The minimum cover on the inner curtain of reinforcing steel shall be 2 inches. Cadwelds or other connectors shall not be considered as reinforcing steel. The minimum cover for ties shall be 1-1/2 inches. The minimum cover for welded wire fabric, when required, shall be 1 inch.

c. Inside face reinforcing steel (when required): The design drawings show the minimum effective depth, d, from the external concrete face to the inside face reinforcing steel.

d. For longitudinal location of bends and ends of bars: ± 3 inches, provided that specified cover at the ends of members shall not be reduced by more than 1/2 inch.

4. Chapter 4, Concrete Quality, Section 4.3.1 -- See exception 7 to ACI 301.

D. Recommended Practice for Concrete Formwork (ACI 347-68) -- Used without exception.

E. Recommended Practice for Hot-Weather Concreting (ACI 305-72) -- Used in its entirety. Since the climate in the region of the site is typical of a desert regime and there is possibly a diurnal temperature change of 30 to 50F which may effect concrete placed or concrete being placed, additional controls are provided for the PVNGS site to supplement the requirements of ACI 305, Section 2.2, "temperature of concrete as placed", and Section 4.4, "curing and protection". A summary of these measures follows:

- Minimize mixing time by utilization of stationary mixing equipment.
- Minimize transporting distance by locating stationary mixing equipment at the jobsite.

- Concrete ingredients used minimize heat of hydration problems.
- Water-reducing agent is adjusted to control setting time.
- Concrete temperature as batched is reduced by addition of ice and cooling of aggregates, as required.
- Dispatching of trucks is closely coordinated with rate of concrete placement.
- As applicable, subgrade is dampened or forms wetted prior to concrete placement.
- A fog spray procedure, judiciously used, is applied on exposed areas, when necessary, prior to final finishing and start of curing.
- Exposed surfaces of slabs are entirely covered and kept wet or sealed until firm enough to permit walking without damage.
- Mats used for initial curing period may be left in place and kept saturated for completing the curing, or may be removed at the end of the initial curing period and the concrete surface cured with one of the following methods:
  - Liquid membrane forming curing compounds
  - Polyethylene sheathing

- Waterproof paper
- Absorbent fabric
- Ponding

- For vertical and other formed surfaces, after concrete is hardened and while the forms are still in place, water may be applied to run down the inside of the form to keep the concrete wet. Except in specific approved instances, the forms may be left in place without loosening where the concrete is placed in two or more placements to obtain the total thickness. The exposed surface is moist cured and the forms have the exterior surfaces protected from the direct sun and wind.

- For construction joints, curing is continued until resumption of concrete placement or until required curing is complete.

- If, for any reason, it becomes necessary to remove supporting forms before the concrete has attained the required strength, provisions are made for additional curing under controlled conditions by water spray or water saturated fabric.

- Curing procedures are continued for a period of 7 days or the time necessary to attain 70% of the specified design strength.

- Procedures are adopted to ensure that saturated cover materials do not dry out and absorb water from the concrete.

- Concrete members 30 inches or more in the least dimension are moist cured, except that the exterior walls (shell) of the containment structure above the foundation are either form cured or liquid membrane cured.

F. Ready-Mixed Concrete (ASTM C94-74) -- Used without exception.

G. NRC Regulatory Guide 1.55 is used for concrete placement as interpreted in section 1.8.

H. Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel during the Construction Phase of Nuclear Power Plants (ANSI N45.2.5) -- Used except as noted below:

1. Section 1.4, Definitions -- The definition of in-process tests as applied to reinforcing steel is interpreted to allow taking the rebar test specimen from a heat or fraction thereof at the fabrication shop, prior to start of fabrication of the rebar.

