of nonconforming items will be produced prior to installation or use and will be approved in accordance with established procedures. The procedures will provide for an established system of nonconformance identification and for timely completion of prescribed corrective action. These items will be tagged "hold" with reference on the tag to the documentation described above.

A final check of the documentation verifying the quality of a particular system and acceptance of nonconformances that have

not been dispositioned will be required before construction tests can be made.

All identified nonconformances shall be documented. When the disposition consists of repair or correction by existing approved procedures, documentation on appropriate forms is acceptable. When the disposition consists of repair by procedures requiring approval, or by design change requiring waiver or other approval, the documentation shall be by appropriate written report of the nonconformance and its resolution, inspection, and approval.

Identified nonconformances shall be evaluated and a recommended disposition proposed by the supplier or contractor performing the work in question. Identified nonconformances, when so resolved by the supplier or contractor, shall be repaired or reworked in accordance with documented procedures. The affected items shall be reinspected for acceptance in accordance with applicable procedures and codes.

Dispositions involving special repair procedures or design changes shall be made and approved by the responsible design organization, or by Bechtel, and reviewed by Bechtel. The evaluation and disposition of the nonconformance shall be controlled by written procedures.

Before equipment is released for shipment, the inspectors (Bechtel, C-E, and others) shall determine that proper disposition has been made of the nonconformance and the necessary documentation is complete and accurate.

Documentation for items that have been repaired or accepted as-is shall describe the change, waiver, or nonconformance which has been accepted, identify the accepting party, and denote the as-built condition. The documentation for all such nonconforming items shall be filed as part of the QA records. These nonconformances are reported to management as described in subsection 17.1A.16.

Bechtel has responsibility for the disposition of nonconformances identified by Bechtel and APS and the review of nonconformance reports of contractors, including C-E. Procedures developed to implement nonconformance systems require that appropriate levels of engineering, QA, and project management are authorized to approve nonconformances. Resolutions of nonconformances requiring "repair" or "accept-as-is" must be approved by the engineering organization that specified the original criteria. The procedures established by Bechtel include requirements to keep the APS Corporate QA Department informed as to the nature and status of identified nonconformances. Arizona Public Service Company requires that BPC and other contractors notify the APS Corporate QA Department immediately when a condition adverse to quality is discovered and appears to be reportable. This shall include immediate notification of all deficiency evaluation reports initiated by BPC.

Arizona Public Service Company has the ultimate responsibility to determine if a nonconformance initiated by APS or by any contractor borders on or meets conditions stated in 10CFR Part 50.55(e) or 10CFR Part 21. Arizona Public Service Company

management, including the PVNGS plant manager; director, technical services; director, Corporate QA/QC; and vice president, nuclear production shall, decide what action is to be taken with regard to formally notifying the NRC and resolving the nonconformance or deficiency.

The APS Corporate QA Department shall periodically review the trend report of nonconforming reports maintained by Bechtel. This review shall concentrate on the types of nonconformances which are occurring on the project and which may indicate trends.

The APS Corporate QA Department shall conduct audits to verify that established procedures are being complied with in the disposition of nonconforming items.

17.1A.16 CORRECTIVE ACTION

The APS QA program requires that procedures be established and implemented to assure that conditions adverse to quality and items discussed in subsection 17.1A.15 are promptly identified and corrected, and that the cause is determined and corrective action is taken to preclude repetition.

Conditions adverse to quality, such as design deficiencies, failures, malfunctions, and nonconformances, shall be promptly identified and reported by cognizant Bechtel or C-E personnel. The report shall be directed to the person, or organization, responsible for correction of these conditions. The reports on conditions adverse to quality may be in the form of inspection reports, audit reports, or by formal letter.

The report shall include a determination of the underlying causes of a problem. Implementation of corrective action shall be verified by reaudit or reinspection, including a determination as to whether the underlying causes of the problem have been adequately corrected to preclude repetition. In these cases, the adverse condition, its cause, and the corrective action taken shall be documented and reported to appropriate levels of management, including Bechtel and APS.

Suppliers and contractors shall be required, in procurement documents and contracts, to have, as part of their QA program, a system for corrective action when conditions adverse to quality are identified, either at their facility or on material and equipment for which they are responsible. If the deficiencies or deviations are discovered at the site, responsible management of the affected supplier or contractor shall be promptly notified and advised of the problem. Followup by Bechtel will assure that the required corrective action is taken. Bechtel shall resolve the technical aspects of problems, or concur with solutions proposed by suppliers or contractors. Nonconformances to approved project procedures shall be reported to Bechtel QA.

17.1A.17 QUALITY ASSURANCE RECORDS

The APS QA program requires that records be provided and maintained to furnish documentary evidence of the quality of items and of activities affecting the quality of items and systems of PVNGS, and that written procedures be implemented

delineating the methods and requirements for receiving, identifying, storing, and preserving these records.

The records required for each safety-related item include the following: design records; as-built data; results of reviews, inspections, tests, work performance monitoring, and materials analyses; operating logs; and closely related data such as qualifications of personnel, procedures, and equipment.

The design records shall include the following information: design basis, drawings, specifications, and design changes. The records shall include deviations and their disposition.

Inspection records and test records shall include the following information: date of the inspection or test; identification of the item inspected or tested; identity of the inspector, data recorder, and/or evaluator; type of observation; results of the inspection or test; acceptability; and action taken in connection with any deficiencies noted.

The specific QA records which suppliers and contractors are required to provide shall be specified in procurement or contract documents, and shall comply with applicable regulatory requirements, codes, standards, and specifications. Quality verification documentation is to be provided prior to or with each shipment of material to the site. If these objectives cannot be met, procedures have been developed to allow the shipment to and receipt at the site of items or equipment that may lack some of the quality verification documents called for in the procurement specification. Procedures provide a

tracking system to ensure that required documentation is received.

Organizations which do work on the design, fabrication, erection, or testing of the structures, systems, or components important to safety are responsible for submitting records of those activities as required by the procurement documents, applicable codes and standards.

Bechtel is responsible for obtaining, processing, and adequately storing and protecting the QA records for the project until these records are turned over to APS on completion of each unit of the station.

Suppliers or contractors who exercise the option to retain QA records beyond the construction phase shall meet APS's requirements on retention, including storage, preservation, and safekeeping. These records shall be made available on demand for use by APS, or its agent.

Arizona Public Service Company is responsible for the permanent storage, protection, and maintenance of the records during the life of the unit, including periodic verification of the availability of such records stored for APS by other organizations.

A record storage facility will be located so as to provide convenient access to information necessary for operations, maintenance, inservice inspection, problem solving, or engineering of station modifications. The record storage facility shall meet the requirements of Regulatory Guide 1.88 as described in section 1.8.

Station orders and procedures are prepared by the station operations staff, as part of the operational QA program. This is discussed in section 17.2.

Bechtel shall carry out a comprehensive system of planned and documented audits to verify compliance with all aspects of the QA program for records management. These audits shall be performed by personnel not having direct responsibilities in the areas being audited. Bechtel shall conduct internal and external audits to assure that both its records management program and the programs of other organizations, including C-E, are being implemented and are satisfactory.

The APS director, Corporate QA/QC, shall be responsible for having audits conducted to verify compliance with the requirements for the management and control of the QA records. This shall include the audit of the audit programs carried out by each responsible organization to determine their effectiveness. The director, Corporate QA/QC, shall ensure Bechtel's audit schedules and results are reviewed on a routine basis and verify that corrective action and followup action, including reaudit of deficient areas, have been taken where indicated by the audit findings.

17.1A.18 AUDITS

The APS QA program requires that a comprehensive system of planned and documented audits be established and implemented to verify compliance with all aspects of the QA program, and to assess its effectiveness.

All organizations which are required to have and implement a QA program are required to conduct audits of their program and the programs of their subcontractors.

Bechtel has the responsibility for audits of vendors and contractors during the design, procurement, and construction phases of the project, as well as for internal audits of its own activities as described in subsection 17.lB.18. AS PVNGS units enter the operations phase, APS has assumed responsibility for vendor audits, and conducts these audits in accordance with subsections 17.2.7 and 17.2.18.

Arizona Public Service Company shall monitor the implementation of the audit program by Bechtel by informal observation and by documented periodic audits. As part of the auditing of Bechtel, APS shall participate in a sampling of the audits conducted by Bechtel. In addition, APS will audit its own project activities, including the QA function itself.

The director, Corporate QA/QC, is responsible for keeping APS management informed on QA matters and for necessary action to correct deficiencies when action by management is needed. He discharges his responsibilities by conducting independent periodic audits of the APS QA program, and by reporting his findings to: management, the executive vice president, ANPP, and others who have corporate responsibility for the areas audited.

Audits shall be performed in accordance with written procedures, or checklists, by trained personnel having no direct responsibilities in the area audited. Audits may be

conducted by QA engineers and/or other qualified personnel, such as technical specialists from other departments, designated by the appropriate QA manager.

The purpose of audits is the evaluation of work areas, activities, processes, items, and documentation, to provide an objective evaluation of compliance with established requirements, methods or procedures; to assess progress in assigned tasks; to determine adequacy of QA program performance; and to verify implementation of recommended corrective action. Audit results shall be documented and reviewed with management responsible for the area audited, who shall take necessary action to correct reported deficiencies.

Audits shall be conducted at either planned, periodic intervals, or on a random unscheduled basis. The director, Corporate QA/QC, shall maintain a schedule for the audits. Audits will selectively cover each of the various elements of APS and Bechtel QA programs, at the beginning of the project activity involving those elements, and at regular intervals thereafter. The scheduled frequency of audits may be changed by the director, Corporate QA/QC, as circumstances dictate; e.g., changes in level of activity, importance of activity, previous findings, changes in organization or procedures, or occurrence of problems.

Audits may be used to determine the acceptability of suppliers' or contractors' QA programs prior to awarding of a purchase order or contract; followup audits shall be used to assure that suppliers and contractors properly implement their QA programs.

Suppliers and contractors shall be required, in procurement and contract documents, to perform internal auditing of their own QA program. Compliance with these requirements shall be verified by APS and/or Bechtel audits.

17.1B BECHTEL QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

The Bechtel quality assurance (QA) program for the Palo Verde Nuclear Generating Station (PVNGS) complies with the applicable provisions of section 1.8 and the following:

A. 10CFR50, Appendix B, Quality Assurance Criteria for Nuclear Power Plants and Fuel Processing Plants

B. 10CFR50, Licensing of Production and Utilization Facilities

C. Section 17 of NRC Regulatory Guide 1.70, Revision 3, Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants

D. Quality assurance requirements of Section III, ASME Boiler and Pressure Vessel Code for items covered by the Code

   Bechtel is the holder of an ASME Certification of Authorization--"N" Stamp

E. American National Standards Institute (ANSI) given in the listing below, except for the noted exceptions or alternatives as described in section 1.8.

   1. ANSI N45.2-1971, Quality Assurance Program Requirements for Nuclear Plants (Regulatory Guide 1.28)

   2. ANSI N45.2.1-1973, Cleaning of Fluid Systems and Associated Components During the Construction Phase of Nuclear Power Plants (Regulatory Guide 1.37)

3. ANSI N45.2.2-1972, Packaging, Shipping, Receiving, Storage, and Handling of Items for Nuclear Power Plants (During the Construction Phase) (Regulatory Guide 1.38)

4. ANSI N45.2.3-1973, Housekeeping During the Construction Phase of Nuclear Power Plants (Regulatory Guide 1.39)

5. ANSI N45.2.4-1972 (IEEE-336), Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During the Construction of Nuclear Power Generating Stations (Regulatory Guide 1.30)

6. ANSI N45.2.5-1974, Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants (Regulatory Guide 1.94)

7. ANSI N45.2.6-1978, Qualifications of Inspection, Examination and Testing Personnel for the Construction Phase of Nuclear Power Plants (Regulatory Guide 1.58)

8. ANSI N45.2.8-1975, Supplementary Quality Assurance Requirements for Installation, Inspection and Testing of Mechanical Equipment and Systems for the Construction Phase of Nuclear Power Plants (Regulatory Guide 1.116)

9. ANSI N45.2.9-1974, Requirements for Collection, Storage and Maintenance of Quality Assurance Records for Nuclear Power Plants (Regulatory Guide 1.88)

10. ANSI N45.2.10-1973, Quality Assurance Terms and Definitions (Regulatory Guide 1.74)

11. ANSI N101.4-1972, Quality Assurance for Protective Coating Applied to Nuclear Facilities (Regulatory Guide 1.54)

12. ANSI N45.2.11-1974, Quality Assurance Requirements for the Design of Nuclear Power Plants (Regulatory Guide 1.64)

13. ANSI N45.2.12-1977, Requirements for Auditing Quality Assurance Programs for Nuclear Power Plants (Regulatory Guide 1.144)

14. ANSI N45.2.13-1976, Requirements for Control of Procurement of Equipment, Materials and Services for Nuclear Power Plants (Regulatory Guide 1.123)

15. ANSI N45.2.23-1978, Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants (Regulatory Guide 1.146)

The program described herein is applied by Bechtel Western Power Corporation (BWPC) and Bechtel Construction Inc. (BCI) to those safety-related structures, systems, and components (Q-list items) identified in table 3.2-1 for which Bechtel

Power Corporation has responsibility under its contract with the Arizona Public Service Company (hereafter referred to as "APS").

The Bechtel Power Corporation scope of work is: To perform engineering, design, construction, cost engineering, procurement, QA, quality control (QC), assist in startup and preoperational testing, and project management coordination work requisite to the construction of three separate and complete nuclear power electric generating units. The construction scope was assigned by Bechtel Power Corporation to BCI. The remaining scope was subcontracted to BWPC.

The term "quality assurance" is defined as all those planned or systematic actions necessary to provide adequate confidence that an item or facility will perform satisfactorily in service.

The term "quality control" is defined as all those QA actions that provide a means to control and measure the characteristics of an item, process, or facility to established requirements.

"Quality" is achieved through the use of planning and procedures, suitable tools, proper definition of job requirements, skilled personnel, and supervision and technical direction.

Quality is verified through surveillance, inspection, testing, checking, and review of work activities and documentation. It is Bechtel policy that QC and verification are the responsibility of the organization or group that performs the activity; i.e., engineering, procurement, or construction.

Quality verification is performed by individuals other than those who performed the work.

The Bechtel QA functions consisting of review, surveillance, and auditing is assigned to the Quality Assurance Group, which is independent of the organizations responsible for the work. The QA Group is responsible for formulating and/or reviewing general quality policies; coordination of QA, control and verification activities; and for monitoring and auditing program activities to verify compliance with established requirements, and to measure program effectiveness. When the term "quality assurance" is applied to personnel titles or procedures, it refers to the personnel and practices of the QA Group. The overall Bechtel QA program, which includes the activities of the organizations performing work as well as QC and QA, is referred to as the Bechtel quality program.

For the purpose of clarity, the QA terms used in this section are the definitions from ANSI N45.2.10 and Regulatory Guide 1.74, Quality Assurance Terms and Definitions, supplemented by the following additional terms and definitions:

A. BPC -- Bechtel Power Corporation

B. BWPC -- Bechtel Western Power Corporation

C. BCI -- Bechtel Construction, Inc.

D. Bechtel QA program -- a jointly developed and applied quality assurance program for BWPC and BCI for the Palo Verde project.

E. Administrative direction (administrative supervision) -- responsible for hiring, salary review, and assignment of an individual

F. Coordination -- bringing together and ensuring communication between independent groups, including responsibility for identification of interface problems, reconciling a position, and arriving at agreement

G. Formulate -- responsibility for coordination of effort by affected organizations in preparation of documentation describing or defining a policy or procedure

H. Monitor -- to watch over, observe, or examine a work operation, (results of the observations and examination may be recorded; however, signoff responsibility is not included.)

I. Project direction -- directions or instructions concerned with project operations includes coordination and day-to-day direction of the project entities receiving technical direction from others, but does not include authority to overrule prescribed procedures or technical decisions of such entities

J. Project home office -- the home office assigned responsibility for management of the project

K. Q-List items -- safety-related systems, components, and structures to which this program applies (refer to table 3.2-1)

L. Quality Assurance Group -- the QA Group consists of the manager of QA, QA manager of projects, project QA manager, and the QA personnel (refer to paragraph 17.1B.1.5.1).

M. Review -- to examine any form of documentation for the purpose of establishing acceptability relative to requirements of the function represented by the reviewer. (Reviews may range from a thorough investigation to a spot check. Reviews are generally not hold points, but signoff on documents or records traceable to the documents is required.)

N. Surveillance -- a broad term pertaining to and including both monitoring and witnessing

O. Technical direction -- instructions and directions defining technical requirements for an activity. (This may include furnishing prescribed procedures, technical requirements, design approaches, specifications, and design details.)

P. Technical guidance -- providing advice representing a preferred method or approach to a function or activity. (This may include establishing general requirements or policy, but not specific procedures or instructions.)

Q. Witness -- to watch over, observe, or examine a specific test or work operation, which includes signoff responsibility for conformance to procedures or specifications

BECHTEL QUALITY ASSURANCE DURING

DESIGN AND CONSTRUCTION

17.1B.1 ORGANIZATION

17.1B.1.1 Bechtel Group, Inc.

Figure 17.1B-1 illustrates the organizational chart of the Bechtel group of companies. The Bechtel group includes: Bechtel Western Power Corporation, Bechtel Eastern Power Corporation, and Bechtel Construction Inc., plus others.

Bechtel Western Power Corporation as a subcontractor of Bechtel Power Corporation is responsible for design and procurement activities associated with PVNGS. Bechtel Construction Inc. by assignment from Bechtel Power Corporation is responsible for construction activities associated with PVNGS as addressed in paragraphs 17.1B.1.5.3 and 17.1B.1.6.4.

17.1B.1.2 Bechtel Western Power Corporation

Members of the BWPC management team are responsible for coordination of, and technical guidance to, activities within their disciplines. Bechtel Western Power Corporation provides quality-related services in the area of design, engineering, procurement, and QA to BCI.

The BWPC president approves basic quality policies for all BWPC projects. The BWPC manager of quality assurance is responsible for technical direction of the Bechtel QA program. He formulates or reviews overall quality policies for BWPC, provides technical guidance to the BWPC QA managers, and evaluates the effectiveness of the total BWPC and BCI quality program. The following is a specific list of the primary responsibilities of the BWPC manager of QA:

A. Formulate or review overall quality policies for use in BWPC and recommend them for approval by the BWPC president

B. Review QA policies and QA procedures prior to release for compliance with BWPC policies

C. Review, obtain concurrence and approval for compliance with BWPC quality policy, quality manuals from Bechtel centralized functions.

D. Formulate and direct audit programs to assure BWPC management that the overall quality program conforms with policy and that the program as implemented is effective.

E. Provide reports to the BWPC president evaluating the effectiveness of the quality program and any problems requiring special attention

F. Coordinate the quality program of centralized functions, i.e., the Procurement Supplier Quality Department, and the Materials and Quality Services (M&QS) Department

G. Conduct quality program coordination meetings with responsible BWPC managers, managers of QA, QC, and engineering.

17.1B.1.3 Materials and Quality Services

The M&QS is a centralized function reporting to Bechtel National, Inc. through the Bechtel Research and Development

vice president and general manager (figure 17.1B-1). The M&QS manager is responsible for furnishing specialized chemical, metallurgical, process evaluations, and procedures. They also assist in auditing of suppliers of ASME Section III materials and/or services to Bechtel. The M&QS quality functions for power projects are coordinated by the BWPC manager of QA.

The M&QS responsibilities include:

A. Develop and qualify welding and nondestructive examination (NDE) procedures

B. Train and qualify Bechtel NDE personnel

C. Support engineering procedures and qualifications of personnel

D. Provide technical guidance to field welding engineers

E. Review supplier and subcontractor welding, nondestructive examination, protective coating procedures, and QC manuals for ASME components and metal structures applications

F. Prepare and maintain the Bechtel QA Manual for ASME Nuclear Components (BQAM-ASME III) and provide liaison with the ASME and authorized inspection agencies in matters associated with compliance with the ASME Code BQAM-ASME, and the control of the ASME nuclear symbol stamps

G. Participate in audits of field construction, which include compliance with the QA Manual for ASME, Nuclear Code Section III, components, and BCI and

subcontractor field welding and NDE and protective coatings programs

H. Participate in surveys and audits of materials and component suppliers and subcontractors, as required

I. Consult with engineering, procurement, construction, QA, and QC on failure analysis problems involving materials, welding, protective coatings, and nondestructive examination

J. Support engineering in the preparation of specifications for components, piping, metal structures, and protective coatings and in the selection of materials.

17.1B.1.4 Procurement

Procurement, as a service organization, does not establish technical or quality requirements contained in procurement documents nor does it approve changes thereto; these functions are the responsibility of the engineering departments.

The quality functions of procurement are supplier surveys, quality program verification, surveillance inspection, and audit of supplier activities for implementation of quality programs. These functions are the responsibility of the manager of supplier quality. The procurement supplier quality function is independent of purchasing and expediting functions. The procurement supplier quality department program as applied to power projects is established by the manager of supplier quality and is coordinated by the BWPC manager of QA. The

manager of supplier quality is responsible for assuring that BWPC purchased items and associated quality verification records subject to source inspection comply with requirements contained in procurement documents. Manager of supplier quality responsibilities are as follows:

A. Prepare and maintain the Procurement Supplier Quality Manual and associated procedures thereto

B. Train and qualify BWPC procurement supplier quality personnel

C. Survey and audit potential suppliers for conformance to 10CFR50, Appendix B, and ANSI N45.2, as applicable, and perform periodic audits and quality program verification activities of selected suppliers and offsite subcontractors as required

D. Prepare source inspection plans

E. Perform progressive surveillance inspection of items and review of quality verification documentation in accordance with the Procurement Supplier Quality Manual and associated procedures and the procurement document requirements.

F. Release items for shipment.

The field services manager directs the operation of source inspectors. He is independent of project-assigned personnel. He is responsible for the quality of the inspectors' performance in implementing the designated source inspection plans for PVNGS (see figure 17.1B-4). The inspection plans are

designated by the project from a book of standard plans (the Procurement Supplier Quality Department Surveillance Inspection Plans) and augmented by the Procurement Supplier Quality Manual requirements. Plans unique to PVNGS or changes to previously approved PVNGS plans must be approved by the project QA manager, as provided by the Project Quality Program Manual. Neither the inspector nor anyone above him in the chain of command is responsible for the cost/schedule impact of project delays or expense caused by deficiencies the inspector may discover in inspected materials. The performance of the inspector is evaluated solely by the field services manager and/or his staff.

17.1B.1.5 Bechtel Western Power Corporation Management

Figure 17.1B-2 illustrates the BWPC organization chart. The BWPC management team, under the direction of the BWPC president, provides effective management direction, administration, and functional guidance to BWPC entities and individuals.

The management team includes the president, vice president and manager of the Los Angeles Office, vice president and manager of International Business Development and Operations, vice president and manager of Domestic Marketing and Business Development Operations, vice president and manager of the San Francisco Office, vice president and manager of the Houston Office, manager of QA, legal counsel, and manager of public relations. Managers have direct responsibility and authority for the functions of their organizations.

17.1B.1.5.1 BWPC Quality Assurance

The BWPC manager of QA is responsible for planning, controlling and managing the QA program. He reports to and receives authority from the BWPC president.

He controls the application and effectiveness of the Bechtel QA program through QA management and project audits of BWPC engineering, procurement supplier quality, procurement, and BCI construction.

The BWPC manager of QA is responsible for assuring that QA has approved the procedures describing the functions, training, and qualification requirements of individuals performing procurement, inspection, and construction QC activities.

The BWPC manager of QA prepares reports of project quality status for distribution to the BWPC president and management. These reports include important quality events, significant items, a comprehensive analysis of problem areas, and the actions taken in their regard.

The project QA manager (PQAM) for the Palo Verde project is assigned by and receives technical and administrative direction from the BWPC manager of QA and the QA manager of projects. The PQAM is responsible for directing and managing the PVNGS quality program.

The Procurement Supplier Quality Manual, describing the functions, training, and qualifications of personnel in procurement inspection, is approved by the BWPC manager of QA.

The quality control training program for the project describing the functions, training, and qualifications of personnel in BCI construction quality control is approved by the BCI chief construction QC and training engineer, after review and acceptance by the project QC engineer (PQCE).

The adequacy of the Procurement Supplier Quality Manual and the quality control training program are selectively evaluated by performing an in-depth review of:

- Basis for determining inspection level and sequence
- Adequacy of inspection methods

The BWPC manager of QA is assisted by the QA manager of projects and is responsible for providing overall management pertaining to QA technical direction to the project. Figure 17.1B-5 illustrates the BWPC QA organization.

The BWPC manager of QA provides technical and administrative direction to the BWPC QA Group which has the following responsibilities:

A. Formulate or review BWPC QA policies for use where necessary to implement or supplement basic QA policy and recommend these for approval by the vice president and general manager

B. Approve QA procedures and instructions that define responsibilities and functions of QA personnel

C. Review, prior to release, quality-related procedures and manuals prepared by departments and projects for conformance to QA policies

D. Formulate audit programs and conduct audits and reviews to assure BWPC management and APS that the QA program conforms with policies and requirements of BWPC, BCI, and APS. Identify the need for corrective action and assure followup

E. Provide periodic reports to the vice president and general manager evaluating the effectiveness of the BWPC quality program and advise of any problems requiring special attention

F. Provide and maintain a qualified and suitably trained staff of QA engineers to carry out required project and staff functions

G. Formulate programs for maintaining the professional competence of personnel within his organization and provide assistance in training and indoctrination programs for BWPC management and engineering personnel whose activities affect quality

H. Participate in quality coordination meetings with responsible BWPC and BCI managers and supervisors of QA and QC.

I. Coordinate the QA, QC, and quality engineering programs within BWPC

The PQAM prepares reports of project QA status. These reports include important QA events, significant items, a comprehensive analysis of problem areas, and the actions taken in their regard. Appropriate action based on the status of project QA activities is taken by the BWPC manager of QA.

17.1B.1.5.2 Bechtel Western Power Corporation Engineering

Figure 17.1B-6 illustrates the BWPC Engineering Organization. The BWPC manager of engineering reports to the vice president and manager of functional operations and provides technical and administrative direction to the Engineering Department. The BWPC manager of engineering is assisted by managers of engineering, engineering managers, chief engineers, and the supervisor of quality engineering. Engineering managers are responsible for the management and technical direction of assigned projects, and for assuring that the projects are provided with adequate personnel and are following prescribed procedures for conduct of engineering activities. Engineering managers provide administrative direction to the project engineering manager (PEM).

The chief engineers are responsible for the technical adequacy of engineering design performed for their respective disciplines. They are responsible for assigning the engineers, designers, and draftsmen required to perform engineering functions within their respective disciplines on projects, and for maintaining an adequate staff of specialists and other support personnel to provide technical guidance to the projects and to perform independent reviews of selected engineering design work. Chief engineers provide administrative and technical direction to the engineers in their respective disciplines.

The supervisor of quality engineering supports the Engineering Department in the preparation and conduct of quality program

functions within the Engineering Department. He provides technical and administrative direction to the quality engineering staff and quality engineers assigned to projects. The supervisor of quality engineering has the following responsibilities:

A. Assists the manager of engineering in preparation of Engineering Department procedures related to the quality program and reviews for compliance to program requirements

B. Provides technical and administrative direction to quality engineers

C. Prepares procedures for conduct of quality engineering functions

D. Provides appropriate indoctrination and training programs for Engineering Department personnel to assure implementation of Engineering Department procedures related to the quality program

E. Represents the Engineering Department in quality coordination meetings.

17.1B.1.5.3 Bechtel Construction, Inc.

Figure 17.1B-7 illustrates the BCI Construction Organization. The BCI manager of construction reports to the BCI president and provides technical and administrative direction to the Construction Department. He is assisted by the construction managers, construction manager services, chief construction engineer, and chief construction QC and training engineer.

Construction managers are responsible for providing overall construction management and technical direction to assigned projects, and for ensuring that projects are provided with adequate personnel and are following prescribed BCI practices and procedures for conduct of construction activities. The chief construction engineer is responsible for providing technical support to the projects.

The BCI chief construction QC and training engineer reports to and receives administrative direction from the BCI manager of construction, and is responsible for planning, directing, and controlling the BCI construction QC program and QC activities in support of project QA program requirements.

The BCI PQCE reports to and receives technical and administrative direction from the BCI chief construction QC and training engineer. Field QC engineers are functionally and administratively responsible to the PQCE. They are responsible for quality witness and inspection verifications of construction and test activities using approved quality control procedures and instructions.

The chief construction QC and training engineer has responsibilities to:

A. Prepare and maintain the Construction Quality Control Manual

B. Approve any special field QC procedures and instruction for the project

C. Hire and assign field QC engineers to the projects

D. Train and certify field QC engineers per ANSI N45.2.6

E. Prepare and/or approve field inspection planning

F. Provide technical and administrative direction to field QC engineers

G. Provide periodic reports to management on the status and effectiveness of the QC program

The activities of BCI construction QC and BWPC QA personnel are independent of construction cost and schedule influences.

The PQAM at the construction site is responsible for directing and managing the project QA program, including the approval of BCI construction QC procedures and instructions prior to use, and the review of QA verification records of compliance to requirements of approved construction inspection instructions and procedures. He is assisted in these responsibilities by QA engineers at the design office and construction site.

17.1B.1.5.4 Bechtel Western Power Corporation Procurement

Figure 17.1B-3 identifies the organization of BWPC procurement. The BWPC manager of procurement reports to the BWPC manager of functional operations and is responsible for providing management of purchasing and administrative direction to procurement supplier quality in accordance with BWPC policies and procedures. The supplier quality supervisor and the procurement operations manager report to the BWPC manager of procurement.

7.1B.1.6 Project Organization and Functions

17.1B.1.6.1 Project Manager

The project manager (PM) reports to the vice president and manager of domestic operations and is responsible for project direction based on the combined BWPC and BCI scope of work, APS requirements, and BWPC policies and procedures. The project manager is the leader of the combined BWPC and BCI project team consisting of the project engineering manager (PEM), the PQAM, the project procurement manager (PPM), the project cost and scheduling supervisor, the field construction manager, and representatives from other Bechtel companies, as required. He provides the necessary direction to the project team to ensure satisfactory performance. Figure 17.1B-8 illustrates the project management organization.

The PM is responsible for the application of the project quality program by the designated departments and for coordinating the activities of project QA and QC to assure that the quality program is implemented in conformance with the quality policies and procedures approved for his project.

The PM is the primary interface with APS and major client vendors. The interface at the project management level concerns matters of establishing, maintaining, and changing the Bechtel scope of work, the project schedule, project costs, and coordinating the quality program. Authority for interface at the project function level concerning technical and QA matters related to the performance of project functions is delegated by the PM to the project team.

17.1B.1.6.2 Project Quality Assurance

The project QA program is implemented through the PQAM. The PQAM is responsible for managing and directing the Palo Verde QA program at the construction site and the design office. The PQAM is assigned by and receives technical and administrative direction from the QA manager/projects. He coordinates with and represents the PM in QA matters. The PQAM supervises the project QA staff, which includes those at the jobsite and at the project home office.

In order to assure that the quality program is sufficiently addressed, the PQAM's duties and responsibilities for the PVNGS include:

A. Review and approval of:

- Material requisitions and specifications for purchase orders and subcontracts
- Subcontractors' QA programs and manuals
- Bid evaluations/selection of project approved suppliers
- Purchase orders and subcontracts
- Selected single-line drawings and P&IDs
- Vendor inspection planning
- Construction work plans and procedures
- Site inspection planning

- Review for reportability and concurrence of nonconformance descriptions and dispositions

B. Coordinate the establishment of the project quality program

C. Overall surveillance of the project quality program and coordination of its implementation

D. Coordinate project quality-related activities of engineering, procurement, and construction and provide necessary interface during audits or inspections by off-project entities of M&QS, ANI, NRC, or regulatory agencies

E. Conduct project surveillance and audit of project quality-related functions and advise management of the status of program implementation

F. Review and provide quality program compliance signoff on project documents described in the Project Quality Program Manual (PQPM), including QA descriptions in safety analysis reports (SARs), subcontractor QA programs, and selected quality verification records packages prior to transfer for prerequisite test, or release for APS preoperational testing.

G. The PQPM delegates the authority to stop work to the PQAM. Stop work action is immediately implemented by verbal notification to the cognizant superintendent and project construction manager. Stop work action is documented on a stop work order, which delineates:

1. Reasons for stopping work

2. Description of the condition that precipitated the stop work action

Distribution of the stop work order includes, as a minimum, the QA manager/projects, project construction manager, PM, and APS. The cognizant superintendent and project construction manager are responsible for implementing the stop work order. Quality assurance verifies that the work has stopped. Activities may proceed after disposition to proceed and/or corrective action has been approved by the PQAM.

H. Identify quality problems, initiate, recommend, or provide solutions and verify implementation of solution through established procedures.

I. Conduct trend analysis program responsive to repetitive problems indicative of ineffective prior corrective action implemented as a result of audit/surveillance findings or SDDR/NCR conditions.

J. Prepares reports for BWPC and BCI management review of PVNGS project quality status. These reports include important quality events, significant items, a comprehensive analysis of problem areas and the actions taken in their regard. Appropriate action based on the status of project QA activities is taken by the manager of division QA.

17.1B.1.6.3 Project Engineering

The PEM provides project direction to the discipline groups and is responsible for the conduct of engineering on the project. He is responsible for ensuring that engineering work under BWPC cognizance is carried out in accordance with the project direction received from the PM and the technical direction received from the engineering manager. Figure 17.1B-9 shows the Project Engineering Organization.

The engineering group supervisors (EGSs) are responsible for the quality and technical adequacy of the engineering work performed under their guidance. The group supervisors receive their technical direction in these matters from the chief engineers for their respective disciplines.

The EGSs are assigned a team of engineers, designers, and draftsmen from their respective chief engineers. The PEM, project engineer (PE), assistant project engineers (APEs), project quality engineer (PQE), EGSs, engineers, designers, and draftsmen comprise the Bechtel project engineering team. This team is responsible for all BWPC engineering design work performed by the project and for checking functions performed on the project. Special design support is furnished to the project by specialty groups. The PE is responsible for coordination of such special design work performed by other than project personnel and for requiring that it be subjected to the same degree of checking and control as that conducted on the project. The PEM is assisted in implementation of the

engineering quality program by the PQE. The project engineering team has the following responsibilities:

A. Prepare calculations, drawings, and specifications which constitute the engineering designs

B. Ensure that drawings, specifications, procedures, and instructions conform to APS requirements and applicable BWPC standards, applicable industry standards, regulatory agency requirements, and the design bases as defined in SARs

C. Prepare specifications for proposed supplier and subcontractor QA programs

D. Establish the need for supplier inspection and review results of same

E. Review and approve design changes and approve non-conformances which include "repair" or "use-as-is" disposition

F. Review drawings, specifications, procedures, test data, manuals, and reports submitted to engineering by suppliers and subcontractors

G. Prepare licensing documents for SAR

H. Conduct work in accordance with Engineering Department procedures authorized for the project

I. Establish the test program requirement where necessary to demonstrate that supplied or procured items will perform satisfactorily in service

17.1B.1.6.4 Project Construction

A BCI project construction manager reports to the construction manager and is responsible for the PVNGS project field construction performance. He is responsible for ensuring that construction work under BCI cognizance is carried out in accordance with the project direction received from the PM. He also is responsible for ensuring that the quality of the work complies with the PVNGS QA program requirements and is properly verified and documented.

The project construction team includes: Superintendents who are in direct charge of the craft; field engineers who perform field engineering, validate nonconformance reports for other than Quality Class Q, and provide technical guidance including in-process control inspection of construction work; field procurement personnel who are responsible for purchase of field procured items and control of materials prior to release for construction; the field contracts administrator who coordinates activities in field subcontracts; the project QA engineer, assigned by and administratively and technically responsible to the PQAM, who is responsible for coordinating the QA program; and PQCE, assigned by and administratively and technically responsible to the BCI chief construction QC and training engineer. The PQCE is responsible for the field QC program, including performance of all quality verification inspection. Project QC is coordinated by the project field construction manager. Figure 17.1B-10 shows the organization of the project construction team.

Project QC is the responsibility of the BCI PQCE whose responsibilities include:

A. Perform all jobsite quality verification inspection

B. Prepare jobsite QC documentation and maintain construction QC records

C. Perform surveillance of subcontractors' quality programs and review of subcontractor's quality verification documentation

D. Provide technical direction to testing laboratories and inspection subcontractors

E. Administer the nonconforming material control systems, validate nonconformance reports for Quality Class Q, and verify acceptance of rework and repairs in accordance with nonconformance dispositions

F. Review supplier quality verification documentation package(s) for completeness and traceability to the item(s)

The PQCE is assigned the responsibility for effective execution of the quality control program at the construction site. The chief construction QC and training engineer, who receives administrative direction from the BCI manager of construction, provides technical and administrative direction to the PQCE for work performance and verification. The PQCE coordinates work scheduling with the project construction manager but does not take direction from him. At no time is the PQCE subjected to

pressures of schedules and cost impact of his inspection findings.

Contractors are assigned first-level responsibility for the quality of their work. Their performance is coordinated and monitored by the BCI field organization. The BCI field QC organization performs the degree of quality verification/surveillance inspection of contractor and documentation performance appropriate for the individual contractor scope of work.

17.1B.1.6.5 Project Procurement

The PPM reports to the PM and provides project direction for procurement activities and coordinates with the project supplier quality supervisor.

Figure 17.1B-11 shows the organization of the project procurement team.

The PPM and project supplier quality supervisor are responsible for:

A. Purchasing

   1. Develop prequalified bid lists

   2. Primary interface with prospective vendors for performing vendor qualification when required

   3. Primary interface with bidders prior to award and, after award, with the vendor concerning matters resulting in purchase order and contract changes

4. Bidding activities, including preparation of the commercial evaluation of bid proposals

B. Procurement Supplier Quality

1. Definition of procurement supplier quality scope of work as required by engineering

2. Coordination of procurement supplier quality inspection services with project requirements

3. Coordinate audits with procurement supplier quality technical services in the conduct of post-award audits of the implementation of suppliers QA/QC programs

4. Preaward surveys of supplier's facilities and QA/QC programs

17.1B.1.6.6 Project Startup Testing

The startup test program is described in section 14.2. The startup test program is conducted in accordance with the QA program described in section 17.2.

17.1B.2 QUALITY ASSURANCE PROGRAM

17.1B.2.1 Scope

The program described in this section is applied to those structures, systems, and components (Q-list items) whose satisfactory performance is required to prevent accidents that may cause undue risk to the health and safety of the public, or to mitigate the consequences of such accidents if they do

occur. These items are defined as safety-related and are identified in table 3.2-1.

17.1B.2.2 Policy

The Bechtel quality program complies with NRC regulations and practices prescribed by ANSI, APS requirements, and BWPC policies. The program assigns the responsibility for quality to the organization performing the work, and includes, as a basic requirement, that individuals responsible for verifying and checking are independent of the individual or group responsible for performing the work. Additionally, independent reviews, audits, and surveillance are provided by individuals who are independent of the organizations responsible for performing the work.

Overall quality policy of the BWPC, approved by the BWPC president, is formulated or reviewed by the BWPC manager of QA, who is independent of individuals responsible for direction or coordination of engineering, procurement, and construction activities, and who reports to management of the BWPC. Quality assurance practices for individual projects are implemented through the PQAM who receives technical and administrative direction from manager of BWPC QA and the QA manager of projects. Project department and BWPC quality practices are subject to audit by QA at various levels.

Design verification includes checking within the project by individuals other than those who perform the original design and review and verification of technical adequacy of designs by

the chief engineers or their technical staff who are independent of the project.

Supplier and subcontractor QC requirements are specified in the procurement specifications by engineering, which requires suppliers and subcontractors to execute appropriate quality programs. Verification of supplier/subcontractor compliance is provided by source surveillance and inspection at suppliers facilities by the Procurement Supplier Quality Department, or by field quality control for onsite subcontractors or by APS personnel or their agent. Also, surveillance and audit of these activities by QA personnel, the Procurement Supplier Quality Department staff, or APS personnel or their agent.

Inspection of construction activities performed directly by BCI includes in-process controls and inspection of the work by formal QC verification inspection activities and audits by QA, supplemented by M&QS personnel as required.

When disputes arise from a difference of opinion between QA/QC personnel and other department personnel (engineering, procurement, QC, and construction personnel) regarding project quality program matters, the final authority rests with the PQAM, subject only to appeal to the BWPC manager of QA by the PM. The PM will assure that the functional department heads are informed of this disagreement and have adequate opportunity to present their position. If the PM agrees with the PQAM, the functional department heads will be informed of the decision and have adequate opportunity to present their position to the manager of BWPC QA.

17.1B.2.3 Program Documentation

The PQPM contains or references the procedures and manuals that comprise the project quality program. This manual is controlled and maintained by the PQAM.

Quality program policy, procedures, and instructions are contained in the documents listed in table 17.1B-1. Copies of Bechtel program documents are available for review by regulatory authorities and APS. Controlled copies of those designated by footnote in the table are available upon request to cognizant regulatory bodies. Controlled copies of project manuals and procedures are made available to APS and, through them, to regulatory authorities when required.

The BWPC and department standard procedures and practices form the basis for the QA program on each nuclear project. These procedures and instructions are contained in standard manuals, modified to meet specific project requirements, and supplemented where necessary by specific inspection plans, work instructions, and check lists.

The method for controlling the distribution of the listed documents is established in each manual. Records shall be maintained identifying the document, the document recipient, and acknowledgment of the receipt of the original issue and subsequent revisions.

These controls require that procedures and revisions are transmitted by letters giving instructions pertaining to the procedures or revisions. This letter also serves as a form to acknowledge receipt. A master file is maintained for records

associated with the procedures, and followup action is taken in 30 days if delinquent manual holders have not responded.

The PQPM is approved by the BWPC manager of QA and PM. The manuals and procedures described in table 17.1B-1 are the basic quality program documents for the project. These manuals are distributed to appropriate personnel who have quality-related responsibilities.

Table 17.1B-2 provides a list of 18 procedures directly related to the 18 criteria of 10CFR50, Appendix B. The total quality program is described in the PQPM.

The project team (refer to paragraph 17.1B.1.6) has the responsibility for preparing and maintaining documentation defining project design criteria and applicable codes, standards, and regulatory requirements. Further, the project team has the responsibility for preparing and maintaining organization charts and documentation defining interface responsibilities among various Bechtel groups and other major non-Bechtel project participants, such as APS and C-E.

17.1B.2.4 Personnel

Responsibilities, education, and experience requirements of individuals involved in quality program-related activities are formally documented in job descriptions that are approved and periodically reviewed by BWPC management. Requirements for education, experience, and proficiency levels are commensurate with the degree of importance of the job assignment (refer to table 17.1B-3).

Bechtel QA and QC personnel participating in the quality program are provided with indoctrination and training covering the standards, policies, and procedures that apply to the specific portions of the work they are performing to assure that suitable proficiency is achieved and maintained.

Table 17.1B-1

BECHTEL QUALITY PROGRAM DOCUMENTS (Sheet 1 of 2)

Document	Originating Authority	Review for QA Policy Compliance	Authorizing Approval	Content
Bechtel QA Manual - ASME Nuclear Components (BQAM-ASME III)[a]	M&QS	BWPC manager of QA	President Bechtel National, Inc. and appropriate authorized code inspection agency	Policies and procedures for overall Bechtel program applicable to ASME work
Procurement Supplier Quality Manual[a]	BWPC manager of Supplier Quality	BWPC manager of QA	BWPC manager of supplier quality	Procurement inspection procedures and standard supplier inspection plans
Nuclear Quality Assurance Manual	BWPC manager of QA	BWPC mana-ger of QA	BWPC president	BWPC policy supplementing and implementing quality policy
BWPC QA Department Procedures Manual	BWPC manager of QA	BWPC manager of QA	BWPC manager of QA	Procedures for conducting BWPC QA activities

a. Available on request to appropriate regulatory bodies.

Table 17.1B-1

BECHTEL QUALITY PROGRAM DOCUMENTS (Sheet 2 of 2)

Document	Originating Authority	Review for QA Policy Compliance	Authorizing Approval	Content
Engineering Department Procedures	Designated individuals	BWPC manager of QA	BWPC manager of engineer-ing	Definition of responsibilities and procedures for conduct of design, design review, and document control in the engineering departments
Project Quality Program Manual	Cognizant project team members	Project QA manager	Project manager, BWPC manager of QA	References to appropriate Bechtel standard procedures and practices, revised and supplemented if necessary to meet specific project requirements
Construction Work Plan Procedures and Quality Control Instructions Manual	Construction/ PQCE	Project QA manager	Project field engineer, project QA manager, PQCE	Responsibilities and practice for construction activities (how the work is performed, inspected, and accepted)
Internal Procedures Manual	Project engineering manager	BWPC manager of QA	Engineering manager	Project design/ interface procedures

Table 17.1B-2

PROJECT QUALITY PROGRAM MANUAL PROCEDURES (Sheet 2 of 5)

Procedure No. and Title	Substance
1.0 Project Organization	Describes the organizational structure and responsibilities for the Bechtel quality program during design, procurement, and construction of PVNGS
2.0 Project Quality Assurance Program Procedures (PQPM)	Describes the procedures and guidelines that facilitate control of: quality program procedures; classification of systems, components, and structures; training of personnel whose activities affect quality; and reporting the effectiveness of the quality program to management
3.0 Design Control	Describes the design process consisting of preparation, review, approval, change control, and distribution of design documents. The process provides for independent review to assure design adequacy, inspectability, testability, and compatibility with the Safety Analysis Report. Also described are the review requirements for the FSAR and ER, and quality- related functions and responsibilities of the project field engineering group
4.0 Procurement Document Control	Describes the method of controlling the quality of supplier furnished material or services

Table 17.1B-2

PROJECT QUALITY PROGRAM MANUAL PROCEDURES (Sheet 3 of 5)

Procedure No.	and Title	Substance
5.0	Instructions Procedures, and Drawings	Defines the governing documents that delineate the responsibilities of engineering, construction, QA, procurement supplier quality, procurement (field), and startup, and the system used as an extension of the Project Quality Program Manual when interpretation of policy/requirements necessitates more detailed procedural instructions
6.0	Document Control	Describes measures for maintaining control of design documents for PVNGS
7.0	Control of Purchased Material, Equipment, and Services	Describes the QA requirements for BWPC and BCI subcontractors and suppliers of materials or services.
8.0	Identification and Control of Material, Parts, and Components	Defines the system of material identification and control for assuring that Quality Class 1 and 2 materials, parts, appurtenances, components, and systems are of the proper configuration, and, when required, are traceable to supporting quality documentation
9.0	Control of Special Processes	Describes the system for the control of special processes, equipment, and personnel
10.0	Inspection	Defines the requirements for supplier and jobsite inspection programs. These requirements apply to structures, systems, and components designated Quality Class Q

Table 17.1B-2

PROJECT QUALITY PROGRAM MANUAL PROCEDURES (Sheet 4 of 5)

Procedure No. and Title		Substance
11.0	Test Control	Describes a system for control of testing for conformance with design disclosures
12.0	Calibration and Control of Measuring and Test Equipment for Construction and Startup	Describes a system of periodic calibration to assure the accuracy of instruments, gages, and measuring devices used in the construction and startup of PVNGS
13.0	Handling, Storage, Shipping, and Preservation	Defines responsibilities to assure adequate handling, storage, shipping, and preservation instructions and procedures are provided for safety-related items
14.0	Inspection, Test, and Operating Status	Describes the requirements and responsibilities of suppliers to identify the inspections, tests, and operating status performed on Quality Class Q materials and equipment
15.0	Nonconforming Materials Parts, and Components	Defines the procedure for identification, control, and disposition of material, equipment, or supplies that do not conform to controlling documents
16.0	Corrective Action	Describes the system that pro-vides corrective action for deficiencies discovered during monitoring of the QA program
17.0	Quality Assurance Records	Defines the controls for design, procurement, supplies, and construction quality-related records

BECHTEL QUALITY ASSURANCE DURING
DESIGN AND CONSTRUCTION

Table 17.1B-2

PROJECT QUALITY PROGRAM MANUAL PROCEDURES (Sheet 5 of 5)

Procedure No. and Title		Substance
18.0	Audits	Defines the procedure for conducting audits of engineering, procurement, construction sup-pliers, and subcontractors' activities performed by or for BWPC
19.0	Glossary of Terms and Definitions	Delineates definitions and terms used in this manual as applicable to PVNGS
20.0	QA Requirements for Fire Protection Systems	Defines the procedures for design, installation, and testing of BWPC or BCI/subcontractor activities consistent with regulatory guidelines and intent of NRC BTP APCSB 9.5-1, Appendix A

Table 17.1B-3

QUALIFICATION AND EXPERIENCE LEVELS

Title	Required Background
BWPC Manager of QA	Advanced degree with 5 or more years of related experience, or engineering degree with 8 or more years of related experience.
QA Manager/ Projects	Advanced degree with 2 to 4 years of related experience, or undergraduate degree with 5 to 7 years of related experience, or no degree with 8 or more years of related experience
Project QA Manager	Advanced degree with 2 to 4 years of related experience, or undergraduate degree with 5 to 7 years of related experience, or no degree with 8 or more years of related experience
Project QA Engineer	Advanced degree with less than 2 years of related experience, or undergraduate degree with 2 to 4 years of related experience, or no degree and 5 to 7 years of related experience
QA Engineer	Advanced degree with less than 2 years of related experience, or undergraduate degree with 2 to 4 years of related experience, or no degree and 4 to 6 years of related experience

NOTE: Qualifications and experience levels described above are to be considered as guidelines and are not absolute when other demonstrated capabilities and managerial characteristics prevail.

Personnel performing inspection, examination, and testing activities to verify quality are qualified in accordance with the established project requirements. Procurement supplier quality personnel are required to meet the requirements established in the Procurement Supplier Quality Manual. Quality assurance personnel and others participating in audits are required to be trained and qualified in accordance with documented procedures. Personnel performing pressure boundary and structural welding and nondestructive examinations are required to meet applicable qualification requirements of the ASTM Code and other appropriate codes and standards.

Personnel assigned to projects are provided with specific indoctrination and training covering project procedures applicable to their work. This is accomplished by general discussion of specific procedures and individual training by project supervisors and staff specialists. Similar programs are employed for indoctrination of individuals assigned to staff and specialist groups.

Formal qualification requirements are applied as follows:

A. Quality Control Personnel

Project QC engineers and home office QC staff and supervision will be qualified in accordance with the project established requirements of ANSI N45.2.6 or SNT-TC-1A, as applicable.

B. Quality Assurance Personnel

Personnel performing audits will be qualified in accordance with the appropriate requirements of ANSI N45.2.23.

C. Procurement Supplier Quality Representatives

A formal training program developed by the Procurement Supplier Quality Department is required for shop inspectors with assigned nuclear plant purchase orders. This program is defined in the Bechtel Procurement Supplier Quality Manual (PSQM) and conforms to requirements equivalent to those of ANSI N45.2.6.

17.1B.2.5 Management Review

Management reviews of the status and adequacy of the QA program are accomplished through periodic reports and presentations by QA management personnel to their respective managers, and through review of QA management audit reports. Meetings at BWPC are conducted by the BWPC manager of QA.

Also, the overall Bechtel program is reviewed annually by individuals outside the QA function. These reviews are performed by or for Bechtel management. The results of these reviews are documented.

17.1B.3 DESIGN CONTROL

The Bechtel design control program is based upon the requirements of ANSI N45.2.11.

Engineering Department policies, design criteria, design guides, standards, procedures, and instructions are employed for control of engineering design work to meet technical and regulatory requirements. These controls identify responsibilities and procedures necessary to ensure that design requirements are correctly translated into the final design. The controls also provide for appropriate documentation to permit review of the process used and results obtained. The controls also specify appropriate quality standards for control of changes and design interfaces.

Design criteria are assembled by the project on a discipline basis during the initial stages of design. These criteria include the criteria contained in SARs and project requirements. The design criteria are maintained current and serve as a basis for preparation of the final design. Departures from BWPC engineering discipline standards require approval by the PEM and appropriate BWPC chief engineer.

The design control program incorporates measures for identification and control of design interfaces among the various engineering disciplines on the project, between the project and technical support groups within BWPC, and of such external interfaces as C-E, APS, other equipment suppliers, and con-tractors performing design work. These measures include identification of technical responsibilities of the various design groups and coordination of design documents among them.

Engineering documents are prepared by project personnel and include drawings, specifications, design analyses, system descriptions, and technical reports. Engineering documents are

checked or reviewed in accordance with project procedures by personnel having technical capabilities commensurate to those of the originating engineer or designer. Engineering group supervisors are responsible for approval of the above engineering documents prepared within their groups. Design work of specialists external to the project is checked, reviewed, and accepted by project personnel qualified in the originating engineering discipline in accordance with project procedures. Design work may also be reviewed/accepted by members of the specialist group qualified in the originating engineering discipline, in accordance with specialist group procedures, and must be accepted by responsible project personnel.

Selected design documents are specified in the Engineering Department Procedures Manual for an additional level of review. This review is the responsibility of the cognizant chief engineer and his staff and is performed by personnel independent of the project team in accordance with Engineering Department procedures. Identification of documents requiring this additional level of control is provided by checklists or matrices prepared by the project during the initial design phase and approved by the cognizant chief engineer. Reviews may take the form of periodic in-process single or multidisciplinary reviews, final review meetings, independent detailed checks, comparison of results with those of the alternate simplified analysis, or comparison with proven standard designs. The specific review employed in each case is determined by the chief engineer and his staff, based upon the

importance of the item to safety, the specific attribute to safety, or its similarity with previously proven designs. Verification of the design review/approval program is provided through appropriate signature on the documents and approval records.

In accordance with ANSI N45.2, Section 4.3, design verification may be provided by tests. The specific test programs and results are reviewed by project and technical staff personnel.

Design changes, including changes recommended by field personnel, are subjected to design control measures commensurate to those applied to the original design. The BWPC policy requires that proposed changes to the design require review and approval by the engineering group that was responsible for the original design. Specifically, changes to design requirements or completed designs produced by project engineering, which may be proposed by vendors, contractors, BCI or others, must be reviewed and accepted by project engineering prior to implementation.

Materials, parts, equipment, and components that are considered "off-the-shelf" are reviewed and selected based on their suitability of application when such items are employed or related to Q-list systems, structures, equipment, or components.

Suppliers are not allowed to make changes from BWPC design or BWPC-approved supplier design documents without approval by BWPC project engineering.

Construction site requests or proposed changes in engineering design are documented by means of change notices or change requests which require authorization by project engineering.

The project engineer may give written authorization to the field engineer to make routine changes.

Design documents, design reviews, records, and changes thereto are distributed to responsible personnel and are filed and maintained through the document control centers as described in subsection 17.1B.6.

Design analyses such as physics, stress, materials, thermal, hydraulic, radiation, and accident are performed when applicable. Accessibility for inservice inspection, maintenance, and repair, as well as delineation of acceptance criteria for inspections and tests, is included.

The Design Criteria Manual is the base design document for the project. It includes BWPC engineering standards, industry standards and accepted design practices, and regulatory agency requirements. The design criteria are maintained current and serve as a basis for preparation of the final design. Design criteria and significant departures from BWPC discipline engineering standards require approval by appropriate division chief engineers, project personnel, and APS.

The QA program provides that design errors and deficiencies which adversely effect safety-related systems, structures, and components are documented and that appropriate corrective actions are taken. The documents used to report deficiencies are:

1. A document review notice (DRN) is used to provide objective evidence of the document review and approval process. It also provides for documenting the resolution of comments.

2. Corrective action requests (CARs), quality audit reports, and nonconformance reports (NCRs) are used to document deficiencies detected during design, procurement, and construction. These documents provide objective evidence for problem identification and corrective action.

3. A deficiency evaluation report (DER) is used to document significant reportable deficiencies, as defined in 10CFR50, Appendix B, Criterion XVI, 10CFR50.55(e), and 10CFR Part 21. The DER provides objective evidence for problem identification and corrective action.

4. A supplier deviation disposition request (SDDR) is used to document deviations from the procurement specifications or contract.

17.1B.4 PROCUREMENT DOCUMENT CONTROL

All procurement actions for Q-list items, or services, include technical specifications and QA requirements established by the project engineering team.

Project engineering is responsible for ensuring that applicable regulatory requirements, design bases, and other requirements such as supplier QA program requirements that are necessary to

obtain and verify quality are included or referenced in the procurement documents. The PQAM reviews and audits procurement documents for conformance to the QA program.

Procurement documents include specific technical specifications for the equipment and services to be furnished by the supplier or subcontractor. The specific codes, standards, tests, inspections, and records to be applied or furnished are included. The procurement documents define requirements for the supplier's QA program by incorporating the appropriate sections and elements of 10CFR50, Appendix B, and the ASME Boiler and Pressure Vessel Code. The procurement document also establishes requirements for source inspection and audit and provides for extension of the applicable requirements to subtier procurements. Requirements for control and approval of supplier nonconformances, and for preparation and delivery of documentation that must be submitted for review and approval are also included.

Changes and/or revisions to procurement documents and procurement documents for spares or replacement parts are reviewed to the same requirements as the original.

The PQAM reviews procurement documents for approval. Disagreements concerning procurement documents are resolved between the PQAM, the PPM, and/or the PE.

Final authority for quality program matters concerning procurement documents rests with the PQAM subject only to the appeal of the PM to the BWPC manager of QA.

The PQPM requires a review of procurement specifications by the PQAM to determine:

A. That the quality requirements are clear and unambiguous

B. That adequate acceptance and rejection criteria have been defined

C. The procurement document has been prepared, reviewed and approved in accordance with the QA program requirements.

(Review and approval is documented by signature on the DRN and retained in the project files.)

Project procedures require that procurement documents for Q items include the applicable requirements for supplier's QA programs consistent with pertinent provisions of 10CFR50, Appendix B, including provisions for preparation, retention, control, maintenance, and delivery of documentation.

Controls and QA requirements for spare or replacement parts for both design office and field procurement are equivalent to those applied to the original equipment procurement. The extent of the controls imposed will be determined by the individual spare part purchased.

17.1B.5 INSTRUCTIONS, PROCEDURES, AND DRAWINGS

The documented instructions and procedures governing the program are identified in subsection 17.1B.2 and table 17.1B-2.

Written, formal instruction from project engineering to construction contractors and suppliers is in the form of engineering specifications and addenda, specification change notices, drawings, drawing change notices, design change packages, and supplier engineering documents. These documents contain references to required procedures and instructions as appropriate and provide necessary acceptance criteria. These documents, when approved by project engineering, provide authorization for construction work.

The requirements, procedures, and instructions for construction QC activities are contained in the Work Plan Procedures/Quality Control Instructions (WPP/QCI) Manual. The elements of this manual include qualifications, indoctrination, certification and training; inspection examination and test control; control of nonconforming items; BCI field procurement control; control of measuring and test equipment; documentation and records control; final inspection and turnover; contractor and subcontractor control.

Bechtel Western Power Corporation procurement documents require suppliers and contractors to submit specified documents to BWPC for review and/or approval prior to start of fabrication or construction. Bechtel Western Power Corporation review of these documents is performed to determine that interfacing design features are compatible with overall design and installation requirements, and that procedures are acceptable.

Verification that work is accomplished in accordance with approved instructions, procedures, and drawings is obtained

through the various levels of surveillance, inspection, and audit described in subsection 17.1B.7.

17.1B.6 DOCUMENT CONTROL

The program documents identified in table 17.lB-1 include requirements for document control. This includes procedures that provide engineering, purchasing, procurement inspection, and preoperational testing control for review, approval, and release of documents and changes thereto.

Document control centers for the project are set up in the project engineering office and the jobsite. Controlled documents (drawings, specifications, vendor data) are released, received, controlled, and distributed through these centers.

Document control centers contain approved drawings and specifications prepared by project engineering. These documents are issued to organizations responsible for performing the work and to those responsible for inspection. Control registers identifying the drawings and specifications and their current status are issued periodically. Bechtel Western Power Corporation procurement supplier quality representatives receive copies of transmittal notices listing applicable documents and their approval status. These lists are used to verify current status of supplier documents. Transmittal forms are employed to forward drawings and specifications which require that signed acknowledgment receipts must be returned to the document control centers.

Changes made to approved documents are reviewed and approved in accordance with established procedures which provide that changes which affect the design of safety-related structures, systems, or components are reviewed and approved in the same manner as the original issue or by assigned alternate qualified personnel.

Changes may not be implemented without appropriate documented approvals. The methods for implementing approved changes into design and construction documents are defined in project design control procedures. Controlled change notices are used to identify and implement design changes. Incorporation of approved change notices into the governing base document is performed at the direction of APS.

Vendor-submitted documents such as drawings, specifications, procedures, manuals, and other data are controlled through the use of the control logs which provide identification and status of vendor documents. Transmittal forms used to return documents to the vendor show approval status of the evaluated vendor documents. BWPC shop inspectors are informed as to the current status of vendor documents and copies of applicable vendor documents are formally transmitted to the construction site with provision for receipt acknowledgment.

The project construction organization at the jobsite employs standard prescribed procedures for control of the distribution of approved drawings, specifications, and other documents. These procedures include provisions for field receipt, review, and distribution of approved documents and for appropriate marking or destruction of obsolete documents.

The transmittal of drawings and specifications is controlled in accordance with procedures which include provisions to prevent inadvertent use of obsolete or superseded documents.

Documents such as instructions, procedures, specifications, drawings, procurement documents, inspection plans, inspection records, supplier manuals, nonconformance reports, supplier deviation disposition requests, corrective action reports, memoranda, and correspondence are included in document control.

As part of their quality verification inspection program, field QC ensures that construction work is not performed if current approved design documents are not available.

Control of documents in the engineering and construction offices are regularly audited by project QA personnel.

17.1B.7 CONTROL OF PURCHASED MATERIAL, EQUIPMENT, AND SERVICES

Bechtel Western Power Corporation may obtain material from APS that has been purchased, received, and stored by APS in accordance with section 17.2. In these cases the material will be considered acceptable based on APS's procurement, control, receipt inspection, and storage control without further receipt inspection, document review, etc., by BWPC.

17.1B.7.1 Supplier Evaluation and Selection

Suppliers shall be evaluated to ensure their capability to meet technical and quality requirements of the procurement document in accordance with paragraph 17.2.7.2. Procedures and instructions within BWPC assure that only vendors that are

determined to be qualified in accordance with this process are selected for procurement of safety-related material, equipment, and services.

17.1B.7.2 Supplier Inspection

Project engineering identifies commodities requiring source inspection and audit. Procurement or QA may recommend additional items when justified. Manufactured or fabricated Q-list items such as vessels, heat exchangers, pumps, piping subassemblies, valves and electrical panels are included in source inspection and audit programs. Items that are typically excluded from the source inspection program include materials and standard manufactured products (catalog items) where required quality can be adequately determined by receipt inspection or post-installation checkout or test. Also excluded are materials where important physical and chemical properties are independently verified on samples taken at the supplier's facilities or at the jobsite.

APS is responsible to coordinate source inspection and surveillance activities. When source inspection is a requirement of a safety-related purchase order, it shall be conducted in accordance with an APS-approved inspection plan. This plan shall provide for identification of witness and hold points and identify the examination and tests which are selected to be witnessed. The source inspection or surveillance will be performed by qualified personnel.

Reports documenting inspections performed, tests witnessed, and discrepancies observed are prepared by the source

inspection/surveillance personnel and distributed to appropriate project personnel. Source inspection/surveillance personnel are responsible for assuring that inspected material, equipment, and specified documentation conform to the requirements of the procurement documents prior to releasing inspected items for shipment. The source inspection surveillance personnel has the authority to refuse release of nonconforming material.

17.1B.7.3 Receiving Inspection

All items are examined on receipt at the jobsite for identification, quantity, and damage. These examinations are performed by the field QC engineers with the assistance of field engineering and the field procurement group. For items not subject to source inspection, appropriate examinations or tests are performed. Examinations and tests are performed in accordance with WPP/QCIs under the supervision of field QC.

Documentary evidence that the item conforms to procurement documents is on file and available to those concerned.

Items received without certifications of conformance and other required supporting documentation are judged nonconforming and are withheld, identified as nonconforming, and segregated until documentation is received. Items determined to have discrepancies are reported on an NRC processed in accordance with applicable WPP/QCIs.

Where complete documents verifying acceptance or certification cannot be sent to the jobsite with shipment, documentation will

be available at the site which allowed shipment without the specified documentation. This equipment will be properly identified as "nonconforming," and may be conditionally released for installation providing that an approved "interim" disposition on an NCR identifies the limitations and conditions for locating the item in place.

Complete quality verification record packages are requested for delivery prior to or with the shipment. Documented control measures, with provisions for followup, are provided to expedite receipt of quality verification packages which are delayed beyond the time of shipment. Completed quality verification record packages received at the construction site are checked for completeness and traceability by QC and are audited by QA. Project engineering may elect to have selected quality verification documentation delivered to the design office for review by so specifying in procurement documents.

17.1B.7.4 Supplier Audits

Audits of suppliers shall be coordinated by APS and conducted in accordance with requirements established in section 17.2.

17.1B.8 IDENTIFICATION AND CONTROL OF MATERIALS, PARTS, AND COMPONENTS

Identification requirements are determined by engineering during the design process and are included in the Technical Specifications and drawings. Items that require traceability are so designated. Procurement documents also provide requirements for identification of purchased items.

Parts, components, subassemblies, equipment, and partially fabricated items may be identified by markings such as stenciled or etched markings, strip marking, imprinted tape, color coding, and tags. Large quantities of small items may be identified to heat, batch, lot, or specification by applying markings to bags, bins, tanks, or other suitable containers.

Identification of installed or assembled items may be transferred to inspection records or as-built documents as required. Markings which are hidden or subject to obliteration during fabrication or installation shall be included on as-built records.

Organizations receiving materials, parts, or components verify that they are properly identified and are accompanied by appropriate documentation. Provisions are made for handling and storing items to retain identification.

17.1B.9 CONTROL OF SPECIAL PROCESSES

Special processes requiring procedures and/or personnel qualification beyond those required by the ASME Code are identified in specifications by reference to appropriate industry codes and standards, where available, or by specific identification in the specification. Supplier and subcontractor special process qualification data are subject to review and/or approval by BWPC.

Special processes performed by BCI, including welding, nondestructive examination, protective coating, and cleaning and flushing, are performed by qualified personnel in

accordance with qualified special process procedures. The requirements for welding and nondestructive examination comply with applicable portions of the ASME Boiler and Pressure Vessel Code, AWS Standards, and SNT-TC-1A and supplements, as applicable. Cleaning and flushing procedures and personnel qualifications conform to the requirements of ANSI N45.2.1.

Other special processes or work operations identified by the nuclear steam system supplier or project engineering are properly qualified and performed by trained personnel in accordance with specified technical requirements.

Current qualification records of procedures, equipment, and personnel are maintained at the jobsite. Controls are provided to ensure that personnel qualification records are regularly reviewed and appropriate requirements for requalification are implemented. Implementation of these controls is verified by field QC personnel and is audited by QA with the assistance of the M&QS Department.

17.1B.10 INSPECTION

As described in subsection 17.1B.7, supplier and subcontractor programs are subject to source inspection as applicable. The inspection of BCI construction work includes inprocess surveillance, examination, and inspection by field engineering personnel who are independent of direct construction craft supervision, and formal quality verification inspection and testing by field QC personnel who are independent of field engineering and craft supervision. Field engineering receives day-to-day supervision from the project construction manager.

Field QC engineers are assigned by and receive technical direction from the chief construction QC and training engineer in the division or area office. The overall inspection program is monitored and audited by resident construction site QA personnel.

Project field engineering provides technical guidance and surveillance of construction work which includes in process examination. The field engineer does not perform acceptance inspection or provide inspection results to QC inspection. Field QC is responsible for quality verification inspection and testing of safety-related, Q class equipment, systems and installations.

Inspection and testing activities are performed in accordance with procedures contained in the Project WPP/QCI Manual. Inspection planning is prepared for receiving inspection, construction and installation inspection, and testing. Inspection planning considers:

- Suitable environmental conditions
- Quality characteristics to be inspected
- Individual or groups responsible for performing the inspection
- Acceptance and rejection criteria
- Suitable equipment for inspections
- Description of the method of inspection

- Evidence of completion and certification of inspection operation
- Results of the inspection operation
- Verification that all inspection operations are complete and acceptable

Inspection of modifications, repairs, and replacements is performed in accordance with the original design and inspection requirements, or acceptable alternatives.

The Construction WPP/QCI Manual includes procedures for certifying all grades of inspectors, including specified renewal periods. The procedure is administered by the PQCE, monitored by the chief construction QC and training engineer, and audited by the PQAM.

The Procurement Supplier Quality Manual provides for a formal system of certifying all grades of BWPC source inspectors, including specified renewal periods. This system is administered by the Procurement Supplier Quality Department and audited by the PQAM.

17.1B.11 TEST CONTROL

Tests required to verify acceptance of completed installations, equipment or systems are defined in engineering drawings, specifications, or test procedures. Construction tests are an extension of construction inspection procedures. Construction testing is conducted to demonstrate that the equipment installation is complete and that the electrical systems are

properly wired. Test plans or procedures, test reports, and records are used to demonstrate that completed tests have met test objectives. Written test procedures include:

A. Instructions for conducting the test and test equipment to be used

B. Test prerequisites which include, but are not limited to, the following:

   1. Calibrated instrumentation

   2. Adequacy of the test equipment

   3. Requirement for trained, qualified, and/or licensed/certified personnel

   4. Preparation, condition, and completeness of item to be tested

   5. Suitable environmental conditions

   6. Where applicable, mandatory inspection hold points, for witness by APS, contractor, or authorized inspector

   7. Provisions for data collection and storage

   8. Acceptance and rejection criteria

   9. Methods of documenting or recording test results

System cleaning, flushing, instrument and control settings, and performance demonstration are part of the startup prerequisite test program. Prerequisite/preoperational testing is under the control of APS. Bechtel Western Power Corporation startup

engineers provide assistance to APS as described in subsection 14.2.1.

17.1B.12 CONTROL OF MEASURING AND TEST EQUIPMENT

The BCI field QC program provides for calibration, maintenance, and control of measuring and test equipment used in the construction, testing, and QC inspection activity. Calibration is conducted using certified equipment having known valid relationship to nationally recognized standards. Procedures provide for unique identification of each measuring or test equipment item requiring calibration or checking. Calibration schedules are established based upon the amount of usage, accuracy, and type of equipment. Procedures provide for identification of calibration status by tags, labels, or markings applied to the item.

The identification of measuring and test equipment used in performing tests is entered in the test records when the validity of the test result is dependent on the accuracy of the test equipment. Also, whenever inspection, test, or measuring equipment is found to be uncalibrated or out of calibration limits, all items that have been inspected, tested, or measured since the last recorded calibration of the equipment will be evaluated to determine acceptability.

The evaluation of performance and effectiveness of the control of measuring and test equipment is verified by supplier surveys and audits performed by BWPC procurement supplier quality or APS personnel. In addition, field QA surveillance and audit of subcontractors and BCI are performed. Field QC is responsible

for verifying the current calibration status and proper functioning of equipment prior to use.

17.1B.13 HANDLING, STORAGE, AND SHIPPING

The requirements for packaging, marking, and shipping are included in procurement documents for Q-list items, which meet the intent of ANSI N45.2.2.

Procedures for equipment and system cleaning, flushing, and cleanness control are contained in WPP/QCIs which conform to the appropriate requirements of ANSI N45.2.1.

Special handling, storage, shipping, and preservation requirements are identified in technical specifications that provide, or require suppliers or subcontractors to provide, the required procedures and instructions. The packaging, handling, and shipping practices of the suppliers are subject to review prior to shipment, to verify compliance with requirements defined in procurement documents.

Materials and equipment received at the construction site are inspected, stored, and maintained in accordance with standard field procedures supplemented by special procedures and requirements issued by project engineering or furnished by suppliers. Materials and equipment are physically inspected upon arrival at the jobsite, and moved into prescribed storage areas or to the installation site if adequate protection is available. Direct movement to the installation site is permitted, to eliminate multiple handling provided direct installation is compatible with the construction schedule.

Special environmental conditions such as inert gas, specific moisture content levels, and temperature levels prescribed in procedures or specifications are controlled at the site.

Procedures are provided, as appropriate, for handling special items and for the care and maintenance of material handling equipment. Otherwise, standard material handling methods are used to ensure care and protection from physical damage. Special handling instructions and procedures for major or special items are included in procedures reviewed by project engineering or BCI specialists. Personnel responsible for handling major or special items are qualified to the extent required by these special handling instructions and procedures. Preparation and performance of rigging operations involving major equipment such as reactor vessels, steam generators, and pressurizers are witnessed by BCI rigging specialists.

Appropriate requirements are achieved through these approved procedures, through inspection planning and QC instructions.

Assurance that special handling and cleaning is accomplished as specified is provided by engineering review and approval of procedures, field QC inspection of special handling, and cleaning and audits of these activities by QA.

17.1B.14 INSPECTION, TESTS, AND OPERATING STATUS

Construction procedures and inspection plans provide for identification of inspection status of receipt inspection or work-in-process by using work sequence plans, inspection records, tags, markings, or other devices compatible with the

item, system, or operation being inspected or tested. Progress of work is entered in records, and status identification is changed to reflect current conditions. At the completion of construction, a tagging system is employed to visually indicate the operating status of equipment and systems that are in test or rework. Records of test results are recorded and maintained in the site document control center.

Procedures and instructions include identification of the individuals or groups responsible for application and removal of status indicators.

Work is performed and inspected according to prescribed sequences to assure quality. Tests, inspection points, or other critical operations may be bypassed only when the element can be inspected at a later time in the sequence and a later hold point exists. Bypassed inspections/operations or tests are concurred with by the signature approvals consistent with the original approvals. In these cases, the inspection point is picked up at a later date. If physical control of the item is required to prevent its inadvertent use or installation beyond the point where the inspection can be performed, the item is tagged as nonconforming and conditionally released with limit placed on future work operations.

Procedures and instructions include identification of individuals or groups responsible for application and removal of status indicators, and for documenting the bypassing of inspections, tests, or other operations. Participation of QA personnel is as follows:

A. Quality assurance reviews and accepts QC instructions, receiving, and construction inspection planning and changes thereto.

B. Quality assurance assures, through audits, that the status of items is correct and maintained throughout construction and inspection activities.

C. Quality assurance assures, through audits, that required inspections of test operations are performed, test results are recorded, and that the construction, installation, and inspection status of items is known and current at all times.

Nonconformances discovered are clearly identified and controlled as described in subsection 17.1B.15. Nonconforming items are required to be identified, tagged, and/or segregated. No further work can proceed on any nonconforming item until an approved disposition is implemented. Suppliers and subcontractors are required to have a BWPC-approved program for handling nonconformances. Activities at the site will comply with standard QC procedures which assure adequate control of nonconformances. Both supplier and subcontractor activities regarding nonconformances will be audited by BWPC QA.

17.1B.15 NONCONFORMING MATERIAL, PARTS, OR COMPONENTS

Suppliers and subcontractors are required to advise BWPC of all nonconformances from procurement documents or BWPC-approved designs for which the recommended disposition is "repair" or "use-as-is." Bechtel Western Power Corporation reserves the

right to accept or reject the disposition. Bechtel Western Power Corporation requires suppliers to submit proposed repair procedures for nonconformances for approval by project engineering and review by the project QA engineer prior to their use. Reports of nonconforming conditions are prepared by the supplier, BWPC procurement supplier quality representatives, or project engineering to ensure complete and adequate documentation. Copies of completed NRCs are forwarded to the jobsite prior to, or included with, the documentation submitted with the equipment. Inspection or surveillance personnel verify inclusion of approved NCRs at the time of equipment release when source inspection/surveillance is required.

Nonconformances discovered during receiving inspection or construction activities (jobsite) are controlled and documented in accordance with standard project QC procedures. The procedures provide for identification, documentation, and control of the nonconforming item. The authority for approval of the proposed resolution and documentation of reinspection results is also provided.

Important elements of the procedure include requirements for:

A. Tagging and segregation whenever practical due to size, quantity, and complexity of the item

B. Determination of interim disposition by project engineering and field QC

C. Approval by project engineering of "repair" or "use-as-is" dispositions prior to correcting significant or unique nonconformances

D. Advising project engineering after implementation of standard approved repair procedures

E. Monthly review of completed NCRs by QA to trend analysis requirements established by the PQPM, which prescribes conditions significant to quality that require corrective action

F. Participation of ASME-authorized inspector for nonconformance disposition on code-covered items

G. Providing the quality systems and engineering manager copies of all "repair" or "use-as-is" NCRs

Repair and reinspection instructions must be prepared and submitted for project engineering approval before repair may proceed. These repair and reinspection instructions will be reviewed to assure that the acceptability of repair is verified by field QC reinspection of the item as originally inspected or by a method at least equivalent. Suppliers are contacted when necessary to provide input to the reinspection instructions as required. Quality assurance will audit for compliance.

Quality assurance periodically reviews and monitors supplier, onsite subcontractor, and BCI NCRs for the identification of significant conditions adverse to quality, the cause of the condition, and corrective action taken.

These are documented and reported to appropriate levels of management. Verification by the PQAM that corrective action to preclude recurrence has been taken is reported to QA management and project management for impacts on other phases of the project.

Nonconformance reports are reviewed by project engineering and QA to determine if the nonconforming condition is potentially reportable under the requirements of Federal Regulations 10CFR50.55(e) or 10CFR Part 21. Project procedures provide for reporting of significant deficiencies to the licensee and substantial safety hazards to the Nuclear Regulatory Commission.

17.1B.16 CORRECTIVE ACTION

The corrective action program provides procedures for prompt identification of conditions adverse to quality that may require corrective action.

Within the Bechtel program, the identification of situations that may need corrective action is accomplished through review of nonconformance reports, procurement supplier quality audits of supplier activities, and QA surveillance and audit program. Corrective action is controlled by project procedures and documented by means of corrective action reports. The procedures provide for the following:

A. Identifying and reporting by any member of the project team those conditions that warrant corrective action including proposed recommended actions

B. Determination of cause and identification of corrective action to be taken by the responsible organization

C. Reporting cause and corrective action to BWPC and APS management

D. Final verification by the PQAM that corrective action has been taken

E. Review by QA management, project management, and project engineering of the implication or effect on other work

F. Consideration for "stop work" by the PQAM, when continued operations will result in unsafe conditions/further nonconforming work or extensive evaluation.

This program also provides for evaluation of conditions reported by project management and APS that may require reporting to the NRC by APS in accordance with the requirements of 10CFR50.55(e).

17.1B.17 QUALITY ASSURANCE RECORDS

Records produced as a result of the quality program are prepared and maintained by BWPC, BCI, suppliers, and subcontractors as their work is being performed. The types of records include approved procedures, procurement records, specifications, drawings, qualifications, quality verification records, operating logs, results of reviews, inspections, tests, audits, and material analyses.

Project engineering records are retained by the project engineering document control centers as design work is performed. It is normal practice to microfilm documents at regular intervals, unless duplicate copies are available at an alternate location. Provisions for collection of completed records in the design office, or at the jobsite, and the criteria for storage and retention recommended in ANSI N45.2.9 are applied to permanent quality records.

Documentation of the design review process is prepared and maintained in accordance with subsections 17.1B.3 and 17.1B.6. Design changes may be issued on an interim basis by means of change notices. However, these are ultimately incorporated in revisions to the governing documents, unless the change is a limited waiver (e.g., "use-as-is" on an NRC) which does not generally apply to the design document. Copies of released drawings, specifications, technical reports, and similar documents are placed in engineering or construction document control center files, and submitted to the client. At the completion of engineering, final copies of these records are provided to the client. At a specified time, mutually agreed to by APS and BWPC, control of original design calculations and analyses will be turned over to APS. APS will maintain and retain the original documentation in accordance with the APS QA operations program for document control and retention. Bechtel Western Power Corporation will no longer be responsible for control of released documents.

Supplier records which identify "as-built" status and verify the quality of their work are requested from the supplier and

are placed in construction site quality record files. In some instances, with the agreement of BWPC and APS, suppliers are permitted to retain custody of certain records, if retention procedures and storage facilities are adequate and access is provided to APS.

Completed quality verification records including NRCs for "repair" and "use-as-is" dispositions are placed in quality record files. Appropriate regulatory groups and APS are provided access to these files while they remain in BWPC custody. At the completion of BWPC and BCI assignments, these files are turned over to APS Nuclear Records Management Group in accordance with procedures established by the client.

The requirements and guidelines for receipt, control, and retention of permanent QA records contained in ANSI N45.2.9 are employed for the control of construction site quality record files. The recommended retention periods of ANSI N45.2.9 or the requirements of ASME Boiler and Pressure Vessel Code, Section III, as applicable, are followed for BWPC and BCI-produced or acquired records. Supplier's nonpermanent records are generally retained by the supplier. Retention periods for these records will be established based upon the date of shipment or acceptance of the item and not the commercial operating date of the power plant.

The BCI WPP/QCI Manual will require that the following listed information be noted in inspection and/or test records:

- A description of the type of operation

- Evidence of completion of each construction inspection, or test operation
- The results of the inspection or test
- Information related to nonconformance(s)
- Inspector or data recorder
- Date
- Acceptance or nonconformance report number

Quality assurance will audit for compliance during their review of these documents.

For suppliers, source inspection/surveillance personnel, during source inspection, will assure that suppliers' inspection and test records contain the listed information. Examples of these reports and records are submitted with the supplier's QA program. Quality assurance engineers will audit suppliers records to assure they contain the listed information.

17.1B.18 AUDITS

A comprehensive program of audits is conducted by BWPC covering the various activities of the QA program.

The BWPC audit program includes scheduled or unscheduled audits conducted by project QA personnel at the construction site or home office as well as periodic team audits performed by personnel independent of project activities. Audit activities include the following:

A. Audits of project engineering activities by office QA personnel assigned to the project. These audits are planned, scheduled, and documented. Results are reported to the PEM, PM, PQAM, and the QA manager of projects. Audit results are also submitted to APS.

B. Audits of BCI field construction, and BWPC resident engineering. and subcontractor activities by resident field QA personnel assigned to the project. These audits are planned, scheduled, and documented. Results are reported to the site construction manager, PM, QA manager of projects, and to APS.

C. Audits of suppliers are coordinated by ANPP and conducted in accordance with requirements established in section 17.2.

D. Audits of project engineering, design, procurement, construction, and QC activities at the jobsite by QA audit teams under the direction of the BWPC manager of QA, assisted by M&QS specialists and others, as required. These audits are conducted at least annually and results are reported to the management of the function audited, cognizant project management, BWPC management, and the BWPC manager of QA.

E. Audits of BWPC Engineering Technical Staff and services activities are performed on an annual basis under the direction of the BWPC manager of QA. These audits cover those groups doing design and/or review

outside of direct control of the project engineer. Results of these audits are reported to the manager or supervisor of the function audited, affected project management, BWPC management, and BWPC manager of QA.

F. Audits of procurement and M&QS are conducted annually by QA personnel under the direction of the BWPC manager of QA. Results of these audits are reported to cognizant management of the audited group, BWPC management, and the BWPC manager of QA.

Audit programs include provisions for identification of deficiencies, determination that corrective action is defined, and followup to verify that corrective action has been taken and is effective. Audits include selective review of procedures, work practices, and examination of items and records. Records of audits are available to projects.

In accordance with the provisions of ANSI N45.2.12, the audit program is carried out to verify compliance with all aspects of the QA program which is defined in documents listed in table 17.1B-1. Specifically, the audit program includes audits of:

A. BCI construction subcontractor and BWPC resident engineering site activity which affect plant safety

B. The preparation, review, approval, and control of designs and specifications

C. Request for proposals and evaluations of bids

D. The preparation, review, approval, and control of procurement documents

E. The preparation, review, approval, and control of instructions, procedures (including test procedures), and drawings

F. Indoctrination and training programs

Audit data are derived from project design office QA audits, procurement supplier quality audits of suppliers, QA audits of construction, and subcontractor activity at the site.

The PQAM is responsible for analysis of Bechtel audit data to determine the effectiveness of the QA program. The results will be reported to QA management and project manager. The data are also reviewed to determine if a quality trend has been established which requires corrective action.

Audit results are sent to and reviewed by responsible management. Corrective action is taken by the management of the group audited. Project audit programs include provisions that corrective action is defined and scheduled completion dates determined. Reaudits are conducted to verify that corrective action has been taken and is effective.

17.1C COMBUSTION ENGINEERING (C-E) QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

The Combustion Engineering Quality Assurance Program is described in topical report CENPD-210A Revision 3, “Quality Assurance Program” dated November 1977.

This page intentionally left blank

17.2 QUALITY ASSURANCE DURING THE OPERATIONS PHASE

Quality Assurance requirements for the Operations Phase are described in the PVNGS Operations Quality Assurance Program Description (QAPD).

18. TMI-2 LESSONS LEARNED IMPLEMENTATION REPORT

The Palo Verde Nuclear Generating Station Lessons Learned Implementation Report (LLIR) addresses those TMI-related items approved for implementation by the Commission as published in the "Clarification of TMI Action Plan Requirements," NUREG-0737, November 1980 and Supplement 1 to NUREG-0737, "Requirements for Emergency Response Capability", December 17, 1982 (Generic Letter 82-33).

Each recommendation is addressed, as it applies to the Palo Verde Nuclear Generating Station (PVNGS) design and operation, in the following manner:

(1) Responses reference the existing PVNGS design as presented in the PVNGS Final Safety Analysis Report (FSAR) as amended, the Combustion Engineering, Inc. (C-E) Standard Safety Analysis Report - Final Safety Analysis Report (CESSAR) as amended, and the PVNGS Emergency Plan.

(2) Future work performed and modifications installed will be summarized as revisions to this report.

(3) This report includes requirements from NUREG-0737 and Supplement 1 to NUREG-0737 related to PVNGS.

(4) The NRC positions presented herein are from NUREG-0737 and Supplement 1 to NUREG-0737 unless otherwise noted.

This page intentionally left blank

18.I OPERATIONAL SAFETY

18.I.A OPERATING PERSONNEL

18.I.A.1.1 SHIFT TECHNICAL ADVISOR

NRC Position

Each licensee shall provide an on-shift technical advisor to the shift supervisor. The shift technical advisor (STA) may serve more than one unit at a multiunit site if qualified to perform the advisor function for the various units.

The STA shall have a bachelor's degree or equivalent in a scientific or engineering discipline and shall have received specific training in the response and analysis of the plant for transients and accidents. The STA shall also receive training in plant design and layout, including the capabilities of instrumentation and controls in the control room. The licensee shall assign normal duties to the STAs that pertain to the engineering aspects of assuring safe operations of the plant, including the review and evaluation of operating experience.

PVNGS Evaluation

Two STAs will be provided onsite in accordance with the requirements of UFSAR Section 18.I.A.1.3, as advisory technical support to the shift manager (shift manager is equivalent to the shift supervisor position referred to in the NRC position above) in the areas of thermal hydraulics, reactor engineering, and plant analysis with regards to operational safety (see Technical Specification 5.2.2.f).

Normal duties of the STA shall include:

- The diagnosis of accidents and plant transients to determine how they may affect the engineered aspects of plant design and safety features
- The review and evaluation of applicable operating experience
- Other functions as assigned, or requested by the shift manager, which pertain to control room activities and engineering aspects that ensure safe operation of the plant.

Organizationally, the STA will report through the STA section leader for STA functions to the department leader, operations support.

The STAs shall have, as a minimum, a Bachelor's Degree in an engineering or science discipline.

The STA training program is discussed in subsection 13.2.1.

18.I.A.1.2 SHIFT MANAGER ADMINISTRATIVE DUTIES

NRC Position (NUREG-0694)

Review the administrative duties of the shift supervisor and delegate functions that detract from or are subordinate to the management responsibility for assuring safe operation of the plant to other personnel not on duty in the control room.

PVNGS Evaluation

The responsibility and authority of the unit shift manager (shift manager is equivalent to the shift supervisor position referred to in the NRC position above) is delineated in paragraph 13.1.2.6.1. The administrative duties of the unit

shift manager are defined in the PVNGS Station Manual and are in accordance with the guidance of the November 9, 1979, NRC letter from D. B. Vassallo to all pending construction permit applicants. Administrative functions which detract from or are subordinate to plant operational safety are assigned to other personnel who do not direct operational functions.

Additionally, the PVNGS operations organization includes a senior licensed unit control room supervisor for each unit, in addition to the assigned unit shift manager. The unit control room supervisor performs many of the administrative functions which typically would be performed by the unit shift manager.

The PVNGS operations organization also includes available personnel during the day shift on week days whose function is to assume administrative functions that might otherwise detract from the ability of shifts organization to devote full attention to the operation of the plant. Refer to subsection 18.I.C.3 for a further discussion of unit shift manager responsibilities.

18.I.A.1.3 SHIFT MANNING

NRC Position

(1) Limit Overtime

Administrative procedures shall be established to limit maximum work hours of all personnel performing a safety-related function.

(2) Minimum Shift Crew

The minimum shift crew for a unit shall include three operators, plus an additional three operators when the

unit is operating. Shift staffing may be adjusted at multiunit stations to allow credit for operators holding licenses on more than one unit.

In each control room, including common control rooms for multiple units, there shall be at all times a licensed reactor operator for each reactor loaded with fuel and a senior reactor operator licensed for each reactor that is operating. There shall also be onsite at all times an additional relief operator licensed for each reactor, a licensed senior reactor operator who is designated as shift supervisor, and any other licensed senior reactor operators required so that their total number is at least one more than the number of control rooms from which a reactor is being operated.

PVNGS Evaluation

(1) Limit Overtime

The following discussion related to operations overtime is historical in nature. 10 CFR 26, *Fitness for Duty Programs*, was amended by a Final Rule published March 31, 2008 in the Federal Register (73FR16966). The Final Rule superseded the NUREG-0737 based operator overtime controls.

PVNGS administrative controls to limit personnel fatigue reflect the additional requirements of the Final Rule, which applies to the operating staff, security and other personnel who perform duties identified in the rule (10 CFR 26.205, *Work hours*).

In accordance with NRC Generic Letter No. 82-02 PVNGS administrative procedures are in effect that limit the maximum hours to be worked by personnel performing safety-related functions. The personnel affected by this requirement include senior reactor operators, reactor operators, radiation protection technicians, auxiliary operators, and key maintenance personnel. Adequate shift coverage shall be maintained without routine heavy use of overtime. The objective shall be to have operating personnel work a nominal 40-hour week while the plant is operating. However, in the event that unforeseen problems require substantial amounts of overtime to be used, or during extended periods of shutdown for refueling, major maintenance, or major plant modifications, on a temporary basis, the following guidelines shall be followed (this excludes the STA and PVNGS Fire Department working hours):

1) An individual should not be permitted to work more than 16 hours straight, excluding shift turnover time.

2) An individual should not be permitted to work more than 16 hours in any 24-hour period, nor more than 24 hours in any 48-hour period, nor more than 72 hours in any 7-day period, all excluding shift turnover time.

3) A break of at least 8 hours should be allowed between work periods, including shift turnover time.

4) Except during extended shutdown periods, the use of overtime should be considered on an individual basis and not for the entire staff on a shift.

Recognizing that very unusual circumstances may arise requiring deviation from the above guidelines, such deviation shall be authorized in advance by personnel at the director level or designees in accordance with approved administrative procedures and with documentation of the basis for granting the deviation. The paramount consideration in such authorization shall be that significant reductions in the effectiveness of operating personnel would be highly unlikely.

Controls shall be included in the procedures such that individual overtime shall be reviewed monthly by the personnel assigned responsibility for authorizing deviations from the working hour guidelines. This review is to ensure that excessive hours have not been assigned and that routine deviation from the working hour guidelines do not occur.

In addition, procedures encourage licensed operators at the controls to be periodically relieved, when conditions permit, and assigned other duties while away from the control board.

Staff working hours are also addressed in the administrative Technical Specification.

(2) Minimum Shift Crew

The minimum requirements for shift crew per unit are identified in table 18.I.A-1.

Table 18.I.A-1

MINIMUM SHIFT CREW COMPOSITION

Position	Number of Individuals Required to Fill Position	
	Mode 1, 2, 3, or 4	Mode 5 or 6
SM	1	1
SRO	1	None
RO	2	1
AO	2	1
STA	(a)	None

(a) A minimum of two STAs are required for the site. See NRC SER dated March 19,2004.

SM - shift Manager (shift manager is an equivalent position to the shift supervisor position referred to in the NRC position above) with a senior reactor operator's license

SRO - Individual with a senior reactor operator's license

RO - Individual with a reactor operator's license

AO - Nuclear Auxiliary Operator or Sr.

STA - Shift technical advisor

Except for the shift manager, the composition of the shift crew may be one less than the minimum of table 18.I.A-1 for a period not to exceed 2 hours in order to accommodate unexpected absence of on-duty shift crew members, provided immediate action will be taken to restore the shift crew composition to within the minimum requirements of table 18.I.A-1. This provision does not permit any shift crew

position to be unmanned upon shift change due to an oncoming shift crewman being late or absent.

At least one licensed Reactor Operator shall be in the Control Room when fuel is in the reactor. In addition, while the reactor is in MODE 1, 2, 3, or 4, at least one licensed Senior Reactor Operator shall be in the Control Room.

During any absence of the shift manager from the control room while the unit is in Mode 1, 2, 3, or 4, an individual (other than the shift technical advisor) with a valid senior operator license shall be designated to assume the control room command function. During any absence of the shift manager from the control room while the unit is in Mode 5 or 6, an individual with a valid senior operator or operator license shall be designated to assume the control room command function. This control room command function is normally delegated to a designated control room supervisor who holds a valid senior reactor operator license.

Normal staffing as discussed in paragraph 13.1.2.6 and PVNGS administrative procedures meet or exceed NUREG-0737 minimum requirements.

18.I.B OVERALL ORGANIZATION

18.I.B.1.2 INDEPENDENT SAFETY ENGINEERING GROUP

NRC Position

Each applicant for an operating license shall establish an onsite independent safety engineering group (ISEG) to perform independent reviews of plant operations.

The principal function of the ISEG is to examine plant operating characteristics, NRC issuances, licensing information service advisories, and other appropriate sources of plant design and operating experience information that may indicate areas for improving plant safety. The ISEG is to perform independent review and audits of plant activities, including maintenance, modifications, operational problems, and operational analysis, and aid in the establishment of programmatic requirements for plant activities. Where useful improvements can be achieved, it is expected that this group will develop and present detailed recommendations to corporate management for such things as revised procedures or equipment modifications.

Another function of the ISEG is to maintain surveillance of plant operations and maintenance activities to provide independent verification that these activities are performed correctly and that human errors are reduced as far as practicable. The ISEG will then be in a position to advise utility management on the overall quality and safety of operations. The ISEG need not perform detailed audits of plant operations and shall not be responsible for sign-off functions such that it becomes involved in the operating organization.

PVNGS Evaluation

The program and related procedures for review of operating experience described at UFSAR 18.I.C.5 are the primary method used at PVNGS to review and act upon internal and external operating experience.

To augment the program and related procedures described at 18.I.C.5, the Director, Nuclear Assurance, is responsible to monitor and assess operational activities to provide assurance that activities important to safety are performed satisfactorily. Specific functions of the Nuclear Assurance staff are described in the Operations Quality Assurance Program Description (QAPD).

18.I.C OPERATING PROCEDURES

18.I.C.1 GUIDANCE FOR THE EVALUATION AND DEVELOPMENT OF PROCEDURES FOR TRANSIENTS AND ACCIDENTS

NRC Position

1. Requirements (from NUREG-0737, Supplement No. 1)

   a. The use of human factored, function oriented, emergency operating procedures (EOPs) will improve human reliability and the ability to mitigate the consequences of a broad range of initiating events and subsequent multiple failures or operator errors, without the need to diagnose specific events.

   b. In accordance with NUREG-0737, Item I.C.1, reanalyze transients and accidents and prepare technical guidelines. These analyses will identify operator tasks, and information and control needs. The analyses also serve as the basis for integrating upgraded emergency operating procedures and the control room design review and verifying the SPDS design.

   c. Upgrade EOPs to be consistent with technical guidelines and an appropriate procedure writer's guide.

   d. Provide appropriate training of operating personnel on the use of upgraded EOPs prior to implementation of the EOPs.

   e. Implement upgraded EOPs.

2. Documentation and NRC Review

   a. Submit technical guidelines to the NRC for review. The NRC will perform a preimplementation review of the technical guidelines. Within 2 months of receipt of the technical guidelines, the NRC will advise the licensees of their acceptability.

   b. Each licensee shall submit to the NRC a procedures generation package at least 3 months prior to the date it plans to begin formal operator training on the upgraded procedures. The NRC approval of the submittal is not necessary prior to upgrading and implementing the EOPs. The procedures generation package shall include:

      (i) Plant-Specific Technical Guidelines -- plant-specific guidelines for plants not using generic technical guidelines. For plants using generic technical guidelines, a description of the planned method for developing plant specific EOPs from the generic guidelines, including plant specific information.

      (ii) A writer's guide that details the specific methods to be used by the licensee in preparing EOPs based on the technical guidelines.

      (iii) A description of the program for validation of EOPs.

(iv) A brief description of the training program for the upgraded EOPs.

c. All procedures generation packages will be reviewed by the staff. On an audit basis for selected facilities, upgraded EOPs will be reviewed. The details and extent of this review will be based on the quality of the procedures generation packages submitted to NRC. A sampling of upgraded EOPs will be reviewed for technical adequacy in conjunction with the NRC reactor inspection program.

PVNGS Evaluation

Arizona Public Service Company (APS) has participated in C-E Owner's Group activities, conducted since the Three Mile Island (TMI) accident, to develop improved emergency procedure guidelines and associated supporting analyses. The initial C-E Owner's Group analysis of inadequate core cooling is documented in Report CEN-117, "Inadequate Core Cooling - A Response to NRC IE Bulletin 79-06C, Item 6 for Combustion Engineering Nuclear Steam Supply Systems." The initial C-E Owner's Group analyses of transients and accidents (non-LOCA) are documented in Report CEN-128, "Response of Combustion Engineering Nuclear Steam Supply Systems to Transients and Accidents."

The emergency procedure technical guidelines for Combustion Engineering pressurized water reactors were submitted to the NRC by the Combustion Engineering Owner's Group as CEN-152, "Combustion Engineering Emergency Procedure Guidelines," Revision 1, dated November 22, 1982. APS has developed an

emergency procedure generation package (PGP) for PVNGS based on the C-E emergency procedure guidelines and has submitted the PGP to the NRC on July 15, 1983. The PVNGS PGP contained the following information as required by Supplement No. 1 to NUREG-0737:

(i) Plant-specific technical guidelines

(ii) Procedure writer's guide

(iii) Description of the EOP verification and validation program

(iv) Description of the operator training program for the EOPs.

Since the initial issue of EOPs based on the PGP, APS has revised the EOPs to maintain them in accordance with the current revision of the C-E emergency procedure guidelines. Operators have received training as needed on the revisions to the EOPs.

PVNGS EOPs are discussed in the Operations Quality Assurance Program Description (QAPD).

18.I.C.2 SHIFT RELIEF AND TURNOVER PROCEDURES

<u>NRC Position (November 9, 1979 Letter from NRC to All Construction Permit Holders)</u>

The licensees shall review and revise as necessary the plant procedure for shift and relief turnover to assure the following:

1. A checklist shall be provided for the oncoming and offgoing control room operators and the oncoming shift

supervisor to complete and sign. The following items, as a minimum, shall be included in the checklist.

a. Assurance that critical plant parameters are within allowable limits (parameters and allowable limits shall be listed on the checklist).

b. Assurance of the availability and proper alignment of all systems essential to the prevention and mitigation of operational transient and accidents by a check of the control console. (What to check and criteria for acceptable status shall be included on the checklist.)

c. Identification of systems and components that are in a degraded mode of operation permitted by the Technical Specifications. For such systems and components, the length of time in the degraded mode shall be compared with the Technical Specifications action statement (this shall be recorded as a separate entry on the checklist).

2. Checklists or logs shall be provided for completion by the offgoing and ongoing auxiliary operators and technicians. Such checklists or logs shall include any equipment under maintenance or test that, by themselves, could degrade a system critical to the prevention and mitigation of operational transients and accidents or initiate an operational transient (what to check and criteria for acceptable status shall be included on the checklist.); and

3. A system shall be established to evaluate the effectiveness of the shift and relief turnover procedure (for example, periodic independent verification of system alignments).

PVNGS Evaluation

Detailed administrative procedures have been developed that meet the guidance of the November 9, 1979, NRC letter from D. B. Vassallo to All Licensees of Plants Under Construction, for shift relief and turnovers to ensure that current plant conditions and system status is conveyed to the oncoming shift. The procedures have been developed for shift relief and turnover for the shift manager (shift manager is an equivalent position to the shift supervisor position referred to in the NRC position above), control room supervisors, nuclear operators, radwaste technicians, and radiation protection technicians.

The procedure for the operations staff includes the use of checklists and logs to ensure that there is a proper turnover of command functions and current operating conditions. Turnover and relief includes a review of tagouts, abnormal conditions, jumpers/bypasses, surveillance testing, and conditions affecting Technical Specifications. Annunciator panels, visual displays, and key operating parameters will also be monitored to verify system status and equipment condition.

18.I.C.3 SHIFT MANAGER RESPONSIBILITIES

NRC Position (NUREG-0694) (NRC Letter, D. B. Vassallo to All Pending Construction Permit Applicants, dated November 9, 1979)

(1) The highest level of corporate management of each licensee shall issue and periodically reissue a management directive that emphasizes the primary management responsibility of the shift supervisor for safe operation of the plant under all conditions on his shift and that clearly establishes his command duties.

(2) Plant procedures shall be reviewed to assure that the duties, responsibilities, and authority of the shift supervisor and control room operators are properly defined to affect the establishment of a definite line of command and clear delineation of the command decision authority of the shift supervisor in the control room relative to other plant management personnel. Particular emphasis shall be placed on the following:

(a) The responsibility and authority of the shift supervisor shall be to maintain the broadest perspective of operational conditions affecting the safety of the plant as a matter of highest priority at all times when on duty in the control room. The idea shall be reinforced that the shift supervisor should not become totally involved in any single operation in times of emergency when multiple operations are required in the control room.

(b) The shift supervisor, until properly relieved, shall remain in the control room at all times during accident situations to direct the activities of control room operators. Persons

authorized to relieve the shift supervisor shall be specified.

(c) If the shift supervisor is temporarily absent from the control room during routine operations, a lead control room operator shall be designated to assume the control room command function. These temporary duties, responsibilities, and authority shall be clearly specified.

(3) Training programs for shift supervisors shall emphasize and reinforce the responsibility for safe operation and the management function the shift supervisor is to provide for assuring safety.

(4) The administrative duties of the shift supervisor shall be reviewed by the senior officer of each utility responsible for plant operations. Administrative functions that detract from or are subordinate to the management responsibility for assuring the safe operation of the plant shall be delegated to other operations personnel not on duty in the control room.

PVNGS Evaluation

The primary onshift responsibility for safe operation of the plant belongs to the unit shift manager (shift manager is an equivalent position to the shift supervisor position referred to in the NRC position above), whose lines of authority and duties are described in section 13.1.2 and in the PVNGS administrative and operating procedures. The unit shift manager shall maintain a broad perspective of all of the operational conditions affecting the safety of the plant. The

unit shift manager should not become totally involved in any single operation in times of emergency when multiple operations are required in the control room. Additionally, the control room supervisor provides a backup to the shift manager and supervises shift personnel in conduct of unit operations, as assigned. The unit shift manager or control room supervisor shall remain in the control room until properly relieved during emergency conditions.

The administrative duties of the unit shift managers will be periodically reviewed by a senior officer of APS. Administrative functions that detract from or are subordinate to the management responsibility for assuring the safe operation of the plant will be delegated to other operations personnel.

18.I.C.4 CONTROL ROOM ACCESS

NRC Position (NRC Letter, D. B. Vassallo to All Pending Construction Permit Applicants, dated November 9, 1979)

The licensee shall make provisions for limiting access to the control room to those individuals responsible for the direct operation of the nuclear power plant (e.g., operations supervisor, shift supervisor, and control room operators), to technical advisors who may be requested or required to support the operation, and to predesignated NRC personnel. Provisions shall include the following:

(1) Develop and implement administrative procedures that establishes the authority and responsibility of the person in charge of the control room to limit access, and

(2) Develop and implement procedures that establish a clear line of authority and responsibility in the control room in the event of an emergency. The line of succession for the person in charge of the control room shall be established and limited to persons possessing a current senior reactor operator's license. The plan shall clearly define the lines of communication and authority for plant management personnel not in direct command of operations, including those who report to stations outside of the control room.