2. Section 4.8, In-Process Tests on Concrete and Reinforcing Steel -- The following methods of sampling fresh concrete apply:

a. Samples for in-process tests of concrete are taken from the discharge of the batch plant stationary mixer.

b. For the containment building, the frequency for air content, temperature, and slump testing shall be once for the first batch placed each day and once for every 50 cubic yards placed thereafter, for each class of concrete.

c. For all other structures, the frequency for air content, temperature, and slump testing shall be once for the first batch placed each day and once for every 100 cubic yards placed thereafter, for each class of concrete (applicable to subsections 3.8.4 and 3.8.5 only).

d. Slump correlation tests are established between the batch plant and the transport discharge. Slump taken at the batch plant is the slump at the transport discharge plus an allowance for slump loss in transit.

e. After slump is established at the batch plant for each class of concrete to be placed, correlation slumps are taken at the transport discharge at intervals not to exceed every 300 cubic yards for each class of concrete placed. A minimum of one correlation slump

is taken each day for each class of concrete placed. Air content is taken when each correlation slump is made if an air entraining agent is used.

3. Table A, Required Qualification Tests, and Table B, Required In-process Tests -- Used except as noted below:

   a. Grout is not tested daily.

   b. Physical properties of reinforcing are not tested as per ASTM A615. This standard is used for mechanical property tests.

   c. Slump, air content, and temperature test frequencies are as provided in paragraph 3.8.1.6.1.2, listings H.2.b and c (applicable to FSAR subsections 3.8.4 and 3.8.5 only).

   d. Same as paragraph 3.8.1.6.1.2, listings A.7.a and b.

4. Section 4.5, Concrete Placement -- ACI Standards 305-72 and 306-66 are used subject to the exceptions and interpretations given elsewhere in this section.

5. Section 4.9, Mechanical (Cadweld) Splice Testing -- Used subject to the related interpretations given for NRC Regulatory Guide 1.10 in section 1.8.

A sister splice may be substituted for a production splice when:

a. Cadwelding to dowels which are too short to take a production splice

b. The responsible quality control engineer, in conjunction with engineering, determines that the area of reinforcing is too congested to take a production splice.

3.8.1.6.2 Reinforcing Steel

Reinforcing bars for concrete are deformed bars meeting requirements of Specification for Deformed and Plain Billet Steel Bars for Concrete Reinforcement (ASTM A615-74a), Grade 60. Splicing of bars is in accordance with ASME B&PV Code, Section III, Division 2, Article CC-3000 (Subsubarticle CC-3530) and placing of bars is in accordance with the Building Code Requirements for Reinforced Concrete (ACI 318-71) except as noted in paragraph 3.8.1.6.7.2. Mill test reports, in accordance with ASTM A615, are obtained from the reinforcing steel supplier to substantiate specification requirements.

In addition, tonnage of reinforcing steel of each size and grade for user tests on full diameter specimens is in accordance with NRC Regulatory Guide 1.15.

The test procedures are in accordance with ASTM A370-71b and acceptance standards are in accordance with ASTM A615-74a.

Lap splices are used for bar sizes No. 11 and smaller, except in areas of membrane tension perpendicular to the spliced bars. Mechanical splicing, as described in paragraph 3.8.1.6.7.2, is used for the remainder of the splices.

3.8.1.6.3 Prestressing System

A description of the types of materials used in the prestressing system is given in paragraph 3.8.1.1. Additional material properties for each component of the prestressing system are described as follows:

A. Prestressing Steel

Wires used are low relaxation type, 1/4-inch nominal diameter conforming to ASTM A421 Type BA. Tests quantifying wire relaxation are performed and results are documented. The quantity (in number of coils) of finished prestressing wires in each production lot represented by each test specimen is in accordance with ASTM A421-65 (reapproved 1972), ASTM A421-74, or ASTM A421-76. For these systems, the prestressing system supplier is required to assign an individual lot number and a tag for each size of wire from each manufactured reel in such a manner that each lot can be accurately identified.

B. Bearing Plates, Anchor Heads, Shims, Sheathing and Filler Material

The testing requirements for evaluating the quality of material and machined end anchorage hardware are discussed in paragraph 3.8.1.6.7.3.

3.8.1.6.3.1 Post-Tensioning Procedures. Post-tensioning installation work is inspected. Measuring equipment used for installation is calibrated and certified by an approved independent testing laboratory. During tensioning operations, records are kept for comparing force measurements with elongation for tendons. The resultant cross-reference provides a final check on measurement accuracy.

The tensioning sequence is based on the design requirements to limit the predicted membrane tension in the concrete and to minimize unbalanced loads and differential stresses in the structure. The procedure for prestressing is coordinated with the post-tensioning vendor. Procedures are subject to the engineer's approval.