PVNGS Evaluation

(1) An administrative procedure has been developed to limit access to the control room. This procedure is contained in the PVNGS Station Manual. The unit shift manager (shift manager is an equivalent position to the shift supervisor position referred to in the NRC position above), and the unit control room supervisor have the responsibility to control access to those personnel who are required, or are requested, to support the operation of the plant.

(2) Procedures have been developed which establish clear lines of authority and communication during all plant conditions, including startups, normal, off-normal, and emergency conditions. These procedures clearly establish the line of succession for the individual in charge of the control room. Additionally, a procedure has been developed to clearly define the lines of communication and authority for plant personnel not in direct command of operations during an emergency.

18.I.C.5 PROCEDURES FOR FEEDBACK OF OPERATING EXPERIENCE TO PLANT STAFF

NRC Position

In accordance with Task Action Plan I.C.5, Procedures for Feedback of Operating Experience to Plant Staff (NUREG-0660), each applicant for an operating license shall prepare procedures to assure that operating information pertinent to plant safety originating both within and outside the utility organization is continually supplied to operators and other personnel and is incorporated into training and retraining programs. These procedures shall:

(1) Clearly identify organizational responsibilities for review of operating experience, the feedback of pertinent information to operators and other personnel, and the incorporation of such information into training and retraining programs;

(2) Identify the administrative and technical review steps necessary in translating recommendations by the operating experience assessment group into plant actions (e.g., changes to procedures, operating orders);

(3) Identify the recipients of various categories of information from operating experience (i.e., supervisory personnel, shift technical advisors, operators, maintenance personnel, health physics technicians) or otherwise provide means through which such information can be readily related to the job functions of the recipients;

(4) Provide means to assure that affected personnel become aware of and understand information of sufficient importance that should not wait for emphasis through routine training and retraining programs;

(5) Assure that plant personnel do not routinely receive extraneous and unimportant information on operating experience in such volume that it would obscure priority information or otherwise detract from overall job performance and proficiency;

(6) Provide suitable checks to assure that conflicting or contradictory information is not conveyed to operators and other personnel until resolution is reached; and,

(7) Provide periodic internal audit to assure that the feedback program functions effectively at all levels.

PVNGS Evaluation

An operating experience review program has been implemented for PVNGS. This program establishes the responsibilities and methodologies for reviewing the operating experience of PVNGS and other nuclear facilities. The Performance Improvement Department under direction of the Director, Performance Improvement, has the primary responsibility for implementing the operating experience review program. Additionally, PVNGS participates in the Institute of Nuclear Power Operations (INPO) Significant Event Evaluation and Information Network (SEE-IN) as discussed in NRC Generic Letter No. 82-04. The operating experience review program and implementing procedures have been developed in accordance with the requirements of NUREG-0737, Item I.C.5.

18.I.C.6 GUIDANCE ON PROCEDURES FOR VERIFYING CORRECT PERFORMANCE OF OPERATING ACTIVITIES

NRC Position

It is required (from NUREG-0660) that licensees' procedures be reviewed and revised, as necessary, to assure that an effective system of verifying the correct performance of operating activities is provided as a means for reducing human errors and improving the quality of normal operations. This will reduce the frequency of occurrence of situations that could result in or contribute to accidents. Such a verification system may include automatic system status monitoring, human verification of operations and maintenance activities independent of the people performing the activity (see NUREG-0585, Recommendation 5), or both.

Implementation of automatic status monitoring, if required, will reduce the extent of human verification of operations and maintenance activities but will not eliminate the need for such verification in all instances. The procedures adopted by the licensees may consist of two phases -- one before and one after installation of automatic status monitoring equipment, if required, in accordance with Item I.D.3.

PVNGS Evaluation

Paragraph 7.5.1.1.6 describes the safety equipment status panel, designed to implement Regulatory Guide 1.47, which displays the availability of selected equipment important to

nuclear safety. The presence of this system will reduce the extent of human verification of operations and maintenance activities. The following additional requirements have been implemented to ensure safety system reliability:

A. Permission to release equipment or systems for maintenance shall be granted by designated operating personnel who currently hold or have held a senior reactor operator license at Palo Verde. Prior to granting permission, such operating personnel shall verify that the equipment or system can be released, and determine how long it may be out of service. Granting of such permission shall be documented. Attention shall be given to the potentially degraded degree of protection when one subsystem of a redundant safety system has been removed for maintenance.

B. After permission has been granted to remove the system for service, it shall be made safe to work on. Measures shall provide for protection of equipment and workers. Equipment and systems in a controlled status shall be clearly identified. Strict control measures for such equipment shall be enforced.

C. Conditions to be considered in preparing equipment for maintenance, in addition to requirements of the Technical Specifications, include, for example: shutdown margin; method of emergency core cooling; establishment of a path for decay heat removal; temperature and pressure of the system; valves between work and hazardous material; venting, draining and flushing; entry into closed vessels; hazardous

atmospheres; handling hazardous materials; and electrical hazards. When entry into a closed system is required, control measures shall be established to prevent entry of extraneous material and to assure that foreign material is removed before the system is reclosed.

D. Procedures shall be provided for control of equipment, as necessary, to maintain personnel and reactor safety and to avoid unauthorized operation of equipment. These procedures shall require control measures such as locking or tagging to secure and identify equipment in a controlled status. The procedures shall require independent verifications, where appropriate, to ensure that necessary measures, such as tagging equipment, have been implemented correctly.

E. Temporary modifications, such as temporary bypass lines, electrical jumpers, lifted electrical leads, and temporary trip point settings, shall be controlled by approved procedures which shall include a requirement for independent verification by either a second person or by a functional test which conclusively proves the proper installation or removal of the temporary modification. A log, or other documented evidence, shall be maintained of the current status of such temporary modifications.

F. When equipment is ready to be returned to service, operating personnel shall place the equipment in operation and verify and document its functional acceptability. Attention shall be given to

restoration of normal conditions, such as removal of jumpers or signals used in maintenance or testing and returning valves, breakers or switches, or proper startup or operating positions from "test" or "manual" positions, and assuring that all alarms which are indicative of inoperative status are extinguished. For safety-related equipment, proper alignment shall be independently verified by a second person unless alignment is proven by functional testing.

18.I.C.7 NSSS VENDOR REVIEW OF PROCEDURES

NRC Position (NUREG-0694)

(1) Low Power Test Program

Obtain nuclear steam supply system (NSSS) vendor review of low-power testing procedures to further verify their adequacy.

(2) Power Ascension and Emergency Procedures

Obtain NSSS vendor review of power ascension test and emergency procedures to further verify their adequacy.

PVNGS Evaluation

Subsection 14.2.5 describes the review process for the test procedures of the low-power and power ascension test programs. The NSSS vendor representative is included on the test results review group to ensure the review of test procedures pertaining to or interfacing with the NSSS vendor-supplied systems.

The NSSS vendor has reviewed the emergency operating procedures that involve the NSSS vendor scope of supply.

18.I.C.8 PILOT MONITORING OF SELECTED EMERGENCY PROCEDURES FOR NEAR-TERM OPERATING LICENSE APPLICANTS

NRC Position (NUREG-0694)

Correct emergency procedures, as necessary, based on the NRC audit of selected plant emergency operating procedures (e.g., small-break LOCA, loss of feedwater, restart of engineered safety features following a loss of ac power, steam line break, or steam generator tube rupture).

PVNGS Evaluation

NRC staff review and approval of the PVNGS Emergency Operating Procedures will be done in accordance with TMI-2 Task Action Plan, Item I.C.1, as stated in Supplement 6 to the staff's Safety Evaluation Report related to the operation of PVNGS Units 1, 2, and 3 dated October 1984. Therefore, a pilot monitoring review of selected plant emergency operating procedures is not required. Please refer to subsection 18.I.C.1.

This page intentionally left blank

18.I.D CONTROL ROOM DESIGN

Note: The revised 10 CFR 50.59 rule became effective March 13, 2001. This revision of the rule eliminated the term "unreviewed safety question". In accordance with the guidance provided in NRC Regulatory Issue Summary 2001-03, "Changes, Tests and Experiments", dated January 23, 2001, Issue 7, any future application of the information contained in NUREG-0737 to proposed changes, tests or experiments should be reviewed in the context of the revised 10 CFR 50.59 rule. The information presented in this section is historical and has been preserved in its original context.

18.I.D.1 DETAILED CONTROL ROOM DESIGN REVIEWS (SUPPLEMENT 1 TO NUREG-0737)

NRC Position

1. Requirements

   a. The objective of the control room design review is to "improve the ability of nuclear power plant control room operators to prevent accidents or cope with accidents if they occur by improving the information provided to them" (from NUREG-0660, Item I.D.1). As a complement to improvements of plant operating staff capabilities in response to transients and other abnormal conditions that will result from implementation of the safety parameter display system (SPDS) and from upgraded emergency operating procedures, this design review will identify any modifications of control room configurations that would contribute to a significant reduction of risk

and enhancement in the safety of operation. Decisions to modify the control room would include consideration of long-term risk reduction and any potential temporary decline in safety after modifications resulting from the need to relearn maintenance and operating procedures. This should be carefully reviewed by persons competent in human factors engineering and risk analysis.

b. Conduct a control room design review to identify human engineering discrepancies. The review shall consist of:

(i) The establishment of a qualified multi-disciplinary review team and a review program incorporating accepted human engineering principles.

(ii) The use of function and task analysis (that had been used as the basis for developing emergency operating procedures technical guidelines and plant specific emergency operating procedures) to identify control room operator tasks and information and control requirements during emergency operations. This analysis has multiple purposes and should also serve as the basis for developing training and staffing needs and verifying SPDS parameters.

(iii) A comparison of the display and control requirements with a control room inventory to identify missing displays and controls.

(iv) A control room survey to identify deviations from accepted human factors principles. This survey will include, among other things, an assessment of the control room layout, the usefulness of audible and visual alarm systems, the information recording and recall capability, and the control room environment.

c. Assess which human engineering discrepancies are significant and should be corrected. Select design improvements that will correct those discrepancies. Improvements that can be accomplished with an enhancement program (paint-tape-label) should be done promptly.

d. Verify that each selected design improvement will provide the necessary correction, and can be introduced in the control room without creating any unacceptable human engineering discrepancies because of significant contribution to increased risk, unreviewed safety questions, or situations in which a temporary reduction in safety could occur. Improvements that are introduced should be coordinated with changes resulting from other improvement programs such as SPDS, operator training, new instrumentation (Regulatory Guide 1.97, Rev. 2), and upgraded emergency operating procedures.

PVNGS Evaluation

The purpose of the PVNGS detailed control room design reviews (DCRDR) was to review the control room design provided to the operator and implement changes that would improve the ability

of the PVNGS control room operator to prevent accidents or cope with accidents. Results of this control room design review (CRDR) identified several modifications to the PVNGS control room configuration that enhanced the safety of plant operation. Only those modifications that provided a control room design improvement to the operators were implemented.

The PVNGS DCRDR was conducted to identify human engineering discrepancies (HEDs). The review performed at PVNGS consisted of:

(1) establishing a qualified multidisciplinary review team,

(2) the use of function and task analysis to identify control room operator tasks and information and control requirements during emergency operations,

(3) a comparison of the displays and control requirements with a control room inventory to identify missing displays and controls,

(4) a control room survey to identify deviations from accepted human factors principles,

(5) an assessment of HEDs to determine which are significant and should be corrected,

(6) a selection of control room design improvements that will correct significant discrepancies,

(7) a verification that each of the selected control room design improvements will provide the necessary corrections of HEDs and will not introduce new HEDs into the control room, and will not result in an

increased risk, unreviewed safety questions, or temporary reduction in safety, and

(8) ensuring that improvements that are introduced to the PVNGS control room are coordinated with changes resulting from other improvement programs such as the PVNGS SPDS, the PVNGS operator training programs, new instrumentation of Regulatory Guide 1.97, Rev. 2, "Instrumentation for Light Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident" (Regulatory Guide 1.97) and the PVNGS emergency operating procedure (EOP).

The above eight issues as they apply to the PVNGS DCRDR are discussed in detail by a letter submitted to the NRC dated August 30, 1985 (ANPP-33302).

Additionally, as part of the licensing of PVNGS Unit 2, the NRC staff required that:

(1) any differences between the Units 1 and 2 control rooms be identified,

(2) evaluate the differences to determine if any HEDs exist, and

(3) propose actions and schedules to correct the HEDs.

In response to this new requirement, ANPP conducted an evaluation which consisted of evaluating the preplanned control room differences between Units 1 and 2, evaluating the temporary differences due to design change packages being implemented at different times between the units, and a walkdown of the control rooms and comparison of the findings. The results of this evaluation identified no new HEDs.

18.I.D.2 PLANT SAFETY PARAMETER DISPLAY SYSTEM

Note: The revised 10 CFR 50.59 rule became effective March 13, 2001. This revision of the rule eliminated the term "unreviewed safety question". In accordance with the guidance provided in NRC Regulatory Issue Summary 2001-03, "Changes, Tests and Experiments", dated January 23, 2001, Issue 7, any future application of the information contained in NUREG-0737 to proposed changes, tests or experiments should be reviewed in the context of the revised 10 CFR 50.59 rule. The information presented in this section is historical and has been preserved in its original context.

NRC Position

1. Requirements - Supplement 1 to NUREG-0737

   a. The safety parameter display system (SPDS) should provide a concise display of critical plant variables to the control room operators to aid them in rapidly and reliably determining the safety status of the plant. Although the SPDS will be operated during normal operations as well as during abnormal conditions, the principal purpose and function of the SPDS is to aid the control room personnel during abnormal and emergency conditions in determining the safety status of the plant and in assessing whether abnormal conditions warrant corrective action by operators to avoid a degraded core. This can be particularly important during anticipated transients and the initial phase of an accident.

b. Each operating reactor shall be provided with a SPDS that is located convenient to the control room operators. This system will continuously display information from which the plant safety status can be readily and reliably assessed by control room personnel who are responsible for the avoidance of degraded and damaged core events.

c. The control room instrumentation required (see General Design Criteria 13 and 19 of Appendix A to 10CFR50) provides the operators with the information necessary for safe reactor operation under normal, transient, and accident conditions. The SPDS is used in addition to the basic components and serves to aid and augment these components. Thus, requirements applicable to control room instrumentation are not needed for this augmentation (e.g., GDC 2, 3, 4 in Appendix A; 10CFR Part 100; single-failure requirements). The SPDS need not meet requirements of the single-failure criteria and it need not be qualified to meet Class 1E requirements. The SPDS shall be suitably isolated from electrical or electronic interference with equipment and sensors that are in use for safety systems. The SPDS need not be seismically qualified, and additional seismically qualified indication is not required for the sole purpose of being a backup for SPDS. Procedures which describe the timely and correct safety status assessment when the SPDS is and is not available will be developed by the licensee in parallel with the SPDS. Furthermore, operators

should be trained to respond to accident conditions both with and without the SPDS available.

d. There is a wide range of useful information that can be provided by various systems. This information is reflected in such staff documents as NUREG-0696, NUREG-0835, and Regulatory Guide 1.97. Prompt implementation of an SPDS can provide an important contribution to plant safety. The selection of specific information that should be provided for a particular plant shall be based on engineering judgment of individual plant licensees, taking into account the importance of prompt implementation.

e. The SPDS display shall be designed to incorporate accepted human factors principles so that the displayed information can be readily perceived and comprehended by SPDS users.

f. The minimum information to be provided shall be sufficient to provide information to plant operators about:

   (i) Reactivity control

   (ii) Reactor core cooling and heat removal from the primary system

   (iii) Reactor coolant system integrity

   (iv) Radioactivity control

   (v) Containment conditions

   The specific parameters to be displayed shall be determined by the licensee.

2. Documentation and NRC Review

a. The licensee shall prepare a written safety analysis describing the basis on which the selected parameters are sufficient to assess the safety status of each identified function for a wide range of events, which include symptoms of severe accidents. Such analysis, along with the specific implementation plan for SPDS, shall be reviewed as described below.

b. The licensee's proposed implementation of an SPDS system shall be reviewed in accordance with the licensee's technical specifications to determine whether the changes involve an unreviewed safety question or change of Technical Specifications. If they do, they shall be processed in the normal fashion with prior NRC review. If the changes do not involve an unreviewed safety question or a change in the Technical Specifications, the licensee may implement such changes without prior approval by NRC or may request a pre-implementation review and approval. If the changes are to be implemented without prior NRC approval, the licensee's analysis shall be submitted to NRC promptly on completion of review by the licensee's offsite safety review committee. Based on the results of NRC review, the director of IE or the director of NRR may request or direct the licensee to cease implementation if a serious safety question is posed by the licensee's proposed system, or if the licensee's analysis is seriously inadequate.

PVNGS Evaluation

The plant system performing the function of the SPDS at PVNGS is integrated into the emergency response facility data acquisition and display system (ERFDADS). This system takes plant process information coming from plant instrumentation, organizes it, applies it to a hierarchy of displays, and presents it to the control room personnel via visual displays in the control room, technical support center, satellite technical support center, and emergency operations facility. The ERFDADS consists of the following major subsystems:

(a) a data acquisition system in each unit's power block,

(b) a computer system in each Unit's power block, and

(c) visual displays and keyboards.

The SPDS portion of ERFDADS presents leading safety parameter display (SPD) information to control room personnel on the leading parameters associated with the plant critical safety function groups.

This information is presented on visual displays using digital readouts, bar graphs, trend charts, and x-y plots. Color coding is used to high-light serious conditions and indicate data quality.

The principal purpose of the SPDS is to aid the control room personnel during normal, abnormal, and emergency conditions for determining the safety status of the plant and addressing whether abnormal conditions warrant corrective actions to avoid a degraded core. At PVNGS, the SPDS is designed to fulfill this purpose by alerting the control room personnel to possible

problem areas so they can be handled by using qualified instrumentation and the applicable procedures.

The PVNGS SPDS was described in the Safety Analysis Report submitted to the NRC on February 27, 1985 (ANPP-32008) and as amended by a letter submitted to the NRC on August 19, 1985 (ANPP-33235).

In response to Generic Letter (GL) 89-06, APS certified in letter 161-02242 that the SPDS would be modified to meet the requirements of NUREG-0737. The NRC Staff responded on April 25, 1990, acknowledging our certification.
Letter 102 03139, SPDS Certification, dated September 30, 1994, informed the NRC of the completion of the implementation requirements of GL 89-06.

18.I.G PREOPERATIONAL AND LOW-POWER TESTING

18.I.G.1 TRAINING DURING LOW-POWER TESTING

NRC Position NUREG-0694

(1) Propose Tests

Define and commit to a special low-power testing program approved by the NRC to be conducted at power levels no greater than 5% for the purposes of providing meaningful technical information beyond that obtained in the normal startup test program and to provide supplemental training.

(2) Submit Analysis and Procedures

(3) Training and Results

Supplement operator training by completing the special low-power test program. Tests may be observed by other shifts or repeated on other shifts to provide training to the operators.

PVNGS Evaluation

(1) See Chapter 13.2 for information pertaining to training of PVNGS personnel.

(2) See Chapter 14.2.12 for information pertaining to pre-operational testing.

This page intentionally left blank

18.II SITING AND DESIGN

18.II.B CONSIDERATION OF DEGRADED OR MELTED CORES IN SAFETY REVIEW

18.II.B.1 REACTOR COOLANT SYSTEM VENTS

NRC Position

Each applicant and licensee shall install reactor coolant system (RCS) and reactor vessel head high point vents remotely operated from the control room. Although the purpose of the system is to vent noncondensable gases from the RCS which may inhibit core cooling during natural circulation, the vents must not lead to an unacceptable increase in the probability of a loss-of-coolant accident (LOCA) or a challenge to containment integrity. Since these vents form a part of the reactor coolant pressure boundary, the design of the vents shall conform to the requirements of Appendix A to 10CFR Part 50, General Design Criteria. The vent system shall be designed with sufficient redundancy that assures a low probability of inadvertent or irreversible actuation.

Each licensee shall provide the following information concerning the design and operation of the high point vent system:

(1) Submit a description of the design, location, size, and power supply for the vent system along with results of analyses for LOCA initiated by a break in the vent pipe. The results of the analyses should demonstrate compliance with the acceptance criteria of 10CFR50.46.

(2) Submit procedures and supporting analysis for operator use of the vents that also include the information available to the operator for initiating or terminating vent usage.

PVNGS Evaluation

PVNGS Units 1, 2, and 3 have installed a reactor coolant gas vent system (RCGVS). A description of the design is as follows:

A. System Design Basis

The RCGVS is designed to be used to remotely vent gases from the reactor vessel head and pressurizer steam space during post-accident situations when large quantities of noncondensable gases may collect in these high points. Although primarily designed to be available during post-accident conditions, the system can also be used to aid in the RCS venting procedures following a maintenance outage.

The design criteria for the vent system are as follows:

1. The system shall permit remote (control room) venting from the reactor vessel head vent or the pressurizer.

2. The vent flowrate capability shall be based upon the following considerations:

   a. The vent rate should be sufficient to preclude the gas accumulation from interfering with core cooling.

b. Coolant loss through the vent should not exceed makeup capacity.

c. The vent mass rate should not result in heat loss from the RCS in excess of the pressurizer heater capacity.

d. Depressurization

1.0 The RCGVS shall be capable of venting non-condensable gases from the reactor coolant system, as a back-up to the Auxiliary Pressurizer Spray system, to control RCS pressure following a steam generator tube rupture (SGTR) event.

2.0 The RCGVS shall be capable of venting non-condensable gases from the reactor coolant system, as a back-up to the Auxiliary Pressurizer Spray system, to control pressure during natural circulation cool down following a loss of offsite power (LOP) event.

3. The vents shall conform to the applicable requirements of 10CFR50, Appendix A, General Design Criteria. In particular, these vents shall be safety grade and satisfy the single failure criterion and the requirements of IEEE-279 in order to ensure a low probability of inadvertent action.

4. The design shall minimize modification of currently installed safety class equipment and piping which

may be radioactive or require major reactor coolant system hydrostatic testing after installation.

5. The system shall be analyzed to determine effects of pipe breakage and the results should be demonstrated acceptable in accordance with the acceptance criteria of 10CFR50.46.

6. The vent system shall be capable of selectively venting to either the containment or the reactor drain tank.

7. The vent system shall be designed to vent superheated steam, steam water mixtures, water, fission gases, helium, nitrogen, and hydrogen at pressures and temperatures as high as 2500 psig and 700F.

8. Control room position indication shall be provided for all power-operated valves.

9. The system shall be designed not to interfere with refueling maintenance activities

The reactor coolant gas vent system is designed to vent noncondensable gases from the reactor coolant system during post-accident conditions. The purpose of venting is to prevent possible interference with core cooling. Small amounts of gas can be vented to the reactor drain tank and thus not enter the containment atmosphere. Larger volumes will require venting to the containment -- either through the ruptured reactor drain tank rupture disk or directly -- where the hydrogen concentration will be controlled by the containment hydrogen

recombiner. Pressure instrumentation is included in the design to monitor system performance.

Although designed for accident conditions, the system may be used to aid in the refueling venting of the reactor coolant system.

Although venting of the CEDMs and RCPs will still be necessary, pressurizer and reactor vessel venting can be accomplished with the system if desired. Vent flow may be directed to the reactor drain tank or the containment sump for this operation to prevent inadvertent release of radioactive fluid.

B. System Description

The Reactor Coolant Vent System (RCGVS) Vent Path originates from two points in the reactor coolant system.

1.0 The reactor vessel head via existing 3/4” head vent pipe.

2.0 The pressurizer steam space via existing 3/4” steam sample/vent lines.

The vent lines are fabricated from 1”, 304 or 316 austenitic stainless steel and have welded connections except where disassembly for maintenance, particularly refueling operations, is required. The reactor vessel head vent line has two remote operated valves, in parallel, that are powered from alternate power sources to assure a vent path exists in the event of a single failure. In addition, upstream of the parallel lines,

the vent path has a 1/4” x 1.25” stainless steel flow restricting orifice provided to limit reactor leakage to less than the capacity of the minimum number of functional charging pumps in the event of a line break or inadvertent valve operation.

The pressurizer steam space vent line also splits into two parallel paths, one path consists of two, class one, seismic one remotely operated solenoid valves powered by the same power source. The two class one, seismic one valves in series are redundant such that in the event of a single failure, the line could still be isolated by the other valve. The other path has one remotely operated solenoid valve and a 7/32” x 1” orifice. The solenoid valve in this line is powered from an alternate source from the valves in the parallel path. The orifice limits flow as described above in the event of a line break or inadvertent valve operation.

The vent lines from the reactor vessel and pressurizer steam space come together then split into two flow paths, one to the reactor drain tank (RDT) and the other to the containment atmosphere. Both lines are isolated by remotely operated solenoid valves which are supplied by alternate power sources to assure a vent path is available in the event of a single failure. The vent path to the RDT enters the tank at a point underwater to cool the steam and gases from the vent line. The vent path into containment is located in an open area near steam generator one.

SITING AND DESIGN

1. System Parameters

The components in the RCGVS consist of piping, valves, and instrumentation to direct vented gas flow from existing components to an existing tank as shown on figure 18.II.B-1. The main design parameters for the vent line are:

Design Flow	500 standard cubic feet per minute
Design Temperature	700F
Design Pressure	2500 psig
Line Size	1 inch

2. Descriptive Summary

The system permits the main control room operator to remotely vent the pressurizer and reactor vessel head. The pressurizer vent ties into an existing 3/4 inch vent line. The reactor vessel head vent ties into the existing 3/4 inch reactor vessel vent and will be flanged to permit head removal for refueling. The vent line is connected to the pressurizer relief valve common discharge header, which terminates in the reactor drain tank, entering below the water level. An existing reactor drain tank penetration is thus utilized. The capability to vent directly to containment is also provided should the operator not desire to allow the rupture disc on the reactor drain tank to rupture when large quantities of gas must be

vented. This line terminates at an open area near steam generator number 1. This area is not restricted in any way. This occurs at the north side of containment at elevation 158 feet 6 inches, above the operating deck. There is adequate ventilation to promote good mixing within the containment, and there is no equipment in the area of the discharge that could be affected by system operation.

The normal vent paths are from either the pressurizer or reactor vessel head to the reactor drain tank. These paths are powered from emergency power sources, Seismic Category I, and of the appropriate quality class to conform to existing standards. The vent flow is directed into the reactor drain tank below the water level to remove energy from the steam and to cool the gas itself. If large quantities of gas must be vented, the reactor drain tank will pressurize and eventually rupture its rupture disc providing a path to containment to continue the venting process. If the rupture is deemed undesirable by the operators, venting can be remotely shifted directly to the containment upon actuation of the reactor drain tank high pressure alarm, which annunciates in the main control room. This path is powered from emergency power sources, Seismic Category I, and of the appropriate quality class to conform to existing standards. No single active failure can

prevent the RCGVS from performing its design function.

For cases when the vented gas is not highly radioactive and containment isolation has not occurred, the gas delivered to the reactor drain tank can be routed to the gaseous radwaste system surge tank. Although unavailable during accident conditions, this path will allow processing of gas removed by the vent system if the system is used to aid in RCS venting for refueling operations.

To preclude inadvertent opening of any one of seven solenoid-operated vent valves, they are placed in their locked-closed position via key lock switches in the main control room. Opening of any solenoid-operated vent valve requires deliberate operator action. To minimize the possibility of common mode failure of solenoid operated valves to shut when deenergized, the operation procedure for the RCGVS will require that when both trains A and B are available, one valve powered from train A and one valve powered from train B will be used to complete a vent path.

The location of the solenoid-operated valves was reviewed on the plant model and it was found that there were no credible missile hazards from them, and no safety-related equipment in their area.

3. Operation

The operator can vent noncondensable gases from the reactor coolant by the following flow paths using the remotely operable vent system:

a. Reactor vessel head vent to the reactor drain tank

b. Pressurizer vent to the reactor drain tank

c. Reactor vessel or pressurizer vent to containment directly

d. Reactor vessel head or pressurizer vent to the gaseous radwaste system surge tank via the reactor drain tank.

Accident events with large gas generation may demand rapid response by the operator to remove the gases and to establish stable plant conditions in a controlled manner. Maintaining core water cover establishes and maintains core cooling which is of primary importance. Other events that may not cause the core to uncover permit a slower response.

Operating considerations for each flow path are given as follows:

a. Reactor Vessel Head Vent to the Reactor Drain Tank

Venting the reactor vessel to the reactor drain tank is accomplished by opening one of two reactor vessel head vent solenoid isolation valves and the solenoid-operated

valve to the reactor drain tank. System pressure integrity is confirmed by vent line pressure indication.

Integrity of the reactor drain tank is confirmed by monitoring tank pressure, temperature, and level. Continuous venting to the reactor drain tank may eventually result in rupture of the rupture disk, particularly if a substantial amount of noncondensable gases are generated in the reactor vessel. In this instance, direct venting to the containment would be preferable. The operator has the capability to monitor the hydrogen levels in containment and start the hydrogen recombiner.

b. Pressurizer Vent to the Reactor Drain Tank

If the operator desires to degas the reactor coolant system or remove accumulated gases in the pressurizer, the pressurizer vent can be aligned to the reactor drain tank. This is accomplished by opening one of two pressurizer vent paths (one path has two solenoid isolation valves and the other has a single solenoid isolation valve and an orifice) and the solenoid-operated valve to the reactor drain tank. System pressure integrity is confirmed by vent line pressure indication. Reactor drain tank conditions are monitored by

pressure, level, and temperature instruments. Continuous venting to the reactor drain tank may lead to failure of the rupture disc. In this case, the precautions noted in sublisting a above are to be followed.

c. Reactor Vessel Head or Pressurizer Vent to Containment Directly

Extended venting from either source to the reactor drain tank may eventually rupture the rupture disc. While this may be of no real consequence during a major accident, there may be times when the operator would desire to maintain the rupture disc intact. In this event, the venting may be directed to the containment directly by opening the solenoid-operated containment vent isolation valve. If this path is used, the precautions with respect to hydrogen in the containment noted in a. item must be followed.

d. Reactor Vessel Head or Pressurizer Vent to the Gaseous Radwaste System

This path may be used if the gases are known to be low in activity (i.e., will not exceed gaseous radwaste system (GRS) Technical Requirements Manual values), normal power is available, low removal rates are acceptable, and adequate storage space is available in the GRS. Alignment of this path is accomplished

by initiating vent flow from the pressurizer or reactor vessel head to the reactor drain tank as in sublistings a or b. Gases directed to the reactor drain tank can be sent to the GRS and collected in the gas surge tank for eventual storage in the gas decay tanks.

This mode of operation is intended for use when the vented gas is not highly radioactive and containment isolation has not occurred.

Consistent with NRC requirements, procedural guidelines for the system will be provided including information relative to initiating or terminating vent system usage.

4. Maintenance

System maintenance is limited to inservice inspection of the system valves. Adequate test connections are provided in the system design to accomplish the requisite testing. To avoid interferences with refueling operations, specific consideration was given to the layout and attachment of the vent system piping and valves to the reactor vessel head. The system is designed not to interfere with the reactor head removal procedures.

C. System Controls

The system is designed to be controlled remotely from the main control room. All valves and instrumentation are powered from Class 1E power sources. Position

indication is provided for all remotely operated valves (open/shut) and displayed in the control room. Pressure instrumentation is also provided to monitor system performance and displayed in the control room. In addition, reactor drain tank pressure, temperature, and level indication is provided in the control room.

D. LOCA Analysis

Consistent with NRC requirements, the system design is acceptable in accordance with 10 CFR 50.46.

The reactor coolant gas vent system is described in Section B above, including a description of the orificed and non-orificed lines. In the event of a line break downstream of the orifice in either the head vent line or pressurizer vent line, or inadvertent valve operation in either of the orificed lines, the orifice would limit reactor leakage to less than the capacity of the minimum number of functional charging pumps. Therefore, the event consequences are bounded by the small line break analysis in UFSAR 9.3.4.4.11, which demonstrates compliance with the requirements of GDC 33 of 10 CFR 50, Appendix A.

A break located at or upstream of the orifices, or inadvertent valve operation in the non-orificed pressurizer vent path, would be bounded by the spectrum of analyzed small break LOCAs in UFSAR 6.3.3. Since the inside diameter of the vent lines from the RCS are less than 3/4 inch, the corresponding cross-sectional area of the lines would be less than 0.003 square feet which is

much smaller than the 0.05 square foot break in the RCS cold leg or the 0.03 square foot break at the top of the pressurizer evaluated in UFSAR 6.3.3.3. Furthermore, a break in the head vent line (i.e., downstream of the core outlet) would result in a more benign plant response than the previously analyzed break in the RCS cold leg (i.e., upstream of the core inlet). Therefore, the emergency core cooling system would meet the acceptance criteria of 10 CFR 50.46 for any postulated breaks or inadvertent valve operations in the reactor coolant gas vent system.

18.II.B.2 DESIGN REVIEW OF PLANT SHIELDING AND ENVIRONMENTAL QUALIFICATION OF EQUIPMENT FOR SPACES/SYSTEMS WHICH MAY BE USED IN POST-ACCIDENT OPERATIONS

NRC Position

With the assumption of a post-accident release of radioactivity equivalent to that described in Regulatory Guides 1.3 and 1.4 (i.e., the equivalent of 50% of the core radioiodine, 100% of the core noble gas inventory, and 1% of the core solids are contained in the primary coolant), each licensee shall perform a radiation and shielding design review of the spaces around systems that may, as a result of an accident, contain highly radioactive materials. The design review should identify the location of vital areas and equipment, such as the control room, radwaste control stations, emergency power supplies, motor control centers, and instrument areas, in which personnel occupancy may be unduly limited or safety equipment may be

unduly degraded by the radiation fields during post-accident operations of these systems.

Each licensee shall provide for adequate access to vital areas and protection of safety equipment by design changes, increased permanent or temporary shielding, or post-accident procedural controls. The design review shall determine which types of corrective actions are needed for vital areas throughout the facility.

PVNGS Evaluation

A radiation and shielding design review of the spaces around systems that may, as a result of an accident, contain highly radioactive materials has been conducted.

General design considerations to keep post-accident exposures ALARA are described in paragraph 12.1.2.4. A summary of the shielding design review results is provided in paragraph 12.3.2.3, and a description of the source terms used in the post-accident shielding review is provided in subsection 12.2.3. Post-accident radiation zones are discussed in paragraph 12.3.1.3, and presented as engineering drawings 13-N-RAR-018 through 13-N-RAR-038.

The qualification of safety-related equipment is provided in paragraph 3.11.5.2.

The function, operation and design of the radiation monitoring system are described in section 11.5.

18.II.B.3 POST-ACCIDENT SAMPLING CAPABILITY

NRC Position

A design and operational review of the reactor coolant and containment atmosphere sampling line systems shall be performed to determine the capability of personnel to promptly obtain (less than 1 hour) a sample under accident conditions without incurring a radiation exposure to any individual in excess of 3 and 18-3/4 rem to the whole-body or extremities, respectively. Accident conditions should assume a Regulatory Guide 1.3 or 1.4 release of fission products. If the review indicates that personnel could not promptly and safely obtain the samples, additional design features or shielding should be provided to meet the criteria.

A design and operational review of the radiological spectrum analysis facilities shall be performed to determine the capability to promptly quantify (in less than 2 hours) certain radionuclides that are indicators of the degree of core damage. Such radionuclides are noble gases (which indicate cladding failure), iodines and cesiums (which indicate high fuel temperatures), and nonvolatile isotopes (which indicate fuel melting). The initial reactor coolant spectrum should correspond to a Regulatory Guide 1.3 or 1.4 release. The review should also consider the effects of direct radiation from piping and components in the auxiliary building and possible contamination and direct radiation from airborne effluents. If the review indicates that the analyses required cannot be performed in a prompt manner with existing equipment,

then design modifications or equipment procurement shall be undertaken to meet the criteria.

In addition to the radiological analyses, certain chemical analyses are necessary for monitoring reactor conditions. Procedures shall be provided to perform boron and chloride chemical analyses assuming a highly radioactive initial sample (Regulatory Guide 1.3 or 1.4 source term). Both analyses shall be capable of being completed promptly (i.e., the boron sample analysis within an hour and the chloride sample analysis within a shift).

Clarification

The following items are clarifications of requirements identified in NUREG-0578, NUREG-0660, or the September 13 and October 30, 1979, clarification letters.

(1) The licensee shall have the capability to promptly obtain reactor coolant samples and containment atmosphere samples. The combined time allotted for sampling and analysis should be 3 hours or less from the time a decision is made to take a sample.

(2) The licensee shall establish an onsite radiological and chemical analysis capability to provide, within the 3-hour time frame established above, quantification of the following:

    (a) certain radionuclides in the reactor coolant and containment atmosphere that may be indicators of the degree of core damage (e.g., noble gases, iodines and cesiums, and nonvolatile isotopes);

(b) hydrogen levels in the containment atmosphere;

(c) dissolved gases (e.g., H_2), chloride (time allotted for analysis subject to discussion below), and boron concentration of liquids;

(d) Alternatively, have inline monitoring capabilities to perform all or part of the above analyses.

(3) Reactor coolant and containment atmosphere sampling during post-accident conditions shall not require an isolated auxiliary system [e.g., the letdown system, reactor water cleanup system (RWCUS)] to be placed in operation in order to use the sampling system.

(4) Pressurized reactor coolant samples are not required if the licensee can quantify the amount of dissolved gases with unpressurized reactor coolant samples. The measurement of either total dissolved gases or H_2 gas inreactor coolant samples is considered adequate. Measuring the 0_2 concentration is recommended, but is not mandatory.

(5) The time for a chloride analysis to be performed is dependent upon two factors: (a) if the plant's coolant water is seawater or brackish water and (b) if there is only a single barrier between primary containment systems and the cooling water. Under both of the above conditions the licensee shall provide for a chloride analysis within 24 hours of the sample being taken. For all other cases, the licensee shall provide for the analysis to be completed within 4 days. The chloride analysis does not have to be done onsite.

(6) The design basis for plant equipment for reactor coolant and containment atmosphere sampling and analysis must assume that it is possible to obtain and analyze a sample without radiation exposures to any individual exceeding the criteria of GDC 19 (Appendix A, 10CFR Part 50) (i.e., 5 rem whole-body, 75 rem extremities). (Note that the design and operational review criterion was changed from the operational limits of 10CFR Part 20 (NUREG-0578) to the GDC 19 criterion (October 30, 1979, letter from H. R. Denton to all licensees).

(7) The analysis of primary coolant samples for boron is required for PWRs. (Note that Revision 2 of Regulatory Guide 1.97, when issued, will likely specify the need for primary coolant boron analysis capability at BWR plants.)

(8) If inline monitoring is used for any sampling and analytical capability specified herein, the licensee shall provide backup sampling through grab samples, and shall demonstrate the capability of analyzing the samples. Established planning for analysis at offsite facilities is acceptable. Equipment provided for backup sampling shall be capable of providing at least one sample per day for 7 days following onset of the accident and at least one sample per week until the accident condition no longer exists.

(9) The licensee’s radiological and chemical sample analysis capability shall include provisions to:

(a) Identify and quantify the isotopes of the nuclide categories discussed above to levels corresponding

to the source terms given in Regulatory Guide 1.3 or 1.4 and 1.7. Where necessary and practicable, the ability to dilute samples to provide capability for measurement and reduction of personnel exposure should be provided. Sensitivity of onsite liquid sample analysis capability should be such as to permit measurement of nuclide concentration in the range from approximately 1 μCi/g to 10 Ci/g.

(b) Restrict background levels of radiation in the radiological and chemical analysis facility from sources such that the sample analysis will provide results with an acceptably small error (approximately a factor of 2). This can be accomplished through the use of sufficient shielding around samples and outside sources, and by the use of ventilation system design which will control the presence of airborne radioactivity.

(10) Accuracy, range, and sensitivity shall be adequate to provide pertinent data to the operator in order to describe radiological and chemical status of the reactor coolant systems.

(11) In the design of the post-accident sampling and analysis capability, consideration should be given to the following items:

(a) Provisions for purging sample lines, for reducing plateout in sample lines, for minimizing sample loss or distortion, for preventing blockage of sample lines by loose material in the RCS or containment,

for appropriate disposal of the samples, and for flow restrictions to limit reactor coolant loss from a rupture of the sample line. The post-accident reactor coolant and containment atmosphere samples should be representative of the reactor coolant in the core area and the containment atmosphere following a transient or accident. The sample lines should be as short as possible to minimize the volume of fluid to be taken from containment. The residues of sample collection should be returned to containment or to a closed system.

(b) The ventilation exhaust from the sampling station should be filtered with charcoal adsorbers and high efficiency particulate air (HEPA) filters.

Further Clarification

The following summary is from the NRC notice of availability for referencing in license amendment applications - Model Safety Evaluation of Technical Specification Improvement to Eliminate Requirements on Post Accident Sampling Systems using the Consolidated Line Item Improvement Process. The notice was published in the Federal Register on page 65018, Volume 65, Number 211, dated Tuesday October 31, 2000.

SUMMARY: Notice is hereby given that the staff of the Nuclear Regulatory Commission (NRC) has prepared a model safety evaluation (SE) relating to the elimination of requirements on post accident sampling imposed on licensees through orders, license conditions, or technical specifications. The NRC staff has also prepared a model no significant hazards consideration

(NSHC) determination relating to this matter. The purpose of these models is to permit the NRC to efficiently process amendments that propose to remove requirements for the Post Accident Sampling System (PASS). Licensees of nuclear power reactors to which the models apply may request amendments, in accordance with Section 50.90 of Title 10 to the Code of Federal Regulations, confirming the applicability of the SE and NSHC determination to their reactors and providing the requested plant-specific verifications and commitments.

PVNGS Evaluation

APS has eliminated PASS as documented in CE-NPSD-1157, as accepted by NRC in Safety Evaluation Report dated May 16, 2000 for CEOG Topical Report CE-1157 Revision 1. NRC letter dated September 28, 2001 documented acceptance of the request to remove PASS from the licensing and technical basis of the plant.

Additional Information

The procedure to be utilized at PVNGS to estimate the degree of core damage was developed from the "Revised Core Damage Assessment Procedure Guidelines," CE-NPSD-241, Revision 1," Combustion Engineering Owner's Group Task 1072, dated July, 1999. The PVNGS procedure uses isotopic analysis data obtained from grab samples, core exit thermocouple readings, containment radiation readings, and hydrogen production estimates. Early core damage estimates can be provided using the core exit thermocouple and containment radiation methods, and upgraded later using the hydrogen production.

The means for sampling reactor coolant, containment sump and containment atmosphere will be by grab sample. Provisions will be maintained for obtaining and analyzing highly radioactive samples of reactor coolant, containment sump and containment atmosphere.

The capability for classifying fuel damage events at the Alert level threshold will be maintained in the PVNGS Emergency Plan implementing procedures. This level of core damage is associated to radioactivity levels of 300 μCi/cc dose equivalent iodine.

The capability to monitor radioactive iodines that have been released to the offsite environs will be maintained in the PVNGS Emergency Plan implementing procedures.

18.II.D REACTOR COOLANT SYSTEM RELIEF AND SAFETY VALVES

18.II.D.1 PERFORMANCE TESTING OF BOILING WATER REACTOR AND PRESSURIZED WATER REACTOR RELIEF AND SAFETY VALVES

NRC Position

Pressurized water reactor and boiling water reactor licensees and applicants shall conduct testing to qualify the reactor coolant system (RCS) relief and safety valves under expected operating conditions for design basis transients and accidents.

PVNGS Evaluation

A qualification testing program of reactor coolant system relief and safety valves under expected operating conditions for design basis transients and accidents was undertaken on an industry-wide generic basis. The Electric Power Research Institute (EPRI) conducted the qualification testing program.

By letter dated December 17, 1979, Mr. Williams J. Cahill, Jr., Chairman of the EPRI Safety and Analysis Task Force, submitted "Program Plan for the Performance Verification of PWR Safety/Relief Valves and Systems," December 13, 1979. As an activity for the C-E Owner's Group, Combustion Engineering (C-E) developed input to this program plan which included System 80 valve design data, piping diagrams, and steam leakage acceptance criteria.

By letter dated December 15, 1980, R. C. Youngdahl of Consumers Power Company provided, on EPRI's behalf, the current pressurized water reactor (PWR) Utilities' positions on NUREG-0737, Item II.D.1, clarifications.

On December 20, 1982, CEN-227 was submitted which provided evidence of pressurizer safety valve operability based on the EPRI test results for C-E plants. The approach applied by the C-E Owner's Group was to select the particular EPRI tests which closely matched the plant-specific conditions and then apply the test results to the plant-specific evaluation.

Arizona Public Service Company (APS) considers CEN-227 to provide the required information on safety valve operability for PVNGS as was stated in a letter to the NRC dated January 31, 1983.

CEN-227 provided two combinations of safety valve adjusting ring settings for PVNGS, demonstrated by the EPRI test results, that would result in satisfactory operation. The ring settings described in CEN-227 for PVNGS with Dresser 31709NA safety valves are (-48, -20, 0) and (-48, -60, 0). The ring settings used for the pressurizer safety valves at PVNGS are (-48, -60, 0). Thus, APS concluded that the present ring settings would result in satisfactory safety valve operability. This was intended to satisfy APS' responsibility to demonstrate safety valve operability in response to Item II.D.1 of NUREG-0737.

On December 18, 1984, a letter from PVNGS to the NRC was submitted for review. The letter contained proposed CESSAR amendments which dealt in part with changes to be incorporated, based upon the results of CEN-227. In response, the NRC transmitted a letter on March 12, 1985, to PVNGS that requested additional information in a five-question format. Contained within these five questions was a concern about pressurizer

safety valve (PSV) blowdown that became PVNGS Unit 1 license condition 2.C(22).

ANPP met with C-E and the NRC on April 3, 1985, to discuss proposed responses to the five NRC questions. A letter from PVNGS on April 12, 1985 (ANPP-32381), formally provided the responses to the NRC. In Section 5.2.2 of Supplement 8 to the PVNGS Safety Evaluation Report (NUREG-0857) dated May 1985, the NRC staff concluded that the proposed safety valve blowdown changes were acceptable. In addition, on March 23, 1987, the NRC transmitted a letter to PVNGS, requesting additional information about the PSVs' installed configuration and structural analyses, so that the NRC's contractor (Idaho National Engineering Laboratory) could complete its review of PVNGS design with respect to Item II.D.1. The NRC issued its endorsement of the contractor's review on 04/25/1988. This was documented in a letter from NRC to APS, "Performance Testing of Relief and Safety Valves for Palo Verde Units 1, 2 and 3 (TAC No. 61841)," April 25, 1988, stating that PVNGS has ". . . provided an acceptable response to TMI Item II.D.1, reconfirming that General Design Criteria 14, 15 and 30 of Appendix A to 10 CFR Part 50 were met. . . ." The contractor's report notes that CE reanalyzed the Loss of Load Event assuming 20% blowdown, and goes on to state that the ". . .20% blowdown is conservative since the maximum blowdown observed in the applicable EPRI tests was 14.2%. . . ." The contractor also states that " . . .only steam discharge was calculated for FSAR type transients. . ." which is consistent with the 14.2% maximum blowdown test results. The contractor also compares the range of pressure peaks in the tests (2505 psia to

2697 psia) to the peak pressurizer pressure reported for the LFWLB and documents the range of pressurization rates during testing was 2.9 to 322 psi/s, compared to the calculated rates of 14 to 105 psi/s. This letter from NRC discusses plant conformance to the GDCs and provides a license basis of 14.2% maximum blowdown for steam-only discharges for UFSAR events. No additional information was requested for pressurizer fill analyses in this letter. Therefore, another part of satisfying Chapter 18.II.D requirements is to demonstrate that the range of test parameters documented in the PSV tests, CEN-227, is valid for the limiting transients for peak pressurizer pressure (LFWLB) and rate of pressurization (LOCV).

On May 16, 1994 NRC issued TS Amendments 75, 61 and 47 for PVNGS Units 1, 2 and 3 respectively. These amendments involve increasing the pressurizer safety valve (PSV) setpoint tolerance from +/-1% to +3% and –1%. The analysis performed by PVNGS to support the TS Amendments 75, 61 and 47 demonstrated that the pressurizer would not fill for the limiting transient (LOCV event) and that the PSVs would discharge only steam.

Since the performance of CEN-227 and PSV setpoint tolerance changes, PVNGS has changed some plant operating conditions (i.e. 10°F reduction in the core inlet temperature, and 2% increase in nominal power level combined with 2°F additional reduction in the core inlet temperature) which affected the initial conditions used in the CEN-227 analysis. Increased initial power level and lower RCS temperature result in larger swelling of the RCS during a heatup transient. Therefore, an analysis was performed by PVNGS using a blowdown of 14% below the minimum PSV set pressure of 2450 psia (2475 psia –

1% tolerance) and initial conditions set to maximize the pressurizer liquid level. The analysis demonstrates that, for the limiting transient (LFWLB with LOP), the maximum pressurizer liquid level for PVNGS units remains below the PSV nozzles and subcooling is maintained during the period when the PSVs are open.

In summary, analyses demonstrate that a blowdown of 14% below the minimum PSV set pressure of 2450 psia is acceptable and that the pressurizer will not fill and pass only steam for the limiting transient.

18.II.D.3 DIRECT INDICATION OF RELIEF AND SAFETY VALVE POSITION

NRC Position

Reactor coolant system relief and safety valves shall be provided with a positive indication in the control room derived from a reliable valve-position detection device or a reliable indication of flow in the discharge pipe.

PVNGS Evaluation

PVNGS does not utilize power-operated relief valves. The PVNGS primary code safety valves, located at the top of the pressurizer, are headered into the reactor drain tank (RDT) inside containment. Upstream of the common header each code safety valve is monitored for seal leakage by an in-line resistive-temperature detector (RTD) (refer to engineering drawings 01, 02, 03-M-RCP-001, -002 and -003).

Indirect indication of code safety valve leakage is provided by an increase of RDT pressure and a decrease of pressurizer

pressure and pressurizer level, monitored by safety grade instrumentation.

Positive indication of safety valve position is provided in the control room. Monitoring is provided by an acoustic monitoring system consisting of an accelerometer (acoustic sensor) mounted downstream of each valve. The sensing instrumentation is environmentally qualified to function in a post-LOCA environment in accordance with Regulatory Guide 1.89. A plant annunciator alarm is provided to alarm valve opening. The acoustic monitoring system is powered from a reliable instrument bus with Class 1E backup power. The system is designed to meet the requirements of Revision 2 to Regulatory Guide 1.97.

Installation of positive pressurizer safety valve position indication and development of emergency procedures are completed prior to fuel loading for each of the PVNGS units.

18.II.E SYSTEM DESIGN

18.II.E.1.1 AUXILIARY FEEDWATER SYSTEM EVALUATION

NRC Position

The Office of Nuclear Reactor Regulation is requiring reevaluation of the auxiliary feedwater (AFW) systems for all PWR operating plant licensees and operating license applications. This action includes:

(1) Perform a simplified AFW system reliability analysis that uses event-tree and fault-tree logic techniques to determine the potential for AFW system failure under various loss of main feedwater transient conditions. Particular emphasis is given to determining potential failures that could result from human errors, common causes, single-point vulnerabilities and test and maintenance outages;

(2) Perform a deterministic review of the AFW system using the acceptance criteria of Standard Review Plan Section 10.4.9 and associated Branch Technical Position ASB 10-1 as principal guidance; and

(3) Reevaluate the AFW system flowrate design bases and criteria.

PVNGS Evaluation

An auxiliary feedwater system review was conducted on August 21 and 22, 1980, and included NRC participation.

This review included a review of the PVNGS auxiliary feedwater system reliability analysis. A transcript of this review was provided to the NRC on October 17, 1980. Responses to open

items of the review were provided to the NRC on March 6, 1981. The PVNGS auxiliary feedwater system reliability analysis was performed in response to the NRC letter of March 10, 1980, from D. F. Ross, Jr., to All Pending Operating License Applicants of Nuclear Steam Supply Systems Designed by Westinghouse and Combustion Engineering. The final analysis was submitted to the NRC by APS letter dated February 10, 1981, from E. E. Van Brunt, Jr., to the Director of Nuclear Reactor Regulation. The final analysis (formerly Appendix 10B) has been archived as historical information-only in PVNGS engineering calculation 13-NC-AF-200, "Auxiliary Feedwater System (AFS) Reliability Analysis."

18.II.E.1.2 AUXILIARY FEEDWATER SYSTEM AUTOMATIC INITIATION AND FLOW INDICATION

Part 1: Auxiliary Feedwater System Automatic Initiation

NRC Position

Consistent with satisfying the requirements of General Design Criterion 20 of Appendix A to 10CFR Part 50 with respect to the timely initiation of the auxiliary feedwater system (AFWS), the following requirements shall be implemented in the short-term:

(1) The design shall provide for the automatic initiation of the AFWS.

(2) The automatic initiation signals and circuits shall be designed so that a single failure will not result in the loss of AFWS function.

(3) Testability of the initiating signals and circuits shall be a feature of the design.

(4) The initiating signals and circuits shall be powered from the emergency buses.

(5) Manual capability to initiate the AFWS from the control room shall be retained and shall be implemented so that a single failure in the manual circuits will not result in the loss of system function.

(6) The ac motor-driven pumps and valves in the AFWS shall be included in the automatic actuation (simultaneous and/or sequential) of the loads onto the emergency buses.

(7) The automatic initiating signals and circuits shall be designed so that their failure will not result in the loss of manual capability to initiate the AFWS from the control room.

In the long-term, the automatic initiation signals and circuits shall be upgraded in accordance with safety grade requirements.

Part 2: Auxiliary Feedwater System Flowrate Indication NRC Position

Consistent with satisfying the requirements set forth in General Design Criterion 13 to provide the capability in the control room to ascertain the actual performance of the AFWS when it is called to perform its intended function, the following requirements shall be implemented:

(1) Safety grade indication of auxiliary feedwater flow to each steam generator shall be provided in the control room.

(2) The auxiliary feedwater flow instrument channels shall be powered from the emergency buses consistent with satisfying the emergency power diversity requirements of the auxiliary feedwater system set forth in Auxiliary Systems Branch Technical Position 10-1 of the Standard Review Plan, Section 10.4.9.

PVNGS Evaluation

A. Automatic Initiation

1. The AFWS shown in engineering drawings 01, 02, 03-M-AFP-001 consists of two Seismic Category I pumps and their associated flow paths and valves and one non-Seismic Category I pump and its associated flow paths and valves.

   The feedwater trains of the AFWS are provided to automatically initiate residual heat removal capability during emergency conditions, such as a steam line rupture, loss of normal feedwater, or loss of offsite and normal onsite power.

   The feedwater trains of the AFWS are automatically actuated by an auxiliary feedwater actuation signal (AFAS) from the engineered safety features actuation system (ESFAS). The AFAS is initiated for each steam generator by a low steam generator level coincident with a "not ruptured" calculated signal for that steam generator (refer to CESSAR Figure 7.3-1d).

The AFAS logic determines whether a steam generator is not intact in the event of a secondary system break by sensing:

- The steam generator has initiated a low water level trip.
- The steam generator pressure is less than the other by a predetermined value.
- The other steam generator has been calculated as not being ruptured.

The startup train portion of the AFWS is provided for normal nonemergency operation during startup, cooldown, and hot standby.

2. The emergency feedwater trains of the AFWS are composed of components in two separate and independent load groups (i.e., load group 1 and load group 2). Each of the four emergency feedwater valves associated with each steam generator is automatically actuated in such a manner that no single failure can prevent either the supply of AFW to an intact steam generator or the isolation of AFW from a ruptured steam generator. Load group 2 powers the emergency motor-driven AFW pump and its associated valves and controls. Load group 1 supplies dc power to the steam-driven turbine controls and the valves associated with the emergency turbine-driven AFW pump. No ac power is required for support of the turbine-driven emergency feedwater train. The

instrumentation and controls of the components and equipment in load group 1 are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in load group 2. This separation is maintained such that both trains are not terminated on common logic circuits.

3. Provisions are made to permit periodic testing of the AFW initiation signals and circuitry. These tests cover the trip actions from sensor input through the protection system and actuation devices. The system test does not interfere with the system protection function. The testing system meets the criteria of IEEE 338-1971, IEEE Trial-Use Criteria for Periodic Testing of Nuclear Power Generating Station Protective Systems, and Regulatory Guide 1.22, Periodic Testing of Protection System Actuator Functions. Testing is performed in accordance with the surveillance test requirements of the PVNGS Technical Specifications.

4. AFAS circuits are a part of the ESFAS. The initiating signals and circuits are powered from Class 1E buses in separate load groups as discussed in sublisting 2. The initiating sensors are powered from separate and redundant Class 1E instrumentation channels, each of which is supplied by either offsite power, or the associated diesel generator when offsite power is

not available and is backed up by a Class 1E battery.

5. Manual initiation capability for each AFW train exists in the control room. Control of individual AFWS components is also available in the control room. No single failure in the manual initiation portion of the circuit can result in the loss of AFWS function.

6. The Seismic Category I ac motor-driven pump and power-operated valves in its train are automatically and sequentially loaded on the associated diesel generator bus upon loss of offsite power.

7. Failure of the AFAS and circuits will not result in the loss of manual capability to control AFWS components from the control room.

8. AFAS circuits are Class 1E.

The PVNGS AFWS complies with the recommendations of NUREG-0737, November 1980.

B. Flow Indication

1. The PVNGS design includes monitoring of AFW flow to both steam generators. These flow indicator channels are displayed on the main control boards. The flow indication system is environmentally qualified. Class 1E (safety grade) pressure indicators located upstream of the manual block valves and Class 1E steam generator level indicators are also provided.

Pressure indicator PI-18A monitors the train A turbine-driven AFW pump discharge pressure and flow indicators FI-40A and FI-41A will monitor flow to steam generator 1 (refer to engineering drawings 01, 02, 03-M-AFP-001). Pressure indicator PI-17A monitors the train B motor-driven AFW pump discharge pressure, and flow indicators FI-40B and FI-41B will monitor the flow to steam generator 2. Four channels of Class 1E steam generator level indication are provided for each steam generator.

2. The safety grade pressure and level and the added flow indication channels are powered from redundant Class 1E buses.

18.II.E.3.1 EMERGENCY POWER SUPPLY FOR PRESSURIZER HEATERS

NRC Position

Consistent with satisfying the requirements of General Design Criteria 10, 14, 15, 17, and 20 of Appendix A to 10CFR Part 50 for the event of loss of offsite power, the following positions shall be implemented:

(1) The pressurizer heater power supply design shall provide the capability to supply, from either the offsite power source or the emergency power source (when offsite power is not available), a predetermined number of pressurizer heaters and associated controls necessary to establish and maintain natural circulation at hot standby conditions. The required heaters and their controls shall

be connected to the emergency buses in a manner that will provide redundant power supply capability.

(2) Procedures and training shall be established to make the operator aware of when and how the required pressurizer heaters shall be connected to the emergency buses. If required, the procedures shall identify under what conditions selected emergency loads can be shed from the emergency power source to provide sufficient capacity for the connection of the pressurizer heaters.

(3) The time required to accomplish the connection of the preselected pressurizer heater to the emergency buses shall be consistent with the timely initiation and maintenance of natural circulation conditions.

(4) Pressurizer heater motive and control power interfaces with the emergency buses shall be accomplished through devices that have been qualified in accordance with safety grade requirements.

PVNGS Evaluation

Preoperational testing determined the actual PVNGS heat loss to be less than 403,000 Btu/h. Assuming a heat loss of 403,000 Btu/h, a heater capacity of 125 kW is sufficient to offset pressurizer heat loss.

The PVNGS pressurizer heaters are configured as follows:

1. The PVNGS pressurizer heaters for Unit 1 (35 elements rated at 50kW each generally connected in groups of three delta-connected elements each) have a total rated capacity of

1750 kW. The PVNGS pressurizer heaters for Unit 2 (34 elements rated at 50kW each generally connected in groups of three delta-connected elements each) have a total rated capacity of 1700 kW. The PVNGS pressurizer heaters for Unit 3 (36 elements rated at 50 kW each, connected in 12 groups of three delta-connected elements each) have a total rated capacity of 1800 kW. The heaters are powered from the non-Class 1E and Class 1E distribution systems as shown in table 18.II.E-1. Redundant heater rated capacity of 150 kW is available for manual loading on the emergency diesel generators upon loss of offsite (preferred) power. The emergency diesel generators are sized to accommodate this heater capacity concurrent with a forced shutdown (refer to table 8.3-3). In the event that heater capacity beyond that powered from a Class 1E source (150 KW on each train) is required, heaters can be supplied from the non-Class 1E power system that is fed from the offsite power system.

Table 18.II.E-1
PVNGS PRESSURIZER HEATERS
Units 1 and 3

Unit 1							
Number of Heaters	Capacity (kW)	480V Bus	1E Power	1E Controls	SIAS Trip	Reset from Control Room	SIAS Override from Control Room
4-3 elements	600	NGN-L11	No	No	No	N/A	N/A
5-3 elements	750	NGN-L12	No	No	No	N/A	N/A
1-2 elements	100	NGN-L11	No	No	No	N/A	N/A
1-3 elements	150	PGA-L33	Train A	Train A	Yes	No	Yes
1-3 elements	150	PGB-L32	Train B	Train B	Yes	No	Yes

Unit 2							
Number of Heaters	Capacity (kW)	480V Bus	1E Power	1E Controls	SIAS Trip	Reset from Control Room	SIAS Override from Control Room
4-3 elements	600	NGN-L11	No	No	No	N/A	N/A
4-3 elements	600	NGN-L12	No	No	No	N/A	N/A
1-2 elements	100	NGN-L11	No	No	No	N/A	N/A
1-2 elements	100	NGN-L12	No	No	No	N/A	N/A
1-3 elements	150	PGA-L33	Train A	Train A	Yes	No	Yes
1-3 elements	150	PGB-L32	Train B	Train B	Yes	No	Yes

Unit 3							
Number of Heaters	Capacity (kW)	480V Bus	1E Power	1E Controls	SIAS Trip	Reset from Control Room	SIAS Override from Control Room
5-3 elements	750	NGN-L11	No	No	No	N/A	N/A
5-3 elements	750	NGN-L12	No	No	No	N/A	N/A
1-3 elements	150	PGA-L33	Train A	Train A	Yes	No	Yes
1-3 elements	150	PGB-L32	Train B	Train B	Yes	No	Yes

2. Heaters fed from the Class 1E power system (300 kW) are automatically shed upon receipt of a safety injection actuation signal (SIAS). They may subsequently be manually reconnected to the engineered safety feature (ESF) buses without shedding of any loads from the Class 1E buses.

   Sufficient margin exists in each diesel generator for at least an additional 150 kW heater.

3. The redundant pressurizer heaters required for maintenance of natural circulation at hot standby are fed from Class 1E buses via Class 1E load side breakers qualified in accordance with safety grade requirements.

4. Appropriate procedures and operator training has been established to make the operator aware of when and how the required pressurizer heaters are to be connected to the emergency buses.

18.II.E.4.1 DEDICATED HYDROGEN PENETRATIONS

NRC Position

Plants using external recombiners or purge systems for post-accident combustible gas control of the containment atmosphere should provide containment penetration systems for external recombiner or purge systems that are dedicated to that service only, that meet the redundancy and single failure requirements of General Design Criteria 54 and 56 of Appendix A to 10CFR50, and that are sized to satisfy the flow requirements of the recombiner or purge system.

The procedures for the use of combustible gas control systems following an accident that results in a degraded core and release of radioactivity to the containment must be reviewed and revised, if necessary.

PVNGS Evaluation

Redundant independent combustible gas control systems are provided. Each system has external hydrogen monitors and connection points for an external hydrogen recombiner. Train A and Train B have a dedicated penetration. Train A meets the requirements of NUREG-0737, Sup 1, Task II.E.4.1. Two portable hydrogen recombiners are onsite and available for connection to the affected unit. Either recombiner is capable of reducing hydrogen levels as noted in subsection 6.2.5. The two systems are completely independent and meet single failure criteria.

An additional hydrogen reduction capability is provided by a charcoal filtered hydrogen purge exhaust air filteration unit. This nonsafety grade unit can be connected to either set of gas control containment penetrations. This capability would only be utilized in the event of separate failures in both recombiner units.

The arrangement of these combustible gas control methods is shown in engineering drawings 01, 02, 03-M-HPP-001.

As noted in paragraph 12.1.2.4, the dose rate during installation of the hydrogen recombiners will be less than 5 rem/hr. This rate allows the requirements of GDC 19 to be met.

18.II.E.4.2 CONTAINMENT ISOLATION DEPENDABILITY

NRC Position

(1) Containment isolation system designs shall comply with the recommendations of Standard Review Plan Section 6.2.4 (i.e., that there be diversity in the parameters sensed for the initiation of containment isolation).

(2) All plant personnel shall give careful consideration to the definition of essential and nonessential systems, identify each system determined to be essential, identify each system determined to be nonessential, describe the basis for selection of each essential system, modify their containment isolation designs accordingly, and report the results of the reevaluation to the NRC.

(3) All nonessential systems shall be automatically isolated by the containment isolation signal.

(4) The design of control systems for automatic containment isolation valves shall be such that resetting the isolation signal will not result in the automatic reopening of containment isolation valves. Reopening of containment isolation valves shall require deliberate operator action.

(5) The containment setpoint pressure that initiates containment isolation for nonessential penetrations must be reduced to the minimum compatible with normal operating conditions.

(6) Containment purge valves that do not satisfy the operability criteria set forth in Branch Technical

Position CSB 6-4 or the Staff Interim Position of October 23, 1979, must be sealed closed as defined in SRP 6.2.4, Item II.6.f, during operational conditions 1, 2, 3, and 4. Furthermore, these valves must be verified to be closed at least every 31 days.

(7) Containment purge and vent isolation valves must close on a high radiation signal.

PVNGS Evaluation

Refer to FSAR subsection 6.2.4. In addition, the PVNGS containment isolation system is designed as follows:

1. As required by SRP 6.2.4, a containment isolation signal is diversely generated by either a high containment pressure signal or a low pressurizer pressure signal. The power access purge and refueling purge are additionally isolated by high containment purge radioactivity.

2. A generic review of fluid systems penetrating the containment for C-E designed plants was conducted for the C-E Owner's Group on Post-TMI Efforts. The results of this review were used by Arizona Public Service to evaluate the PVNGS containment isolation system.

   Essential systems are those systems critical to ensure the capability to mitigate consequences of accidents, to ensure the integrity of the reactor coolant pressure boundary, and to ensure the capability to shut down the reactor and maintain it in a safe shutdown condition. Table 18.II.E-2

lists essential systems penetrating the PVNGS containment. No essential systems are functionally isolated by a containment isolation actuation signal (CIAS) with the exception of the hydrogen control system, as classified in the table. This system is not immediately required for accident mitigation. The isolation valves can be manually opened from the control room as part of the hydrogen recombiner startup procedures.

The steam supply for the turbine-driven AFW pump is from the main steam lines, upstream of the main steam isolation valves (MSIVs). The steam supply valves on the main steam lines are normally closed. These valves automatically open on an AFAS, and can be manually overridden from the main control room. A CIAS does not affect the operation of the isolation valves.

The atmospheric dump valves (ADVs) are normally closed and are manually operated from the main control room and remote shutdown panel. These valves are used to release steam from the steam generators to the atmosphere for reactor heat removal. The ADVs are located upstream of the MSIVs and are not affected by a CIAS.

3. Nonessential systems penetrating the PVNGS containment are listed in table 18.II.E-3. Nonessential systems are automatically isolated

by a CIAS with the exception of the following systems:

- Those containing locked closed valves or flanged closed connections

Table 18.II.E-2
ESSENTIAL SYSTEMS PENETRATING THE PVNGS CONTAINMENT

System	Normal Position	Post CIAS Position	Notes
HPSI	Closed	Open	(a)(h)
LPSI	Closed	Open	(a)(h)
Containment spray	Closed	Closed	(b)(h)
Recirculation sump suction	Closed	Closed	(c)(h)
Long-term recirculation	Closed	Closed	(d)(h)
Auxiliary feedwater	Closed	Closed	(e)(h)
H_2 control	Closed	Closed	(d)(g)
Containment pressure sensor	Open	Open	(f)(h)
Shutdown cooling system	Closed	Closed	(d)(h)

a. Opens on safety injection actuation signal

b. Opens on containment spray actuation signal

c. Opens on recirculation actuation signal

d. Manually opened from control room

e. Opens on auxiliary feedwater actuation signal

f. Function requires it to remain open

g. Isolates on containment isolation actuation signal

h. These penetrations are not directly affected by a CIAS. However, some of the same conditions that cause a CIAS will result in other signals or actuations that could result in valves and systems shifting position. The positions shown for these penetrations would generally result from conditions that would cause a CIAS, or would be the normal positions during plant operations and would not be expected to change following a CIAS. The actual plant conditions, resulting signals, or valve lineups must be examined to accurately determine each system's post-CIAS alignment.

- Main steam and feedwater
- Steam generator blowdown and blowdown sample and safety injection drain
- Reactor coolant pump (RCP) seal injection and chemical and volume control system (CVCS) charging
- Nuclear cooling water system
- CVCS RCP seal bleedoff
- Instrument air

The nuclear cooling water system, CVCS RCP seal bleedoff, and instrument air are all required to support continued operation of two reactor coolant pumps following a safety injection activation (which occurs concurrently with a containment isolation actuation). Continued operation of two reactor coolant pumps is required to support the RCP trip two/leave two strategy which is discussed in subsection 18.II.K.3.5.

The main steam and feedwater systems, while not essential, aid in heat removal during a small loss-of-coolant accident (LOCA). These systems should not, therefore, be isolated by a CIAS generated on low pressurizer pressure. The steam and feedwater systems are isolated for a main steam line break by a main steam isolation actuation signal (MSIS) on high containment pressure or low steam generator pressure.

Table 18.II.E-3
NONESSENTIAL SYSTEMS PENETRATING THE
PVNGS CONTAINMENT (Sheet 2 of 2)

System	Normal Position	Post CIAS Position	Notes
Safety injection drain	Closed	Closed	(e) (i)
RCP seal injection	Open	Open	(f) (i)
CVCS charging	Open	Open	(f) (i)
Gaseous radwaste	Open	Closed	(a)

a. Closes on containment isolation actuation signal

b. Closes on containment purge isolation actuation signal

c. Closes on main steam isolation signal

d. Closes on main steam isolation signal, auxiliary feedwater actuation signal, or safety injection actuation signal

e. Closes on safety injection actuation signal

f. Seismic Category I check valve inside containment

g. Sealed closed during normal operations (modes 1-4)

h. Closes on containment spray actuation signal

i. These penetrations are not directly affected by a CIAS. However, some of the same conditions that cause a CIAS will result in other signals or actuations that could result in valves and systems shifting position. The positions shown for these penetrations would generally result from conditions that would cause a CIAS, or would be the normal positions during plant operations and would not be expected to change following a CIAS. The actual plant conditions, resulting signals, or valve lineups must be examined to accurately determine each system's post-CIAS alignment.

The steam generator blowdown and blowdown sample systems are isolated by either a MSIS, AFAS, or a SIAS. The safety injection drain is isolated on a SIAS. Plant parameters which generate SIAS also generate CIAS.

It is desirable to leave RCP seal injection and CVCS charging paths open to provide additional core protection after an accident in which offsite power is available. See Section 9.3.4.7.A.2 for a description of emergency power for the charging pumps. Conversely, it is undesirable to lose charging or seal injection capability during normal operation due to an inadvertent CIAS. The potential release of fission products through the penetration is not a concern for the following reasons:

- Flow is into the containment and RCS.
- Check valves inside the containment prevent backflow out of the containment if the charging pumps stop.
- The connecting portions of the CVCS outside of containment are designed to Safety Class 2, Seismic Category I standards and have design pressure well in excess of containment design pressure.

- The operator has the capability of isolating these lines if continued charging or seal injection proves to be unnecessary.

4. Override of a CIAS signal is available for each containment isolation valve via the control switch for that valve. Resetting of a CIAS does not result in the automatic opening of containment isolation valves. Reopening requires operator action for each valve and does not compromise the containment isolation signal.

5. The containment high-pressure setpoint is shown in Table 7.3-11A. Both the CIAS and the SIAS are actuated at this setpoint. The setpoint was established to conservatively bound expected fluctuations in containment pressure due to such factors as instrument air leakage, containment air temperature changes, and changes in differential pressure between inside and outside containment. It also takes into account instrument error.

   Since the high containment pressure setpoint actuates both the CIAS and SIAS, it was conservatively established to minimize spurious challenges to the safety injection system.

6. Containment power access purge isolation valves satisfy the operability criteria set forth in Branch Technical Position CSB 6-4. Containment refueling purge isolation valves will be sealed closed except during operational modes 5 and 6.

These valves will be verified closed once every 31 days (cold shutdown and refueling, respectively).

7. The power access purge and the refueling purge isolate on containment purge high radioactivity.

18.II.F INSTRUMENTATION AND CONTROLS

18.II.F.1 ADDITIONAL ACCIDENT MONITORING INSTRUMENTATION

A human factor analysis has been performed to ensure that the displays and controls added for additional accident monitoring do not increase the potential for operator error. For information on the analysis see Section 18.I.D.1.

18.II.F.1.1 NOBLE GAS EFFLUENT MONITOR

NRC Position

Noble gas effluent monitors shall be installed with an extended range design to function during accident conditions as well as during normal operating conditions. Multiple monitors are considered necessary to cover the ranges of interest.

(1) Noble gas effluent monitors with an upper range capacity of $10^{(5)}$ μCi/cc (Xe-133) are considered to be practical and should be installed in all operating plants.

(2) Noble gas effluent monitoring shall be provided for the total range of concentration extending from normal condition (as low as reasonably achievable (ALARA)) concentrations to a maximum of $10^{(5)}$ μCi/cc (Xe-133). Multiple monitors are considered to be necessary to cover the ranges of interest. The range capacity of individual monitors should overlap by a factor of 10.

PVNGS Evaluation

Section 11.5 provides detailed descriptions of the effluent monitors installed at Palo Verde Units 1, 2, and 3. This

includes the additional monitors that have been added specifically to address NUREG-0737 and Regulatory Guide 1.97, Revision 2, requirements for radiation monitoring. A description of the calibration sources, frequency of calibration, and technique is provided in table 11.5-1 and paragraph 11.5.2.1.6.2 respectively. The instrumentation is described in detail in table 11.5-1.

A description of effluent radiation monitoring is presented in paragraph 11.5.2.1.4. Included in this section are discussions of monitors located on the plant vent and fuel building vent. The main steam line monitors are area monitors required for post-accident monitoring and are discussed in paragraph 11.5.2.1.5.6.

These monitors operate in conjunction with other monitors, as described in section 11.5, and fulfill the requirements as outlined in NUREG-0737 and Regulatory Guide 1.97, Revision 2.

18.II.F.1.2 SAMPLING AND ANALYSIS OF PLANT EFFLUENTS

<u>NRC Position</u>

Because iodine gaseous effluent monitors for the accident condition are not considered to be practical at this time, capability for effluent monitoring of radio iodines for the accident condition shall be provided with sampling conducted by adsorption on charcoal or other media, followed by onsite laboratory analysis.

PVNGS Evaluation

The effluent sampling assembly is discussed in paragraph 11.5.2.1.1.7.2. For high range particulate and iodine samplers, the sampler is a lead-shielded filter assembly.

Sampling of effluents meets the criteria of ANSI N13.1-1969 as discussed in paragraphs 11.5.2.1.1.7.2 and 11.5.2.2.1. Paragraph 11.5.2.1.1.7.2 also describes the sampling assembly.

Monitors are designed to meet a 90% efficiency level for particulates and 90% efficiency for iodine as required by NUREG-0737, Table II.F.1-2. They are also designed to conform with design basis shielding envelopes for sampling media as discussed in paragraph 12.1.2.4. Monitors are designed to allow personnel to remove, replace, and transport sampling media without exceeding the criteria of General Design Criterion 19 of 5 rem whole-body and 75 rem to the extremities.

18.II.F.1.3 CONTAINMENT HIGH RANGE RADIATION MONITOR

NRC Position

In containment radiation-level monitors with a maximum range of 10^8 rad/hr shall be installed. A minimum of two such monitors that are physically separated shall be provided. Monitors shall be developed and qualified to function in an accident environment.

This requirement was revised in the October 30, 1979 letter, from H. R. Denton to All Operating Nuclear Power Plants, to provide for photon-only measurement with an upper range of 10^7 rad/hr.

PVNGS Evaluation

As noted in table 11.5-1, in-containment area monitors XJ-SQA-RU-148 and XJ-SQB-RU-149 are provided to measure γ-photon activity with an upper range of 10^7 rad/hr.

Table II.F.1-3 of NUREG-0737 specifies that, for containment high-range monitors, an in situ calibration for at least one decade below 10 R/hr shall be by means of a calibrated radiation source. In lieu of an external source, PVNGS utilizes a calibrated source that is internal to each containment high-range radiation monitor. The specific calibration method used (described in section 11.5.2.1.6.2) is technically comparable to methods that use external sources and meets the intent of performing an situ calibration (i.e., verify detector operability and accuracy after in situ installation).

18.II.F.1.4 CONTAINMENT PRESSURE MONITOR

NRC Position

A continuous indication of containment pressure shall be provided in the control room of each operating reactor. Measurement and indication capability shall include three times the design pressure of the containment for concrete, four times the design pressure for steel, and -5 psig for all containments.

PVNGS Evaluation

Wide range containment pressure measurement is provided in paragraph 7.5.1.1.5 Table 1.8-1, and the appendix 6A response to Question 6A.14.

Wide range containment pressure measurement is provided, consisting of redundant pressure transmitters whose signals of containment pressure are continuously displayed within the control room. Continuous recording is provided for one channel over the entire range of pressure measurement. The transmitters are located outside of the containment structure and measure the containment pressure through sensing lines penetrating the containment structure. The range of the system is from -5 to 180 psig, three times the containment pressure.

The transmitters are physically separated, redundant, environmentally qualified to function in a post-LOCA environment in accordance with Regulatory Guide 1.89, Rev. 1 and seismically qualified to function during and following an SSE in accordance with Regulatory Guide 1.100. The safety grade pressure instrumentation is powered from redundant Class 1E buses. The instrumentation is designed to meet Regulatory Guide 1.97, Revision 2.

18.II.F.1.5 CONTAINMENT WATER LEVEL MONITOR

NRC Position

A continuous indication of containment water level shall be provided in the control room for all plants. A narrow range instrument shall be provided for pressurized water reactors (PWRs) and cover the range from the bottom to the top of the

containment sump. A wide range instrument shall also be provided for PWRs and shall cover the range from the bottom of the containment to the elevation equivalent to a 600,000 gallon capacity. For boiling water reactors (BWRs), a wide range instrument shall be provided and cover the range from the bottom to 5 feet above the normal water level of the suppression pool.

PVNGS Evaluation

Narrow range water level instrumentation monitoring the containment radwaste sumps, and wide range containment water level instrumentation are discussed in paragraph 7.5.1.1.5, and Table 1.8-1.

Continuous indication of the containment radwaste sumps (containment normal sumps) water level is provided in the control room by narrow range level instrumentation. Each sump is monitored from 6 inches above the bottom of the sump to 6 inches above the top of the sump. The instrumentation ispowered from a reliable instrument bus with Class 1E backup power. The instrumentation is designed to meet the requirement of Regulatory Guide 1.97, Revision 2.

Continuous control room indication is provided for containment water level by wide range level instrumentation from 6 inches above the top of the radwaste sump to 6-inches above the maximum expected flood level, providing a total range of 12 feet. The sensors are physically separated, redundant, environmentally qualified to function in a post-LOCA environment in accordance with Regulatory Guide 1.89, and seismically qualified to function during and following an SSE

in accordance with Regulatory Guide 1.100. The safety grade level instrumentation is powered from redundant Class 1E buses. Recording for one channel is provided in the control room. The instrumentation is designed to meet Regulatory Guide 1.97, Revision 2.

18.II.F.1.6 CONTAINMENT HYDROGEN MONITOR

NRC Position

A continuous indication of hydrogen concentration in the containment atmosphere shall be provided in the control room. Measurement capability shall be provided over the range of 0 to 10% hydrogen concentration under both positive and negative ambient pressure.

PVNGS Evaluation

A description of the containment hydrogen monitoring system is provided in paragraph 6.2.5.2.2.2. The range and accuracy of the hydrogen analyzer control room indication provided to meet Item II.F.1.6 is given in table 7.5-1.

A remote control panel mounted on the main control board provides control of each analyzer. Recording for one channel is also provided in the control room. The analyzers, one per each train, are in standby during normal operation and can provide continuous indication of hydrogen concentration in less than 30 minutes after activation from the control room. The analyzers can operate under containment design conditions from -5 to 60 psig, the containment design pressure. The analyzers are environmentally qualified to function in a post-LOCA environment in accordance with Regulatory Guide 1.89 and

seismically qualified to function during and following an SSE in accordance with Regulatory Guide 1.100. The safety grade hydrogen analyzer instrument channels are powered from redundant Class 1E buses.

The instrumentation is designed to meet Regulatory Guide 1.97, Revision 2.

18.II.F.2 INSTRUMENTATION FOR DETECTION OF INADEQUATE CORE COOLING

NRC Position

Licensees shall provide a description of any additional instrumentation or controls (primary or backup) proposed for the plant to supplement existing instrumentation (including primary coolant saturation monitors) in order to provide an unambiguous, easy to interpret indication of inadequate core cooling (ICC). A description of the functional design requirements for the system shall also be included. A description of the procedures to be used with the proposed equipment, the analysis used in developing these procedures, and a schedule for installing the equipment shall be provided.

PVNGS Evaluation

In addition to the NRC position stated above, 38 itemized design requirements pertaining to inadequate core cooling (ICC) were submitted within NUREG-0737, Section II.F.2. Combustion Engineering (C-E) has provided in CESSAR a generic response to these design requirements which is applicable to PVNGS except for minor deviations, and requirements that are plant specific.

The subsequent PVNGS response provides a description of the instrumentation and equipment that has been incorporated into the PVNGS design to meet ICC requirements. The exceptions previously taken to the C-E response within CESSAR, Appendix B, Section II.F.2 have been incorporated into that responses and are now presented below.

(1) Description of ICC Instrumentation and Equipment Incorporated by PVNGS

The instrumentation added by PVNGS to supplement existing instrumentation for detection of ICC is comprised of core exit thermocouples (CET), heated junction thermocouples (HJT), and a subcooled margin monitor (SMM). The function of this ICC instrumentation is to enhance the ability of the control room operators to diagnose the approach to, existence of, and recovery from ICC.

An unambiguous and easy to interpret indication of ICC is provided by two channels of safety grade microcomputers, which process inputs from ICC instrumentation and transmittal of ICC status to seismically qualified displays located in the control room. Trending of ICC parameters is provided by paperless recorders which are also located in the control room.

(2) Exceptions Taken to C-E Response Within CESSAR, Appendix B, Section II.F.2

Only the description of the qualified safety parameter display system (QSPDS) in Appendix 18B, relates to the system which PVNGS has incorporated to provide for ICC. PVNGS has similar design capabilities to the accident

monitoring system described in Appendix 18B but it is not all related to ICC requirements of NUREG-0737, Section II.F.2.

The saturation margin monitor (SMM) referred to in CESSAR is designated the subcooled margin monitor (SMM) at PVNGS.

Figure 18B-1 shows "Other QSPDS inputs" to QSPDS. These other inputs are not ICC related parameters.

(3) PVNGS Responses to the Requirements of NUREG-0737, Section II.F.2

Table 18.II.F.2-1 addresses the Documentation Required section of NUREG-0737, Section II.F.2.

Table 18.II.F.2-2 addresses the requirements of NUREG-0737, Section II.F.2, Attachment I, Design and Qualification Criteria for Pressurized-Water Reactor Incore Thermocouples.

Table 18.II.F.2-3 addresses the requirements of NUREG-0737, Appendix B, Design and Qualification Criteria for Accident Monitoring Instrumentation.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 1 of 8)

NRC Requirements

The licensee shall provide a report detailing the planned instrumentation system for monitoring of ICC. The report should contain the necessary information, either by inclusion or by reference to previous submittals including pertinent generic reports, to satisfy the requirements which follow:

(1) A description of the proposed final system including:

  (a) a final design description of additional instrumentation and displays;

  (b) a detailed description of existing instrumentation systems (e.g., subcooling meters and incore thermocouples), including parameter ranges and displays, which provide operating information pertinent to ICC considerations; and

  (c) a description of any planned modifications to the instrumentation systems described in item 1.b above.

(2) The necessary design analysis, including evaluation of various instruments to monitor water level, and available test data to support the design described in item 1 above.

(3) A description of additional test programs to be conducted for evaluation, qualification, and calibration of additional instrumentation.

(4) An evaluation, including proposed actions, on the conformance of the ICC instrument system to this document, including Attachment 1 and Appendix A. Any deviations should be justified.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 2 of 8)

(5) A description of the computer functions associated with ICC monitoring and functional specifications for relevant software in the process computer and other pertinent calculators. The reliability of nonredundant computers used in the system should be addressed.

(6) A current schedule, including contingencies, for installation, testing and calibration, and implementation of any proposed new instrumentation or information displays.

(7) Guidelines for use of the additional instrumentation, and analyses used to develop these procedures.

(8) A summary of key operator action instructions in the current emergency procedures for ICC and a description of how these procedures will be modified when the final monitoring system is implemented.

(9) A description and schedule commitment for any additional submittals which are needed to support the acceptability of the proposed final instrumentation system and emergency procedures for ICC.

Requirement	PVNGS Response
(1)(a)	Description of the ICC Detection Instrumentation is provided in Appendix 18B, section 2.0.
(1)(b)	The instrumentation described in Appendix 18B, section 2.0, will be the ICC detection instrumentation design for the System 80 plant.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 3 of 8)

Requirement	PVNGS Response
(1)(c)	There are no changes planned for instrumentation or displays related to ICC functions based upon previous evaluation.
(2)	The design analysis and evaluation of the ICC detection instrumentation is presented in Appendix 18B, Section 1.0 and Appendix 18B-A. The HJTC-based reactor vessel level monitoring system has been tested in three phases: Phase 1 - Proof of Principle Tests, Phase 2 - Design Development Tests, and Phase 3 - Prototype Tests. The results of these tests are available in the Phase 1, Phase 2, and Phase 3 Test Reports.
(3)	The Phase 3 test program consisted of high temperature and pressure testing of a manufactured production prototype system HJTC probe assembly and processing electronics. The Phase 3 test program was executed at the C-E test facility used for the Phase 2 test.
	No special verification or experimental tests are planned for the hot leg and cold leg RTD sensors, the pressurizer pressure sensors, or the Type K (chromelalumel) core exit thermocouples since they are standard high quality nuclear instruments with well known responses.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 4 of 8)

For qualification testing, all out-of-vessel sensors and equipment, including the QSPDS up to and including the ERFDADS isolation, is environmentally qualified according to the methodology presented in Section 3.11, and seismically qualified according to the methodology presented in Section 3.10.

(4) Evaluation, proposed actions, and conformance to NUREG-0737, Section II.F.2, is inclusive in this response.

(5) The ICC detection instrumentation processing and display consists of two computer systems; the 2 redundant channel safety grade microcomputer based QSPDS, and the single large scale non safety grade computer based ERFDADS. The ICC inputs are acquired and processed by the safety grade QSPDS and isolated and transmitted to the primary display in the non-safety-grade ERFDADS. The QSPDS also has the seismically qualified displays for the ICC detection instruments. The software functions for processing are listed in Appendix 18B, Section 2.2; the functions for display are listed in Appendix 18B, Section 2.3.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 5 of 8)

The software for the QSPDS has been designed using the recommendations of the draft standard, IEEE Std. P742/ANS 4.3.2, "Criteria for the Application of Programmable Digital Computer Systems in the Safety Systems of Nuclear Power Generating Stations" as a design guideline. This design procedure verifies and validates that the QSPDS software is properly implemented and integrated with the system hardware to meet the system's functional requirements. This procedure is quality assured by means of the C-E QADP. Although the ERFDADS is designed as a non-safety class system, a similar procedure is being applied to the ERFDADS design to assure compatibility with the QSPDS.

The QSPDS hardware is designed as a redundant safety grade qualified computer system which is designed to the availability goal of 0.99 with the appropriate spare parts and maintenance support. The ERFDADS is a single highly reliable computer system that is designed to the availability goal of (0.99) with the appropriate spare parts and maintenance support.

(6) The ICC instrumentation is expected to be fully operational prior to a unit exceeding 5% power for the first time.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 6 of 8)

(7) Guidance for the use of ICC instrumentation is contained in the C-E Owner's Group Emergency Procedure Guidelines, CEN-152, and in the PVNGS Emergency Procedure Generation Packages.

(8) The PVNGS Emergency Procedures currently contain guidance with respect to ICC. The ICC modifications are in the base design of the plant.

Assessment of ICC indication and response actions are contained in the PVNGS Emergency Operations Procedures and are performed during Standard Post Trip Actions (SPTAs) conducted at the initiation of an event.

Assessment of ICC indicators together with assessment of other key safety functions are used to diagnose an event and progress to an appropriate procedure to mitigate the event.

Additional assessments and recovery actions used to maintain or restore adequate core cooling are specified explicitly in the Emergency Operation Procedure Set.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 7 of 8)

The summary of typical key operator actions is given below:

A. Assessment Actions

- Check the RCS loop ΔT is less than the maximum expected value for adequate core cooling.
- Check that the RCS subcooling is acceptable for adequate core cooling.
- If Forced Circulation is not available additional checks are performed on RCS hot leg, RCS cold leg and core exit thermocouple temperature values and relationships to detect indications of inadequate core cooling.

B. Response Actions

Recover of, or maintenance of, adequate core cooling is accomplished in the Emergency Operations Procedures by performance of specific actions to establish and maintain supporting safety functions in the following priority.

- Establish RCS Inventory Control using the CVCS system or the Safety Injection System.

Table 18.II.F.2-1

REQUIRED DOCUMENTATION

(Sheet 8 of 8)

- Establish RCS Pressure Control using Normal Pressurizer Pressure Control System, CVCS, Safety Injection, Controlled Steaming of Steam Generators, or RCS venting.
- Establish RCS Heat Removal by use of Steam Generators and/or Safety Injection.

(9) No additional submittals are needed to support the final ICC instrumentation or the emergency procedures related to ICC, based upon previous NRC evaluations.

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED WATER REACTOR INCORE THERMOCOUPLES

(Sheet 1 of 6)

NRC Requirements

(1) Thermocouples located at the core exit for each core quadrant, in conjunction with core inlet temperature data, shall be of sufficient number to provide indication of radial distribution of the coolant enthalpy (temperature) rise across representative regions of the core. Power distribution symmetry should be considered when determining the specific number and location of thermocouples to be provided for diagnosis of local core problems.

(2) There should be a primary operator display (or displays) having the capabilities which follow:

(a) A spatially oriented core map available on demand indicating the temperature or temperature difference across the core at each core exit thermocouple location.

(b) A selective reading of core exit temperature, continuous on demand, which is consistent with parameters pertinent to operator actions in connecting with plant-specific inadequate core cooling procedures. For example, the action requirement and the displayed temperature might be either the highest of all operable thermocouples or the average of five highest thermocouples.

(c) Direct readout and hard-copy capability should be available for all thermocouple temperatures. The range should extend from 200F (or less) to 1800F (or more).

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED

WATER REACTOR INCORE THERMOCOUPLES

(Sheet 2 of 6)

NRC Requirements

(d) Trend capability showing the temperature-time history of representative core exit temperature values should be available on demand.

(e) Appropriate alarm capability should be provided consistent with operator procedure requirements.

(f) The operator display device interface shall be human factor designed to provide rapid access to requested displays.

(3) A backup display (or displays) should be provided with the capability for selective reading of a minimum of 16 operable thermocouples, four from each core quadrant, all within a time interval no greater than 6 minutes. The range should extend from 200F (or less) to 2300F (or more).

(4) The types and locations of displays and alarms should be determined by performing a human factors analysis taking into consideration:

(a) the use of this information by an operator during both normal and abnormal plant conditions,

(b) integration into emergency procedures,

(c) integration into operator training, and

(d) other alarms during emergency and need for prioritization of alarms.

(5) The instrumentation must be evaluated for conformance to Appendix B, Design and Qualification Criteria for

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED WATER REACTOR INCORE THERMOCOUPLES

(Sheet 3 of 6)

NRC Requirements

Accident Monitoring Instrumentation, as modified by the provisions of items 6 through 9 which follow.

(6) The primary and backup display channels should be electrically independent, energized from independent station Class 1E power sources, and physically separated in accordance with Regulatory Guide 1.75 up to and including any isolation device. The primary display and associated hardware beyond the isolation device need not be Class 1E, but should be energized from a high-reliability power source, battery backed, where momentary interruption is not tolerable. The backup display and associated hardware should be Class 1E.

(7) The instrumentation should be environmentally qualified as described in Appendix B, Item 1, except that seismic qualification is not required for the primary display and associated hardware beyond the isolator/input buffer at a location accessible for maintenance following an accident.

(8) The primary and backup display channels should be designed to provide 99% availability for each channel with respect to functional capability to display a minimum of four thermocouples per core quadrant. Availability shall be addressed in technical specifications.

(9) The quality assurance provisions cited in Appendix B, Item B, should be applied except for the primary display and associated hardware beyond the isolation device.

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED WATER REACTOR INCORE THERMOCOUPLES

(Sheet 4 of 6)

Requirement	PVNGS Response
(1)	The System 80 design has 61 core exit thermocouples (CETs) distributed uniformly over the top of the core. Appendix 18B, Section 2.1.3 has a description of the CET sensors. Figure 18B-5 depicts the locations of the CETs.
(2)(a)	A spatially oriented core map for each channel is available as an option on the QSPDS display.
(2)(b)	A display of the highest CET for each channel, and the two highest CETs per quadrant for each channel is available on the QSPDS displays.
(2)(c)	The ERFDADS provides direct readout of CET temperatures with a dedicated display page. The printer provides the hardcopy capability for recording CET temperatures.
(2)(d)	Trending capability of CET temperatures is provided by a paperless recorder located in the control room that tracks a representative CET temperature.
(2)(e)	When one or more QSPDS parameters enter on alarm condition, a QSPDS system annunciator alarm actuates, and the QSPDS displays attract and direct the attention of the control room operators to the relevant display pages.

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED WATER REACTOR INCORE THERMOCOUPLES

(Sheet 5 of 6)

Requirement	PVNGS Response
(2)(f)	The ERFDADS is an extensively human-factor designed display system which allows quick access to requested displays by means of the hierarchy described in Appendix 18B and Section 2.3.
(3)	The QSPDS displays fulfill the requirements for the safety grade backup displays. Both channels of QSPDS displays together display all CET temperatures. All CET temperatures can be displayed within 6 minutes.
(4)	The types and locations of displays and alarms are determined by performing a human-factors analysis. The ERFDADS incorporates extensive human-factors engineering. The QSPDS also incorporates human factors engineering. The use of these display systems will be addressed in operating procedures, emergency procedures, and operator training.
(5)	Refer to table 18.II.F.2-3.

Table 18.II.F.2-2

DESIGN AND QUALIFICATION CRITERIA FOR PRESSURIZED WATER REACTOR INCORE THERMOCOUPLES

(Sheet 6 of 6)

Requirement	PVNGS Response
(6)	The ERFDADS (primary display) and the QSPDS (two redundant safety grade display channels) are electrically independent. The QSPDS channels are powered from the Class 1E power sources for channel A & B and physically separated according to Reg. Guide 1.75 up to and including the isolation device portion transmitting data to the ERFDADS (see Figure 18B-1). The ERFDADS is highly reliable non safety grade system which is powered by a highly reliable battery-backed power source.
(7)	The ICC detection instrumentation is environmentally and seismically qualified as specified in the response 18.II.F.2-3 Requirement 1. The ERFDADS is not seismically qualified. The isolation devices in the QSPDS are accessible for maintenance following an accident.
(8)	QSPDS is designed to provide 99% availability. The PVNGS Technical Specifications address CET availability.
(9)	Refer to table 18.II.F.2-3.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 1 of 13)

NRC Requirements

(1) The instrumentation should be environmentally qualified in accordance with Regulatory Guide 1.89 (NUREG-0588). Qualification applies to the complete instrumentation channel from sensor to display where the display is a direct-indicating meter or recording device. Where the instrumentation channel signal is to be used in a computer-based display, recording and/or diagnostic program, qualification applies to and includes the channel isolation device. The location of the isolation device should be such that it would be accessible for maintenance during accident conditions. The seismic portion of environmental qualification should be in accordance with Regulatory Guide 1.100. The instrumentation should continue to read within the required accuracy following, but not necessarily during, a safe shutdown earthquake. Instrumentation, whose ranges are required to extend beyond those ranges calculated in the most severe design basis accident event for a given variable, should be qualified using the following guidance.

The qualification environment shall be based on the design basis accident events, except the assumed maximum of the value of the monitored variable shall be the value equal to the maximum range for the variable. The monitored variable shall be assumed to approach this peak by extrapolating the most severe initial ramp associated with the design basis accident events. The decay for

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 2 of 13)

this variable shall be considered proportional to the decay for this variable associated with the design basis accident events. No additional qualification margin needs to be added to the extended range variable. All environmental envelopes except that pertaining to the variable measured by the information display channel shall be those associated with the design basis accident events.

The above environmental qualification requirement does not account for steady-state elevated levels that may occur in other environmental parameters associated with the extended range variables. For example, a sensor measuring containment pressure must be qualified for the measured process variable range, but the corresponding ambient temperature is not mechanistically linked to that pressure. Rather, the ambient temperature value is the bounding value for design basis accident events analyzed in chapter 15 of the Final Safety Analysis Report (FSAR). The extended range requirement is to ensure that the equipment will continue to provide information should conditions degrade beyond those postulated in the safety analysis. Since variable ranges are non-mechanistically determined, extension of associated parameter levels is not justifiable and has, therefore, not been required.

(2) No single failure within either the accident monitoring instrumentation, its auxiliary supporting features or its power sources concurrent with the failure that are a condition or result of a specific accident should prevent

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 3 of 13)

the operator from being presented the information necessary for him to determine the safety status of the plant and to bring the plant to a safe condition and maintain it in a safe condition following that accident. Where failure of one accident monitoring channel results in ambiguity (that is, the redundant displays disagree) which could lead the operator to defeat or fail to accomplish a required safety function, additional information should be provided to allow the operator to deduce the actual conditions in the plant. This may be accomplished by: (a) providing additional independent channels of information of the same variable (addition of an identical channel), (b) providing an independent channel which monitors a different variable bearing a known relationship to the multiple channels (addition of a diverse channel), or (c) providing the capability, if sufficient time is available, for the operator to perturb the measured variable and determine which channel has failed by observation of the response on each instrumentation channel. Redundant or diverse channels should be electrically independent, energized from station Class 1E power source, and physically separated in accordance with Regulatory Guide 1.75 up to and including any isolation device. At least one channel should be displayed on a direct-indicating or recording device. (NOTE: Within each redundant division of a safety system, redundant monitoring channels are not required.)

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 4 of 13)

(3) The instrumentation should be energized from station Class 1E power sources.

(4) An instrumentation channel should be available prior to an accident except as provided in Paragraph 4.11, Exemption, as defined in IEEE-279 or as specified in technical specifications.

(5) The recommendations of the following regulatory guides pertaining to quality assurance should be followed:

1.28	Quality Assurance Program Requirements (Design and Construction)
1.30	Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment
1.38	Quality Assurance Requirements for Packaging, Shipping, Receiving, Storage, and Handling of Items for Water-Cooled Nuclear Power Plants
1.58	Qualification of Nuclear Power Plant Inspection, Examination, and Testing Personnel
1.64	Quality Assurance Requirements for the Design of Nuclear Power Plants
1.74	Quality Assurance Terms and Definitions
1.88	Collection, Storage, and Maintenance of Nuclear Power Plant Quality Assurance Records

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 5 of 13)

1.123	Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants
1.144	Auditing of Quality Assurance Programs for Nuclear Power Plants
Task RS 810-5	Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants (Guide number to be inserted)

Reference to the above regulatory guides (except Regulatory Guides 1.30 and 1.38) are being made pending issuance of a regulatory guide endorsing NQA-1 (Task RS 002-5), now in progress.

(6) Continuous indication (it may be by recording) display should be provided at all times. Where two or more instruments are needed to cover a particular range, overlapping of instrument span should be provided.

(7) Recording of instrumentation readout information should be provided. Where trend or transient information is essential for operator information or action, the recording should be analog strip chart or stored and displayed continuously on demand. Intermittent displays, such as data loggers and scanning recorders, may be used if no significant transient response information is likely to be lost by such devices.

(8) The instruments should be specifically identified on the control panels so that the operator can easily discern that they are intended for use under accident conditions.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR
ACCIDENT MONITORING INSTRUMENTATION
(Sheet 6 of 13)

(9) The transmission of signals from the instrument or associated sensors for other use should be through isolation devices that are designated as part of monitoring instrumentation and that meet the provisions of the document.

(10) Means should be provided for checking, with a high degree of confidence, the operational availability of each monitoring channel, including its input sensor, during reactor operation. This may be accomplished in various ways; for example:

(a) By perturbing the monitored variable

(b) By introducing and varying, as appropriate, a substitute input to the sensor of the same nature as the measured variable

(c) By cross-checking between channels that bear a known relationship to each other and that have readouts available.

(11) Servicing, testing, and calibration programs should be specified to maintain the capability of the monitoring instrumentation. For those instruments where the required interval between testing will be less than the normal time interval between generating station shutdowns, a capability for testing during power operation should be provided.

(12) Whenever means for removing channels from service are included in the design, the design should facilitate administrative control of the access to such removal means.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR
ACCIDENT MONITORING INSTRUMENTATION
(Sheet 7 of 13)

(13) The design should facilitate administrative control of the access to all setpoint adjustments, module calibration adjustments, and test points.

(14) The monitoring instrumentation design should minimize the development of conditions that would cause meters, annunciators, recorders, alarms, etc., to give anomalous indications potentially confusing to the operator.

(15) The instrumentation should be designed to facilitate the recognition, location, replacement, repair, or adjustment of malfunctioning components or modules.

(16) To the extent practical, monitoring instrumentation inputs should be from sensors that directly measure the desired variables.

(17) To the extent practical, the same instruments should be used for accident monitoring as are used for the normal operations of the plant to enable the operator to use, during accident situations, instruments with which the operator is most familiar. However, where the required range of monitoring instrumentation results in a loss of instrumentation sensitivity in the normal operating range, separate instruments should be used.

(18) Periodic testing should be in accordance with the applicable portions of Regulatory Guide 1.118 pertaining to testing of instrument channels.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 8 of 13)

Requirement	PVNGS Response
(1)	The qualification for the ICC Detection instrumentation can be divided into three categories: (1) Instrumentation components and systems which extend from the primary pressure boundary up to and including the primary display isolator and including the backup displays. (2) Sensor instrumentation within the pressure vessel. (3) Instrumentation systems which comprise the primary display equipment. All out-of-vessel sensors and equipment, including the QSPDS up to and including the ERFDADS isolation, will be environmentally qualified to IEEE Std. 323-1974 as interpreted by CENPD-255 Rev. 01, "Qualification of C-E Class 1E Instruments”, and seismically qualified to IEEE Std. 344-1975 as interpreted by CENPD-182, "Seismic Qualification of C-E Instrumentation Equipment".