A detailed typical prestressing sequence is shown in Figure 6-4 of BC-TOP-5-A.

3.8.1.6.4 Containment Liner

The containment structure is lined with 1/4-inch thick welded steel plate, except in limited areas where thickened plate is utilized, conforming to the requirements of ASME SA-285, Low and Intermediate Tensile Strength Carbon Steel Plates for

Pressure Vessels, Grade A, to ensure a leaktight membrane. This steel has a minimum yield strength of 24,000 psi and a minimum elongations in an 8-inch specimen of 27%. The ASME SA-285 material was chosen because it has sufficient strength, low yield point, and ductility to resist the expected stresses from design criteria loading, limit forces due to thermal differentials and, at the same time, to preserve all required leaktightness of the containment. It is readily weldable by all of the commercially available arc and gas welding processes. ASTM A285 Grade C and A515 Grade 70 are other materials of quite similar characteristics which were used for liner material. All thickened steel plate conforms to the requirements of ASME SA-516 Grade 70 or ASTM A516 Grade 70.

Design of the liner plate is subject to the provisions of C-TOP-1. Construction, inspection, and testing of the liner plate were performed using the applicable sections of the ASME B&PV Code, Section III, Division 2, as a guide only.

The equipment hatch and personnel and escape locks must resist the full design pressure and are designed in accordance with the ASME B&PV Code, Section III, Division 1, Subsection NE, Class MC components with the following exceptions:

A. Article NE-4232, Maximum Offset of Aligned Section:

   Misalignment in completed butt-welded joints shall not exceed 10% of the plate thickness or 1/16 inch, whichever is greater.

B. Article NE-4426, Reinforcement of Welds:

1. The finished surface of the reinforcement of all manually-welded butt joints may be flush with the base material or may have reasonably uniform crowns, the maximum on each side not to exceed: 3/32 inch in thickness for material thickness 1/2 inch or less; 1/8 inch in thickness for material thickness over 1/2 inch to 1 inch; 3/16 inch in thickness for material thickness over 1 inch to 2 inches.

2. The finished surface of the reinforcement of automatic machine-welded butt joints may be flush with the base material or may have reasonably uniform crowns, the maximum on each side not to exceed 5/32 inch in thickness.

Materials used for equipment hatch and personnel air locks conform to the requirements of ASME B&PV Code, Section III, Division 1, Article NE-2000.

The interior projections of all penetration assemblies must resist the full design pressure. The design of all penetration assemblies is controlled by the provisions of BC-TOP-1.

The liner plate is designed to function only as a leaktight membrane. It is not designed to resist the tension stresses from internally applied pressure, which may result from any credible accident conditions. Structural integrity of the containment is maintained by the post-tensioned concrete. Since the principal applied stress to the liner plate membrane

is in compression from shrinkage and creep of the concrete, there is no need to apply special nil ductility transition temperature criteria to the liner plate material. On the other hand, all material for containment parts that resists applied internal pressure stresses, such as penetrations, is impact tested in accordance with the requirements of ASME B&PV Code, Section III, Division I, Article NE-2320.

For stud welding to nonpressure-retaining parts of the containment liner system (i.e., the containment liner plate), welding procedures and welding operators are qualified as specified in AWS D1.1-72, Revision 1, 1973, Section 5.

For all other welding of the containment liner system, all welding procedures and welding operators are qualified by tests, as specified in ASME B&PV Code, Section IX. This Code requires testing of welded transverse root and face bend samples in order to verify adequate weld metal ductility.

Specifically, Section IX of the Code requires that the transverse root and face bend samples be capable of being bent cold 180° to an inside radius equal to twice the thickness of the test sample. Satisfactory completion of these bend tests is accepted as adequate evidence of required weld metal and plate material compatibility.