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 9 of 13)

Requirement	PVNGS Response
	The "best available equipment" is designed for the in-vessel equipment, including the HJTC probe assemblies and Core Exit Thermocouple (CET) sensors. This equipment is designed consistent with industry practice for components which are located inside the reactor vessel.
	The ERFDADS (primary display) will not be designed as a safety grade system, but will be designed for high reliability; thus it will not be qualified environmentally or seismically to the standards listed. However, the ERFDADS will be separated from the safety grade sensors, processing and backup display equipment by means of an isolation device which will be qualified to the standards listed and be accessible for maintenance following an accident.
(2)	All ICC instrumentation is designed with two redundant safety grade channels. The sensor inputs are fed into the QSPDS. The QSPDS is a safety grade two redundant channel microcomputer based processing and backup display system that transmits the ICC instrument variables to the non-safety grade ERFDADS via isolated data links. (See figure 18B-1) Also see Section 1.8, for description of Regulatory Guide 1.75 compliance.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 10 of 13)

Requirement	PVNGS Response
	If (in the remote chance) one complete channel of the QSPDS fails, the operator deduces ICC conditions by the following means: (1) Cross-checking the variables in the available channel. Each ICC function (SMM, HJTCS and CET) have multiple variables which can be cross-checked. (2) Cross-checking the variables with other instruments on the control board which have a known relationship to the QSPDS variables. For example additional safety-grade instruments exist for hot leg and cold leg temperatures, and pressurizer pressure.
(3)	The ICC detection instrumentation through the QSPDS is powered from the Class 1E power sources for Channels A and B.
(4)	PVNGS Technical Specifications address instrument channel availability.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 11 of 13)

Requirement	PVNGS Response
(5)	The ICC detection instrumentation through the QSPDS incorporates the recommendations of Regulatory Guides 1.28, 1.30, 1.38, 1.58, 1.64, 1.74, 1.88 Except as Stated in Section 1.8.
(6)	The ICC Detection Instrumentation outputs are continuously available on the QSPDS displays.
(7)	Paperless recorders located in the control room track reactor vessel level, representative CET temperature, and subcooling margin.
(8)	ICC displays are clearly identified per the PVNGS Detailed Control Room Design Review.
(9)	The signals transmitted to the ERFDADS from the QSPDS are isolated with isolation devices qualified to the provisions of Appendix 18B.
(10)	The operational availability of the ICC instruments of each channel can be checked according to the description addressing single failure in item 2. In addition periodic tests of the QSPDS verify complete system operability. (see Item 15).
(11)	The servicing, testing, and calibration of ICC instrumentation is specified within the respective PVNGS procedures.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 12 of 13)

Requirement	PVNGS Response
(12)	Refer to Appendix 18B. In addition, PVNGS administrative controls are in effect with regard to the removal of power from an ICC channel.
(13)	The QSPDS facilitates administrative control for access to setpoints by using programmable read-only memory modules which can be changed by removing and reprogramming the modules. Calibration and testing can be accessed at the input/output (I/O) equipment at the QSPDS cabinets.
(14)	The design meets this requirement.
(15)	The design meets this requirement. The QSPDS performs on-line surveillance tests to detect malfunctions. The following on-line surveillance tests are performed in the QSPDS: 1. The temperature inside the QSPDS cabinet with a cooling system alarm on high temperature. 2. Power failure to the processor with alarm on failure. 3. Bad sensors and broken communication links with indication on the display.

Table 18.II.F.2-3

DESIGN AND QUALIFICATION CRITERIA FOR

ACCIDENT MONITORING INSTRUMENTATION

(Sheet 13 of 13)

Requirement	PVNGS Response
	4. CPU memory check and data communication checks with alarm and indication on the visual display and digital panel meter on the cabinet. (These checks are performed periodically.)
	5. Analog input offset voltage with compensation performed automatically.
	6. Inputs out of range with alarm.
	7. Low HJTCS differential temperature with alarm.
(16)	The design meets this requirement.
(17)	The design meets this requirement.
(18)	Periodic testing according to Reg. Guide 1.118 can be performed on the ICC instruments. Except as stated in Section 1.8.

This page intentionally left blank

18.II.G ELECTRICAL POWER

18.II.G.1 EMERGENCY POWER FOR PRESSURIZER EQUIPMENT

NRC Position

Consistent with satisfying the requirements of General Design Criteria 10, 14, 15, 17, and 20 of Appendix A to 10CFR Part 50 for the event of loss of offsite power, the following positions shall be implemented:

Power Supply for Pressurizer Relief and Block Valves and Pressurizer Level Indicators

(1) Motive and control components of the power-operated relief valves (PORVs) shall be capable of being supplied from either the offsite power source or the emergency power source when the offsite power is not available.

(2) Motive and control components associated with the PORV block valves shall be capable of being supplied from either the offsite power source or the emergency power source when the offsite power is not available.

(3) Motive and control power connections to the emergency buses for the PORVs and their associated block valves shall be through devices that have been qualified in accordance with safety grade requirements.

(4) The pressurizer level indication instrument channels shall be powered from the vital instrument buses. The buses shall have the capability of being supplied from either the offsite power source or the emergency power source when offsite power is not available.

PVNGS Evaluation

PVNGS does not use pressurizer PORVs or block valves.

Two channels of Class 1E level instrumentation are provided for PVNGS. Pressurizer level channels L-110X and L-110Y are indicated in the control room. Channel L-110X is also recorded in the control room.

The pressurizer level instrumentation is powered from 120 V-ac, Class 1E instrument buses E-PNA-D25 and E-PNB-D26 (refer to engineering drawings 01, 02, 03-E-PKA-001). These buses are normally powered through inverters from Class 1E batteries. The Class 1E battery chargers are powered from offsite power or from the diesel generators when offsite power is not available.

The pressurizer level indicators comply with the recommendations of Regulatory Guide 1.97, Rev. 2 (see section 1.8).

18.II.K MEASURES TO MITIGATE SMALL-BREAK LOCAs AND LOSS OF FEEDWATER ACCIDENTS

18.II.K.1 IE BULLETINS ON MEASURES TO MITIGATE SMALL-BREAK LOCAs AND LOSS OF FEEDWATER ACCIDENTS

18.II.K.1.5 REVIEW OF ESF VALVES

NRC Position (IE Bulletin No. 79-06B)

Review all safety-related valve positions, positioning requirements and positive controls to assure that valves remain positioned (open or closed) in a manner to ensure the proper operation of engineered safety features. Also review related procedures, such as those for maintenance, testing, plant and system startup, and supervisory periodic (e.g., daily/shift checks) surveillance to ensure that such valves are returned to their correct positions following necessary manipulations and are maintained in their proper positions during all operational modes.

PVNGS Evaluation

The valves of the Engineered Safety Features (ESF) Systems are designed and tested to ensure proper operation in the event of an accident. This is accomplished in several ways.

1. The valves of the ESF systems are interlocked to automatically provide the sequence of operations required after an actuation of the ESF.

2. Actuator operated valves are provided with key-operated control switches, where considered necessary, to prevent unintentional misalignment of safety injection flow paths during power operation.

3. All valves that are not required to operate on initiation of safety injection or recirculation, in the injection flow path, are locked in the post accident position. Administrative controls ensure that the valves are locked in the correct position.

4. Periodic tests and inspections are performed to verify proper operation of each active component of the safety injection system. This includes valves.

In addition, PVNGS has tagout procedures and surveillance test procedures that control safety system status. These procedures provide appropriate logs and checklists to ensure control of plant systems. Additionally, reviews are conducted to verify that procedures for safety-related systems return those systems to service after having been tagged out for repair or surveillance testing. Refer to subsection 18.I.C.2 for a discussion of procedures for shift relief and turnovers to ensure current plant conditions and system status is conveyed to the oncoming shift.

Refer to subsection 18.I.C.6.F for a discussion of the independent verification to ensure the restoration of systems following repair or testing.

18.II.K.1.10 OPERABILITY STATUS

NRC Position (IE Bulletin No. 79-06B)

Review and modify as necessary your maintenance and test procedures to ensure that they require:

Verification, by test or inspection, of the operability of redundant safety-related systems prior to the removal of any safety-related system from service.

Verification of the operability of all safety-related systems when they are returned to service following maintenance or testing.

Explicit notification of involved reactor operational personnel whenever a safety-related system is removed from and returned to service.

PVNGS Evaluation

The PVNGS evaluation of item 18.I.C.6 adequately addresses the concerns of this item.

18.II.K.2 COMMISSION ORDERS ON BABCOCK & WILCOX PLANTS

(selected items applicable to PVNGS)

18.II.K.2.13 THERMAL MECHANICAL REPORT -- EFFECT OF HIGH-PRESSURE INJECTION ON VESSEL INTEGRITY FOR SMALL-BREAK LOSS-OF-COOLANT ACCIDENT WITH NO AUXILIARY FEEDWATER

NRC Position

A detailed analysis shall be performed of the thermal-mechanical conditions in the reactor vessel during recovery from small breaks with an extended loss of all feedwater.

PVNGS Evaluation

As an activity for the C-E Owners Group, Combustion Engineering has prepared CEN-189, "Evaluation of Pressurized Thermal Shock

Effects Due to Small Break LOCAs with Loss of Feedwater for the Combustion Engineering NSSS," December 1983. The report was transmitted to the NRC staff by letter dated December 31, 1981 from K. P. Baskin (C-E Owners Group) to D. G. Eisenhut.

The basic CEN-189 report presents methods applicable to all C-E NSSSs, and an appendix applying these methods to plant-specific parameters was provided for each docketed C-E plant at the time of submittal (December, 1981).

18.II.K.2.17 POTENTIAL FOR VOIDING IN THE REACTOR COOLANT SYSTEM DURING TRANSIENTS

NRC Position

Analyze the potential for voiding in the reactor coolant system (RCS) during anticipated transients.

PVNGS Evaluation

As an activity for the C-E Owners Group, Combustion Engineering has prepared CEN-199, "Effects of Vessel Head Voiding During Transients and Accidents in C-E NSSSs", March 1982.

18.II.K.3 FINAL RECOMMENDATIONS OF B&O TASK FORCE

18.II.K.3.2 REPORT ON OVERALL SAFETY EFFECT OF POWER-OPERATED RELIEF VALVE ISOLATION SYSTEM

NRC Position

(1) The licensee should submit a report for staff review documenting the various actions taken to decrease the probability of a small-break LOCA caused by a stuck-open, power-operated relief valve (PORV) and show

how those actions constitute sufficient improvements in reactor safety.

(2) Safety valve failure rates based on past history of the operating plants designed by the specific nuclear steam supply system (NSSS) vendor should be included in the report submitted in response to (1) above.

PVNGS Evaluation

PVNGS does not use pressurizer PORVs.

18.II.K.3.3 REPORTING SAFETY VALVE AND RELIEF VALVE FAILURES AND CHALLENGES

NRC Position (NUREG-0694)

Assure that any failure of a PORV or safety valve to close will be reported to the NRC promptly. All challenges to the PORVs or safety valves should be documented in the annual report.

PVNGS Evaluation

PVNGS does not use PORVs. Documentation of all failures and challenges to RCS safety valves shall be submitted in a monthly report, in accordance with Technical Specifications.

18.II.K.3.5 AUTOMATIC TRIP OF REACTOR COOLANT PUMPS DURING LOSS-OF-COOLANT ACCIDENT

NRC Position

Tripping of the reactor coolant pumps in case of a LOCA is not an ideal solution. Licensees should consider other solutions to the small-break LOCA problem (for example, an increase in safety injection flowrate). In the meantime, until a better

solution is found, the reactor coolant pumps should be tripped automatically in case of a small-break LOCA. The signals designated to initiate the pump trip are discussed in NUREG-0623.

PVNGS Evaluation

Arizona Public Service Company has participated with the Combustion Engineering Owner's Group (CEOG) in the resolution of Item II.K.3.5. The CEOG has submitted CEN-268, "Justification of Trip 2/Leave 2 Reactor Coolant Pump Trip Strategy During Transients" and CEN-152, Revision 02, "Emergency Procedure Guidelines" which pertain to the resolution of Item II.K.3.5. Also, the PVNGS Emergency Operating Procedures are based upon CEN-152 and incorporate the trip 2/leave 2 reactor coolant pump strategy of CEN-152, Revision 02.

18.II.K.3.17 REPORT ON OUTAGES OF EMERGENCY CORE COOLING SYSTEMS LICENSEE REPORT AND PROPOSED TECHNICAL SPECIFICATION CHANGES

NRC Position

Several components of the emergency core cooling (ECC) systems are permitted by technical specifications to have substantial outage times (e.g., 72 hours for one diesel generator; 14 days for the HPCI system). In addition, there are no cumulative outage time limitations for ECC systems. Licensees should submit a report detailing outage dates and lengths of outages for all ECC systems for the last 5 years of operation. The report should also include the causes of the outages (e.g., controller failures, spurious isolation).

PVNGS Evaluation

A program has been established for the collection of data related to outage dates, lengths of outages, cause of the outage, emergency core cooling systems (ECCS) or components involved in the outage, and the corrective action taken for the ECCS.

18.II.K.3.25 EFFECT OF LOSS OF ALTERNATING CURRENT POWER ON PUMP SEALS

NRC Position

The licensees should determine, on a plant-specific basis, by analysis or experiment, the consequences of a loss of cooling water to the reactor recirculation pump seal coolers. The pump seals should be designed to withstand a complete loss of alternating current (ac) power for at least 2 hours. Adequacy of the seal design should be demonstrated.

PVNGS Evaluation

The reactor coolant pump normal cooling water system (nuclear cooling water system (NCWS) is backed up by the essential cooling water system (ECWS) to supply cooling water to the seals during a loss of offsite power. In the event of a loss of offsite power, the operator can open the train A-NCWS crosstie valves from the control room, permitting the ECWS train A to supply cooling water to the reactor coolant pump seals. If train A fails, the operator must manually open the train B-NCWS crosstie valves and shut the train A crosstie valves to permit the same function. The crosstie of the ECWS to supply the NCWS priority heat loads is described in a PVNGS

Station Manual procedure which allows 10 minutes for the operator to align the ECWS. Also the, ECWS is described in subsection 9.2.2.

A test program was conducted to determine the effect on the reactor coolant pump seals due to a loss of component cooling water to the pump seal assembly. The test results demonstrate that the pumps will continue to operate for extended periods without exceeding design seal leakage limits and seal temperature limits. It has been shown that the System 80 reactor coolant pumps are capable of operating without component cooling water for 30 minutes without sustaining damage to the pump thrust bearings.

The preceding PVNGS Evaluation is the original response to Item II.K.3.25 of NUREG-0737, which is considered to be historical.

Updated PVNGS Evaluation

The current reactor coolant pump (RCP) water seals are a Sulzer seal design and can withstand the consequences of a loss of offsite power (LOP) for at least two hours with no cooling water available. The loss of cooling scenario should last approximately 30 minutes when seal injection is restored and cools the seals; after which there is no immediate need to restore seal cooling water flow.

The PVNGS design provides for non-safety related Nuclear Cooling (NC) water (i.e., component cooling water) to the RCP seal coolers and for class-powered seal injection from the Chemical and Volume Control System (CVCS). During a LOP, the RCPs would trip as would the NC water pumps; and seal cooling

by NC would be lost. Seal injection flow to the seals, which is provide by the class-powered charging pumps of the CVCS would initially be lost and then manually reestablished.

As described in Appendix 5C, section 3.1, the LOP also results in loss of instrument air which causes the RCP seal injection flow control valve to fail open and the individual CBO valves to fail-as-is, in the open position. The normal seal return flow path to the volume control tank (VCT) containment isolation valves close on loss of instrument air. The valve in the flow path to the CBO relief valve to the reactor drain tank (RDT) fails open, however, which ensure a flow path for the RCP seal CBO.

When the vital 4160 VAC buses are denergized by the LOP, the charging pump breakers must be manually reset and the pumps restarted from the control room. Therefore, no charging (or RCP seal injection) flow is assumed for 30 minutes. During this period, the RCP seals are exposed to RCS water at approximately 565 degrees F flowing through the open CBO pathway. The Sulzer seal assembly is designed to maintain integrity for periods in excess of 2 hours with approximately 600 degree F water during the LOP with no seal injection or (NC) water to the seal coolers. However, restoration of seal injection flow terminates the exposure of the seals to RCS temperatures.

Given the design capability of the seal assembly, the NRC position that the seals should be designed to withstand a loss of off-site power for at least two hours is achieved and the adequacy of the seal design demonstrated, with no restoration of cooling water to the seal coolers being required.

18.II.K.3.30 REVISED SMALL-BREAK LOSS-OF-COOLANT ACCIDENT METHODS TO SHOW COMPLIANCE WITH 10CFR PART 50 APPENDIX K

NRC Position

The analysis methods used by NSSS vendors and/or fuel suppliers for small-break LOCA analysis for compliance with Appendix K to 10CFR Part 50 should be revised, documented, and submitted for NRC approval. The revisions should account for comparisons with experimental data, including data from the LOFT Test and Semiscale Test facilities.

PVNGS Evaluation

In the summer of 1979, C-E prepared for the C-E Owner's Group (CEOG) two reports to the NRC, CEN-114-P and CEN-115-P, which use C-E's small-break LOCA evaluation model to predict typical pressurized water reactor (PWR) behavior following a small-break LOCA. These submittals were prepared in response to NRC requests following the TMI-2 accident. After review of these documents, the NRC identified a number of questions with the small-break model and requested a response to these questions.

At a meeting held on January 26, 1981, with members of the NRC staff and representatives of the CEOG and C-E, the NRC described seven specific questions concerning the C-E small-break LOCA evaluation model. The NRC staff also indicated that responding to these seven questions would fulfill the response to Item II.K.3.30 of the NRC TMI Action Plan. In March 1982, report CEN-203-P, Revision 1-P, which contained the answers to the seven NRC questions, was submitted

to the NRC. This report provided justification for maintaining approval of the C-E small-break LOCA evaluation model. In August 1983, the NRC issued a letter to the CEOG asking eight additional questions with the subject title "Request Number 1 for Additional Information on CEN-203-P". Responses to five of the eight additional questions were provided in Supplement 1-P to CEN-203-P, Revision 1-P. Responses to the three remaining questions dealing with steam generator modeling were provided in Supplement 2-P to CEN-203-P, Revision 1-P. In keeping with the intent of report CEN-203-P, these supplementary responses continued to justify the conservatism of the currently approved C-E small-break LOCA evaluation model.

During a meeting held on October 4, 1984, in Windsor with CEOG, NRC, and C-E representatives, the NRC indicated that without a post-test analysis of Semiscale Test S-UT-8 the responses to the steam generator modeling questions were insufficient. Subsequently, in March 1985, the C-E Owner's Group committed to provide to NRC a confirmatory post-test analysis of Semiscale Test S-UT-8 to show the acceptability of the steam generator thermal-hydraulic models of CEFLASH-4AS to calculate the Test S-UT-8 preloop seal clearing core level depression.

The NRC completed the review of CEN-203-P and Supplements 1-P and 2-P in June 1985, and issued a conditional Safety Evaluation Report. The NRC staff concluded that the material submitted, which justified the conservatism of the C-E small-break LOCA evaluation model, was acceptable pending one condition. The one condition required "...confirmation that the CEFLASH-4AS computer program can acceptably calculate core level depression, prior to clearing of the reactor coolant pump

loop seals, as observed in the data from Semiscale Test S-UT-8."

In response to the NRC's conditional Safety Evaluation Report, a post-test analysis was submitted for Semiscale Test S-UT-8. This analysis also fulfilled a CEOG commitment to the NRC, made prior to the issuance of the Safety Evaluation Report, to submit a post-test analysis of Test S-UT-8. The results of the post-test analysis confirmed that C-E's small-break LOCA thermal-hydraulic computer code, CEFLASH-4AS, can acceptably calculate core level depression, prior to clearing of the reactor coolant pump loop seals, as observed in the data from Semiscale Test S-UT-8. These results were discussed with NRC representatives (R. Jones, et al.) in a meeting on October 30, 1985.

The post-test analysis included first, a best-estimate analysis, which showed overall excellent agreement with the Test S-UT-8 data. Then, specific best estimate component models important for steam generator liquid holdup and preloop seal clearing core uncovery were replaced by their C-E small-break LOCA evaluation model counterparts. This best estimate/evaluation model analysis compare well to the depth and duration of the core uncovery data and conservatively underpredicts the core coolant levels after loop seal clearing. This demonstrates that the C-E small-break LOCA evaluation model incorporates component modes which permit acceptable prediction of Test S-UT-8 type core uncovery. Thus, the condition in the Safety Evaluation Report is satisfied and TMI Action Plan Item II.K.3.30 is considered closed.

18.II.K.3.31 PLANT-SPECIFIC CALCULATIONS TO SHOW COMPLIANCE WITH 10CFR PART 50.46

NRC Position

Plant-specific calculations using NRC-approved models for small-break LOCAs as described in Item II.K.3.30 to show compliance with 10CFR50.46 should be submitted for NRC approval by all licensees.

PVNGS Evaluation

Reports submitted in response to TMI Action Plan Item II.K.3.30 show that using the currently approved C-E small-break LOCA evaluation model results in conservatively high cladding temperatures for the break spectrum analysis of a nuclear steam supply system. Therefore, the need for submittal of new small break analyses in accordance with TMI Action Plan Item II.K.3.31 is obviated and this item is considered closed.

This page intentionally left blank

18.III EMERGENCY PREPAREDNESS AND RADIATION EFFECTS

18.III.A NRC AND LICENSEE PREPAREDNESS

18.III.A.1.1 UPGRADE EMERGENCY PREPAREDNESS

NRC Position (NUREG-0694)

(1) Comply with 10CFR50, Appendix E

Comply with Appendix E, Emergency Facilities, to 10CFR Part 50, and for the offsite plans, or have a favorable finding from Federal Emergency Management Agency (FEMA).

(2) Comply with NUREG-0654

Provide an emergency response plan in substantial compliance with NUREG-0654, Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants, except that only a description of and completion schedule for the means for providing prompt notification to the population, the staffing for emergencies in addition to that already required, and an upgraded meteorological program need be provided. The NRC will give substantial weight [to FEMA] findings on offsite plans in judging the adequacy against NUREG-0654.

(3) Conduct Exercise

Perform an emergency response exercise to test the integrated capability and a major portion of the basic elements existing within emergency preparedness plans and organizations.

NRC Position (Continued)

(4) Meteorological Data (NUREG-0737, Item III.A.2)

Revision 1 to NUREG-0654, Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants, provides meteorological criteria to fulfill, in part, the standard that "Adequate methods, systems, and equipment for assessing and monitoring actual or potential offsite consequences of a radiological emergency condition are in use" (see 10CFR50.47). The position in Appendix 2 to NUREG-0654 outlines four essential elements that can be categorized into three functions: measurements, assessment, and communications. The four essential elements are as follows:

(a) Establish an adequate operational meteorological measurement program.

(b) Provide backup systems/procedures to obtain real-time local meteorological data.

(c) Establish a system for making real-time, site specific estimates and predictions of atmospheric effluent transport and diffusion during and immediately following an accidental airborne radioactivity release.

(d) Provide the capability for remote interrogation of systems producing meteorological data and effluent transport and diffusion elements.

PVNGS Evaluation

(1) Comply with 10CFR50, Appendix E

The PVNGS emergency plan submitted with the FSAR complies with Appendix E, Emergency Facilities, to 10CFR Part 50. The Arizona Division of Emergency Services prepared a comprehensive emergency response plan for fixed nuclear facilities which incorporated actions to be taken by levels of government within the State of Arizona. This plan was found acceptable by FEMA.

(2) Comply with NUREG-0654

The PVNGS emergency plan addresses the emergency planning criteria contained in NUREG-0654, including a description of the means for providing prompt notification to the public, staffing for emergencies, and an upgraded meteorological program. The comprehensive emergency response plan for fixed nuclear facilities has been developed by the Arizona Division of Emergency Services, and addresses the emergency planning criteria contained in NUREG-0654.

(3) Conduct Exercise

ANPP has conducted emergency response exercises which have been evaluated by the NRC.

(4) Meteorological Data

The PVNGS meteorology atmospheric transport and diffusion assessment program has been established using the guidance of NUREG-0654 (Revision 1) and Regulatory Guide 1.23 (Revision 0). A meteorological tower shall be operated with the following instrumentation:

- Temperature (35 foot)[a]
- Differential temperature (DT nominal 195-35[a] foot) one channel
- Precipitation (ground)
- Dewpoint (35 foot)
- Windspeed (35 and 200 nominal foot)[a]
- Wind direction (35 and 200 nominal foot)[a]

Display of meteorological indications is available in the control room by use of the ERFDADS display and via dialup using a personal computer located at the STA station. Additionally, displays are available at the following locations:

- Technical support center (TSC)
- Satellite TSC in each unit
- Emergency operation facility (EOF)

a. Redundant sensors are provided as backups to the primary sensors.

In the event the PVNGS meteorological monitoring system is unavailable, the National Weather Service (NWS), Phoenix office, has an instrumentation unit which can be brought to the plant site to provide backup meteorological information during emergencies.

The NWS also establishes a facility at the State Emergency Operation Center (EOC) when it is fully activated.

Further information about the PVNGS meteorological system, the criteria it was designed to, and the regulatory guides and NUREG requirements it satisfies, is provided in paragraph 2.3.3.1.

18.III.A.1.2 UPGRADE EMERGENCY SUPPORT FACILITIES

NRC Position (NRC Generic Letter 82-33, Supplement 1 to NUREG-0737, Requirements for Emergency Response Capability)

1. Regulations

   10CFR50.47(b)(6) (for Operating License applicants) -- Requirement for prompt communications among principal response organizations and to emergency personnel and to the public.

   10CFR50.47(b)(8) -- Requirement for emergency facilities and equipment to support emergency response.

   10CFR50.47(b)(9) -- Requirement that adequate methods, systems and equipment for assessing and monitoring

NRC Position (Continued)

actual or potential offsite consequences of a radiological emergency condition are in use.

10CFR50.54(q) (for Operating Reactors) -- Same requirement as 10CFR50.47(b) plus 10CFR50, Appendix E.

10CFR50, Appendix E, Paragraph IV.E

Requirement for:

"1. Equipment at the site for personnel monitoring;"

"2. Equipment for determining the magnitude of and for continuously assessing the impact of the release of radioactive materials to the environment;"

"3. Facilities and supplies at the site for decontamination of onsite individuals;"

"4. Facilities and medical supplies at the site for appropriate emergency first aid treatment;"

"5. Arrangements for the services of physicians and other medical personnel qualified to handle radiation emergencies onsite;"

"6. Arrangements for transportation of contaminated injured individuals from the site to specifically identified treatment facilities outside the site boundary;"

"7. Arrangements for treatment of individuals injured in support of licensed activities of the site at treatment facilities outside the site boundary;"

NRC Position (Continued)

"8. A licensee onsite technical support center and a licensee near-site emergency operations facility from which effective direction can be given and effective control can be exercised during an emergency;"

"9. At least one onsite and one offsite communications system; each system shall have a backup power source."

All communication plans shall have arrangements for emergencies, including titles and alternates for those in charge at both ends of the communication links and the primary and backup means of communication. Where consistent with the function of the governmental agency, these arrangements will include:

"a. Provision for communications with contiguous State/local governments within the plume exposure pathway (emergency planning zone) EPZ. Such communications shall be tested monthly."

"b. Provisions for communication with Federal emergency response organizations. Such communication systems shall be tested annually."

NRC Position (Continued)

"c. Provision for communications among the nuclear power reactor control room, the onsite technical support center, and the near-site emergency operations facility; and among the nuclear facility, the principal State and local emergency operations centers, and the field assessment teams. Such communications systems shall be tested annually."

"d. Provisions for communication by the licensee with NRC Headquarters and the appropriate NRC Regional Office Operations Center from the nuclear power reactor control room, the onsite technical support center, and the near-site emergency operations facility. Such communications shall be tested monthly."

Within this section on emergency response facilities, the technical support center (TSC), operational support center (OSC), and emergency operations facility (EOF) are addressed separately in terms of their functional statements and recommended requirements. The subsections on documentation and NRC review and reference documents that follow the EOF discussion apply to this entire section on emergency response facilities.

NRC Position (Continued)

2. Technical Support Center (TSC)

2.1 Requirements

a. The TSC is the onsite technical support center for emergency response. When activated, the TSC is staffed by predesignated technical, engineering, senior management, and other licensee personnel, and five predesignated NRC personnel. During periods of activation, the TSC will operate uninterrupted to provide plant management and technical support to plant operations personnel, and to relieve the reactor operators of peripheral duties and communications not directly related to reactor system manipulations. The TSC will perform EOF functions for the alert emergency class and for the site area emergency class and general emergency class until the EOF is functional.

The TSC will be:

b. Located within the site-protected area so as to facilitate necessary interaction with control room, OSC, EOF, and other personnel involved with the emergency.

c. Sufficient to accommodate and support NRC and licensee predesignated personnel, equipment, and documentation in the center.

NRC Position (Continued)

d. Structurally built in accordance with the Uniform Building Code.

e. Environmentally controlled to provide room air temperature, humidity, and cleanliness appropriate for personnel and equipment.

f. Provided with radiological protection and monitoring equipment necessary to assure that radiation exposure to any person working in the TSC would not exceed 5 rem whole-body, or its equivalent to any part of the body, for the duration of the accident.

g. Provided with reliable voice and data communications with the control room and EOF and reliable voice communications with the OSC, NRC Operations Centers, and state and local operations centers.

h. Capable of reliable data collection, storage, analysis, display and communication sufficient to determine site and regional status, determine changes in status, forecast status and take appropriate actions. The following variables shall be available in the TSC:

(i) the variables in the appropriate Table 1 or 2 of Regulatory Guide 1.97 (Rev. 2) that are essential for performance of TSC functions; and

NRC Position (Continued)

(ii) the meteorological variables in Regulatory Guide 1.97 (Rev. 2) for site vicinity and National Weather Service data available by voice communication for the region in which the plant is located.

Principally those data must be available that would enable evaluating incident sequence, determining mitigating actions, evaluating damages, and determining plant status during recovery operations.

i. Provided with accurate, complete, and current plant records (drawings, schematic diagrams, etc.) essential for evaluation of the plant under accident conditions.

j. Staffed by sufficient technical, engineering, and senior designated licensee officials to provide needed support, and be fully operational within approximately 1 hour after activation.

k. Designed taking into account good human factors engineering principles.

3. Operations Support Center (OSC)

3.1 Requirements

a. When activated, the OSC will be the onsite area separate from the control room where pre-designated

NRC Position (Continued)

operations support personnel will assemble. A pre-designated licensee official shall be responsible for coordinating and assigning the personnel to tasks designated by control room, TSC, and EOF personnel.

The OSC will be:

b. Located onsite to serve as an assembly point for support personnel and to facilitate performance of support functions and tasks.

c. Capable of reliable voice communications with the control room, TSC, and EOF.

4. Emergency Operations Facility (EOF)

4.1 Requirements

a. The EOF is a licensee controlled and operated facility. The EOF provides for management of overall licensee emergency response, coordination of radiological and environmental assessment, development of recommendations for public protective actions, and coordination of emergency response activities with Federal, State, and local agencies.

When the EOF is activated, it will be staffed by pre-designated emergency personnel identified in the emergency plan. A designated senior licensee

NRC Position (Continued)

official will manage licensee activities in the EOF.

Facilities shall be provided in the EOF for the acquisition, display and evaluation of radiological and meteorological data and containment conditions necessary to determine protective measures. These facilities will be used to evaluate the magnitude and effects of actual or potential radioactive releases from the plant and to determine dose projections.

The EOF will be:

b. Located and provided with radiation protection features as described in Table 1 (previous guidance approved by the Commission) and with appropriate radiological monitoring systems.

c. Sufficient to accommodate and support Federal, State, local, and licensee pre-designated personnel, equipment and documentation in the EOF.

d. Structurally built in accordance with the Uniform Building Code.

e. Environmentally controlled to provide room air temperature, humidity, and cleanliness appropriate for personnel and equipment.

f. Provided with reliable voice and data communications facilities to the TSC and control

NRC Position (Continued)

room, and reliable voice communication facilities to OSC and to NRC, State, and local emergency operations centers.

g. Capable of reliable collection, storage, analysis, display, and communication of information on containment conditions, radiological releases, and meteorology sufficient to determine site and regional status, determine changes in status, forecast status, and take appropriate actions. Variables from the following categories that are essential to EOF functions shall be available in the EOF:

   (i) variables from the appropriate Table 1 or 2 of Regulatory Guide 1.97 (Rev. 2), and

Table 1

EMERGENCY OPERATIONS FACILITY

Option 1
Two Facilities

Close-in Primary: Reduce Habitability*

- within 10 miles
- protection factor = 5
- ventilation isolation with HEPA (no charcoal)

Backup EOF

- between 10-20 miles
- no separate, dedicated facility
- arrangements for portable backup equipment
- strongly recommended location be coordinated with offsite authorities
- continuity of dose projection and decision making capability

Option 2
One Facility

- At or Beyond 10 miles.
- No special protection factor.
- If beyond 20 miles, specific approval required by the Commission, and some provision for NRC site team closer to site.
- Strongly recommended location be coordinated with offsite authorities.

For both Options:

- located outside security boundary
- space for about 10 NRC employees
- none designated for severe phenomena, e.g.,
- earthquakes

*Habitability requirements are only for the part of the EOF in which dose assessments communications and decision making take place.

If a utility has begun construction of a new building for an EOF that is located with 5 miles, that new facility is acceptable (with less than protection factor of 5 and ventilation isolation and HEPA) provided that a backup EOF similar to "B" in Option 1 is provided.

NRC Position (Continued)

(ii) the meteorological variables in Regulatory Guide 1.97 (Rev. 2) for site vicinity and regional data available via communication from the National Weather Service.

h. Provided with up to date plant records (drawings, schematic diagrams, etc.), procedures, emergency plans, and environmental information (such as geophysical data) needed to perform EOF functions.

i. Staffed using Table 2 (previous guidance approved by the Commission) as a goal. Reasonable exceptions to goals for the number of additional staff personnel and response times for their arrival should be justified and will be considered by NRC staff.

j. Provided with industrial security when it is activated to exclude unauthorized personnel and when it is idle to maintain its readiness.

k. Designed taking into account good human factors engineering principles.

NRC Position (Continued)

*For each unaffected nuclear unit in operation, maintain at least one shift foreman, one control room operator, and one auxiliary operator except that units sharing a control room may share a shift foreman if all functions are covered.

**May be provided by shift personnel assigned other functions.

***Overall direction of facility response to be assumed by EOF director when all centers are fully manned. Direction of minute-to-minute facility operations remains with senior manager in technical support center or control room.

****May be performed by engineering aide to shift supervisor.

PVNGS Evaluation

The position of Shift Manager at PVNGS is equivalent to the shift supervisor position referred to in table 2 of the NRC position above.

A. Operations Support Center (OSC)

An area separate from the unit control rooms has been designated as the Palo Verde Nuclear Generating Station (PVNGS) onsite OSC. This is an assembly area where plant operations support personnel will report to in an emergency situation for further orders or assignment. The OSC is located in each unit at elevation 140 feet 0 inch of the auxiliary and operations support buildings, adjacent to the main access corridor into the radiological control area (see engineering drawings 13-P-OOB-001 and 13-P-OOB-005). The OSC has communication with the control room and the onsite TSC. The emergency plan reflects the existence of the OSC and establishes the methods and lines of communication and management.

B. Onsite Technical Support Center (TSC) and Satellite TSCs

An onsite TSC and the satellite TSCs for PVNGS have been established and are fully operational prior to fuel load for each Palo Verde unit. The TSC is an underground structure of approximately 10,000 square feet of area located within the site protected area adjacent to the main entry into the plant protected

area (see engineering drawings 13-P-OOB-001 and A0-A-ZYD-187). The TSC provides a work area for supervisory and technical personnel from Arizona Public Service Company and the NRC. It has communications with the control room and the other response centers. Satellite TSCs have been established adjacent to the control room in each unit to facilitate face to face communications between control room personnel and support personnel.

The satellite TSC has the same display capabilities as the main TSC (see engineering drawings 13-P-OOB-001 and 13-P-OOB-005). An analysis has been performed to determine equipment to be incorporated into the TSC to monitor and display the status of the affected unit. Display of data at the TSC is in accordance with NUREG-0696. The TSC will be habitable to permit occupancy following a loss of coolant accident. Monitoring equipment will be provided for direct and airborne radioactive contaminants to provide warning if radiation levels in the TSC are reaching dangerous levels. The TSC has permanently installed radiation monitoring and filtered ventilation systems. As-built drawings and other appropriate records will be available in readily retrievable form at the site and will be accessible to the TSC. The TSC HVAC system is designed and tested using Regulatory Guide 1.52. Regulatory Guide 1.52 is used to supply technical guidance in the performance of testing.

B.1 Radiological Design Bases

The TSC is provided with radiological protection to assure that radiation exposure to any person working in the TSC during an accident would not exceed 5 rem whole-body, or its equivalent 30 rem to any part of the body, for the duration of the accident.

B.1.1 HVAC System

The TSC essential HVAC system is a single ventilation train, that consists of a nuclear air treatment system (NATS). The location of components and ducting within the TSC envelope ensures an adequate supply of filtered air to all areas requiring access. The essential ventilation system is also used for normal operation. The TSC pressure is maintained at a positive pressure (above atmospheric pressure) compared to adjacent areas during emergency operation. This insures that inleakage to habitable areas is kept at a minimum. The system parameters are as follows:

Table 18.III.A-3
Essential TSC HVAC System Parameters

Essential outside air intake (SCFM)	less than 2100
Recirculation flow through charcoal filtration (SCFM)	8900 +/- 10%
Total unfiltered system inleakage (SCFM) (Includes 10 SCFM for personnel ingress/egress)	Less than 30 SCFM
Charcoal bed thickness	2 inch
TSC free volume (SCF)	1.18E+05

B.1.2 Radiological Evaluation

The TSC NATS system and shielding designs are based on the most limiting design basis assumptions contained in NRC Regulatory Guide 1.4, and source term is based on Technical Information Document TID-14844 U.S. Atomic Energy Commission, March 23, 1962.

At time zero or during the initiating event the essential system is continuously in operation, there are no changes in HVAC system configuration at the initiating event.

The airborne fission product source term in the reactor containment following the postulated LOCA is assumed to leak from the containment at a rate of 0.1% per day for the first 24 hours after the accident, and 0.05% per day thereafter. For a more complete discussion of LOCA refer to section 15.6.

The concentration of radioactivity, which is postulated to surround the TSC after the postulated accident, is evaluated as a function of the fission product decay constants, the containment spray system effectiveness, the containment leak rate, and the meteorology conditions in effect. The assessment of the amount of radioactivity within the TSC takes into consideration the flowrate through the TSC outside air intake, the effectiveness of the TSC NATS, the radiological decay of fission products, and the exfiltration rate from the TSC.

Air within the TSC is recirculated continuously through the emergency air conditioning units, which contain high efficiency filters, charcoal adsorbers, HEPA after-filters, cooling coil, and fan, to control and reduce airborne radioactivity. The outside air required for pressurization is mixed with the return air as it enters the NATS.

The TSC HVAC is designed to pressurize the TSC to minimize unfiltered system inleakage. As required by standard review plan, an additional 10 SCFM inleakage has been assumed during personnel ingress/egress.

The calculated doses as a result of a postulated LOCA are given in tables 18.III.A-5. Refer to section 15.6.5 and table 15.6.5-2.

Table 18.III.A-4

TSC Habitability Parameters

Time After Accident	**Short Term X/Q**	**Occupation Factor**	**Breathing Rate**
	Sec/m^3		m^3/Sec
0 - 8 hrs	8.552E-4	1.0	3.47E-4
8 - 24 hrs	5.766E-4	1.0	1.75E-4
1 - 4 days	1.994E-4	0.6	2.32E-4
4 - 30 days	2.546E-5	0.4	2.32E-4

Table 18.III.A-5

TSC Occupant 30 Day Exposure (REM)

	Thyroid	Whole-Body	Beta Skin
Internal Cloud Exposure	15.5	1.17	26.0
Direct dose due to Iodine build-up on charcoal filtration	N/A	0.10	N/A
Total	15.5	1.27	26.0

TSC shielding design is based on the most limiting design basis LOCA fission product release. The evaluations demonstrate that the only source of direct radiation exposures to TSC occupants is the NATS, housed plant north of TSC facility at the same elevation. All other direct radiation sources such as containment/RWT direct shine and external cloud, have a negligible contribution to occupant dose since TSC facility is built below ground elevation. Total exposures resulting from Design Basis Accident are below the dose limits specified by General Design Criterion 19.

B.1.3 Testing and Inspection

The NATS will be tested periodically by standard methods in general conformance with Regulatory Guide 1.52, as noted in section 1.8.

HEPA filter banks are tested in-place prior to operation and periodically thereafter in conformance with ANSI N510, and comply with Position C.5.c of Regulatory Guide 1.52, except as noted in section 1.8.

Impregnated, activated carbon is batch tested prior to loading into the adsorber section. Acceptance criteria are those described in Table 5.1 of ANSI N509-1980 version. The carbon adsorber section is filled with carbon in a manner to ensure a uniform packing density and to minimize dusting. In addition, a periodic laboratory test of a representative sample

of the impregnated activated carbon is performed to verify iodine removal efficiencies in accordance with Position C.6 and Table 2 of Regulatory Guide 1.52 for the assigned decontamination efficiency and bed depth.

The PVNGS emergency plan has been revised to describe the TSC and its function.

B.2.0 HVAC SYSTEM OPERATION

The TSC essential HVAC system consists of a nuclear air treatment system (NATS) that includes: Hepa filters, a charcoal adsorber and an environmental cooling system. The NATS is used for protection against airborne radioactivity and controlling the environment of the TSC. Air within the TSC is continuously recirculated through the NATS and cooling system components. The components are arranged in the following order: NATS air heater (for adsorber humidity control) high efficiency prefilters, HEPA filters, charcoal adsorber, HEPA after-filters, NATS fan, cooling coil, and cooling system fan.

The TSC essential HVAC system is normally engaged in a filtration mode utilizing the above system except when maintenance is performed. The location of components and ducting within the TSC envelope ensures an adequate supply of filtered air to all areas requiring access.

C. Emergency Operations Facility (EOF)

The information presented in section C (with exception of C.3) is historical and has been preserved in its original context. The following PVNGS Evaluation is the original response to Item 18.III.A.1.2 Upgrade Emergency Support Facilities.

An EOF for PVNGS has been established and is operational. This facility is located outside of the protected area and occupies approximately 6000 square feet of the basement floor in the Technical Training building “E” (see engineering drawings 13-P-OOB-001 and A0-A-ZYD-101). The EOF provides space for operations personnel in support of the TSC. Plant personnel will be able to evaluate the magnitude and effect of radioactive releases from the plant and recommend appropriate protective measures. A study has been conducted to determine analysis and monitoring equipment required. Display of data at the EOF is in accordance with NUREG-0696 and Supplement 1 to NUREG-0737. Communications with the TSC are provided.

The EOF provides space for recovery operations following an accident as well as training facilities for the site.

The PVNGS emergency plan describes the EOF and its functions.

Additionally, the display of those plant parameters recommended by Regulatory Guide 1.97, Revision 2, is addressed in section 1.8.

The EOF HVAC system is designed and tested using Regulatory Guide 1.52. Regulatory Guide 1.52 is used to supply technical guidance in the performance of testing.

C.1 Radiological Design Bases

The EOF is provided with radiological protection to assure that radiation exposure to any person working in the EOF during an accident would not exceed 5 rem whole-body, or its equivalent 30 rem to any part of the body, for the duration of the accident.

C.1.1 HVAC System

The EOF essential HVAC system is a single ventilation train, that consists of a nuclear air treatment system (NATS). The location of components and ducting within the EOF envelope ensures an adequate supply of filtered air to all areas requiring access. The essential ventilation system is also used for normal operation. The EOF pressure is maintained at a positive pressure (above atmospheric pressure) compared to adjacent areas during emergency operation.

This insures that inleakage to habitable areas is kept at a minimum. The system parameters are as follows:

Table 18.III.A-6
Essential EOF HVAC System Parameters

Essential outside air intake (SCFM)	less than 2100
Recirculation flow through charcoal filtration (SCFM)	4400 +/- 10%
Total unfiltered system inleakage (SCFM)	Less than 30 SCFM
Charcoal bed thickness	2 inch
EOF free volume (SCF)	1.19E+05

C.1.2 Radiological Evaluation

The EOF NATS and shielding designs are based on the most limiting design basis assumptions contained in NRC Regulatory Guide 1.4, and the source term is based on Technical Information Document TID-14844 U.S. Atomic Energy Commission, March 23, 1962.

Since the essential system is continuously in operation, there are no changes in HVAC system configuration at the initiating event.

The airborne fission product source term in the reactor containment following the postulated LOCA is assumed to leak from the containment at a rate of 0.1% per day for the first 24 hours after the accident, and 0.05% per day thereafter. For a more complete discussion of LOCA refer to section 15.6.

The concentration of radioactivity, which is postulated to surround the EOF after the postulated

accident, is evaluated as a function of the fission product decay constants, the containment spray system effectiveness, the containment leak rate, and the meteorology conditions in effect. The assessment of the amount of radioactivity within the EOF takes into consideration the flowrate through the EOF outside air intake, the effectiveness of the EOF NATS, the radiological decay of fission products, and the exfiltration rate from the EOF.

Air within the EOF is recirculated continuously through the emergency air conditioning units, which contain high efficiency filters, charcoal adsorbers, HEPA after-filters, cooling coil and fan, to control and reduce airborne radioactivity. The outside air required for pressurization is mixed with the return air as it enters the NATS.

The EOF HVAC is designed to pressurize the EOF to minimize unfiltered system inleakage. As required by standard review plan additional 10 SCFM inleakage has been assumed during personnel ingress/egress.

The calculated doses as a result of a postulated LOCA are given in table 18.III.A-8. Refer to section 15.6.5 and table 15.6.5-2.

Table 18.III.A-7

EOF Habitability Parameters

Time After Accident	Short Term X/Q Sec/m^3	Occupation Factor	Breathing Rate m^3/Sec
0 - 8 hrs	8.864E-4	1.0	3.47E-4
8 - 24 hrs	6.126E-4	1.0	1.75E-4
1 - 4 days	2.241E-4	0.6	2.32E-4
4 - 30 days	4.434E-5	0.4	2.32E-4

Table 18.III.A-8

EOF Occupant 30 Day Exposure (REM)

	Thyroid[1]	Whole-Body	Beta Skin
Internal Cloud Exposure	28.5	1.23	26.5
Direct dose due to Iodine build-up on charcoal filtration	N/A	0.00[2]	N/A
Total	28.5	1.23	26.5

1. Primary EOF is within 10 miles from PVNGS. The applicable criterion for acceptability is 10 CFR 50 Appendix A, GDC 19, PVNGS does not calculate or apply a protection factor of 5 as stated in NUREG 0737. The 10 CFR 50 criteria is more limiting than NUREG 0737.

2. The EOF facility is located below ground elevation and the NATS filter unit is at ground level (plant elevation ~ 100). There is no direct line of sight between the filtration unit and occupant of EOF. The filtration unit is shielded by earth and therefore contribution from the filtration unit due to built up iodine is neglected.

EOF shielding design is based on the most limiting design basis LOCA fission product release. The evaluations demonstrate that there are no sources of direct radiation exposures to EOF occupants. All other direct radiation sources such as containment/RWT direct shine and external cloud, have a negligible contribution to occupant dose since EOF facility is built below ground elevation. Total exposures resulting from Design Basis Accident are below the dose limits specified by General Design Criterion 19.

C.1.3 Testing and Inspection

The NATS will be tested periodically by standard methods in general conformance with Regulatory Guide 1.52.

HEPA filter banks are tested in-place prior to operation and periodically thereafter in conformance with ANSI N510, and comply with Position C.5.c of Regulatory Guide 1.52.

Impregnated, activated carbon is batch tested prior to loading into the adsorber section. Acceptance criteria are those described in Table 5.1 of ANSI N509-1980 version. The carbon adsorber section is filled with carbon in a manner to ensure a uniform packing density and to minimize dusting. In addition, a periodic laboratory test of a representative sample of the impregnated activated carbon is performed to verify iodine removal efficiencies in accordance with Position

C.6 and Table 2 of Regulatory Guide 1.52 for the assigned decontamination efficiency and bed depth.

C.2. HVAC System Operation

The EOF essential HVAC system consists of a nuclear air treatment system (NATS) that includes: Hepa filters, a charcoal adsorber and an environmental cooling system.

The NATS is used for protection against airborne radioactivity and controlling the environment of the EOF. Air within the TSC is continuously recirculated through the NATS and cooling system components. The components are arranged in the following order: NATS air heater (for adsorber humidity control) high efficiency prefilters, HEPA filters, charcoal adsorber, HEPA after-filters, NATS fan, cooling coil, and cooling system fan.

The EOF essential HVAC system is normally engaged in a filtration mode utilizing the above system except when maintenance is performed. The location of components and ducting within the TSC envelope ensures an adequate supply of filtered air to all areas requiring access.

C.3 New Emergency Operations Facility (EOF)

EOF and new Joint Information Center (JIC) was added to the Emergency Plan, the Back-up EOF was removed as the regulatory basis for a back-up facility no longer exists due to the new EOF being located greater than 10 miles from PVNGS. The Radiation Protection Support Technician position was removed due to the lack of a need for

radiological protection within the new facility given its distance from the site. New EOF added as an Alternate response facility for the TSC and OCS staff addressing item 4. in the NRC Bulletin 2005-02.

D. Minimum Staffing Requirements for PVNGS Emergency Response

PVNGS Emergency Plan Table 1 "Minimum Staffing Requirements for PVNGS for Nuclear Power Plant Emergencies" is the PVNGS response to the NRC position shown in UFSAR 18.III.A.1.2 Table 2.

NUREG-0737 Supplement 1 Table 2, which is the NRC position shown in UFSAR 18.III.A.1.2 Table 2, incorrectly stated the title of NUREG-0654. NUREG-0654 is entitled, "Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants."

18.III.A.2 IMPROVING LICENSEE EMERGENCY PREPAREDNESS – LONG-TERM

NRC Position

Each nuclear facility shall upgrade its emergency plans to provide reasonable assurance that adequate protective measures can and will be taken in the event of a radiological emergency. Specific criteria to meet this requirement are delineated in NUREG-0654 (FEMA-REP-1), Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparation in Support of Nuclear Power Plants.

PVNGS Evaluation

PVNGS response to this item is included in the evaluation of NUREG-0737, Item III.A.1.1, requirements. Refer to subsection 18.III.A.1.1.

This page intentionally left blank

18.III.D RADIATION PROTECTION

18.III.D.1.1 INTEGRITY OF SYSTEMS OUTSIDE CONTAINMENT LIKELY TO CONTAIN RADIOACTIVE MATERIAL FOR PRESSURIZED WATER REACTORS AND BOILING WATER REACTORS

NRC Position

Applicants shall implement a program to reduce leakage from systems outside containment that would or could contain highly radioactive fluids during a serious transient or accident to as low as practical levels. This program shall include the following:

(1) Immediate Leak Reduction

(a) Implement all practical leak reduction measures for all systems that could carry radioactive fluid outside of containment.

(b) Measure actual leakage rates with system in operation and report them to the NRC.

(2) Continuing Leak Reduction -- establish and implement a program of preventive maintenance to reduce leakage to as low as practical levels. This program shall include periodic integrated leak tests at intervals not to exceed each refueling cycle.

PVNGS Evaluation

1. Design Review

A PVNGS design review was performed on the systems below to assure that potential radioactive release paths

following a serious transient or accident is reduced to as-low-as-reasonably achievable (ALARA) levels.

A. Shutdown Cooling System (SCS)

The existing design incorporates all-welded piping. Vent and drain lines throughout the system are capped when practical. Relief valves on the system (external to containment) relieve to the equipment drain tank (a tank designed to accept radioactive fluids). The leakage from the LPSI pump seals and system valve stems is ALARA. Potential leakage from the SCS into the essential cooling water system (through the shutdown cooling heat exchanger) can be detected during normal operation by installed radiation monitoring.

B. Containment Spray Recirculation System (CS)

The existing design incorporates all-welded piping. Vent and drain lines throughout the system are capped when practical. Relief valves on the system (external to the containment) relieve to the equipment drain tank. The leakage from the CS pump seals and system valve stems is ALARA. Potential leakage during normal operation from the CS into the essential cooling water system (through the shutdown cooling heat exchanger) can be detected by installed radiation monitoring.

C. Chemical and Volume Control System (CVCS) Charging and Letdown System

The existing design incorporates all-welded piping. The letdown system isolates upon initiation of the containment isolation actuation system (CIAS) and the safety injection actuation system (SIAS). Relief valves in the system relieve to the equipment drain tank.

The leakage from the CVCS charging pumps (positive displacement pumps) and other system equipment is ALARA as they are hard-piped to drains. The nuclear cooling water system is monitored for potential leakage from the CVCS through the letdown heat exchanger during normal operation.

D. Sampling System

The design of the normal sampling system, which would come into contact with post-accident fluids, consists of all-welded piping for the portion of the system that isolates upon CIAS and SIAS up to the instrument root valve. Downstream of the instrument root valve, external to cabinets, the use of "Swagelok" connections has been minimized. Relief valves relieve to the equipment drain tank. Leakage from the systems is minimized by the small size of the lines.

E. High-Pressure Injection Recirculation (HPSI)

The design incorporates all-welded piping. Relief valves in the system that are exposed to highly radioactive fluids during the recirculation mode of operation (external to the containment) relieve to the equipment drain tank. The vent and drain lines throughout the system are capped when practical. Leakage from the HPSI pump seals and system valve stems is ALARA. Miniflow connections to the refueling water tank (RWT) are isolated upon the recirculation actuation signal (RAS). Manual cross-over valves to the CVCS are normally locked shut.

F. Waste Gas System

The waste gas system isolates from the containment upon initiation of CIAS. (The normal vent path from the reactor drain tank (RDT) and the reactor head vent system is isolated.) By design, the introduction of highly radioactive fluids to the system is precluded.

As part of the system testing program, each of the above systems is hydrostatically tested to 150% normal operating pressure per the requirements of ANSI B31.1, Summer 1976 Addendum for ANSI B31.1 piping systems, and to 125% normal operating pressure per the requirements of ASME Boiler & Pressure Vessel Code, Section III, 1977 Edition, for ASME piping systems.

2. Leakage Reduction Program

PVNGS will institute a program to maintain leakage rates of systems outside containment to as low as practical which consists of the following:

A. Systems Included in the Program

1. High-pressure safety injection system (recirculation portion only)

2. Low-pressure safety injection system (shutdown cooling portion only)

3. Reactor coolant sampling system (post-accident sampling piping only) This is removed in those units where DMWO 2778159 has isolated the applicable line.

4. Containment spray system

5. Containment combustible gas and atmospheric sampling system (hydrogen, monitoring subsystem and post-accident sample piping associated with this function) DMWO 2529758 removes piping and valves (manual and/or solenoid) from selected portions of the PASS System piping that are connected to safety-related piping and/or components. In Units where DMWO 2529758 has been implemented for the appropriate isolation points, both the PASS System/Piping and PASS containment isolation valves have been removed and/or

de-terminated with lines capped as appropriate.

B. Systems Excluded from the Program: (They will not preclude any option of cooling the reactor core nor will they prevent the use of needed safety systems).

1. Radioactive liquid waste system, except as discussed above

2. Radioactive waste gas system, except as discussed above. (The system is not required for post-accident use.)

3. Reactor coolant letdown system, except for portions required for post-accident sampling described in paragraph 9.3.2.2.2. (The system is not required to function post-accident. The plant can be brought to a cold shutdown condition without the letdown system. The letdown system is isolated on SIAS and CIAS.)

4. Reactor coolant pump seal bleed-off system. (The system is not required to function outside containment post-accident. The seal bleed-off system is isolated outside containment on CSAS. The system remains isolated post-accident. If seal bleed-off is required post-accident, pressure in the seal bleed-off header will increase and the header

relief valve will lift providing a flow path to the reactor drain tank.)

5. Charging system. Under post-accident conditions, the charging system does not contain radioactive fluid since the letdown system is isolated, as discussed in item 3 above. The charging system takes suction from the refueling water tank.)

6. Fuel pool cooling system (FPCS). (The FPCS is normally isolated from potentially highly contaminated systems by double, locked shut isolation valves.)

C. Program Features

Immediate leak reduction measures: The program will consist of periodic monitoring of the systems during operation and inservice leak testing. Leaks will be identified and corrective maintenance performed.

1. Vent and drain lines will be capped to prevent release due to seal leakage when practical to do so.

2. The packing of valves (except Kerotest which is a packless, stainless steel diaphragm valve) in the scoped liquid systems will be inspected for leakage or evidence of leakage (such as boric acid accumulation). Maintenance will be performed on the packing

of liquid system valves identified as requiring work.

3. The seals and packing on pumps in the scoped liquid systems will be inspected for leakage or signs of leakage.

4. Valves, fittings, and compressor seals in the scoped gaseous systems will be checked for leakage. Maintenance will be performed on gas system valves and instrument fittings identified during leak tests as requiring work.

5. Systems and subsystems identified in paragraph 18.III.D.1.1.2A will be leak-tested prior to exceeding 5% power and on an interval not to exceed the period between refueling outages. Test records including measured leak rates will be maintained at PVNGS for NRC review. A report including the measured leak rates has been submitted for NRC staff review prior to operation above 5% power for Units 1 and 2. A report for Unit 3 will also be submitted. Leak rate test techniques will include:

   a. Liquid Systems

   A visual examination will be performed on items 1 through 3 of paragraph 18.III.D.1.1.2C, with the system at or near operating pressure. If leakage is identified

during these examinations, an integrated leakage rate will be determined by monitoring the applicable sump and tank levels. For sumps and tanks that do not contain a level indicator, the levels will be determined by physical measurement. In addition, the local leak rate tests performed on isolation valves will be utilized for the portion of each system located between the containment and the isolation valves if practical. These tests will be performed in accordance with written Station Manual procedures.

b. Gas Systems

The leakage will be determined by detecting gas leakage at individual valves, fittings, seals, and bolted connections with the system at or near operation pressure. Leakage will be detected by use of acoustic, bubble, or equivalent method (such as a tracer gas method). In addition, the local leak rate tests performed on isolation valves will be utilized for that portion of each system located between the containment and the isolation valves, if practical. These tests will be performed in accordance with written Station Manual procedures.

The PVNGS design was reviewed to confirm that the design and construction of PVNGS systems minimize unplanned releases of radioactivity including the related incidents identified in NRC letter dated October 17, 1979, to All Operating Nuclear Power Plants. The following summarizes that review:

Radioactive liquid atmospheric tanks are provided with overflows, with either no isolation valve or a locked-open valve. Overflow lines have loop seals and are routed to appropriate radioactive building sumps.

The sump liquid is routed to the liquid radwaste system (LRS) holdup tanks. Overflow lines from the RWT and the LRS concentrate monitor tanks are heat-traced to prevent plugging. Radioactive liquid pressurized tanks, with the exception of the volume control tank (VCT) and RDT, are provided with relief lines routed to the appropriate sumps. A summary of the overflow provisions for the radioactive tanks is provided in table 18.III.D-1.

Storm drains are located away from areas with a high potential for radioactive spills. No storm drains exist in the immediate vicinity of the containment, auxiliary, or radwaste buildings.

Radioactive pumps are generally located in isolated compartments whose drains are designed to catch all potential leakage. These drains are routed to the appropriate radioactive building sump. In addition, certain pumps, whose potential for radioactive leakage is greatest, are equipped with drip pans with lines hard-piped to the associated building

Table 18.III.D-1

RADIOACTIVE TANKS OVERFLOW AND LEAKAGE PROTECTION

sump. A summary of the radioactive pumps and their leakage provisions is given in table 18.III.D-2.

Radioactive valves are located in shielded compartments, such as valve galleries, equipped with floor drains that are designed to collect all potential valve leakage. These drains are routed to appropriate building sumps.

Radioactive tanks located inside the auxiliary and radwaste buildings are located in compartments with curbs to contain tank leakage. These compartments are also equipped with floor drains routed to the appropriate radioactive building sump. Outside liquid radwaste tanks are surrounded by a dike sufficient to hold the contents of a tank rupture. Outside CVCS tanks are concrete tanks with steel liners. The concrete tanks will retain potential liner leakage.

The hot laboratory, cold laboratory, decontamination area, and sample station are equipped with floor drains routed to the non-ESF sump. There are no piping systems between units which could become contaminated.

Based on this discussion, the North Anna-type event is not expected to occur at PVNGS.

18.III.D.3.3 IMPROVED INPLANT IODINE INSTRUMENTATION UNDER ACCIDENT CONDITIONS

NRC Position

(1) Each licensee shall provide equipment and associated training and procedures for accurately determining the airborne iodine concentration in areas within the

facility where plant personnel may be present during an accident.

(2) Each applicant for a fuel loading license to be issued prior to January 1, 1981, shall provide the equipment, training, and procedures necessary to accurately determine the presence of airborne radio iodine in areas within the plant where plant personnel may be present during an accident.

PVNGS Evaluation

Procedures have been developed for determining airborne iodine concentration. Silver-Zeolite or charcoal cartridges will be used in conjunction with a portable pump. The cartridges will be removed and brought to the counting laboratory for gamma spectrum analysis. Cartridges may be purged prior to counting. A low background counting facility is available on the site. The results of airborne concentration can be obtained within 15 to 30 minutes after collection of iodine on filtered cartridges. Procedures also define ALARA concepts for removal, transport, and analysis of filter cartridges. There are three such portable airborne samplers available at each unit which meet the NUREG-0737 recommendations. PVNGS response to this item is included in section 18.II.F.1.

18.III.D.3.4 CONTROL ROOM HABITABILITY REQUIREMENTS

NRC Position

In accordance with Task Action Plan Item III.D.3.4 and control room habitability, licensees shall assure that control room

operators will be adequately protected against the effects of accidental release of toxic and radioactive gases and that the nuclear power plant can be safely operated or shut down under design basis accident conditions (Criterion 19, Control Room, of Appendix A, General Design Criteria for Nuclear Power Plants, to 10CFR Part 50).

PVNGS Evaluation

Potential risks in the vicinity of the site are discussed in FSAR section 2.2. The operators in the control room are adequately protected from these risks and the release of radioactive gases as discussed in FSAR section 6.4. The required information provided below is in the format suggested by Attachment 1 to NUREG-0737, Section III.D.3.4.

INFORMATION REQUIRED FOR CONTROL ROOM HABITABILITY EVALUATION

(1) Control room modes of operation: automatic filtered recirculation with filtered makeup for pressurization for radiological accident; manual filtered recirculation without makeup for smoke isolation and manual makeup and exhaust for smoke removal (operators alerted by smoke detector).

(2) Control room characteristics:

(a) Air volume control room:

1.6×10^5 cubic feet

(b) Control room emergency zone (control room, critical files, kitchen, washroom, computer room, etc.):

140-foot elevation, control building

(c) Control-room ventilation system schematic with normal and emergency air flow rates:

See engineering drawings 01, 02, 03-M-HJP-001, -002 and 02-M-HJP-003

Normal rate = 29,900 cubic feet per minute

Emergency rate = 28,600 cubic feet per minute

(d) Infiltration leakage rate:

see section 6.4.2.4

(e) High efficiency particulate air (HEPA) filter and charcoal adsorber efficiencies:

HEPA = 99.97% of 0.3 micron particles

Charcoal <95% of particulates and iodines

(f) Closest distance between containment and air intake:

150 feet, approximately

(g) Layout of control room, air intakes, containment building, and chlorine, or other chemical storage facility with dimensions:

See engineering drawings 13-C-ZVA-005, 13-P-OOB-001, 13-P-OOB-005 and Figure 6.4.1.

(h) Control-room shielding including radiation streaming from penetrations, doors, ducts, stairways, etc:

See FSAR paragraph 6.4.4.3, listing E

(i) Automatic isolation capability-damper closing time, damper leakage and area:

See FSAR paragraph 6.4.2.2.2, listing I

(j) Chlorine detectors or toxic gas (local or remote):

There is no onsite storage of liquid or gaseous chlorine at PVNGS. Chlorine is maintained as sodium hypochlorite in a liquid form. Due to the absence of a chlorine gas source, no chlorine detectors are present in the control room HVAC system.

Smoke detectors are provided in the outside air intake plenum to alert the control room operator to manually isolate the control room.

(k) Self-contained breathing apparatus availability (number), refer to FSAR paragraph 6.4.2.2.2, listing K.

(l) Bottled air supply (hours supply), refer to FSAR paragraph 6.4.2.2.2, listing K.

(m) Emergency food and potable water supply (how many days and how many people):

Presently, the PVNGS control room design has emergency food and water supply for six people for 7 days (within the closed control room).

(n) Control room personnel capacity (normal and emergency):

Refer to paragraph 6.4.4.3, listing C for the personnel capacity of the control room.

(o) Potassium iodide drug supply:

Sufficient potassium iodine will be maintained in a central location at the station to supply six persons for 7 days, as noted in FSAR paragraph 6.4.4.3, listing D.

(3) Onsite storage of chlorine and other hazardous chemicals:

NOTE: No onsite storage of liquid or gaseous chlorine. It is stored as sodium hypochlorite (liquid).

(a) Total amount and size of container:

Hydrogen:

319,200 scf at 2300 psi is stored in three sets of 14 steel cylinders.

Sulfuric acid:

154,986 gallons in six 25,831-gallon tanks

76,938 gallons in six 12,823-gallon tanks

240,000 gallons in six 40,000-gallon tanks

16,590 gallons in three 5,530-gallon tanks

Carbon dioxide:

45,000 in three 15,000 lb tanks

(b) Closest distance from control room air intake:

Hydrogen: >550 ft (and obstructed)

Sulfuric acid: closest is >300 feet,

Carbon dioxide >150 feet

(4) Offsite manufacturing, storage, or transportation facilities of hazardous chemicals:

(a) Identify facilities within a 5-mile radius;
Arlington Valley Power Plant
Mesquite Power Plant
Redhawk Power Plant

(b) Distance from control room intake;
Arlington Valley Power Plant: 3 miles
Mesquite Power Plant: 2.5 miles
Redhawk Power Plant: 3.3 miles

(c) Quantity of hazardous chemicals in one container;
The hazardous chemicals for the identified facilities above have been evaluated for control room habitability following a postulated chemical release. The quantities of chemicals are not listed here due to confidentiality of data.

(d) Frequency of hazardous chemical transportation traffic (truck, rail, and barge);

The data for frequency of hazardous chemical transportation is deemed Security Sensitive Information that is controlled under 49 CFR parts 15 and 1520, and is not listed here.

(5) Technical Specifications (refer to standard Technical Specifications)

(a) Chlorine detection system:

Refer to the discussion provided in item 2j.

(b) Control room emergency filtration system including the capability to maintain the control room pressurization at 1/8-inch water gauge, verification of isolation by test signals and damper closure times, and filter testing requirements:

Refer to Technical Specifications.

RESPONSES TO NRC REQUESTS

FOR INFORMATION

CONTENTS

APPENDIX 18A

<u>QUESTION 18A.1</u> (F. J. Miraglia letter dated January 8, 1982) (III.D.1.1)

Your response to our earlier request for additional information relating to this action plan item has not addressed the following items. These should be addressed:

a. Leak test methods for liquid and gaseous systems.

b. Applicability to Palo Verde of North Anna and related incidents (identified in NRC's letter dated October 17, 1979, to all operating nuclear power plants).

c. Measured actual leak rates from all applicable systems with the system in operation (at this time, at least a commitment must be made that these will be submitted according to the schedule given in NUREG-0737).

d. Frequency of the periodic integrated leak tests.

e. Major features of the continuing leak reduction program.

f. Leak testing for the containment sampling system.

g. Leak testing for residual heat removal system.

RESPONSE:

a. The response is given in subsection 18.III.D.1.1.

b. The response is given in subsection 18.III.D.1.1.

c. The response is given in subsection 18.III.D.1.1.

d. The response is given in subsection 18.III.D.1.1.

e. The response is given in subsection 18.III.D.1.1.

f. The response is given in subsection 18.III.D.1.1.

g. The function of a "residual heat removal system" is performed by the shutdown cooling system which consists of portions of the high-pressure and low-pressure safety injection and containment spray systems, which are included in the leakage reduction program described in paragraph 18.III.D.1.1(2).

APPENDIX 18B
SYSTEM 80 GENERIC INADEQUATE CORE COOLING INSTUMENTATION PACKAGE

The following provides a preliminary description of the C-E Accident Monitoring System as it is intended for II.F.2 ICC.

1.0 INTRODUCTION

1.1 BACKGROUND

C-E Owners Group efforts on the evaluation of Inadequate Core Cooling have been ongoing since early 1979. Results of initial studies by the C-E Owners Group are documented in reports CEN-117 and CEN-125. These results have been considered in the preparation of emergency operating procedures guidelines. All studies have been based on the requirements to indicate the approach to, the existence of, and the recovery from ICC.

The C-E Owners Group has performed an evaluation of response characteristics of potential Inadequate Core Cooling (ICC) detection instrumentation. This study provided detailed analyses of the existing instruments, as well as investigating the performance characteristics of selected new instruments. Specifically, the instruments whose response characteristics have been evaluated are the subcooled margin monitor, the heated junction thermocouple reactor vessel level monitor, core-exit thermocouples, in-core thermocouples, self powered neutron detectors, hot leg resistance temperature detectors and ex-core neutron detectors. A summary of the details of this effort is contained in Appendix 18B-A.

Based on the results of the above instrument evaluation study, C-E has selected a Generic Inadequate Core Cooling Instrumentation (ICCI) package consisting of:

1) hot and cold leg Resistance Temperature Detectors (RTDs)
2) pressurizer pressure sensors
3) Core Exit Thermocouples (CETs)
4) Reactor Vessel Level Monitoring System (RVLMS) probes employing the Heated Junction Thermocouple (HJTC) concept

These sensor inputs have been integrated into the Accident Monitoring System core heat removal safety function and displayed via the primary SPDS in the Emergency Response Facility Data Acquisition and Display System (ERFDADS). The QSPDS portion of the AMS provides the Class 1E signal processing for the ICC sensors.

1.2 BASES FOR ICC INSTRUMENT SELECTION

The ICC instrumentation sensor package selected is designed to:

1) provide the operator with an advanced warning of the approach to ICC
2) cover the full range of ICC from normal operation to complete core uncovery

The Accident Monitoring System employing the ICC sensors package enables the reactor operator to monitor system conditions associated with the approach to, existence of, and the recovery from ICC.

1.2.1 DESCRIPTION OF ICC PROGRESSION (COOLANT STATES RELATED TO ICC)

The instrument sensor package for ICC detection provides the reactor operator a continuous indication of the thermal-hydraulic states within the Reactor Pressure Vessel (RPV) during the progression towards and away from ICC. This progression can be divided into conditions based on physical processes occurring within the RPV. These are characterized as follows:

Conditions Associated with the Approach to ICC

Condition 1a Loss of fluid subcooling prior to the first occurrence of saturation conditions in the coolant.

Condition 2a Decreasing coolant inventory within the upper plenum, (from the top of the vessel to the top of the active fuel).

Condition 3a Increasing core exit temperature produced by uncovery of the core resulting from the drop in level of the mixture of vapor bubbles and liquid from the top of the active fuel.

Conditions Associated with Recovery from ICC

Condition 3b Decreasing core exit steam temperature resulting from the rising of the level within the core.

Condition 2b Vessel fill by the increase in inventory above the fuel.

Condition 1b Establishment of saturation conditions followed by an increase in fluid subcooling.

These conditions encompass all possible coolant situations associated with any ICC event progression. The conditions denoted with an "a" refer to fluid situations that occur during the approach to ICC. Conditions denoted by a "b" refer to fluid situations which occur during the recovery from ICC. Thus, "a" conditions differ from "b" conditions in the trending (directional behavior) of the associated parameters.

In order to provide indicators during the entire progression of an event, an ICC instrument system consists of instruments which provide at least one appropriate indicator for each of the physical Conditions described above.

Applying this description of the "approach to", and "recovery from" ICC to ICC instrument selection:

1) provides assurance that the selected ICC system detects the entire progression

2) demonstrates the extent of instrument diversity or redundancy which is possible with the available instruments.

Furthermore, by defining the ICC progression on a physical basis the general labels of "approach to", and "recovery from" ICC can now be associated with specific physically measurable processes. (See Section 1.2.2, 1.2.3, and 1.2.4).

The instrument sensor package selected to monitor the ICC event progression consists of (1) Resistance Temperature Detectors (RTDs) (2) pressurizer pressure sensors, (3) reactor vessel level monitors employing the HJTC design concept and (4) core exit thermocouples. The signals from the RTDs, unheated thermocouples in the HJTC system, and pressure sensors can be

combined to indicate the loss of subcooling and occurrence of saturation (Condition 1a) and the achievement of a subcooled condition following core recover (Condition 1b). The reactor vessel level monitors provide information to the operator on the decreasing liquid inventory in the reactor pressure vessel (RPV) regions above the fuel alignment plate (FAP), as well as the increasing RPV liquid inventory above the FAP following core recovery (Conditions 2a and 2b). The core exit thermocouples (CETs) monitor the increasing steam temperatures associated with ICC and the decreasing steam temperatures associated with recovery from ICC (Conditions 3a and 3b).

1.2.2 ADVANCED WARNING OF THE APPROACH TO ICC

The ICC instrumentation provides the operator with an advanced warning of the approach to ICC by providing indications of:

1) the loss of subcooling and occurrence of saturation (Condition 1a) with a saturation margin monitor (SMM) receiving input from primary system RTDs, upper head HJTCs, and the pressurizer pressure sensors.

2) the loss of inventory in the RPV (Condition 2a) with the RVLMS.

3) the increasing core coolant exit temperature (Condition 3a) with CETs.

It should be noted that the RVLMS measures inventory (collapsed liquid level) rather than two-phase level. This measurement provides the operator with an advanced indication of the coolant level should conditions arise to cause the two-phase

froth to collapse via system overpressurization, or the loss of operating reactor coolant pumps.

1.2.3 APPLICATION OF ICC INSTRUMENTS

Following an event leading to ICC the ICC instruments will provide information to the reactor operator so that he may:

1) verify that the core heat removal safety function is being met,

2) establish the potential for fission product release.

ICC Instrumentation indications will be used to support the operator in helping to verify that the core heat removal safety function is being met. ICCI indications available to the operator are (1) an increasing inventory level above the fuel alignment plate, (2) an increasing subcooling in the RPV and RCS piping or (3) a decreasing core exit steam superheat. The operator is informed about the progression of an event by both static and trend displays. The trending of ICC information enables the operator to quickly assess the success of automatically or manually performed mitigating actions. A chart indicating the ICCI trending during the various ICC progression conditions associated with the approach to and recovery from ICC is presented in Table 18B-1.

1.2.4 INSTRUMENT RANGE

In the ICCI sensor package, saturation temperature and water inventory are used as indicators for the approach to and recovery from ICC when there is water inventory above the fuel

alignment plate. These measurements characterize conditions 1a, 1b, 2a, and 2b of the ICC progression.

When the two-phase level is below the fuel alignment plate, the measurement of core exit fluid temperature represents a direct indication of the approach to, and recovery from ICC (Conditions 3a and 3b). Therefore, the ICC sensor package is sufficient to provide information to the reactor operator on the entire progression of an event with the potential of resulting in ICC.

TABLE 18B-1

ICC STATUS AS AVAILABLE TO THE OPERATOR FROM ICC INSTRUMENTATION TRENDING

I. APPROACHING AN ICC CONDITION

CONDITION	SUBCOOLING MEASURED BY SMM	WATER INVENTORY MEASURED BY HJTC PROBE	COOLANT SUPERHEAT MEASURED BY CET
1a	DECREASING	CONSTANT	CONSTANT
2a	CONSTANT	DECREASING	CONSTANT
3a	CONSTANT	CONSTANT	INCREASING

II. RECEDING FROM AN ICC CONDITION

CONDITION	SUBCOOLING MEASURED BY SMM	WATER INVENTORY MEASURED BY HJTC PROBE	COOLANT SUPERHEAT MEASURED BY CET
3b	CONSTANT	CONSTANT	DECREASING
2b	CONSTANT	INCREASING	CONSTANT
1b	INCREASING	CONSTANT	CONSTANT

2.0 INADEQUATE CORE COOLING INSTRUMENTATION DESIGN DESCRIPTION

This section provides a preliminary description of a generic Accident Monitoring System (AMS) approach to address II.F.2, Inadequate Core Cooling (ICC) requirements. The Accident Monitoring System (AMS) consists of two major subsystems; 1) Emergency Response Facility Data Acquisition and Display System (ERFDADS) and 2) Qualified Safety Parameter Display System (QSPDS). A functional overview of the AMS highlighting the ICC sensor inputs is shown in Figure 18B-1. As discussed previously, the reactor vessel liquid inventory above the core and the fluid conditions at various locations in the primary system will be measured by RTDs, pressurizer pressure sensors, reactor vessel level HJTCs, and CETs. As shown in Figure 18B-1 the ICC sensors are input to the Qualified Safety Parameter Display System (QSPDS) for processing and then integrated into the Primary Safety Parameter Display in the Emergency Response Facility Data Acquisition and Display System (ERFDADS) portion of the AMS.

2.1 SENSOR DESIGN

Detailed information on the associated ICC sensors is presented in the following sections.

2.1.1 SATURATION MARGIN

Subcooled Margin Monitoring (SMM) provides information to the reactor operator on (1) the approach to and existence of saturation and (2) existence of core uncovery.

The SMM includes inputs from RCS cold and hot leg temperatures measured by RTDs, the temperature of the maximum of the top three Unheated Junction Thermocouples (UHJTC), and pressurizer pressure sensors. The UHJTC input comes from the output of the HJTCS processing units. In summary, the sensor inputs are as follows:

Input	Range
Pressurizer Pressure	0-3000 psia
Cold Leg Temperature	50-750°F
Hot Leg Temperature	50-750°F
Maximum UHJTC Temperature of top three sensors (from HJTC processing)	32-2300°F
Representative CET Temperature	32-2300°F

2.1.2 HEATED JUNCTION THERMOCOUPLE (HJTC) PROBE ASSEMBLY

The HJTC Probe Assembly measures reactor coolant liquid inventory above the fuel alignment plate with discrete HJTC sensors located at different levels within a separator tube ranging from the top of the fuel alignment plate to the reactor vessel head. The basic principle of operation is the detection of a temperature difference between adjacent heated and unheated thermocouples.

As pictured in Figure 18B-2, the HJTC sensor consists of a Chromel-Alumel thermocouple near a heater (or heated junction) and another Chromel-Alumel thermocouple positioned away from the heater (or unheated junction). In a fluid with relatively good heat transfer properties, the temperature difference

between the adjacent thermocouples is small. In a fluid with relatively poor heat transfer properties, the temperature difference between the thermocouples is large.

Two probe assemblies are provided to allow two channels of HJTC instruments. Each HJTC probe assembly includes eight (8) HJTC sensors, a separator tube, a seal plug, and electrical connectors (Figure 18B-3). The eight (8) HJTC sensors are electrically independent. Should a sensor fail during operation, the circuitry can be temporarily modified to electrically isolate the failed sensor provided the minimum Technical Specification Requirements are adhered to (see Table 1.8-1 for status).

Two design features ensure proper operation under all thermal-hydraulic conditions. First, each HJTC is shielded to avoid overcooling due to direct water contact during two phase fluid conditions. The HJTC with the splash shield is referred to as the HJTC sensor (See Figure 18B-2). Second, a string of HJTC sensors is enclosed in a tube that separates the liquid and gas phases that surround it.

The separator tube (See Figure 18B-4) creates a collapsed liquid level that the HJTC sensors measure. This collapsed liquid level is directly related to the average liquid fraction of the fluid in the reactor head volume above the fuel alignment plate. This mode of direct in-vessel sensing reduces spurious effects due to pressure, fluid properties, and non-homo-geneities of the fluid medium. The string of HJTC sensors and the separator tube is referred to as the probe assembly.

The probe assembly is housed in a stainless steel structure that protects it from flow loads.

2.1.3 CORE EXIT THERMOCOUPLES (CET)

The core exit thermocouples provide a measure of core heatup via measurement of core exit steam temperature.

The design of the System 80 In-core Instrumentation (ICI) system will be modified to include Type K (Chromel-Alumel) thermocouples within each of the ICI detector assemblies. These Core Exit Thermocouples (CET) monitor the temperature of the reactor coolant as it exits the fuel assemblies. The core locations of the ICI detector assemblies are shown in Figure 18B-5.

The CETs have a usable temperature range from 200°F to up to 2300°F.

2.2 DESCRIPTION OF ICC PROCESSING

The following sections provide a preliminary description of the processing control and display functions associated with each of the ICC detection instruments in the AMS. The sensor inputs for the major ICC parameters; saturation margin, reactor vessel inventory/temperature above the core, and core exit temperature are processed in the two channel QSPDS and transmitted to the ERFDADS for primary display and trending.

2.2.1 SATURATION MARGIN

The QSPDS processing equipment will perform the following saturation margin monitoring functions:

1. Calculate the saturation margin

   The saturation temperature is calculated from the minimum pressure input. The temperature subcooled or superheat margin is the difference between saturation temperature and the sensor temperature input. Three temperature subcooled or superheat margin presentations will be available. These are as follows:

   a. RCS saturation margin - the temperature saturation margin based on the difference between the saturation temperature and the maximum temperature from the RTDs in the hot and cold legs.

   b. Upper head saturation margin - temperature saturation margin based on the difference between the saturation temperature and the UHJTC temperature (based on the maximum of the top three UHJTC)

   c. CET saturation margin - temperature saturation margin based the difference between the saturation temperature and the representation core exit temperature calculated from the CETs (Section 2.2.3).

2. Process sensor outputs for determination of temperature saturation margin.

3. Provide an alarm output for an annunciator when temperature saturation margin reaches a preselected (to be determined) setpoint for RCS, upper head, or CET saturation margin.

2.2.2 HEATED JUNCTION THERMOCOUPLE

The QSPDS processing equipment performs the following functions for the HJTC:

1. Determine collapsed liquid level above core.

   The heated and unheated thermocouples in the HJTC are connected in such a way that absolute and differential temperature signals are available. This is shown in Figure 18B-6. When liquid water surrounds the thermocouples, their temperature and voltage output are approximately equal. The voltage $V_{(A-C)}$, on Figure 18B-6 is, therefore, approximately zero. In the absence of liquid, the thermocouple temperatures and output voltages become unequal, causing $V_{(A-C)}$ to rise. When $V_{(A-C)}$ of the individual HJTC rises above a predetermined setpoint, liquid inventory does not exist at this HJTC position.

2. Determine the maximum upper plenum/head fluid temperature of the top three unheated thermocouples for use as an output to the SMM calculation. (The temperature processing range is from 100°F to 2300°F.)

3. Process input signals to display collapsed liquid level and unheated junction thermocouple temperatures.

4. Provide an alarm output when any of the HJTC detects the absence of liquid level.

5. Provide control of heater power for proper HJTC output signal level. Figure 18B-7 shows the design for one of the two channels which includes the heater controller power supplies.

2.2.3 CORE EXIT THERMOCOUPLE SYSTEM

The QSPDS performs the following CET processing functions:

1. Process core exit thermocouple inputs for display.
2. Calculate a representative core exit temperature. Although not finalized, this temperature will be either the maximum valid core exit temperature or the average of the five highest valid core exit temperatures.
3. Provide an alarm output when temperature reaches a preselected value.
4. Process CETs for display of CET temperature and superheat.

These functions are intended to meet the design requirements of NUREG-0737, II.F.2 Attachment 1.

2.3 SYSTEM DISPLAY

The QSPDS ICC outputs are incorporated into the Emergency Response Facility Data Acquisition and Display System (ERFDADS) alarm logic and displays. The ERFDADS is a dedicated, computer-based plant information and display system that provides a Primary Safety Parameter Display directly monitoring critical plant functions:

1. Core reactivity control
2. Core heat removal control
3. RCS inventory control
4. RCS pressure control
5. RCS heat removal control
6. Containment pressure/temperature control

7. Containment isolation control

8. Radiation emissions control

These critical safety functions are directly monitored by a set of algorithms which process the measured plant variables to determine the plants safety status relative to safety functions control. If any of the critical functions are violated, (by exceeding logic setpoints) a Critical Function Alarm (CFA) is initiated. The ICC instruments outputs are incorporated in this critical function alarm logic. Specifically the ICC inputs are incorporated into the core heat removal control level 1 display and also lower level detail displays.

The ERFDADS displays data to computer displays in the Control Room and TSC. The data has three levels of information:

Level 1 - Monitor (Critical functions status)

Level 2 - Control (System overview)

Level 3 - Diagnostic (System detail)

This hierarchy allows the operator to progress from an overall plant safety status, to system overview to a detailed diagnostic view. The ICC instrument outputs are incorporated in all three levels of display. The detailed ICC information is anticipated to be displayed on a dedicated display. ICC trending displays for saturation margin, reactor vessel inventory, representative core exit temperature, and representative core exit temperature saturation margin are also provided with the ERFDADS. The ERFDADS is the Primary Control room display of ICC information.

Each QSPDS safety grade backup display also has available the most reliable basic information for each of the ICC instruments. These displays are human engineered to give the operator clear unambiguous indications. The backup displays are designed:

1. to give instrument indications in the remote chance that the primary display becomes inoperable.
2. to provide confirmatory indications to the primary display.
3. to aid in surveillance tests and diagnostics.

The following sections describe displays as presently conceived for each of the ICC instrument systems. Both primary and backup displays are intended to be designed consistent with the criteria in II.F.2 Attachment 1 and Appendix 18B-A.

2.3.1 ICC DISPLAYS

The ICC detection instrumentation displays in both the ERFDADS (primary displays) and the QSPDS (backup displays) have an ICC summary page as part of the core heat removal control critical function supported by more detailed display pages for each of the ICC variable categories.

The summary page will include:

1. RCS/Upper Head saturation margin - the maximum of the RCS and Upper Head saturation margin.
2. Reactor vessel level above the core.
3. Representative core exit temperature.

Since the ERFDADS has more display capabilities than the QSPDS such as color-graphics, trending, and a larger format, additional information may be added and with a better presentation than is available with the QSPDS. These variables are incorporated in other ERFDADS system displays.

Since the ERFDADS receives both QSPDS channels of ICC input, the ERFDADS displays both channels of ICC information. The QSPDS displays only one channel of ICC information for each video display unit.

Although all inputs are accessible for trending and historical recall, the ERFDADS has a dedicated ICC trend page for RCS/upper head saturation margin, reactor vessel level, and representative core exit temperature and core exit saturation margin. These are also available as analog outputs from the QSPDS cabinet.

2.3.2 SATURATION MARGIN DISPLAY

The following information is presented on the primary (ERFDADS) and backup (QSPDS) displays:

1. Temperature and pressure saturation margins for RCS, Upper Head, Core Exit Temperature.
2. Temperatures and pressure inputs.

2.3.3 HEATED JUNCTION THERMOCOUPLE SYSTEM DISPLAY

The following information is displayed on the ERFDADS and QSPDS displays:

1. Liquid inventory level above the fuel alignment plate derived from the eight discrete HJTC positions.

2. 8 discrete HJTC positions indicating liquid inventory above the fuel alignment plate.

3. Inputs from the HJTCS:

   a. Unheated junction temperature at the 8 positions.

   b. Heated junction temperature at the 8 positions.

   c. Differential junction temperature at the 8 positions.

2.3.4 CORE EXIT THERMOCOUPLE DISPLAY

The following information is displayed on the ERFDADS display:

1. A spatially oriented core map indicating the temperature at each of the CET's.

2. A selective reading of CET temperatures.

3. The representative core exit temperature.

The following information is displayed on the QSPDS display:

1. Representative core exit temperature.

2. A selective reading of the CET temperatures.

3. A listing of all core exit temperatures.

APPENDIX 18B-A

EVALUATION OF INSTRUMENTATION FOR DETECTION OF INADEQUATE CORE COOLING

CONTENTS

TABLES

APPENDIX 18B-A
EVALUATION OF INSTRUMENTATION FOR DETECTION OF INADEQUATE CORE COOLING

The C-E Owners Group has conducted an evaluation of instrumentation for the potential application to the detection of Inadequate Core Cooling. The performance characteristics of selected instruments were compared for representative transients resulting in various degrees of reactor coolant system voiding. The respective instruments then were evaluated based on their developmental and post-accident qualification status, response characteristics, and signal clarity.

A.1 DESCRIPTION OF ICC EVENT PROGRESSION

The state of progression of an event resulting in ICC can be divided based on physical processes occurring within the RPV, into the following six conditions:

Conditions Associated with the Approach to ICC

Condition 1A   Loss of fluid subcooling prior to the first occurrence of saturation conditions in the coolant.

Condition 2A   Decreasing coolant inventory within the upper plenum, from the top of the vessel to the top of the active fuel.

Condition 3A   Increasing core exit temperature produced by uncover of the core resulting from the drop in level of the mixture of vapor bubbles and liquid below the top of the active fuel.

Conditions Associated with Recovery From ICC

Condition 3b Decreasing core exit steam temperature resulting from the rising of the level within the core.

Condition 2b Increasing inventory above the fuel.

Condition 1b Establishment of saturation conditions followed by an increase in fluid subcooling.

The instrument system used for the detection of ICC should provide the reactor operator with the current status of selected key parameters and the trending of prior status of selected key parameters as the event progresses through each of the above conditions.

A.2 SUMMARY OF SENSOR EVALUATION

The instruments evaluated in this effort were the subcooled margin monitor (SMM), resistance temperature detectors (RTDs), reactor vessel level monitor employing the heated junction thermocouples (HJTC), core exit thermocouples (CETs),

self-powered neutron detectors (SPNDs), ex-core detectors and incur thermocouples. The instruments are listed in

Table 18B-A-1, where their capabilities are summarized. Significant conclusions about each instrument are given below.

A.2.1 Subcooled Margin Monitor

The Subcooled Margin Monitor (SMM), using input from existing Resistance Temperature Detectors (RTD) in the hot and cold legs and from the pressurizer pressure sensors, will detect the

initial occurrence of saturation during LOCA events and during loss of heat sink events.

The usefulness of the SMM, will be significantly increased by also feeding into it the signals from the fluid temperature measurements from the HJTCS and by modifying the SMM to calculate and display degrees superheat in addition to degrees subcooling. The signals from the HJTCS temperature measurements provide information about possible local differences in temperature between the reactor vessel upper head/upper plenum (location of the HJTCS) and the hot or cold legs (location of the RTDs).

With these modifications, the SMM can be used not only for detection of the approach to ICC, namely Condition 1a (loss of subcooling), but also for Conditions 3a and 3b (core uncovery) and Condition lb (core recovery). Even with the modifications, the SMM will not be capable of indicating the existence of Conditions 2a and 2b when the coolant is at saturation conditions and the level is between the top of the vessel and the top of the core.

A.2.2 Resistance Temperature Detectors

The RTD are adequate for sensing the initial occurrence of saturation for events initiated at power and for events initiated from zero power or shutdown conditions.

The RTD range is not adequate for ICC indications during core uncovery. For depressurization LOCA events, the core may uncover at low pressure, when the saturation temperature is below the lower limit of the hot leg RTD. Initial superheat of

the steam will therefore not be detected by the hot leg RTD. As the uncovery proceeds, the superheated steam temperature may quickly exceed the upper limit of the RTD range.

A.2.3 Heated Junction Thermocouple System (HJTCS)

The HJTC probe is designed to create and measure a collapsed liquid level in a localized plenum region. The height of the collapsed liquid level within the probe is sensed using pairs of heated junction thermocouples. This mode of sensing reduces spurious effects due to pressure, fluid properties, and non-homogeneities of the fluid medium.

The signal which is produced by the HJTC probe is a small electrical current similar in magnitude to, or greater than, the current produced by typical temperature sensing devices presently used in the reactor coolant system. This signal may be transmitted from within the reactor vessel to outside of the containment building with no intermediate electronics. Furthermore, the signal is not subject to external disturbances, such as containment environment as would be present with a hydraulic signal transmission system.

The HJTC can provide significant information to the operator for two conditions associated with an ICC event - Condition 2a, the approach to uncovery and Condition 2b, the refill. For a large small break event, the two-phase level drops to the top of the core within 5 to 15 minutes of the break initiation. In this event, the HJTC would show the rapidly decreasing coolant inventory and would quantify for the operator the status of the degrading situation which is otherwise evident to him from

numerous existing instruments. For smaller breaks, the progression of the event is slower, and the HJTC can provide significant information on the effectiveness of his mitigating actions. It is probably for such long term conditions, prior to core uncovery, that the HJTC would have its greatest usefulness.

Following recovery of the core, the operator could use the HJTC to verify that the core is again covered and therefore is being adequately cooled. Through monitoring the HJTC level the operator has better indication of the correctness and effectiveness of this actions in maintaining the coolant inventory.

A.2.4 Core Exit Thermocouples (CETs)

The core exit thermocouples will show the approach to and existence of ICC after core uncovery for the events analyzed. The core exit thermocouples respond to the coolant temperature at the core exit and indicate superheat after the core is no longer completely covered by coolant. The trend of the change in superheat corresponds to the trend of the change in cladding temperature.

Existing thermocouples in C-E reactors have been qualified to industry standard accuracy for operation to 750°F. However, thermocouples of this design (i.e., stainless steel sheathed, alumina insulated, Type K, Chromel-Alumel) are suitable for nuclear service to 1650°F. Tests have been run on such thermocouples to simulate severe accidents (See Reference 4 of text). Results from these tests demonstrated the shunting

error caused by the increase in electrical conductance of the alumina at high temperature is shown to be negligible up to 1650°F and is acceptably small to 1800°F. It is concluded that the thermocouples in operating C-E designed reactors could satisfy the minimum NRC requirement for 1650°F and are adequate to 1800°F. In addition, tests performed at ORNL indicate that CETs may be used for purposes of trending of steam temperatures up to 2300°F.

A.2.5 Self-Powered Neutron Detectors (SPNDs)

The SPND yield a signal caused by high temperature as the two-phase level falls below the elevation of the SPND. However, testing would be required to identify the phenomena responsible for the anomalous behavior of the SPND at TMI-2. At the present, their use is limited to low temperature events (less than 1000°F clad temperature) or to only the initial uncovery portion of an event.

A.2.6 Ex-Core Neutron Detectors

Existing source range neutron detectors are sensitive enough to respond to the formation of coolant voids within the vessel during the events analyzed. However, the signal magnitude is ambiguous because of the effects of varying boron concentration and deuterium concentration in the reactor coolant.

A stack of ex-core detectors gives less ambiguous information on voids and level in the vessel. The relative shape of the axial distribution of signals from a stack of five detectors

shows promise as an ICC indicator, but additional development would be needed.

A.2.7 In-Core Thermocouples

Although the loss of other instrumentation such as the SPND's would have to be considered, in general, it appears feasible that in-core thermocouples may be added to or substituted for some SOND in the in-core instrument string. In-core thermocouples sense the surrounding environment via radiation, as well as, steam convection. The information provided to the operator by in-core thermocouples is qualitatively the same as that provided by CETs.

TABLE 18B-A-1

INSTRUMENT INCLUDED IN EVALUATIONS

FOR ICC INSTRUMENTATION SYSTEM

INSTRUMENTS	DEVELOPMENT STATUS	POST-ACCIDENT QUALIFICATION STATUS	INDICATION PROVIDED BY INSTRUMENT	CLARITY OF SIGNAL	CONDITIONS MONITORED
Subcooled Margin Monitor	Exists	Qualified	Degree Of Subcooling In RCS	Good	1a, 1b
Reactor Vessel Level Monitor	Under Develop.	Will Be Qualified	1) Liquid Inventory In Upper Head	Good	2a, 2b
			2) Liquid Inventory in Upper Plenum	Good	
			3) Axial Temperature Distribution In Head And Plenum	Good	
Core Exit Thermocouples	Exist	Can Be Done	1) Fluid Temperature at Core Exit	Good	3a, 3b
In-Core Thermocouples	Concept Stage	Can Be Done	1) Metal Temperature Inside Guide Tube When RCP Off	Good	3a, 3b
Self-Powered Neutron Detectors	Exist	Can Be Done	Indirect Measure of Mixture Level (Low Pressure Uncovery)	Poor	3a, 3b
Hot Leg RTD (5 Each)	Exist	Qualified	Fluid Temperature in Hot Leg	Good	1a, 1b, 3a, 3b
Ex-Core Neutron Detector (Off, Source Range)	Exist	Can Be Done	Indirect Measure of Gross Voiding	Fair	3a, 3b
			Indirect Indication of Mixture Level Level in Core, RCP Off	Fair	
Ex-Core Neutron Detector (Stack of 5, Source Range)	Concept	Can Be Done	Same as One Ex-Core Detector, But More Axial Resolution	Fair	3a, 3b

19.0 INTRODUCTION

In compliance with Unit 1 license condition 2.C.(16)(a), Unit 2 license condition 2.C.(11)(a), and Unit 3 license condition 2.C.(7)(a) of the PVNGS renewed operating licenses, this chapter of the PVNGS UFSAR contains the information required by 10 CFR 54.21(d) that was contained in the PVNGS license renewal application, Appendix A, "Updated Final Safety Analysis Report Supplement." The PVNGS license renewal application was submitted to the NRC in a letter dated December 11, 2008, and supplemented by letters submitted to the NRC through March 17, 2011. The NRC review of the PVNGS license renewal application is documented in NUREG-1961, "Safety Evaluation Report Related to the License Renewal of Palo Verde Nuclear Generating Station, Units 1, 2, and 3," issued April 2011.

Section 19.1 contains summary descriptions of the programs used to manage the effects of aging during the period of extended operation. Section 19.2 contains summary descriptions of programs used for management of time-limited aging analyses during the period of extended operation. Section 19.3 contains evaluation summaries of TLAAs for the period of extended operation. Section 19.4 contains any newly identified systems, structures, and components subject to an aging management review or evaluation of time-limited aging analyses. Section 19.5 contains a listing of license renewal commitments.

This page intentionally left blank

19.1 SUMMARY DESCRIPTIONS OF AGING MANAGEMENT PROGRAMS

The integrated plant assessment and evaluation of time-limited aging analyses (TLAA) identified existing and new aging management programs necessary to provide reasonable assurance that components within the scope of License Renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) for the period of extended operation. Sections 19.1 and 19.2 describe the programs and their implementation activities.

Three elements common to all aging management programs discussed in Sections 19.1 and 19.2 are corrective actions, confirmation process, and administrative controls. These elements are included in the PVNGS Quality Assurance (QA) Program, which implements the requirements of 10 CFR 50, Appendix B. The PVNGS Quality Assurance Program is applicable to all safety-related and nonsafety-related systems, structures and components that are subject to aging management review activities.

19.1.1 ASME SECTION XI INSERVICE INSPECTION, SUBSECTIONS IWB, IWC, AND IWD

ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD program manages cracking, loss of fracture toughness, and loss of material in Class 1, 2, and 3 piping and components within the scope of license renewal. The program includes periodic visual, surface, volumetric examinations and leakage tests of Class 1, 2 and 3 pressure-retaining components, including welds, pump casings, valve bodies, integral

attachments, and pressure-retaining bolting. PVNGS inspections meet ASME Section XI requirements. The PVNGS third interval ISI Program is in accordance with 10 CFR 50.55a and ASME Section XI, 2001 Edition, through 2003 Addenda. PVNGS will use the ASME Code Edition consistent with the provisions of 10 CFR 50.55a during the period of extended operation.

19.1.2 WATER CHEMISTRY

The Water Chemistry program includes maintenance of the chemical environment in the reactor coolant system and related auxiliary systems and includes maintenance of the chemical environment in the steam generator secondary side and the secondary cycle systems to manage cracking, denting, loss of material, reduction of heat transfer, and wall thinning in primary and secondary water systems. The Water Chemistry program is based upon the guidelines of EPRI 1014986, "*PWR Primary Water Chemistry Guidelines*", Volumes 1 and 2, and EPRI 1016555, "*PWR Secondary Water Chemistry Guidelines*".

The effectiveness of the program is verified under the One-Time Inspection program (19.1.16).

19.1.3 REACTOR HEAD CLOSURE STUDS

The Reactor Head Closure Studs program manages reactor vessel stud, nut and washer cracking and loss of material. The Reactor Head Closure Studs program includes periodic visual, surface, and volumetric examinations of reactor vessel flange stud hole threads, reactor head closure studs, nuts, and

washers and performs visual inspection of the reactor vessel flange closure during primary system leakage tests. The program implements ASME Section XI code, Subsection IWB, 2001 Edition through the 2003 addenda.

19.1.4 BORIC ACID CORROSION

The Boric Acid Corrosion program manages loss of material due to boric acid corrosion. The program includes provisions to identify, inspect, examine and evaluate leakage, and initiate corrective actions. The program relies in part on implementation of recommendations of NRC Generic Letter 88-05, "*Boric Acid Corrosion of Carbon Steel Reactor Pressure Boundary Components in PWR Plants*". Additionally, the program includes scheduled inspection of all plant borated water systems and examinations conducted during ISI pressure tests performed in accordance with ASME Section XI requirements. The Nickel-Alloy Penetration Nozzles Welded to the Upper Reactor Vessel Closure Heads of Pressurized Water Reactors program (19.1.5) and the Nickel Alloy Aging Management Program (19.1.34) as well as the Boric Acid Corrosion control program, implement reactor coolant pressure boundary inspections of reactor coolant pressure boundary components to identify degradation that would impact the reactor coolant pressure boundary.

SUMMARY DESCRIPTIONS

OF AGING MANAGEMENT PROGRAMS

19.1.5 NICKEL-ALLOY PENETRATION NOZZLES WELDED TO THE UPPER REACTOR VESSEL CLOSURE HEADS OF PRESSURIZED WATER REACTORS

The Nickel-Alloy Penetration Nozzles Welded to the Upper Reactor Vessel Closure Heads of Pressurized Water Reactors program manages cracking due to primary water stress corrosion cracking (PWSCC) and loss of material due to boric acid wastage in nickel-alloy pressure vessel head penetration nozzles and includes the reactor vessel closure head, upper vessel head penetration nozzles and associated welds. The term "primary water stress corrosion cracking" applies to the nozzles and J-welds and "Wastage" applies to the reactor closure head. The aging management for the aging effect of wastage is addressed in Boric Acid Corrosion program (19.1.4). This program was developed in response to NRC Order EA-03-009. ASME Code Case N-729-1, subject to the conditions specified in 10 CFR 50.55a(g)(6)(ii)(D)(2) through (6) has superseded the requirements of NRC Order EA-03-009.

Detection of cracking is accomplished through implementation of a combination of bare metal visual examination (external surface of head) and surface and volumetric examination (underside of head) techniques. Reactor Pressure Vessel Head bare metal visual examinations, surface examinations, and volumetric examinations are performed consistent with the ASME Code Case N-729-1, subject to the conditions specified in 10 CFR 50.55a(g)(6)(ii)(D)(2) through (6).

SUMMARY DESCRIPTIONS

OF AGING MANAGEMENT PROGRAMS

19.1.6 FLOW-ACCELERATED CORROSION

The Flow-Accelerated Corrosion (FAC) program manages wall thinning due to FAC on the internal surfaces of carbon or low alloy steel piping, elbows, reducers, expanders, and valve bodies which contain high energy fluids (both single phase and two phases).

The objectives of the FAC program are achieved by (a) identifying system components susceptible to FAC, (b) an analysis using a predictive code such as CHECWORKS to determine critical locations for inspection and evaluation, (c) providing guidance of follow-up inspections, (d) repairing or replacing components, as determined by the guidance provided by the program, and (e) continual evaluation and incorporation of the latest technologies, industry and plant in-house operating experience.

Procedures and methods used by the FAC program are consistent with APS commitments to NRC Bulletin 87-01, "*Thinning of Pipe Wall in Nuclear Power Plants,*" and NRC Generic Letter 89-08, "*Erosion/Corrosion-Induced Pipe Wall Thinning.*"

The program relies on implementation of the EPRI guidelines of NSAC-202L, "Recommendations for an Effective Flow Accelerated Corrosion Program."

19.1.7 BOLTING INTEGRITY

The Bolting Integrity program manages cracking, loss of material, and loss of preload for pressure retaining bolting and ASME component support bolting. The program includes

preload control, selection of bolting material, use of lubricants/sealants consistent with EPRI good bolting practices, and performance of periodic inspections for indication of aging effects. The program is supplemented by Inservice Inspection requirements established in accordance with ASME Section XI, Subsections IWB, IWC, IWD, and IWF for ASME Class bolting.

PVNGS good bolting practices are established in accordance with plant procedures. These procedures include requirements for proper disassembling, inspecting, and assembling of connections with threaded fasteners. The general practices that are established in this program are consistent with EPRI NP-5067, "*Good Bolting Practices, Volume 1 and Volume 2*," and the recommendations of NUREG-1339, "*Resolution of Generic Safety Issue 29: Bolting Degradation or Failure in Nuclear Power Plants.*"

19.1.8 STEAM GENERATOR TUBE INTEGRITY

The Steam Generator Tube Integrity program includes the preventive measures, condition monitoring inspections, degradation assessment, repair and leakage monitoring activities necessary to manage cracking, wall thinning, and loss of material. The aging management measures employed include: non-destructive examination, visual inspection, sludge removal, tube plugging, in-situ pressure testing, maintaining the chemistry environment by removal of impurities, and addition of chemicals to control pH and oxygen.

NDE inspection scope and frequency, and primary to secondary leak rate monitoring are conducted consistent with the requirements of the PVNGS Units 1, 2, and 3 Technical Specifications. PVNGS evaluates tube integrity in accordance with the structural integrity performance criteria specified in Technical Specifications which encompasses and exceeds the requirements of Regulatory Guide 1.121. In addition, Technical Specifications include accident induced leakage performance criterion and operational leakage performance criterion. The PVNGS steam generator management practices are consistent with NEI 97-06, "*Steam Generator Program Guidelines.*"

19.1.9 OPEN-CYCLE COOLING WATER SYSTEM

The Open-Cycle Cooling Water System program manages loss of material and reduction of heat transfer for components exposed to the raw water of the open-cycle cooling water system. The program includes surveillance techniques and control techniques to manage aging effects caused by biofouling, corrosion, erosion and silting in the open-cycle cooling water system and in structures and components cooled by the open-cycle cooling water system for the period of extended operation. The program is consistent with commitments as established in PVNGS responses to Generic Letter 89-13 "Service Water System Problems Affecting Safety-Related Components."

The Open-Cycle Cooling Water System program provides the general requirements of implementation and maintenance of programs and activities which mitigate aging of the open-cycle cooling water system and components. The various aspects of

the PVNGS program (control, monitoring, maintenance and inspection) are implemented in plant procedures.

Prior to the period of extended operation, the program will be enhanced to clarify guidance in the conduct of piping inspections using NDE techniques and related acceptance criteria.

19.1.10 CLOSED-CYCLE COOLING WATER SYSTEM

The Closed-Cycle Cooling Water System program manages loss of material, cracking, and reduction in heat transfer for components in closed cycle cooling water systems. The program includes maintenance of system corrosion inhibitor concentrations and chemistry parameters following the guidance of EPRI TR-107396 to minimize aging, and periodic testing and inspections to evaluate system and component performance. Inspection methods include visual, ultrasonic testing and eddy current testing.

19.1.11 INSPECTION OF OVERHEAD HEAVY LOAD AND LIGHT LOAD (RELATED TO REFUELING) HANDLING SYSTEMS

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems program manages loss of material for all cranes, trolley and hoist structural components, fuel handling equipment and applicable rails within the scope of license renewal. Program inspection activities verify the structural integrity of the components required to maintain their intended function. The inspection requirements are

consistent with the guidance provided by NUREG-0612, "*Control of Heavy Loads at Nuclear Power Plants,*" for load handling systems that handle heavy loads which can directly or indirectly cause a release of radioactive material, applicable industry standards (such as CMAA Spec 70) for other components within the scope of license renewal in this program, and applicable OSHA regulations (such as 29 CFR Volume XVII, Part 1910 and Section 1910.179).

Prior to the period of extended operation, procedures will be enhanced to inspect for loss of material due to corrosion or rail wear.

19.1.12 FIRE PROTECTION

The Fire Protection program manages loss of material for fire rated doors, fire dampers, diesel-driven fire pumps, and the halon/CO_2 fire suppression systems, cracking, spalling, and loss of material for fire barrier walls, ceilings, and floors, and hardness and shrinkage due to weathering of fire barrier penetration seals. Periodic visual inspections of fire barrier penetration seals, fire dampers, fire barrier walls, ceilings and floors, and periodic visual inspections and functional tests of fire-rated doors manage aging. Periodic testing of the diesel-driven fire pumps ensures that there is no loss of function due to aging of diesel fuel supply lines. Drop tests are performed on 10 percent of fire dampers on an 18 month basis to manage aging. Visual inspections manage aging of fire-rated doors every 18 months to verify the integrity of door surfaces and for clearances to detect aging of the fire

doors. A visual inspection and function test of the halon and CO_2 fire suppression systems every 18 months (along with the destructive testing of the Electro-Thermal Links (ETLs) and functional testing of the dampers which are both performed every 54 months) manages aging. Ten percent of each type of penetration seal is visually inspected at least once every 18 months. Fire barrier walls, ceilings, and floors including coatings and wraps are visually inspected at least once every 18 months.

Prior to the period of extended operation procedures will be enhanced to perform the testing of the Electro-Thermal Links (ETLs) and functional testing of the halon and CO2 dampers every 18 months or at the frequency specified in the current licensing basis in effect upon entry into the period of extended operation.

19.1.13 FIRE WATER SYSTEM

The Fire Water System program manages loss of material for water-based fire protection systems. Periodic hydrant inspections, fire main flushing, sprinkler inspections, and flow tests are performed considering applicable National Fire Protection Association (NFPA) codes and standards. The fire water system pressure is continuously monitored such that loss of system pressure is immediately detected and corrective actions are initiated. The Fire Water System program conducts an air or water flow test through each open head spray/sprinkler head to verify that each open head spray/sprinkler nozzle is unobstructed. Visual inspections of

the fire protection system exposed to water, evaluating wall thickness to identify evidence of loss of material due to corrosion, are covered by the Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program (19.1.22). The Buried Piping and Tanks Inspection program (19.1.18) is credited with the management of aging effects on the external surface of buried fire water system piping.

Prior to the period of extended operation, the following enhancements will be implemented:

- Specific procedures will be enhanced to include review and approval requirements under the Nuclear Administrative Technical Manual (NATM).
- Procedures will be enhanced to be consistent with the current code of record or NFPA 25 2002 Edition.
- Procedures will be enhanced to field service test a representative sample or replace sprinklers prior to 50 years in service and test thereafter every 10 years to ensure that signs of degradation are detected in a timely manner.
- Procedures will be enhanced to be consistent with NFPA 25 Section 7.3.2.1, 7.3.2.2, 7.3.2.3, and 7.3.2.4.

19.1.14 FUEL OIL CHEMISTRY

The Fuel Oil Chemistry program manages loss of material on the internal surface of components in the emergency diesel generator (EDG) fuel oil storage and transfer system, diesel

fire pump fuel oil system, and station blackout generator (SBOG) system. The program includes (a) surveillance and monitoring procedures for maintaining fuel oil quality by controlling contaminants in accordance with applicable ASTM Standards, (b) periodic draining of water from fuel oil tanks, (c) visual inspection of internal surfaces during periodic draining and cleaning, (d) ultrasonic wall thickness measurements from external surfaces of fuel oil tanks if there are indications of reduced cross sectional thickness found during the visual inspection, (e) inspection of new fuel oil before it is introduced into the storage tanks, and (f) one-time inspections of a representative sample of components in systems that contain fuel oil by the One-Time Inspection program.

The effectiveness of the program is verified under the One-Time Inspection program (19.1.16).

Prior to the period of extended operation:

Procedures will be enhanced to extend the scope of the program to include the SBOG fuel oil storage tank and SBOG skid fuel tanks.

Procedures will be enhanced to include ten-year periodic draining, cleaning, and inspections on the diesel-driven fire pump day tanks, the SBOG fuel oil storage tank, and SBOG skid fuel tanks.

Ultrasonic testing (UT) or pulsed eddy current (PEC) thickness examination will be conducted to detect corrosion-related wall thinning if degradation is found during the visual inspections

and once on the tank bottoms for the EDG fuel oil storage tanks, EDG fuel oil day tanks, diesel-driven fire pump day tanks, SBOG fuel oil storage tank, and SBOG skid fuel tanks. The one-time UT or PEC examination on the tank bottoms will be performed before the period of extended operation.

19.1.15 REACTOR VESSEL SURVEILLANCE

The Reactor Vessel Surveillance program manages loss of fracture toughness and is consistent with ASTM E 185. Actual reactor vessel plate coupons are used. Weld and heat-affected-zone coupons are made from sections of the same plate welded together with identical weld material heats and weld parameters. The surveillance coupons are tested by a qualified offsite vendor, to its procedures. The testing program and reporting conform to requirements of 10 CFR 50, Appendix H, "*Reactor Vessel Material Surveillance Program Requirements.*"

As shown in Tables 5.3-13, 5.3-14, 5.3-15, 15.3-18, 5.3-19 and 5.3-19A the reactor vessel surveillance capsule removal schedules have been revised to withdraw the next capsules at the equivalent clad-base metal exposure of approximately 54 EFPY (40, 39, and 42 actual EFPY in Units 1, 2, and 3, respectively) expected for the 60-year period of operation. This withdrawal schedule is in accordance with NUREG-1801, Section XI.M31, item 6, and with the ASTM E 185-82 criterion which states that capsules may be removed when the capsule neutron fluence is between one and two times the limiting fluence calculated for the vessel at the end of expected life.

This withdrawal schedule was approved by the NRC in a letter to APS dated April 9, 2012.

If an 80-year second period of extended operation is anticipated, actions would be taken to request approval to withdraw remaining standby capsules at equivalent clad-base metal exposures not exceeding the 72 EFPY expected for the possible 80-year second period of extended operation (at about 50 to 54 actual operation EFPY). Schedule changes must be approved by the NRC, as required by 10 CFR 50 Appendix H and as discussed in NRC Administrative letter 97-04 "NRC Staff Approval for Changes to 10 CFR Part 50, Appendix H, Reactor Vessel Surveillance Specimen Withdrawal Schedules." The need to monitor vessel fluence following removal of the remaining standby capsules, and ex-vessel or in-vessel methods, would be addressed prior to removing the remaining capsules.

19.1.16 ONE-TIME INSPECTION

The One-Time Inspection program conducts one-time inspections of plant system piping and components to verify the effectiveness of the Water Chemistry program (19.1.2), Fuel Oil Chemistry program (19.1.14), and Lubricating Oil Analysis program (19.1.23). The aging effects to be evaluated by the One-Time Inspection program are loss of material, cracking, and reduction of heat transfer. The One-Time Inspection program will include the specific attributes for the components crediting this program for aging management in the license renewal application.

Plant system piping and components will be subject to one-time inspection on a sampling basis using qualified inspection personnel following established ASME, "*Boiler and Pressure Vessel Code*", Section V, "Nondestructive Examination", (NDE) techniques appropriate to each inspection. Inspection sample sizes will be determined using a methodology that is based on 90% confidence that 90% of the population of components will not experience aging effects in the period of extended operation. The One-Time Inspection program specifies corrective actions and increased sampling of piping/components if aging effects are found during material/environment combination inspections. The one-time inspections will be performed no earlier than 10 years prior to the period of extended operation. All one-time inspections will be completed prior to the period of extended operation. Completion of the One-Time Inspection program in this time period will assure that potential aging effects will be manifested based on at least 30 years of PVNGS operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

Major elements of the PVNGS One-Time Inspection program include:

a) Identifying piping and component populations subject to one-time inspection based on common materials and environments

b) Determining the sample size of components to inspect using established statistical methods based on the population size of the material-environment groups

c) Selecting piping and components within the material-environment groups for inspection based on criteria provided in the One-Time Inspection procedure

d) Conducting one-time inspections of the selected components within the sample using ASME Code Section V NDE techniques and acceptance criteria consistent with the design codes/standards or ASME Section XI as applicable to the component

19.1.17 SELECTIVE LEACHING OF MATERIALS

The Selective Leaching of Materials program manages the loss of material due to selective leaching for brass (copper alloy >15% zinc), aluminum-bronze (copper alloy >8% aluminum), and gray cast iron components exposed to closed-cycle cooling water demineralized water, secondary water, raw water and wetted gas within the scope of license renewal. The Selective Leaching of Materials program is in addition to the Open-Cycle Cooling Water program (19.1.9) and the Closed-Cycle Cooling Water program (19.1.10) in these cases.

The program includes a one-time inspection (visual and/or mechanical methods) of a selected sample of components internal surfaces to determine whether loss of material due to selective leaching is occurring. A sample size of 20% of the population, up to a maximum of 25 component inspections, will be

established for each of the system material and environment combinations at the Palo Verde site. If indications of selective leaching are confirmed, follow up examinations or evaluations are performed.

19.1.18 BURIED PIPING AND TANKS INSPECTION

The Buried Piping and Tanks Inspection program manages loss of material of buried components in the chemical and volume control, condensate storage and transfer, diesel fuel storage and transfer, domestic water, fire protection, SBOG fuel system, service gas and essential spray ponds systems. Visual inspections monitor the condition of protective coatings and wrappings found on carbon steel, gray cast iron or ductile iron components and assess the condition of stainless steel components with no protective coatings or wraps. The program includes opportunistic inspection of buried piping and tanks as they are excavated or on a planned basis if opportunistic inspections have not occurred.

The Buried Piping and Tanks Inspection program is a new program that will be implemented prior to the period of extended of operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

Within the ten year period prior to entering the period of extended operation an opportunistic or planned inspection of buried tanks at the Palo Verde site will be performed. Upon entering the period of extended operation, a planned inspection

within ten years will be required unless an opportunistic inspection has occurred within this ten year period.

The visual inspections noted below of piping in a soil environment within the scope of license renewal will be conducted within the ten-year period prior to entering the period of extended operation, and during each ten year period after entering the period of extended operation, except the initial diesel generator fuel oil piping inspection will be performed between January 1, 2012 and December 31, 2015. Each inspection will:

- select accessible locations where degradation is expected to be high;
- excavate and visually inspect the circumference of the pipe; and
- examine at least ten feet of pipe.

a. Metallic Piping not Cathodically-Protected

At least two excavations and visual inspections of stainless steel piping will be conducted in each unit. Stainless steel piping within the scope of license renewal exists in the following systems:

- o Chemical and Volume Control (CH),
- o Condensate Transfer and Storage (CT), and
- o Fire Protection (FP).

b. Steel Piping Cathodically-Protected

At least two excavations and visual inspections of cathodically-protected steel piping will be conducted in each unit. In one of the units, at least one of these inspections will be performed on diesel generator fuel oil piping.

c. Steel Piping with Potentially Degraded Cathodic Protection

At least three excavations and visual inspections of fire protection steel piping with potentially degraded bonding straps will be conducted at the Palo Verde site.

Prior to the period of extended operation, the Buried Piping and Tanks Inspection program will include provisions to (1) ensure electrical power is maintained to the cathodic protection system for in-scope buried piping at least 90% of the time (e.g., monthly verification that the power supply circuit breakers are closed or other verification that power is being provided to the system), and (2) ensure that the National Association of Corrosion Engineers (NACE) cathodic protection system surveys are performed at least annually.

19.1.19 ONE-TIME INSPECTION OF ASME CODE CLASS 1 SMALL-BORE PIPING

The One-Time Inspection of ASME Code Class 1 Small-Bore Piping program manages cracking of stainless steel ASME Code Class 1 piping less than or equal to 4 inches.

For ASME Code Class 1 small-bore piping, volumetric examinations on selected butt weld locations will be performed to detect cracking. Butt weld volumetric examinations will be conducted in accordance with ASME Section XI with acceptance criteria from Paragraph IWB-3000 and IWB-2430. Weld locations subject to volumetric examination will be selected based on the guidelines provided in EPRI TR-112657. Socket welds that fall within the weld examination sample will be examined following ASME Section XI Code requirements. At least 10% of the socket welds in ASME Code Class 1 piping that is less than four inches nominal pipe size and greater than or equal to one inch nominal pipe size will be selected per unit for ultrasonic testing examination, up to a maximum of 25 weld examinations. The sample will be selected based on risk insights and those welds with the potential for aging degradation.

Socket welds that fall within the weld examination sample will be examined following ASME Section XI Code requirements. If a qualified volumetric examination procedure for socket welds endorsed by the industry and the NRC is available and incorporated into the ASME Section XI Code at the time of PVNGS small-bore socket weld inspections then this will be used for the volumetric examinations. If no volumetric examination procedure for ASME Code Class 1 small bore socket welds has been endorsed by the industry and the NRC and incorporated into ASME Section XI at the time PVNGS performs inspections of small-bore piping, a plant procedure for volumetric examination of ASME Code Class 1 small-bore piping with socket welds will be used.

The One-Time Inspection of ASME Code Class 1 Small-Bore Piping program is a new program that will be implemented within the six year period prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

19.1.20 EXTERNAL SURFACES MONITORING PROGRAM

The External Surfaces Monitoring Program manages loss of material for steel, aluminum, and copper alloy components and hardening and loss of strength for elastomer components. The program includes those systems and components within the scope of license renewal that require external surface monitoring. Visual inspections conducted during engineering walkdowns will be used to identify aging effects and leakage. Physical manipulation during the visual inspections must also be used to verify absence of hardening or loss of strength for elastomers.

Loss of material for external surfaces is managed by the Boric Acid Corrosion program (19.1.4) for components in a system with treated borated water or reactor coolant environment on which boric acid corrosion may occur, Buried Piping and Tanks Inspection program (19.1.18) for buried components, and Structures Monitoring Program (19.1.32) for civil structures, and other structural items which support and contain mechanical and electrical components.

The External Surfaces Monitoring Program is a new program that will be implemented prior to the period of extended operation.

Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

19.1.21 REACTOR COOLANT SYSTEM SUPPLEMENT

Section 3.1 of NUREG-1800, "*Standard Review Plan for the Review of License Renewal Applications for Nuclear Power Plants*," supplements the aging management programs for the reactor coolant system components with the following additional requirements.

APS will:

A. Reactor Coolant System Nickel Alloy Pressure Boundary Components

Implement applicable (1) NRC Orders, Bulletins and Generic Letters associated with nickel alloys and (2) staff-accepted industry guidelines, (3) participate in the industry initiatives, such as owners group programs and the EPRI Materials Reliability Program, for managing aging effects associated with nickel alloys, (4) upon completion of these programs, but not less than 24 months before entering the period of extended operation, APS will submit an inspection plan for reactor coolant system nickel alloy pressure boundary components to the NRC for review and approval, and

B. Reactor Vessel Internals

The PWR Internals Aging Management Program (AMP) Plan for Palo Verde Nuclear Generating Station Units 1, 2, and 3 has been

created to address the reactor vessel internals aging concerns consistent with NUREG-1801 (GALL Report), Revision 2, Chapter XI.M.16A, "PWR Vessel Internals". The program relies on implementation of the EPRI MRP-227 and MRP-228 to manage the aging effects on the reactor vessel internal components, including:

(a) various forms of cracking, including SCC, PWSCC, irradiation-assisted stress corrosion cracking (IASCC), or cracking due to fatigue/cyclical loading

(b) loss of material induced by wear

(c) loss of fracture toughness due to either thermal aging or neutron irradiation embrittlement

(d) dimensional changes and potential loss of fracture toughness due to void swelling and irradiation growth

(e) loss of preload due to thermal and irradiation-enhanced stress relaxation or creep

APS submitted the PVNGS Units 1, 2, and 3 reactor vessel internals aging management program and inspection plans in accordance with MRP-227-A for NRC review and approval via letter 102-06599, dated September 28, 2012, and supplemented by letter 102-06908, dated July 23, 2014. The program was approved by the NRC on March 27, 2015 via letter ML15058A029. APS will manage the Reactor Vessel Internals (RVI) inspections during the period of extended operation through the augmented Inservice Inspection Program.

19.1.22 INSPECTION OF INTERNAL SURFACES IN MISCELLANEOUS PIPING AND DUCTING COMPONENTS

The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program manages cracking, loss of material, and hardening and loss of strength. The internal surfaces of piping, piping components, ducting and other components that are not covered by other aging management programs are included in this program.

The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program uses the work control process to conduct and document inspections. The program will perform visual inspections to detect aging effects that could result in a loss of component intended function. The visual inspections will be conducted during periodic maintenance, predictive maintenance, surveillance testing and corrective maintenance.

Within 10 years before entering the period of extended operation, a review will be conducted to determine the number of inspection opportunities afforded by the work control process for all systems within the scope of this program. In the vast majority of cases, it is expected that the number of work opportunities existing will be sufficient to detect aging and provide reasonable assurance that intended functions are maintained. For those systems or components where inspections of opportunity are insufficient, an inspection will be conducted prior to the period of extended operation to provide reasonable assurance that the intended functions are maintained. Additionally, visual inspections may be augmented

by physical manipulation to detect hardening and loss of strength of both internal and external surfaces of elastomers. The program also includes volumetric evaluation to detect stress corrosion cracking of the internal surfaces of stainless steel components exposed to diesel exhaust.

The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

19.1.23 LUBRICATING OIL ANALYSIS

The Lubricating Oil Analysis program manages loss of material and reduction of heat transfer for components within the scope of license renewal that are exposed to lubricating and hydraulic oil. The program monitors and maintains lubricating and hydraulic oil properties within acceptance criteria, thereby preserving an environment that is not conducive to aging effects. Acceptance criteria are based upon vendor and industry guidelines for oil chemical and physical properties and for foreign material such as water contamination. Increased contamination and degradation of oil properties provide an indication of aging of the lubricating oil. Monitoring and trending of lubricating and hydraulic oil properties and particles found within the oil identifies risk to components due to aging prior to loss of intended function.

The effectiveness of the program is verified under the One-Time Inspection program (19.1.16).

19.1.24 ELECTRICAL CABLES AND CONNECTIONS NOT SUBJECT TO 10 CFR 50.49 ENVIRONMENTAL QUALIFICATION REQUIREMENTS

The Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program manages the aging effects of embrittlement, melting, cracking, swelling, surface contamination, or discoloration to ensure that electrical cables, connections and terminal blocks not subject to the environmental qualification (EQ) requirements of 10 CFR 50.49 and within the scope of license renewal are capable of performing their intended functions.

Non-EQ cables, connections and terminal blocks within the scope of license renewal in accessible areas with an adverse localized environment are inspected. The inspections of Non-EQ cables, connectors and terminal blocks in accessible areas are representative, with reasonable assurance, of cables, connections and terminal blocks in inaccessible areas with an adverse localized environment. At least once every ten years, the Non-EQ cables, connections and terminal blocks within the scope of license renewal in accessible areas are visually inspected for embrittlement, melting, cracking, swelling, surface contamination, or discoloration.

The acceptance criterion for visual inspection of accessible Non-EQ cable jacket, connection and terminal blocks insulating material is the absence of anomalous indications that are signs

of degradation. Corrective actions for conditions that are adverse to quality are performed in accordance with the corrective action program as part of the QA program.

The Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

19.1.25 ELECTRICAL CABLES AND CONNECTIONS NOT SUBJECT TO 10 CFR 50.49 ENVIRONMENTAL QUALIFICATION REQUIREMENTS USED IN INSTRUMENTATION CIRCUITS

The scope of this program includes the cables and connections used in sensitive instrumentation circuits with sensitive, high voltage low-level signals within the Ex-core Neutron Monitoring and Radiation Monitoring Systems including the source range, intermediate range, power range monitors, and non-EQ area radiation monitors. The Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits program manages embrittlement, cracking, melting, discoloration, swelling, or loss of dielectric strength leading to reduced insulation resistance.

This program provides reasonable assurance that the intended function of cables and connections used in instrumentation circuits with sensitive, low-level signals that are not subject

to the environmental qualification requirements of 10 CFR 50.49 and are exposed to adverse localized environments caused by heat, radiation, or moisture are maintained consistent with the current licensing basis through the period of extended operation. In most areas, the actual ambient environments (e.g., temperature, radiation, or moisture) are less severe than the plant design environment for those areas.

Calibration surveillance tests are used to manage the aging of the cable insulation and connections for non-EQ area radiation monitors so that instrumentation circuits perform their intended functions. When an instrumentation channel is found to be out of calibration during routine surveillance testing, troubleshooting is performed on the loop, including the instrumentation cable and connections. A review of calibration results will be completed prior to the period of extended operation and every 10 years thereafter.

Cable testing will be used to manage the aging of the cable insulation and connections for the ex-core neutron monitoring system. Cable tests such as insulation resistance testing or other tests will be performed to detect deterioration of the cable insulation system. The cable will be tested prior to the period of extended operation and every 10 years thereafter. Acceptance criteria will be determined prior to testing based on the type of cable and type of test performed.

Prior to the period of extended operation, procedures will be enhanced to identify license renewal scope, require cable testing of ex-core neutron monitoring cables, require an

evaluation of the calibration results for non-EQ area radiation monitors, and require acceptance criteria for cable testing be established based on type of cable and type of test performed.

19.1.26 INACCESSIBLE MEDIUM VOLTAGE CABLES NOT SUBJECT TO 10 CFR 50.49 ENVIRONMENTAL QUALIFICATION REQUIREMENTS

The Inaccessible Medium Voltage Cables Not Subject to 10 CFR 50.49 EQ Requirements program manages localized damage and breakdown of insulation leading to electrical failure in inaccessible cables (480V and above) exposed to adverse localized environments caused by significant moisture (moisture that lasts more than a few days) to ensure that inaccessible cables (480V and above) not subject to the environmental qualification (EQ) requirements of 10 CFR 50.49 and within the scope of license renewal are capable of performing their intended function.

All cable manholes that contain in-scope non-EQ inaccessible cables (480V and above) will be inspected for water collection. Collected water will be removed as required. This inspection and water removal will be performed based on actual plant experience with water accumulation in the manhole and site rain events. The inspection frequency is event driven and at least annually.

The program provides for testing of in-scope non-EQ inaccessible cables (480V and above) to provide an indication of the conductor insulation condition. At least once every six years, a polarization index test as described

in EPRI TR-103834-P1-2 or other testing that is state-of the- art at the time of the testing is performed.

Prior to the period of extended operation procedures will be enhanced to:

- Extend the scope of the program to include low voltage (480V and above) non-EQ inaccessible power cables and associated manholes.
- Perform the cable inspections on at least an annual frequency and perform the cable testing on a six year frequency.

19.1.27 ASME SECTION XI, SUBSECTION IWE

The ASME Section XI, Subsection IWE containment inservice inspection program manages loss of material and loss of sealing of the steel liner of the concrete containment building, including the containment liner plate, piping and electrical penetrations, access hatches, and the fuel transfer tube. Inspections are performed to identify and manage any containment liner aging effects that could result in loss of intended function. Acceptance criteria for components subject to Subsection IWE exam requirements are specified in Article IWE-3000. In conformance with 10 CFR 50.55a(g)(4)(ii), the PVNGS ISI Program is updated during each successive 120-month inspection interval to comply with the requirements of the latest edition and addenda of the Code specified twelve months before the start of the inspection interval.

19.1.28 ASME SECTION XI, SUBSECTION IWL

The ASME Section XI, Subsection IWL program manages cracking, loss of material, and increase in porosity and permeability of the concrete containment building and post-tensioned system. Inspections are performed to identify and manage any aging effects of the containment concrete, post-tensioned tendons, tendon anchorages, and concrete surface around the anchorage that could result in loss of intended function. In conformance with 10 CFR 50.55a(g)(4)(ii), the ASME Section XI, Subsection IWL Program is updated during each successive 120-month inspection interval to comply with the requirements of the latest edition and addenda of the Code specified twelve months before the start of the inspection interval.

19.1.29 ASME SECTION XI, SUBSECTIONS IWF

The ASME Section XI, Subsection IWF program manages loss of material, cracking, and loss of mechanical function that could result in loss of intended function for Class 1, 2 and 3 component supports. There are no Class MC supports at PVNGS. In conformance with 10 CFR 50.55a(g)(4)(ii), the PVNGS ISI Program is updated during each successive 120-month inspection interval to comply with the requirements of the latest edition and addenda of the Code specified twelve months before the start of the inspection interval.

19.1.30 10 CFR 50, APPENDIX J

The 10 CFR 50, Appendix J program manages loss of material, loss of leak tightness, and loss of sealing. The program monitors leakage rates through the containment pressure boundary, including the penetrations and access openings, in order to detect degradation of containment pressure boundary. Seals, gaskets, and bolted connections are also monitored under the program.

Containment leak rate tests are performed in accordance with 10 CFR 50 Appendix J, "*Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors,*" Option B; Regulatory Guide 1.163, "*Performance*-Based Containment Leak-Testing Program"; NEI 94-01, "Industry Guideline for Implementing Performance-Based Option of 10 CFR Part 50 Appendix J"; and ANSI/ANS 56.8, "Containment *System Leakage Testing Requirements.*"

Containment leak rate tests are performed to assure that leakage through the primary containment, and systems and components penetrating primary containment does not exceed allowable leakage limits specified in the Technical Specifications. Corrective actions are taken if leakage rates exceed established administrative limits for individual penetrations or the overall containment pressure boundary.

19.1.31 MASONRY WALL PROGRAM

The Masonry Wall Program, which is part of the Structures Monitoring Program, manages cracking of masonry walls, and

structural steel restraint systems of the masonry walls, within scope of license renewal based on guidance provided in IE Bulletin 80-11, "*Masonry Wall Design,*" and NRC Information Notice 87-67, "*Lessons Learned from Regional Inspections of Licensee Actions in Response to NRC IE Bulletin 80-11.*" The Masonry Wall Program contains inspection guidelines and lists attributes that cause aging of masonry walls, which are to be monitored during structural monitoring inspections, as well as establishes examination criteria, evaluation requirements, and acceptance criteria.

Prior to the period of extended operation, procedures will be enhanced to specify ACI 349.3R-96 as the reference for qualification of personnel to inspect structures under the Masonry Wall Program, which is part of the Structures Monitoring Program.

19.1.32 STRUCTURES MONITORING PROGRAM

The Structures Monitoring Program manages the cracking, loss of material, and change in material properties by monitoring the condition of structures and structural supports that are within the scope of license renewal. The Structures Monitoring Program implements the requirements of 10 CFR 50.65 and is consistent with the guidance of NUMARC 93-01, Revision 4A and Regulatory Guide 1.160, Revision 3.

The Structures Monitoring Program provides inspection guidelines for concrete elements, structural steel, masonry walls, structural features (e.g., caulking, sealants, roofs,

etc.), structural supports, and miscellaneous components such as doors. The Structures Monitoring Program includes all masonry walls and water-control structures within the scope of license renewal. The Structures Monitoring Program also monitors settlement for each major structure and inspects supports for equipment, piping, conduit, cable tray, HVAC, and instrument components.

Prior to the period of extended operation:

The Structures Monitoring Program will be enhanced to specify ACI 349.3R-96 as the reference for qualification of personnel to inspect structures under the Structures Monitoring Program.

For structures within the scope of license renewal, the Structures Monitoring Program will be enhanced to establish the frequency of inspection for each unit at a 5 year interval, with the exception of exterior surfaces of the following nonsafety-related structures, below-grade structures, and structures within a controlled interior environment, which will be inspected at an interval of 10 years:

- Fire Pump House (Yard Structures)
- Radwaste Building
- Station Blackout Generator Structures
- Turbine Building
- Non-Safety Related Tank Foundations and Shells
- Non-Safety Related Transformer Foundations and Electrical Structures

The Structures Monitoring Program will be enhanced to quantify the acceptance criteria and critical parameters for monitoring degradation, and to provide guidance for identifying unacceptable conditions requiring further technical evaluation or corrective action. Procedures will also be enhanced to incorporate applicable industry codes, standards and guidelines for acceptance criteria.

19.1.33 REGULATORY GUIDE 1.127, INSPECTION OF WATER-CONTROL STRUCTURES ASSOCIATED WITH NUCLEAR POWER PLANTS

The PVNGS Structures Monitoring Program, which includes all water-control structural components within the scope of RG 1.127, Inspection of Water Control Structures Associated with Nuclear Power Plants, manages cracking, loss of material, loss of bond, loss of strength, and increase in porosity and permeability due to extreme environmental conditions. PVNGS meets the recommendations of RG 1.127, Revision 1.

This program includes inspection and surveillance activities for water-control structures associated with emergency cooling water systems and includes periodic inspections and monitoring of the in-scope water-control structures; i.e., the Ultimate Heat Sink and associated structures.

Prior to the period of extended operation, procedures will be enhanced to specify that the essential spray ponds inspections include concrete below the water level.

19.1.34 NICKEL ALLOY AGING MANAGEMENT PROGRAM

The Nickel Alloy Aging Management Program manages cracking due to primary water stress corrosion cracking in all plant locations that contain Alloy 600, with the exception of steam generator tubing (aging management of steam generator tubing is performed by the Steam Generator Tubing Integrity program (19.1.8)) and reactor vessel internals (aging management of reactor vessel internals is addressed in Reactor Coolant System Supplement (19.1.21)). The original Reactor Vessel Heads (RVH) contained Alloy 600 nozzles and were managed under this program. The replacement RVHs now contain Alloy 690 nozzles which are no longer required to be managed under this program. This program includes Alloy 600 reactor coolant pressure boundary locations in the reactor coolant system (RCS) and ESF systems.

The Alloy 600 aging management program uses inspections, mitigation techniques, repair/replace activities and monitoring of operating experience to manage the aging of Alloy 600 at PVNGS. Detection of indications is accomplished through a variety of examinations consistent with ASME Section XI Subsections IWB, ASME Code Case N-729-1 subject to the conditions specified in 10 CFR 50.55a(g)(6)(ii)(D)(2) through (6), ASME Code Case N-722 subject to the conditions listed in 10 CFR 50.55a(g)(6)(ii)(E)(2) through (4), and ASME Code Case N-770-1 subject to the conditions listed in 10 CFR 50.55a (g)(6)(ii)(F) (2) through (10). Mitigation techniques are implemented when appropriate to preemptively remove conditions

that contribute to primary water stress corrosion cracking. Repair/replacement activities are performed to proactively remove or overlay Alloy 600 material, or as a corrective measure in response to an unacceptable flaw. Mitigation and repair/replace activities are consistent with those detailed in ASME Code Case N-770-1 as conditioned above.

19.1.35 ELECTRICAL CABLE CONNECTIONS NOT SUBJECT TO 10 CFR 50.49 ENVIRONMENTAL QUALIFICATION REQUIREMENTS

The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program manages the effects of loosening of bolted external connections due to thermal cycling, ohmic heating, electrical transients, vibration, chemical contamination, corrosion, and oxidation. As part of the PVNGS predictive maintenance program, infrared thermography testing is being performed on non-EQ electrical cable connections, associated with active and passive components within the scope of license renewal. A representative sample will be tested at least once prior to the period of extended operation using infrared thermography to confirm that there are no aging effects requiring management during the period of extended operation. The selected sample is based upon application (medium and low voltage), circuit loading, and environment.

The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating

experience will be evaluated in the development and implementation of this program.

19.1.36 METAL ENCLOSED BUS

The Metal Enclosed Bus (MEB) program manages the effects of loose connections, embrittlement, cracking, melting, swelling, or discoloration of insulation, loss of material of bus enclosure assemblies, hardening of boots and gaskets, and cracking of internal bus supports to ensure that metal-enclosed buses within the scope of license renewal. Internal portions of MEBs are visually inspected for cracks, corrosion, foreign debris, excessive dust buildup, and evidence of water intrusion. The bus insulation is inspected for signs of embrittlement, cracking, melting, swelling, hardening or discoloration, which may indicate overheating or aging degradation. The internal bus supports are inspected for structural integrity and signs of cracks. The bus enclosure assemblies are inspected for loss of material due to corrosion and hardening of boots and gaskets. Samples of the accessible bolted connections on the internal bus work are checked for loose connections by measuring connection resistance.

The Metal Enclosed Bus program is a new program and will be completed before the period of extended operation and once every 10 years thereafter. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

19.1.37 FUSE HOLDERS

The Fuse Holders program manages thermal fatigue, mechanical fatigue, vibration, chemical contamination, and corrosion of the metallic portions of fuse holders to ensure that fuse holders within the scope of license renewal are capable of performing their intended function.

The Fuse Holder program is a new program that will be completed before the period of extended operation and once every 10 years thereafter. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program.

This page intentionally left blank

19.2 SUMMARY DESCRIPTIONS OF TIME-LIMITED AGING ANALYSIS AGING MANAGEMENT PROGRAMS

19.2.1 Metal Fatigue of Reactor Coolant Pressure Boundary

The Metal Fatigue of Reactor Coolant Pressure Boundary program uses cycle counting and usage factor tracking to ensure that actual plant experience remains bounded by design assumptions and calculations reflected in the PVNGS UFSAR.

PVNGS Technical Specification 5.5.5 requires the establishment of a "Component Cyclic or Transient Limit" program to track the occurrences specified in PVNGS UFSAR section 3.9.1.1 and states in total:

> "5.5.5 Component Cyclic or Transient Limit
>
> This program provides controls to track the UFSAR Section 3.9.1.1 cyclic and transient occurrences to ensure that components are maintained within the design limits."

The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will use cycle counting (CC), cycle-based fatigue (CBF) cumulative usage factor (CUF) calculations and stress based fatigue CUF calculations (SBF) to monitor fatigue. FatiguePro will be used for cycle counting and cycle-based fatigue (CBF) monitoring methods. FatiguePro is an EPRI licensed product. The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will use a fatigue monitoring software program that incorporates a three-dimensional, six-component stress tensor method meeting ASME III NB-3200 requirements for stress-based fatigue monitoring (SBF). The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will provide action limits on cycles and on CUF that

will initiate corrective actions before the licensing basis limits on fatigue effects at any location are exceeded.

The scope of the enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will include transient cycle counting required by the existing Metal Fatigue of Reactor Coolant Pressure Boundary program and adds CUF monitoring for all but one of the PVNGS NUREG/CR-6260 locations which are the leading indicators for monitoring the usage due to environmentally assisted fatigue. The RPV shell and lower head (juncture) location will be monitored by cycle counting. The usage factors calculated by the enhanced program for NUREG/CR-6260 locations will include environmental effects of the reactor coolant environment as determined by NUREG/CR-6583 and NUREG/CR-5704.

No later than two years prior to the period of extended operation, the following enhancements will be implemented:

- Cumulative usage factor tracking will be implemented for NUREG/CR-6260 locations not monitored by cycle counting (the reactor vessel shell and lower head (juncture) location will be monitored by cycle counting).

- The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced to include a computerized program to track and manage both cycle counting and fatigue usage factor. FatiguePro will be used for cycle counting and cycle-based fatigue (CBF) monitoring methods. FatiguePro

SUMMARY DESCRIPTIONS OF TIME-LIMITED

AGING ANALYSIS AGING MANAGEMENT PROGRAMS

is an EPRI licensed product. A fatigue monitoring software program that incorporates a three-dimensional, six-component stress tensor meeting ASME III NB-3200 requirements will be used for stress-based fatigue monitoring (SBF).

- The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will monitor plant transients as required by PVNGS Technical Specification 5.5.5. Cumulative usage factors (CUFs) will be calculated for a subset of ASME III Class 1 reactor coolant pressure boundary vessel and piping locations, and component locations with Class 1 analyses. The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will provide action limits on cycles and on CUF that will initiate corrective actions before the licensing basis limits on fatigue effects at any location are exceeded.
- The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced with additional cycle count and fatigue usage action limits, and with appropriate corrective actions to be invoked if a component approaches a cycle count action limit or a fatigue usage action limit. Action limits will be established to permit completion of corrective actions before the design limits are exceeded.

SUMMARY DESCRIPTIONS OF TIME-LIMITED

AGING ANALYSIS AGING MANAGEMENT PROGRAMS

- The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced to add CUF monitoring. The following methods will be used:

  1) The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced to use cycle-based fatigue (CBF) and stress-based fatigue (SBF) CUF calculations to monitor fatigue. FatiguePro will be used for cycle counting and cycle-based fatigue (CBF) monitoring methods. FatiguePro is an EPRI licensed product.

  2) The SBF method will use a fatigue monitoring software program that incorporates a three-dimensional, six-component stress tensor method meeting ASME III NB-3200 requirements.

- Action limits will be established to require corrective action when the cycle count of any of the monitored transients is projected to reach the action limit. In order to ensure sufficient margin to accommodate occurrence of a low-probability transient, corrective actions must be taken before the remaining number of allowable occurrences for any specified transient becomes less than 1.

  If a cycle count action limit is reached, the following actions will be considered and those deemed appropriate will be taken:

SUMMARY DESCRIPTIONS OF TIME-LIMITED

AGING ANALYSIS AGING MANAGEMENT PROGRAMS

1) Review of fatigue usage calculations

   a. To determine whether the transient in question contributes significantly to CUF.

   b. To identify the components and analyses affected by the transient in question.

   c. To ensure that the analytical bases of the high-energy line break (HELB) locations are maintained.

   d. To ensure that the analytical bases of a fatigue crack growth and stability analysis in support of relief from ASME Section XI flaw removal and inspection requirements for hot leg small-bore half nozzle repairs and other similar repairs/analyses are maintained.

2) Evaluation of remaining margins on CUF based on cycle-based or stress-based CUF calculations using the PVNGS fatigue management program software.

3) Redefinition of the specified number of cycles (e.g., by reducing specified numbers of cycles for other transients and using the margin to increase the allowed number of cycles for the transient that is approaching its specified number of cycles).

4) Redefinition of the transient to remove conservatism in predicting the range of pressure and temperature values for the transient.

SUMMARY DESCRIPTIONS OF TIME-LIMITED

AGING ANALYSIS AGING MANAGEMENT PROGRAMS

- For PVNGS locations identified in NUREG/CR-6260 and monitored by CUF, fatigue usage factor action limits will be based on accrued fatigue usage calculated with the F(en) environmental fatigue factors determined by NUREG/CR-5704 and NUREG/CR-6583 methods required for including effects of the reactor coolant environment.

Cumulative Fatigue Usage Action Limit and Corrective Actions

- Action limits will be established to require corrective action when the calculated CUF (from cycle-based or stress-based monitoring) for any monitored location is projected to reach 1.0 within the next 2 or 3 operating cycles. In order to ensure sufficient margin to accommodate occurrence of a low-probability transient, corrective actions will be taken while there is still sufficient margin to accommodate at least one occurrence of the worst-case design transient event (i.e., with the highest fatigue usage per event cycle).

  If a CUF action limit is reached, the following actions will be considered and those deemed appropriate will be taken:

  1) Determine whether the scope of the enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program must be enlarged to include additional affected reactor coolant pressure boundary locations. This determination

will ensure that other locations do not approach design limits without an appropriate action.

2) Adjust fatigue monitoring methods to confirm continued conformance to the code limit.

3) Repair/modify the component.

4) Replace the component.

5) Perform a more rigorous analysis of the component to demonstrate that the design code limit will not be exceeded.

6) Modify plant operating practices to reduce the fatigue usage accumulation rate.

7) Perform a flaw tolerance evaluation and impose component-specific inspections, under ASME Section XI Appendices A or C (or their successors) and obtain required approvals from the regulatory agency.

19.2.2 Environmental Qualification (EQ) of Electrical Components

The Environmental Qualification (EQ) of Electrical Components program manages component thermal, radiation, and cyclic aging effects, using 10 CFR 50.49(f) methods. As required by 10 CFR 50.49, EQ components are to be refurbished or replaced, or have their qualification extended prior to reaching the aging limits established in the evaluation. Maintaining qualification through the extended license renewal period

requires that existing EQ evaluations (EEQDFs) be re-evaluated. The Environmental Qualification (EQ) of Electrical Components program is consistent with the guidance of 10 CFR 50.49, NUREG-0588, and Regulatory Guide 1.89, "*Environmental Qualification of Certain Electric Equipment Important to Safety for Nuclear Power Plants,*" Revision 1 for maintaining qualifications of equipment. Reanalysis of aging evaluations to extend the qualifications of components is performed on a routine basis as part of the EQ Program. Important attributes for the reanalysis of aging evaluations include analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria and corrective actions (if acceptance criteria are not met).

19.2.3 Concrete Containment Tendon Prestress

The Concrete Containment Tendon Prestress program, within the PVNGS ASME Section XI Subsection IWL Program, manages the loss of tendon prestress in the post-tensioning system.

The PVNGS post-tensioning system consists of inverted-U-shaped tendons, extending up through the basemat, through the full height of the cylindrical walls and over the dome; and horizontal circumferential (hoop) tendons, at intervals from the basemat to about the 45-degree elevation of the dome. The basemat is conventionally-reinforced concrete. The tendons are ungrouted, in grease-filled glands.

SUMMARY DESCRIPTIONS OF TIME-LIMITED

AGING ANALYSIS AGING MANAGEMENT PROGRAMS

The beginning of the first IWL tendon examination interval was August 1, 2001 for all three units. The beginning of the second interval will be August 1, 2011 for all three units. As required by 10 CFR 50.55a, beginning August 1, 2011, the program will conform to a later edition of ASME Section XI, Subsection IWL which permits a 10-year interval between tendon prestress surveillance tests, for each unit of a multi-unit plant. The entire scope of IWL-2500, including prestress liftoff measurements, will be required only every 10-years in each unit; except that the visual inspections and anti-corrosion medium surveillances of IWL-2524 and IWL-2525 must be repeated at the intervening 5-year intervals.

The program includes randomly-selected surveillance tendons for a 40-year license (through the year 35 surveillance).

Prior to the period of extended operation, procedures will be enhanced to require an update of the regression analysis for each tendon group of each unit, and of the joint regression of data from all three units, after every tendon surveillance. The documents will invoke and describe regression analysis methods used to construct the lift-off trend lines, including the use of individual tendon data in accordance with Information Notice (IN) 99-10, "*Degradation of Prestressing Tendon Systems in Prestressed Concrete Containments.*"

19.3 EVALUATION SUMMARIES OF TIME-LIMITED AGING ANALYSES

10 CFR 54.21(c) requires that an applicant for a renewed license identify time-limited aging analyses (TLAAs) and evaluate them for the period of extended operation. The following TLAAs have been identified and evaluated for PVNGS.

19.3.1 REACTOR VESSEL NEUTRON EMBRITTLEMENT

Ferritic materials of the reactor vessel are subject to embrittlement (loss of fracture toughness) due to high-energy neutron exposure. The following predictions of neutron fluence and of its embrittlement effects are TLAAs:

- Neutron Fluence, Upper Shelf Energy, Adjusted Reference Temperature (Fluence, USE, and ART)
- Pressurized Thermal Shock (PTS)
- Reactor Vessel Thermal Limit Analysis and Pressure-Temperature (P-T) Limits
- Low Temperature Overpressure Protection (LTOP)

The Reactor Vessel Surveillance program is described in Section 19.1.15.

19.3.1.1 Neutron Fluence, Upper Shelf Energy and Adjusted Reference Temperature (Fluence, USE, and ART)

The critical time-dependent parameter for determining radiation embrittlement effects is lifetime fluence of neutrons with energies greater than 1 MeV. The original design basis fluence predictions for a 32 EFPY life were the standard Combustion

Engineering estimates for the CESSAR-80 plants. Power uprate (PUR) had no effect on these fluence projections because this original analysis of record used a power level of 4200 MW_t, which is higher than the PUR level of 3990 MW_t.

Increased plant capacity factors prompted the increase in the lifetime capacity factor assumed for fluence estimates from 80 to 90 percent, and hence increased the assumed EFPY for the period of extended operation to 54 EFPY. With continued use of low-leakage cores, the current Unit 1, 2, and 3 projections of the clad-base metal interface neutron fluence at 54 EFPY are less than the original 32 EFPY projection used to determine the EOL ART and USE reported in the NRE Reactor Vessel Integrity Database. Therefore the original projections remain valid for the period of extended operation.

Fluence, USE, and ART will be managed for the extended licensed operating period by continuing the Reactor Vessel Surveillance program (Section 19.1.15), with adjustments to the coupon examination schedule to withdraw the next capsule at an equivalent clad-base metal exposure of approximately 54 EFPY, and to withdraw remaining standby capsules at equivalent clad-base metal exposures not exceeding 72 EFPY if an 80-year second period of extended operation is anticipated. The validity of these parameters and the analyses that depend upon them will therefore be adequately managed for the period of extended operation.

19.3.1.2 Pressurized Thermal Shock (PTS)

If the reference temperature for pressurized thermal shock (RT_{PTS}) for each heat of material of the reactor pressure vessel does not exceed the applicable screening criterion, only the reactor pressure vessel is "relied on to demonstrate compliance" with the 10 CFR 50.61 PTS rule.

The original PTS evaluation of the PVNGS vessels demonstrated low values of the RT_{PTS} screening parameter. The originally-assumed 32 EFPY neutron fluence is not expected to be exceeded in a 54 EFPY period of extended operation, and no changes to the material composition information or to embrittlement assessment methods have significantly affected the RTPTS screening values. Therefore the conclusions of the original evaluation are unaffected. The original evaluation of the PTS screening parameters, and the conclusion of the evaluation, is therefore valid for the period of extended operation.

19.3.1.3 Pressure-Temperature (P-T) Limits

The P-T limit curves are operating limits, based on material embrittlement effects that are valid up to the vessel fluence for which these embrittlement effects are calculated.

The current P-T limit curves permit operation up to 32 EFPY. However, the P-T limit curves were based on an assumed 32 EFPY beltline neutron fluence that is in excess of the maximum fluence now projected for 54 EFPY. Therefore the P-T limit curves are valid for the period of extended operation. New P-T limits will not be required.

19.3.1.4 Low Temperature Overpressure Protection (LTOP)

LTOP is required by Technical Specifications and is provided by relief valves in the two suction lines of the shutdown cooling system (SCS), or by operating with the reactor coolant system (RCS) depressurized and with an open RCS vent of sufficient size.

The LTOP setpoints depend on the P-T limit curves and the ART, both of which will remain valid for the period of extended operation. Therefore the LTOP licensing and design basis analyses will remain valid for the period of extended operation.

19.3.2 METAL FATIGUE ANALYSIS

This section describes:

- ASME Section III Class 1 Fatigue Analysis of Vessels, Piping, and Components
- ASME Section III Subsection NG Fatigue Analysis of Reactor Pressure Vessel Internals
- Effects of the Reactor Coolant System Environment on Fatigue Life of Piping and Components (Generic Safety Issue 190)

- Assumed Thermal Cycle Count for Allowable Secondary Stress Range Reduction Factor in B31.1 and ASME Section III Class 2 and 3 Piping

ASME III requires no fatigue analysis for Class 2 components. However, design of the following PVNGS Class 2 components is supported by Class 1 fatigue analyses:

- Secondary sides of the replacement steam generators
- Regenerative and letdown heat exchangers
- HPSI and LPSI pumps
- Main steam safety valves

Basis of Fatigue Analysis

ASME Section III Class 1 design specifications define a design basis set of static and transient load conditions. The design number of each transient specified was selected to be larger than expected to occur during the 40-year licensed life of the plant, based on operating experience, and on projections of future operation based on innovations in the system designs. Although original design specifications commonly state that the transients are for a 40-year design life, the fatigue analyses themselves are based on the specified number of occurrences of each transient rather than on this lifetime.

Metal Fatigue of Reactor Coolant Pressure Boundary Program

The Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 ensures that actual plant experience remains bounded by the assumptions used in the

design calculations, or that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded and before the ASME Section III limit of 1.0 for the fatigue cumulative usage factor is reached.

> The PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) was implemented in response to PVNGS Technical Specification 5.5.5 which requires the establishment of a "Component Cyclic or Transient Limit" program to track the occurrences specified in PVNGS UFSAR section 3.9.1.1."

19.3.2.1 ASME Section III Class 1 Fatigue Analysis of Vessels, Piping, and Components

Fatigue analyses exist for ASME III Division 1 Class 1 piping, vessels, heat exchangers, pumps, and valves; and if applicable, their supports.

Class 1 fatigue analyses also support design of the following Class 2 components:

- Secondary sides of the replacement steam generators
- Regenerative and letdown heat exchangers
- HPSI and LPSI pumps
- Main steam safety valves

The Class 1 analyses have been updated to incorporate redefinitions of loads and design basis events, operating changes, and power uprate with steam generator replacement.

The PVNGS reactor vessel internals were analyzed to ASME-Section III Subsection NG. See Subsection 19.3.2.2.

19.3.2.1.1 Reactor Pressure Vessel, Nozzles, Head, and Studs

The PVNGS reactor pressure vessels were designed, built, and analyzed by Combustion Engineering to ASME Section III, Subsection NB (Class 1), 1971 Edition with addenda through Winter 1973. The reactor vessel primary coolant inlet and outlet nozzles and lower-head-to-shell juncture are evaluated for effects of the reactor coolant environment on fatigue behavior of these materials, consistent with NUREG/CR-6260. See Section 19.3.2.3.

The analyses performed to incorporate the effects of power uprate (PUR) and replacement steam generators (RSG) into the current design bases demonstrated that the effects on fatigue analyses were limited to the inlet and outlet nozzles. The modification increased the CUF of the inlet nozzles and the outlet nozzles.

The 1991 CE Owner's Group review of Combustion Engineering Infobulletin 88-09, "Nonconservative Calculation of Cumulative *Fatigue Usage*," identified a possible increase in the reactor vessel stud cumulative usage factor. The Owner's Group review found that the usage factor of reactor vessel studs at PVNGS could increase to greater than 1.0, if the more-conservative

pressure curves were used. To accommodate the more-conservative pressure curves, the number of heatup-cooldown transients was reduced and the number of bolt-up transients was reduced.

The replacement reactor vessel closure heads will have been installed after more than 20 years of operation of each unit. The replacement reactor vessel closure heads were designed to ASME III, 1998 Edition up to and including the 2000 Addenda, for a 40-year operating period, and the design specification for the replacement heads includes design transients and seismic loads consistent with those for the original vessel and head. The fatigue analysis for the replacement heads and associated components therefore extends beyond the end of the period of extended operation.

The PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track the UFSAR Section 3.9.1.1 cyclic and transient occurrences to ensure that components are maintained within the design limits and will ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. In the period of extended operation the PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will monitor the environmentally assisted fatigue usage at NUREG/CR-6260 locations not monitored by cycle counting. Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) action limits permit completion of corrective actions before the design basis number of events is exceeded, and before the ASME

code cumulative fatigue usage limit of 1.0 is reached. The effects of fatigue in the reactor pressure vessel pressure boundary and its supports will thereby be managed for the period of extended operation.

19.3.2.1.2 Control Element Drive Mechanism (CEDM) and Reactor Vessel Level Monitoring System (RVLMS) Pressure Housings

The CEDM and RVLMS pressure housings will have been replaced with the replacement reactor vessel closure heads after more than 20 years of operation of each unit. The replacement CEDM pressure housings and RVLMS pressure housings are designed to ASME III, Subsection NB (Class 1), 1998 Edition up to and including the 2000 Addenda, for a 40-year operating period, and the design specification for the replacement CEDM and RVLMS pressure housings included design transients and seismic loads consistent with those for the original vessel, head, and CEDM pressure housings. The CEDM pressure housing design includes a corrosion analysis for the design life.

Since the design life of the replacement CEDM and RVLMS pressure housings extend beyond the end of the period of extended operation, the respective analyses have been projected beyond the end of the period of extended operation.

19.3.2.1.3 Reactor Coolant Pump Pressure Boundary Components

The CE System 80 reactor coolant pumps are designed to ASME III, 1974 Edition (no addenda) for Class 1 Vessels. The

load definitions were updated for replacement steam generators (RSG) with power uprate and the code analyses were evaluated to determine the applicability of the analyses of record fatigue analyses with the new loads.

Fatigue usage factors in the reactor coolant pumps do not depend on effects that are time-dependent at steady-state conditions, but depend only on effects of operational and upset transient events, principally on heatup and cooldown transients. The PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) tracks events to ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded and ensure that fatigue will be adequately managed for the period of extended operation.

19.3.2.1.4 Pressurizer and Pressurizer Nozzles

The PVNGS pressurizers are designed to ASME III, Subsection NB (Class 1), 1971 Edition with addenda through Winter 1973. The analyses have been updated from time to time to incorporate redefinitions of loads and design basis events, operating changes, power uprate, and modifications including effects of NRC Bulletin 88-11 thermal stratification in the surge line, effects of Combustion Engineering Infobulletin 88-09 “Nonconservative Calculation of Cumulative Fatigue Usage,” crack growth and fracture mechanics stability of postulated defects in heater sleeve attachment welds, thermal effects of replaced heater sleeves and their welds, and effects of nozzle

weld overlays of the surge, spray, and relief nozzles and their safe ends and welds.

The pressurizer heater penetrations were screened for effects of the reactor coolant environment on fatigue behavior of these materials, consistent with NUREG/CR-6260 and found to maintain an EAF <1.0 for the period of extended operation. See Section 19.3.2.3.

The PVNGS pressurizers have operated since startup with a continuous spray flow to prevent boron concentration stratification, and to mitigate spray line and spray nozzle fatigue.

The Linear Elastic Fracture Mechanics fatigue crack growth analysis of indications in a Unit 2 pressurizer support skirt forging weld will remain valid as long as the number of cyclic events assumed by the analysis is not exceeded. The PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 will be used to track events that are analyzed in non-fatigue cycle-based analyses such as this crack growth analysis, and will thereby ensure that appropriate corrective actions are completed before the design basis number of events is exceeded.

All other fatigue analyses supporting the pressurizer design either exhibit an acceptable fatigue usage factor and remain valid for the period of extended operation, or depend on an effect found to be acceptable for a limiting number of transient events. The PVNGS Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 will

ensure that the fatigue usage factors based on those transient events will remain within the code limit of 1.0 for the period of extended operation, or that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded and before the cumulative usage factor exceeds the code limit of 1.0.

19.3.2.1.5 Steam Generator ASME Section III Class 1, Class 2 Secondary Side, and Feedwater Nozzle Fatigue Analyses

The replacement steam generators (RSGs) are designed to ASME III, Subsection NB (Class 1) and NC (Class 2), 1989 Edition with no addendum. The design reports included design for a concurrent power uprate. Although the secondary side is Class 2, all pressure retaining parts of the steam generator satisfy the Class 1 criteria, including a Division 1, Section III fatigue analysis.

The design of the PVNGS steam generators includes a code fatigue analysis of the steam generator tubes. However, the cyclic stress range for the steam generator tubes is less than the endurance limit allowing an infinite number of cycles, so the CUF was determined to be zero. Since the steam generator tube CUF is zero, the analysis of record will remain valid through the period of extended operation for all three PVNGS units.

With the exception of the steam generator tubes, PVNGS has chosen to apply aging management to all the Unit 1, 2 and 3 steam generators. The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track events to ensure that appropriate reevaluation or other corrective action will be initiated if an action limit is reached. Action limits will permit completion of corrective actions before the design basis number of events is exceeded, and before the cumulative usage factor exceeds the code limit of 1.0.

19.3.2.1.6 ASME Section III Class 1 Valves

PVNGS Class 1 valves are designed to ASME Section III, Subsection NB, 1974 Edition with multiple addenda, the 1977 Edition with Winter 1977 addendum, and the 1989 Edition no addendum. ASME Section III requires a fatigue analysis only for Class 1 valves with inlets greater than four inches nominal. At PVNGS, specifications for some Class 1 valves with inlets four inches or less also require a fatigue analysis.

For the valve models with an NB-3545.3 normal duty operating cycle evaluation, the allowed NB-3545.3 N_A normal duty operations far exceed those expected to occur.

The calculated worst-case usage factors for the 16” Shutdown Cooling Suction Containment Isolation Valves, the 14” Safety Injection Tank Injection Discharge Isolation Gate Valves, the 14" Safety Injection Tank Injection Discharge Check Valves, the 12" HPSI/LPSI check valves, the ¾” Safety Injection Line Thermal Relief Valves, the pressurizer safety valves, the

pressurizer relief valves, and the 2” isolation valves for the auxiliary spray indicate that the designs have large margins, and therefore that the pressure boundaries would withstand fatigue effects for at least 1.5 times the original design lifetimes.

The calculated worst-case usage factors for the Unit 1, Class 1 Shutdown Cooling Suction Isolation Valve, and Charging Line Isolation Valves exceed 0.7. However, fatigue usage factors in these valves do not depend on effects that are time-dependent at steady-state conditions, but depend only on effects of operational, abnormal, and upset transient events. The Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track events to ensure that appropriate reevaluation or other corrective action will be initiated if an action limit is reached. Action limits will be established to permit completion of corrective actions before the design basis number of events is exceeded. Effects of fatigue in Class 1 valve pressure boundaries will thereby be managed for the period of extended operation.

19.3.2.1.7 ASME Section III Class 1 Piping and Piping Nozzles

Class 1 reactor coolant main-loop piping supplied by Combustion Engineering is designed to ASME Section III, Subsection NB, 1974 edition with addenda through Summer 1974. The main loop piping fatigue analysis was performed to the 1974 edition with addenda through Summer 1974. The fatigue analyses of piping outside the main loop used the 1974 edition with addenda through Winter 1975 or the 1977 edition with addenda

through Summer 1979. These analyses have been updated from time to time to incorporate redefinitions of loads and design basis events, operating changes, power uprate, steam generator replacement, and minor modifications.

See Section 19.3.2.1.8 for fatigue in the pressurizer surge lines.

In the primary coolant system, the most limiting calculated design basis usage factor occurs in the charging nozzle and approaches the limit of 1.0. The high usage factors are primarily due to transient thermal stresses from normal operating and upset injection events.

However, with the exception of the charging line nozzles, and possibly the pressurizer surge line discussed in Section 19.3.2.1.8 (if thermal stratification has not been completely mitigated); fatigue usage factors in these components do not depend on effects that are time-dependent at steady-state conditions, but depend only on effects of operational, abnormal, and upset transient events. Since the Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track these events, the design basis fatigue usage factor limit (1.0) will not be exceeded in these locations without an appropriate evaluation and any necessary mitigating actions.

The charging nozzle safe ends, the safety injection nozzle forging knuckle and safe ends, and the shutdown cooling line long-radius elbow are evaluated for effects of the reactor

coolant environment on fatigue behavior of these materials, consistent with NUREG/CR-6260. See Section 19.3.2.3.

With the exception of the CVCS charging lines and nozzles and the pressurizer surge lines and nozzles, fatigue usage factors in Class 1 piping and nozzles do not depend on effects that are time-dependent at steady-state conditions, but depend only on effects of operational, abnormal, and upset transient events.

The Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 counts significant transient events and thermal cycles, and tracks usage factors in a subset of Class 1 components to ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded and before the ASME code cumulative fatigue usage limit of 1.0 is reached.

19.3.2.1.8 Bulletin 88-11 Revised Fatigue Analysis of the Pressurizer Surge Line for Thermal Cycling and Stratification

NRC Bulletin 88-11 requested that licensees establish and implement a program to confirm pressurizer surge line integrity in view of the occurrence of thermal stratification and required them to inform the staff of the actions taken to resolve this issue.

The surge line hot leg elbow was evaluated for effects of the reactor coolant environment on fatigue behavior of these

materials, consistent with NUREG/CR-6260. See Section 19.3.2.3.

The surge lines are designed to ASME III, Subsection NB, 1977 edition with addenda through Summer 1979. The surge line design was reevaluated in 1991 through the Combustion Engineering Owners Group (CEOG) in response to the NRC Bulletin 88-11 thermal stratification concerns. The maximum calculated design basis (nominal 40-year) CUF at any location in the surge lines, including thermal stratification effects, is less than 1.0. However, when the environmental effects of reactor coolant on fatigue are considered, the EAF exceeds 1.0 when the maximum Fen is applied. Therefore during the period of extended operation the surge line will be subject to stress-based fatigue monitoring under the Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1, which will ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded, and before the ASME code cumulative fatigue usage limit of 1.0 is reached.

19.3.2.1.9 Class 1 Fatigue Analyses of Class 2 Regenerative and Letdown Heat Exchangers

The regenerative heat exchangers were designed and constructed to Class 2 rules on both shell and tube sides. The applicable code version date is 1974 with addenda through the Winter of 1975. The letdown heat exchangers were designed and constructed to Class 2 rules on the tube side, Class 3 on the

shell side. However, although these are Class 2 and 3 heat exchangers, the specifications require a Class 1, NB-3222 fatigue analyses.

The regenerative heat exchanger fatigue analysis was performed with transients specified in the CE general specification for System 80 plants. The number of cycles for each transient event required by these specifications is consistent with or is greater than the number of cycles for each transient event that will be used as cycle counting action limits in the Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1).

The fatigue analysis for standard System 80 letdown heat exchanger was performed using the original System 80 transients. The letdown heat exchanger for PVNGS was built to Revision 4 of the CE general letdown heat exchanger specification for System 80 plants, which combined multiple transients from the previous revision of the specification. The new transients were found to bound those used in the standard System 80 letdown heat exchanger fatigue analysis. The numbers of events required by these specifications are consistent with or are greater than the number of transients that will be used as cycle counting action limits in the Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1)

19.3.2.1.10 Class 1 Fatigue Analyses of Class 2 High Pressure Safety Injection (HPSI) and Low Pressure Safety Injection (LPSI) Pumps for Design Thermal Cycles

The HPSI and LPSI pumps were designed to ASME III Class 2, for which the code requires no fatigue analysis. However UFSAR 3.9.3.5.3.3 describes design for a stated number of thermal transient cycles, and the Structural Integrity & Operability Analysis design reports for both the HPSI and LPSI pumps cite the Class 1 methods of ASME III Subparagraph NB-3222.4 when addressing these thermal transients.

Both the HPSI and LPSI pumps are designed for initiation of safety injection, which is classified as an upset condition. The LPSI pumps are also designed for shutdown cooling, which is a normal operating condition. The structural integrity and operability analyses for these pumps analyzed these transients and demonstrate sufficient margin for any possible increase in operating cycles above the original estimate.

Although there is sufficient margin in the design of these pumps for the projected operating cycles, these components are subject to aging management. The Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track events to ensure that appropriate corrective action will be initiated if an action limit is reached. Action limits will be established to permit completion of corrective actions before the design basis number of events is exceeded, and before the cumulative usage factor exceeds the code limit of 1.0. Cycle counting

will assure that the effects of aging in the HPSI and LPSI pumps are managed for the period of extended operation.

19.3.2.1.11 Class 1 Analysis of Class 2 Main Steam Safety Valves

The main steam safety valves are ASME III Class 2. However UFSAR 5.2.2.4.3.2 describes a stated number of design transients, and the design includes a Class 1 fatigue analysis to Subarticle NB-3550, "Cyclic Loads for Valves."

The existing analysis demonstrates that the design is suitable for at least nine of the original 40-year design lifetimes and therefore remains valid for the period of extended operation.

19.3.2.1.12 High Energy Line Break Postulation Based on Fatigue Cumulative Usage Factor

A leak-before-break analysis (LBB) eliminated large breaks in the main reactor coolant loops. Outside the main loop breaks are selected in accordance with Regulatory Guide 1.46 and Standard Review Plan Branch Technical Position MEB 3-1.

The citation of MEB 3-1 means that "intermediate breaks" between terminal ends in piping with ASME Section III Class 1 fatigue analyses are identified at any location where cumulative usage factor is equal to or greater than 0.1, with the stated exception of the reactor coolant system primary loops, to which the LBB analysis applies.

Break locations that depend on usage factor will remain valid as long as the calculated usage factors are not exceeded. The

Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 will track events to ensure that the originally-calculated maximum usage factors are not exceeded, or that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits for the HELB design basis permit completion of corrective actions before the calculated design basis usage factors in Class 1 lines (outside the reactor coolant system loops) is exceeded.

19.3.2.2 Fatigue and Cycle-Based TLAAs of ASME III Subsection NG Reactor Pressure Vessel Internals

The reactor vessel internals were designed and fabricated to Subsection NG rules of ASME III, 1974 Edition. The design reports indicate use of some later addenda for some parts.

The ASME Subsection NG design reports and addenda include calculated usage factors for the components. The report addenda for power uprate and steam generator replacement concluded that all code and specification requirements were satisfied.

The Subsection NG fatigue usage factors do not depend on flow-induced vibration or other high-cycle effects that are time-dependent at steady-state conditions, but depend more strongly on effects of operational, upset, and emergency transient events. Therefore, the increase in operating life to 60 years will not have a significant effect on these fatigue usage factors so long as the number of design basis transient cycles

remains within the number assumed by the original analysis. The Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 will track events to ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded.

19.3.2.3 Effects of the Reactor Coolant System Environment on Fatigue Life of Piping and Components (Generic Safety Issue 190)

Concerns with possible effects of elevated temperature, reactor coolant chemistry environments, and different strain rates prompted NRC-sponsored research to assess these effects, culminating in the guidance of NUREG/CR-6260, "*Application of NUREG/CR-5999 Interim Fatigue Curves to Selected Nuclear Power Plant Components.*" Although GSI 190 has been closed for plants with 40-year initial licenses, NUREG-1800 states that "The applicant's consideration of the effects of coolant environment on component fatigue life for license renewal is an area of review," noting the staff recommendation "…that the samples in NUREG/CR-6260 should be evaluated considering environmental effects for license renewal."

NUREG/CR-6260 identifies seven sample locations for newer Combustion Engineering plants such as PVNGS:

- Reactor vessel shell and lower head
- Reactor vessel inlet nozzles

- Reactor vessel outlet nozzles
- Surge line
- Charging system nozzle
- Safety injection system nozzle
- Shutdown cooling line.

The thermal sleeves were removed from both the Loop 1 and Loop 2 safety injection nozzles, potentially increasing the CUF for the entire interior surface of the nozzle, including the knuckle location and safe end, because they were no longer protected by the thermal sleeves. Therefore two values were calculated for the safety injection nozzles, at the knuckle location and at the safe end. The safe ends were found to be limiting in the charging and safety injection nozzles.

The pressurizer heater penetrations may be subject to the effects of thermal stratification and insurge-outsurge transients, and have been subject to significant repair, modification, and reanalysis. APS has therefore elected to evaluate them with the locations listed in NUREG/CR-6260 for effects of environmentally-assisted fatigue. However, the screening evaluation determined that the EAF for the pressurizer heater penetrations is less than 1.0 when analyzed for the original number of design transients, and it was determined that the pressurizer heater penetrations need not be added to the list of NUREG/CR-6260 locations for EAF monitoring.

APS therefore evaluated a total of nine locations for effects of the reactor coolant system environment on fatigue life and selected seven for monitoring.

PVNGS performed plant-specific calculations for the NUREG/CR-6260 sample locations. The analyses used F_{en} relationships as appropriate for the material at each of the locations. F_{en} values for carbon and low-alloy steels are taken from NUREG/CR-6583. F_{en} values for stainless steels are from NUREG/CR-5704. F_{en} values for the charging nozzle safe ends and safety injection nozzle safe ends were developed using EPRI MRP-47 integrated strain rate methods and the NUREG/CR-5704 values. EAF values for the charging nozzle safe end, the pressurizer surge line elbow, and the shutdown cooling line elbow were developed using reasonable projections of transients based on analyst review of plant-specific transient data. The analyses found that the EAF usage factor in the surge line elbow, when projected to the end of a 60-year design life, may exceed 1.0. The charging inlet nozzle safe end, safety injection nozzle safe end, and shutdown cooling long radius elbow may also exceed an EAF of 1.0 if the 60 year projected cycles are exceeded.

NUREG/CR-6260 advises that conservative assumptions remain which could be removed to reduce the CUF values below the 1.0 allowable. The best method to lower the CUF for the few worst locations is fatigue monitoring, using realistic numbers of cycles, realistic severity of transients, and more refined

analyses. However, in some cases, a combination of fatigue monitoring and revised analyses may be needed.

All of the NUREG/CR-6260 locations except the first, the vessel lower head to shell juncture, will be monitored for EAF in the Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 during the period of extended operation. The reactor vessel shell and lower head (juncture) will be monitored by cycle counting. The Metal Fatigue of Reactor Coolant Pressure Boundary program (19.2.1) will track events and usage factors to ensure that appropriate reevaluation or other corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of events is exceeded, and before the ASME code cumulative fatigue usage limit of 1.0 is reached.

19.3.2.4 Assumed Thermal Cycle Count for Allowable Secondary Stress Range Reduction Factor in ANSI B31.1 and ASME Section III Class 2 and 3 Piping

PVNGS ASME III Class 2 and 3 piping is designed to the 1974 edition, Summer 1975 addenda; plus later editions and addenda for certain requirements. None of ANSI B31.1 or ASME Section III Subsections NC and ND invokes fatigue analyses. However, if the number of full-range thermal cycles is expected to exceed 7,000, these codes require the application of a stress range reduction factor (SRRF) to the allowable stress range for expansion stresses (secondary stresses). The allowable secondary stress range is 1.0 SA for

7000 equivalent full-temperature thermal cycles or less and is reduced in steps to 0.5 SA for greater than 100,000 cycles. Partial cycles are counted proportional to their temperature range. Therefore, so long as the estimated number of cycles remains less than 7000 for a 60-year life, the stress range reduction factor remains at 1 and the stress range reduction factor used in the piping analysis will not be affected by extending the operation period to 60 years.

The survey of all plant piping systems found that the reactor coolant hot leg sample lines may be subject to more than 7000 significant thermal cycles in 60 years, requiring a reduction in SRRF to 0.9; and that the steam generator downcomer and feedwater recirculation lines may be subject to more than 15,000, requiring a reduction in SRRF to 0.8. The applicable PVNGS design analyses were revised, and found that the secondary stress ranges are within the limits imposed by these reduced SRRFs. The pipe break analysis included in the revised analysis of the steam generator downcomer and feedwater recirculation lines required no change to break locations or break types. These analyses have therefore been extended to the end of the period of extended operation.

The number of equivalent full-range thermal cycles for all other B31.1 and ASME III Class 2 and 3 lines within the scope of license renewal is expected to be only about 1500 or less in 60 years, which is only a fraction of the 7000-cycle threshold for which a stress range reduction factor is required in the applicable piping codes. The piping analyses for these

remaining lines therefore require no change to the SRRF of 1.0 and remain valid for the period of extended operation.

19.3.3 ENVIRONMENTAL QUALIFICATION (EQ) OF ELECTRICAL COMPONENTS

Aging evaluations that qualify electrical and I&C components required to meet the requirements of 10 CFR 50.49 are evaluated to demonstrate qualification for the 40 year plant life are TLAAs. The existing PVNGS Environmental Qualification program will adequately manage component thermal, radiation, and cyclical aging through the use of aging evaluations based on 10 CFR 50.49(f) qualification methods. As required by 10 CFR 50.49, EQ components not qualified for the current license term are to be refurbished or replaced, or have their qualification extended prior to reaching the aging limits established in the evaluation.

Continuing the existing 10 CFR 50.49 EQ program ensures that the aging effects will be managed and that the EQ components will continue to perform their intended functions for the period of extended operation. The Environmental Qualification of Electrical Components program is described in Section 19.2.2.

Reanalysis of aging evaluations to extend the qualifications of components is performed on a routine basis as part of the EQ Program. Important attributes for the reanalysis of aging evaluations include analytical methods, data collection and

reduction methods, underlying assumptions, acceptance criteria and corrective actions (if acceptance criteria are not met).

19.3.4 CONCRETE CONTAINMENT TENDON PRESTRESS

The PVNGS containment is a prestressed concrete, hemispherical-dome-on-a-cylinder structure, with a steel membrane liner. Post-tensioned tendons compress the concrete and permit the structure to withstand design basis accident internal pressures. The reinforced concrete basemat is conventionally reinforced.

To ensure the integrity of the containment pressure boundary under design basis accident loads, design predictions of loss of prestress demonstrate that prestress will remain adequate for the design life. An inspection program confirms that the tendon prestress remains within design limits throughout the life of the plant [UFSAR Section 3.8.1, TRM Surveillance Requirement TSR 3.6.200.1].

Original design predictions of prestress force were projected to the end of the period of extended operation. The extended predicted force lines remain above minimum required values (MRVs) for the period of extended operation. Trend lines calculated by regression analyses of tendon surveillance data to date predict that the future performance of the post-tensioning system will remain above the minimum required values (MRV), and therefore that the assumptions of the containment vessel design will remain valid through the end of the period of extended operation.

Continuing the existing Concrete Containment Tendon Prestress program (19.2.3) ensures that loss of prestress aging effects will be managed and that the containment tendons will continue to perform their intended functions for the period of extended operation.

19.3.5 CONTAINMENT LINER PLATE, EQUIPMENT HATCHES, PERSONNEL AIR LOCKS, PENETRATIONS, AND POLAR CRANE BRACKETS

NUREG-1800 Section 4.6.1 notes that in some designs "Fatigue of the liner plates or metal containments may be considered in the design based on an assumed number of loading cycles for the current operating term."

The PVNGS post-tensioned concrete containment vessels are designed to Bechtel Topical Report BC-TOP-5-A Revision 3. The containment design report has been revised to address effects of power uprate and steam generator replacement.

At PVNGS the only metallic components of the containment pressure boundary that are designed for a specific number of load cycles in a design lifetime were the main steam, main feedwater, and recirculation sump suction penetrations (See Sections 19.3.5.1 and 19.3.5.2). The remaining penetrations were designed to stress limit criteria, independent of the number of load cycles, and with no fatigue analyses.

UFSAR Section 3.8.1.5.4, "Liner Plate System," item B, "Loads," describes annual, startup-shutdown, and loss-of-coolant-accident thermal cycles affecting the liner plate system. Containment liner design documents address these loads. Palo

Verde has confirmed that no significant fatigue effects would occur in the liner plate through the period of extended operation; and the design documents are therefore valid for the period of extended operation.

19.3.5.1 Design Cycles for the Main Steam and Main Feedwater Penetrations

The BC-TOP-1, "Containment Building Liner Plate Design Report," Part II Section 1.1, describes the main steam penetration design for cyclic loads. The design basis includes

- 100 lifetime steady state operating thermal gradient plus normal operating cyclic loads (Loading Condition V), and
- 10 steady state operating thermal gradient plus steam pipe rupture cyclic loads (Loading Condition IV).

The operating history to date indicates that the original design basis 100 operating cycles assumed for main steam penetrations will be exceeded during the extended operating period. However the number of Condition IV events assumed for design does not change with an increase in the design life, and Condition V events do not contribute significantly to usage factor. Examination of possible changes to the BC-TOP-1 analysis for any reasonably-expected increase in the number of Condition V events demonstrates adequate margin to the stress limit determined by the elastic-plastic analysis. Design of the main feedwater penetrations is bounded by that of the main steam penetrations due to their smaller size, similar geometry and similar operating conditions. The design of the main steam

and main feedwater penetrations is therefore valid for the period of extended operation.

19.3.5.2 Design Cycles for the Recirculation Sump Suction Line Penetrations

Recirculation sump suction line containment penetrations were evaluated for an NE-3222.4(d) exemption from fatigue analysis. The exemption criteria depend on the number of cycles for which loads are applied; therefore the exemption is supported by a TLAA.

The analysis of these penetrations was based on the alternating stress range for pressure cycles, and demonstrated that the allowable number of cycles is far greater than the number expected for the period of extended operation. There is sufficient margin in the design for any possible increase in operating cycles above the original estimate. The design of the recirculation penetrations is therefore valid for the period of extended operation.

19.3.6 PLANT-SPECIFIC TIME-LIMITED AGING ANALYSES

19.3.6.1 Load Cycle Limits of Cranes, Lifts, and Fuel Handling Equipment to CMAA-70

UFSAR Section 9.1.4 describes design of lifting machines to Crane Manufacturers Association of America Specification No. 70 (CMAA-70, 1975). The CMAA-70 crane service classification (“class” or “service level”) for each machine depends, in part, on the assumption that the number of stress cycles at or near

the maximum allowable stress will not exceed the number assumed for that design class. In operation, this means the number of significant lifts (i.e., those which approach or equal the design load) will not exceed the number of stress cycles assumed for that design class.

In all cases, the design standard full-capacity lifts exceed the number expected of the machine for a 60-year life. The lifting machine designs therefore remain valid for the period of extended operation.

19.3.6.2 Fatigue Crack Growth and Fracture Mechanics Stability Analyses of Half-Nozzle Repairs to Alloy 600 Material in Reactor Coolant Hot Legs and Supporting Corrosion Analysis

PVNGS obtained exemptions from the flaw removal and successive inspection requirements of ASME XI (1992), Sections IWA-3300 and IWB-2420, for the alternative half-nozzle method used to repair Alloy 600 small bore, hot leg nozzles.

Fatigue crack growth and stability analyses of nozzle remnants and welds left in the hot legs depend on the number of heatup-cooldown and operating basis earthquake (OBE) cycles assumed for a 40-year life, and are therefore TLAAs.

The fatigue crack growth and stability analysis will remain valid for the period of extended operation if the assumed cycle count is not exceeded. The Metal Fatigue of Reactor Coolant Pressure Boundary program described in Section 19.2.1 will track events to ensure that appropriate reevaluation or other

corrective action is initiated if an action limit is reached. Action limits permit completion of corrective actions before the design basis number of either of these events is exceeded.

Analysis of corrosion in the hot leg piping walls, exposed by the repairs, depends on time at cold shutdown and was evaluated consistent with WCAP-15973-P for a period in excess of the period of extended operation. The corrosion analysis is valid for the period of extended operation and is therefore a TLAA.

19.3.6.3 Building Absolute or Differential Heave or Settlement. Including Possible Effects of Changes in a Perched Groundwater Lens

The review of site soil mechanics and hydrogeology for the original PVNGS license application identified two related areas: (1) possible effects of heave and settlement on building foundation levels and stability, and (2) possible effects of changes in level of a perched groundwater lens on heave, settlement, and foundation stability.

Evaluations for the effects on heave and settlement prompted interrelated calculations and estimates of these effects by APS and by NRC reviewers. The licensing bases, particularly the PSAR, UFSAR, and SER contain discussions of heave and settlement, and perched groundwater, including references to the plant life. Because of these references to the plant life, APS has elected to classify these original evaluations and analyses as TLAAs.

The PVNGS licensing basis includes a commitment to monitor settlement of structures for the life of the plant. This surveillance is performed as part of the Structures Monitoring Program (19.1.32).

The settlement monitoring data indicate that the post-construction settlement for individual structures, differential settlement between adjacent structures having critical connections, and post-construction containment tilt indicate no significant trends and will remain stable. The settlement monitoring, which is conducted as part of the Structures Monitoring Program (19.1.32), will continue through the period of extended operation to ensure that settlement remains below the limits.

The groundwater monitoring data indicate no potential for settlement due to changes in groundwater level. These results confirm that the assumptions of the original projections of increases in groundwater levels were very conservative and that the conclusions of their safety determination - that there will be no effect on building foundation stability - apply to the foreseeable future and at least to the end of the period of extended operation. The conclusion of the predictions of groundwater level, and the safety determination based on them, therefore remain valid for the period of extended operation.

19.3.6.4 Corrosion Analyses of Pressurizer Ferritic Materials Exposed to Reactor Coolant by Half-Nozzle Repairs of Pressurizer Heater Sleeve Alloy 600 Nozzles

Analysis of corrosion in the pressurizer heater sleeve due to exposure to reactor coolant by half-nozzle repairs depends on time at cold shutdown and was evaluated consistent with WCAP-15973-P for a period in excess of the period of extended operation. The corrosion analysis is valid for the period of extended operation and is therefore a TLAA.

This page intentionally left blank

19.4 NEWLY IDENTIFIED SYSTEMS, STRUCTURES, AND COMPONENTS SUBJECT TO AN AGING MANAGEMENT REVIEW OR EVALUATION OF TIME-LIMITED AGING ANALYSES

10 CFR 54.37(b) requires the following:

> *After the renewed license is issued, the FSAR update required by 10 CFR 50.71(e) must include any systems, structures, and components newly identified that would have been subject to an aging management review or evaluation of time-limited aging analyses in accordance with § 54.21. This FSAR update must describe how the effects of aging will be managed such that the intended function(s) in § 54.4(b) will be effectively maintained during the period of extended operation*.

Guidance regarding compliance with this regulation has been provided by the NRC in Regulatory Information Summary (RIS) 2007-16, as supplemented.

There have been no systems, structures, and components newly identified that would have been subject to an aging management review or evaluation of time-limited aging analyses in accordance with 10 CFR 54.21.

This page intentionally left blank

19.5 LICENSE RENEWAL COMMITMENTS

Table 19.5-1 contains a listing of license renewal commitments. As described in the PVNGS Regulatory Commitment Tacking Procedure, any changes to these commitments in the UFSAR would be made by applying the provisions of 10 CFR 50.59 to determine if a change requiring prior NRC approval exists. If a 10 CFR 50.59 review determines that prior NRC approval is not required, the change can be made and reported to the NRC in accordance with 10 CFR 50.59 and 10 CFR 50.71(e). Otherwise, prior NRC review and approval of the change is required. The NRC should be notified of any change to a license renewal commitment listed in Table 19.5-1 as soon as practicable after the change is approved by PVNGS management, but before the completion date, as described in the PVNGS Regulatory Commitment Tacking Procedure and in NEI 99-04, "Guidelines for managing NRC Commitment Changes."

Unit 1 license condition 2.C.(16)(b), Unit 2 license condition 2.C.(11)(b), and Unit 3 license condition 2.C.(7)(b) state the following:

> *The UFSAR supplement, as revised, submitted pursuant to 10 CFR 54.21(d), describes certain future activities to be completed prior to and/or during the period of extended operation. The licensee shall complete these activities in accordance with Appendix A of NUREG-1961, "Safety Evaluation Report Related to the License Renewal of Palo Verde Nuclear Generating Station, Units 1, 2, and 3," issued April 2011. The licensee shall notify the NRC in writing when activities to be completed prior to the*

period of extended operation are complete and can be verified by NRC inspection.

The NRC provided guidance to APS stating that this license condition does not preclude changing a commitment or schedule under 50.59. However, the commitments that are due “prior to the period of extended operation” must be completed prior to the period of extended operation, as committed, and those that are due during the period of extended operation must be completed during the period of extended operation as committed.

LICENSE RENEWAL COMMITMENTS (Sheet 7 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
18	The One-Time Inspection program conducts one-time inspections of plant system piping and components to verify the effectiveness of the Water Chemistry program (19.1.2), Fuel Oil Chemistry program (19.1.14), and Lubricating Oil Analysis program (19.1.23). The aging effects to be evaluated by the One-Time Inspection program are loss of material, cracking, and reduction of heat transfer. (RCTSAIs 3246906 [U1]; 3247258 [U2]; 3247259 [U3])	A1.16 B2.1.16 One-Time Inspection	Within the ten year period prior to the period of extended operation[1]
19	The Selective Leaching of Materials program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. The Selective Leaching of Materials program includes a one-time inspection (visual and/or mechanical methods) of a selected sample of components internal surfaces to determine whether loss of material due to selective leaching is occurring. A sample size of 20% of the population, up to a maximum of 25 component inspections, will be established for each of the system material and environment combinations at the Palo Verde site. If indications of selective leaching are confirmed, follow up examinations or evaluations are performed. (RCTSAIs 3246908 [U1]; 3247260 [U2]; 3247261 [U3]; 3563030)	A1.17 B2.1.17 Selective Leaching Of Materials	Within the ten year period prior to the period of extended operation[1]

LICENSE RENEWAL COMMITMENTS (Sheet 8 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
20	The Buried Piping and Tanks Inspection program is a new program that will be implemented prior to the period of extended operation. Within the ten year period prior to entering the period of extended operation an opportunistic or planned inspection of buried tanks at the Palo Verde site will be performed. Upon entering the period of extended operation, a planned inspection within ten years will be required unless an opportunistic inspection has occurred within this ten year period. The visual inspections noted below of piping in a soil environment within the scope of license renewal will be conducted within the ten-year period prior to entering the period of extended operation, and during each ten year period after entering the period of extended operation, except the initial diesel generator fuel oil piping inspection will be performed between January 1, 2012 and December 31, 2015. Each inspection will: • select accessible locations where degradation is expected to be high; • excavate and visually inspect the circumference of the pipe; and • examine at least ten feet of pipe. a. Metallic Piping not Cathodically-Protected At least two excavations and visual inspections of stainless steel piping will be conducted in each unit. Stainless steel piping within the scope of license renewal exists in the following systems: o Chemical and Volume Control (CH), o Condensate Transfer and Storage (CT), and o Fire Protection (FP)	A1.18 B2.1.18 Buried Piping And Tanks Inspection	Perform the buried piping and tanks inspections within the ten year period prior to the period of extended operation[1], except the initial diesel generator fuel oil piping inspection will be performed between 1/1/12 and 12/31/15. AND Perform the buried piping inspections during each ten year period after entering the period of extended operation[1]. AND

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 9 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
	b. Steel Piping Cathodically-Protected At least two excavations and visual inspections of cathodically-protected steel piping will be conducted in each unit. In one of the units, at least one of these inspections will be performed on diesel generator fuel oil piping. c. Steel Piping with Potentially Degraded Cathodic Protection At least three excavations and visual inspections of fire protection steel piping with potentially degraded bonding straps will be conducted at the Palo Verde site. Prior to the period of extended operation, the Buried Piping and Tanks Inspection program will include provisions to (1) ensure electrical power is maintained to the cathodic protection system for in-scope buried piping at least 90% of the time (e.g., monthly verification that the power supply circuit breakers are closed or other verification that power is being provided to the system), and (2) ensure that the National Association of Corrosion Engineers (NACE) cathodic protection system surveys are performed at least annually. (RCTSAIs 3246909 [U1]; 3247263 [U2]; 3247264 [U3])		Implement the additional enhancements to the buried piping and tanks inspection program prior to the period of extended operation[1].

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 10 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
21	The One-Time Inspection of ASME Code Class 1 Small-Bore Piping program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. For ASME Code Class 1 small-bore piping, volumetric examinations on selected butt weld locations will be performed to detect cracking. Butt weld volumetric examinations will be conducted in accordance with ASME Section XI with acceptance criteria from Paragraph IWB-3000 and IWB-2430. Weld locations subject to volumetric examination will be selected based on the guidelines provided in EPRI TR-112657. Socket welds that fall within the weld examination sample will be examined following ASME Section XI Code requirements. At least 10% of the socket welds in ASME Code Class 1 piping that is less than four inches nominal pipe size and greater than or equal to one inch nominal pipe size will be selected per unit for ultrasonic testing examination, up to a maximum of 25 weld examinations. The sample will be selected based on risk insights and those welds with the potential for aging degradation. (RCTSAIs 3246910 [U1]; 3247265 [U2]; 3247266 [U3])	A1.19 B2.1.19 One-Time Inspection of ASME Code Class 1 Small-Bore Piping	Within the six year period prior to the period of extended operation[1]
22	The External Surfaces Monitoring Program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. (RCTSAIs 3246911 [U1]; 3247272 [U2]; 3247273 [U3])	A1.20 B2.1.20 External Surfaces Monitoring Program	Prior to the period of extended operation[1]

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 11 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
23	APS will: A. Reactor Coolant System Nickel Alloy Pressure Boundary Components Implement applicable (1) NRC Orders, Bulletins and Generic Letters associated with nickel alloys and (2) staff-accepted industry guidelines, (3) participate in the industry initiatives, such as owners group programs and the EPRI Materials Reliability Program, for managing aging effects associated with nickel alloys, (4) upon completion of these programs, but not less than 24 months before entering the period of extended operation, APS will submit an inspection plan for reactor coolant system nickel alloy pressure boundary components to the NRC for review and approval, and B. Reactor Vessel Internals APS will submit the PVNGS Units 1, 2, and 3 reactor vessel internals aging management program and inspection plans in accordance with MRP-227-A no later than October 1, 2012 for NRC review and approval. C. Pressurizer Spray Heads Comply with applicable NRC Orders and implement applicable (1) Bulletins and Generic Letters, and (2) staff-accepted industry guidelines. (RCTSAIs 3246912 [U1]; 3247274 [U2]; 3247276 [U3])	A1.21 B2.1.21 Reactor Coolant System Supplement 3.1.2.2.16.2 Pressurizer spray head cracking	Not less than 24 months prior to the period of extended operation[1] Item 23.B is complete. APS submitted the PVNGS Units 1, 2, and 3 reactor vessel internals aging management program and inspection plans in accordance with MRP-227-A for NRC review and approval via letter 102-06599, dated September 28, 2012, and supplemented by letter 102-06908, dated July 23, 2014. The program was approved by the NRC on March 27, 2015 via letter ML15058A029. APS will manage the Reactor Vessel Internals (RVI) inspections during the period of extended operation through the augmented Inservice Inspection Program. This augmented program will implement the requirements of MRP-227-A. Any deviations from the MRP-227-A "Needed" requirements will require NRC notification. (RCTSAIs 4861593 [U1]; 4861603 [U2}; and 4861605 [U3])

24	The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. (RCTSAIs 3246914 [U1]; 3247277 [U2]; 3247278 [U3])	A1.22 B2.1.22 Inspection Of Internal Surfaces In Miscellaneous Piping And Ducting Components	Prior to the period of extended operation[1].
25	Existing Lubricating Oil Analysis program is credited for license renewal. (RCTSAI 3246915)	A1.23 B2.1.23 Lubricating Oil Analysis	Ongoing
26	The Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. (RCTSAI 3246917)	A1.24 B2.1.24 Electrical Cables And Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements	Prior to the period of extended operation[1]

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 13 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
27	Existing Electrical Cables And Connections Not Subject To 10 CFR 50.49 Environmental Qualification Requirements Used In Instrumentation Circuits program is credited for license renewal , AND Prior to the period of extended operation: • Procedures will be enhanced to identify license renewal scope, require cable testing of ex-core neutron monitoring cables, require an evaluation of the calibration results for non-EQ area radiation monitors, and require acceptance criteria for cable testing be established based on the type of cable and type of test performed. (RCTSAI 3246919)	A1.25 B2.1.25 Electrical Cables And Connections Not Subject To 10 CFR 50.49 Environmental Qualification Requirements Used In Instrumentation Circuits	Prior to the period of extended operation[1]
28	The Inaccessible Medium Voltage Cables Not Subject to 10 CFR 50.49 EQ Requirements program is credited for license renewal, AND Prior to the period of extended operation procedures will be enhanced to: • Extend the scope of the program to include low voltage (480V and above) non-EQ inaccessible power cables and associated manholes. • Perform the cable inspections on at least an annual frequency and perform the cable testing on a six year frequency. (RCTSAI 3246920)	A1.26 B2.1.26 Inaccessible Medium Voltage Cables Not Subject To 10 CFR 50.49 Environmental Qualification Requirements	Prior to the period of extended operation[1]
29	Existing ASME Section XI, Subsection IWE program is credited for license renewal. (RCTSAI 3246921)	A1.27 B2.1.27 ASME Section XI, Subsection IWE	Ongoing

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 14 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
30	Existing ASME Section XI, Subsection IWL program is credited for license renewal. (RCTSAI 3246922)	A1.28 B2.1.28 ASME Section XI, Subsection IWL	Ongoing
31	Existing ASME Section XI, Subsection IWF program is credited for license renewal. (RCTSAI 3246923)	A1.29 B2.1.29 ASME Section XI, Subsection IWF	Ongoing
32	Existing 10 CFR 50, Appendix J program is credited for license renewal. (RCTSAI 3246924)	A1.30 B2.1.30 10 CFR 50, Appendix J	Ongoing
33	Existing Masonry Wall Program is credited for license renewal, AND Prior to the period of extended operation, procedures will be enhanced to specify ACI 349.3R-96 as the reference for qualification of personnel to inspect structures under the Masonry Wall Program, which is part of the Structures Monitoring Program. (RCTSAI 3246926)	A1.31 B2.1.31 Masonry Wall Program	Prior to the period of extended operation[1]

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 15 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule

34	Existing Structures Monitoring Program is credited for license renewal, AND
	Prior to the period of extended operation:
	• The Structures Monitoring Program will be enhanced to specify ACI 349.3R-96 as the reference for qualification of personnel to inspect structures under the Structures Monitoring Program.
	• For structures within the scope of license renewal, the Structures Monitoring Program will be enhanced to establish the frequency of inspection for each unit at a 5 year interval, with the exception of exterior surfaces of the following nonsafety-related structures, below-grade structures, and structures within a controlled interior environment, which will be inspected at an interval of 10 years:
	  • Fire Pump House (Yard Structures)
	  • Radwaste Building
	  • Station Blackout Generator Structures
	  • Turbine Building
	• The Structures Monitoring Program will be enhanced to quantify the acceptance criteria and critical parameters for monitoring degradation, and to provide guidance for identifying unacceptable conditions requiring further technical evaluation or corrective action. Procedures will also be enhanced to incorporate applicable industry codes, standards and guidelines (e.g., ACI 349.3R-96, ANSI/ASCE 11-90, etc.) for acceptance criteria.

35	Existing RG 1.127, Inspection Of Water-Control Structures Associated With Nuclear Power Plants program is credited for license renewal, AND Prior to the period of extended operation, procedures will be enhanced to specify that the essential spray ponds inspections include concrete below the water level. (RCTSAI 3246928)	A1.33 B2.1.33 RG 1.127, Inspection Of Water-Control Structures Associated With Nuclear Power Plants	Prior to the period of extended operation[1]
36	Existing Nickel Alloy Aging Management Program is credited for license renewal. (RCTSAI 3260208)	A1.34 B2.1.34 Nickel Alloy Aging Management Program	Ongoing
37	The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new program that will be implemented prior to the period of extended operation. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. (RCTSAIs 3246930 [U1]; 3247228 [U2]; 3247231 [U3])	A1.35 B2.1.35 Electrical Cable Connections Not Subject To 10 CFR 50.49 environmental qualification requirements	Prior to the period of extended operation[1]
38	The Metal Enclosed Bus program is a new program and will be completed before the period of extended operation and once every 10 years thereafter. Industry and plant-specific operating experience will be evaluated in the development and implementation of this program. (RCTSAIs 3246932 [U1]; 3247220 [U2]; 3247221 [U3])	A1.36 B2.1.36 Metal Enclosed Bus	Prior to the period of extended operation and once every ten years thereafter.

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 17 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
39	No later than two years prior to the period of extended operation, the following enhancements will be implemented o Cumulative usage factor tracking will be implemented for NUREG/CR-6260 locations not monitored by cycle counting (the reactor vessel shell and lower head (juncture) location will be monitored by cycle counting). For PVNGS locations identified in NUREG/CR-6260 and monitored by CUF, fatigue usage factor action limits will be required for including effects of the reactor coolant environment. o The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced to include a computerized program to track and manage both cycle counting and fatigue usage factor. FatiguePro® will be used for cycle counting and cycle-based fatigue (CBF) monitoring methods. FatiguePro® is an EPRI licensed product. o The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will monitor plant transients as required by PVNGS Technical Specification 5.5.5. Cumulative usage factors (CUFs) will be calculated for a subset of ASME III Class 1 reactor coolant pressure boundary vessel and piping locations, and component locations with Class 1 analyses. The following methods will be used: 1) The Metal Fatigue of Reactor Coolant Pressure Boundary program will be enhanced to use cycle based fatigue (CBF) and stress based fatigue (SBF) CUF calculations to monitor fatigue. FatiguePro® will be used for cycle counting and cycle-based fatigue (CBF) monitoring methods. FatiguePro® is an EPRI licensed product.	4.3.1 Fatigue Aging Management Program A2.1 B3.1 Metal Fatigue of Reactor Coolant Pressure Boundary	No later than two years prior to the period of extended operation[1]

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 18 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
	2) The SBF method will use a fatigue monitoring software program that incorporates a three-dimensional, six-component stress tensor method meeting ASME III NB-3200 requirements. o The enhanced Metal Fatigue of Reactor Coolant Pressure Boundary program will provide action limits on cycles and on CUF that will initiate corrective actions before the licensing basis limits on fatigue effects at any location are exceeded. o In order to ensure sufficient cycle count margin to accommodate occurrence of a low-probability transient, corrective actions must be taken before the remaining number of allowable occurrences for any specified transient becomes less than 1. o CUF action limits will be established to require corrective action when the calculated CUF (from cycle-based or stress-based monitoring) for any monitored location is projected to reach 1.0 within the next 2 or 3 operating cycles. In order to ensure sufficient margin to accommodate occurrence of a low-probability transient, corrective actions will be taken while there is still sufficient margin to accommodate at least one occurrence of the worst-case design transient event (i.e., with the highest fatigue usage per event cycle). (RCTSAI 3246934)		

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 19 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
40	Existing Environmental Qualification program is credited for license renewal, AND maintaining qualification through the extended license renewal period requires that existing EQ evaluations (EEQDFs) be re-evaluated. (RCTSAI 3246935)	A2.2 B3.2 Environmental Qualification (EQ) Of Electrical Components	Prior to the period of extended operation[1]
41	Existing Concrete Containment Tendon Prestress program is credited for license renewal, AND • The program will be enhanced to continue to compare regression analysis trend lines of the individual lift-off values of tendons surveyed to date, in each of the vertical and hoop tendon groups, with the MRV and PLL for each tendon group, to the end of the licensed operating period, and to take appropriate corrective actions if future values indicated by the regression analysis trend line drop below the PLL or MRV. The regression analyses will be updated for tendons of the affected unit and for a combined data set of all three units following each inspection of an individual unit. • Prior to the period of extended operation, procedures will be enhanced to require an update of the regression analysis for each tendon group of each unit, and of the joint regression of data from all three units, after every tendon surveillance. The documents will invoke and describe regression analysis methods used to construct the lift-off trend lines, including the use of individual tendon data in accordance with Information Notice (IN) 99-10, "Degradation of Prestressing Tendon Systems in Prestressed Concrete Containments." • The Tendon Integrity test procedure will be revised to extend the list of surveillance tendons to include random samples for the year 45 and 55 surveillances. (RCTSAI 3246937)	A2.3 B3.3 Concrete Containment 4.5 Concrete Containment Tendon Prestress	Prior to the period of extended operation[1]

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
60	Completed (RCTSAI 3531679)		
61	In response to the NRC staff concern regarding potential failure of the SG reactor coolant system pressure boundary due to possible PWSCC of SG divider plate bar welds in all units and the divider plate bars in Unit 2, APS commits to perform one of the following three resolution options: 1. Perform an inspection of each Palo Verde Unit 1, 2, and 3 steam generator to assess the condition of the divider plate bar welds in all units, and the accessible surfaces of the divider plate bars in Unit 2. The examination technique(s) will be capable of detecting PWSCC in the divider plate bar welds in all units, and in the accessible surfaces of the divider plate bars in Unit 2. OR 2. Perform an analytical evaluation of the steam generator divider plate bar welds in all units, and the divider plate bars in Unit 2, in order to establish a technical basis which concludes that the SG reactor coolant system pressure boundary is adequately maintained with the presence of steam generator divider plate bar weld cracking.	Response to Draft RAI Regarding Steam Generators in APS letter No. 102-06285, dated November 23, 2010. and Supplemental Response to Draft RAI Regarding Steam Generators in APS letter No. 102-06324, dated February 25, 2011.	If Option (1) is selected, it will be completed for each SG in each unit during an SG tube eddy-current inspection outage between 20 and 25 calendar years of SG operation.

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 23 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
	3. If results of industry and NRC studies and operating experience document that potential failure of the SG reactor coolant system pressure boundary due to PWSCC cracking of SG divider plate bar welds and the divider plate bars in Unit 2 is not a credible concern, this commitment will be revised to reflect that conclusion. (RCTSAIs 3561775 [U1], 3561777 [U2], 3561779 [U3])	and Clarification in APS letter No. 102-06331, dated March 17, 2011.	If Option (2) or Option (3) is selected, it will be completed prior to September 1, 2023.

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 24 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
62	In response to the NRC staff concern regarding potential failure of the steam generator primary-to-secondary pressure boundary due to PWSCC cracking of tube-to-tubesheet welds, APS commits to perform one of the following two resolution options: 1. Perform a one-time inspection of a representative number of tube-to-tubesheet welds in each steam generator to determine if PWSCC cracking is present. If weld cracking is identified: a. The condition will be resolved through repair or engineering evaluation to justify continued service, as appropriate. AND b. An ongoing monitoring program will be established to perform routine tube-to-tubesheet weld inspections for the remaining life of the steam generators. OR 2. Perform an analytical evaluation of the steam generator tube-to-tubesheet welds in order to: a. Establish a technical basis which concludes that the structural integrity of the steam generator tube-to-tubesheet interface is adequately maintained with the presence of tube-to-tubesheet weld cracking. AND b. Establish a technical basis which concludes that the steam generator tube-to-tubesheet welds are not required to perform a reactor coolant pressure boundary function. (RCTSAIs 3561782 [U1], 3561784 [U2], 3561788 [U3])	Response to Draft RAI Regarding Steam Generators in APS letter No. 102-06285, dated November 23, 2010.	If Option (1) is selected, it will be completed for each SG in each unit during an SG tube eddy-current inspection outage between 20 and 25 calendar years of SG operation. If Option (2) is selected, it will be completed prior to September 1, 2023.

Table 19.5-1
LICENSE RENEWAL COMMITMENTS (Sheet 25 of 25)

Item No.	Commitment	License Renewal Application Section	Implementation Schedule
63	a) No later than two years prior to the period of extended operation, APS will confirm that the plant-specific components listed in LRA Table 4.3-11 (except the pressurizer surge line pressurizer elbow) are bounding for the generic NUREG/CR-6260 locations and the additional location (pressurizer heater penetrations). If locations are found that are not bounded by the Table 4.3-11 components, APS will perform new analyses as necessary to bound such locations. And No later than two years prior to the period of extended operation, APS will confirm that the LRA Table 4.3-11 locations selected for environmentally assisted fatigue analyses consist of the most limiting cumulative usage factor (CUF) locations for the plant (beyond the generic EAF locations identified in the NUREG/CR-6260 guidance). If the Table 4.3-11 locations are not bounding, APS will perform an environmentally assisted fatigue analysis for the additional CUF locations not bounded by the Table 4.311 locations. If the component with the most limiting CUF is composed of nickel alloy, the methodology used to perform the environmentally-assisted fatigue calculation for nickel alloy will be consistent with NUREG/CR-6909. b) (RCTSAI 3563689)	Response to Draft RAI 4.3.4-1 in APS letter No. 102-06290, dated December 03, 2010.	No later than two years prior to the period of extended operation[1]

(1) "Prior to period of extended operation" and "prior to operation beyond 32 EFPY" is prior to the following original PVNGS Operating License expiration dates: Unit 1: June 1, 2025; Unit 2: April 24, 2026; Unit 3: November 25, 2027.