Welding materials used to join various parts of the liner plate system are as follows:

A. E6010 is general purpose welding rod for liner seam welds and pressure-retaining parts.

B. E7018 is a low hydrogen rod used for the following conditions:

1. For welds made with gas tungsten-arc root passes

2. For design temperatures below 0F

3. For steels having a specified minimum tensile strength of 70,000 psi and greater in thicknesses over 1 inch

4. Where stress relieving by post-weld heat treatment is required

C. EM12K (SFA 5.17) wire and flux is used for submerged arc welding of the 1/4-inch horizontal liner plate welds.

D. E70T-G (AWS A5.20/SFA 5.20) is used for flux core arc welding of liner plate and dome liner plate.

E. E70S-3 (SFA 5.18) is used for attachment fillet welds.

F. F74-EF2-F2 (SFA 5.23) is used for equipment hatches (exception to F2 analysis is manganese less than 1.5%).

G. E7024 is used in nonpressure-retaining fillet welds.

Mill test reports are obtained on all material giving heat numbers and material analysis. This information is traceable to the in-place penetration for all material except welding filler metal (weld rod).

3.8.1.6.4.1 Liner Plate Erection. Vertical and dome liner plates are used as forms and erection precedes the concrete

placements. Tolerances for erection of the liner plate and the penetration assemblies are specified as follows and in the event of conflict shall prevail over tolerances listed in BC-TOP-1, Section 1.3.8:

A. Liner Plate

1. The radial location of any point on the wall liner plate does not vary from the design radius, referred to the vertical centerline of the containment structure, by more than ±3 inches. At any given elevation, the maximum diameter minus the minimum diameter does not exceed 6 inches.

   Measurements are made at 30° spacing for each 10 feet of height.

2. Plates to be joined by butt welding are matched accurately and retained in position during the welding operation. Misalignment in completed joints does not exceed 10% of the plate thickness or 1/16 inch, whichever is greater.

3. A 15-foot long template curved to the required radius does not show deviations of more than 1 inch when placed against the completed surface of the shell within a single plate section and not closer than 12 inches to a welded seam. When the template is placed across one or more welded seams, the deviation does not exceed 1-1/2 inches. The effect of change in plate thickness or of weld

reinforcement is excluded when determining deviations.

4. A 15-inch long template curved to the required radius does not show deviations of more than 1/8 inch inward and 3/8 inch outward when placed against the completed surface of the shell within a single plate section. Where the deviation exceeds these limits, remedial action is taken to correct the deficiency.

5. The slope of any 10-foot section of cylindrical liner plate, referred to true vertical, does not exceed 1:120. The shell is not out of plumb in excess of 3 inches overall.

6. A 10-foot straight edge does not show deviations greater than ±1 inch in the vertical direction between seam welds.

7. Sharp bends are not permitted unless provision has been made for them in the design. A sharp bend is defined as any local bend that deviates from the design radius or a vertical straight edge by an offset of more than 1/2 inch in 1 foot. The template used to measure the local deviations is only 1 to 2 feet longer than the area of the deviation itself.

8. The maximum allowable overall as-built dome profile shall be within +8-1/2 inches and -13 inches of the design location.

3.8.1.6.4.2 Cathodic Protection. Cathodic protection is not provided for corrosion protection of the containment steel liner, reinforcing steel, or tendon sheathing.

Permanent reference electrodes are installed below the containment basemat to monitor the structure-to-earth potential.

3.8.1.6.4.3 Containment Liner Plate Coating. To prevent corrosion and to increase the visibility required for safe conditions during inspection and maintenance, the inside face of the liner plate is coated with a coating system that meets the intent of ANSI N101.2-1972 for LOCA environment conditions for pressurized water reactors and Regulatory Guide 1.54, as clarified by section 1.8.

3.8.1.6.5 Containment Liner Plate Attachments and Associated Hardware

Material for penetration sleeves conforms to the requirements of the three specifications listed below. The lowest service metal temperature is 40F and the maximum impact test temperature is 10F.

A. Penetration sleeves - Seamless and Welded Steel Pipe for Low-Temperature Service, ASME SA-333, Grade 1 or 6, and ASME SA-516, Grade 70.

B. Penetration sleeve reinforcing - ASME SA-516, Grade 70

C. Anchor rings and plates - ASME SA-516, Grade 70

Material for bolts, nuts, studs, cadwelds, and unistruts conforms to the requirements of the specifications listed below:

A. Machine bolts - ASME SA-307, Low-Carbon Steel Externally and Internally Threaded Standard Fasteners

B. Nelson studs - ASTM A108, Cold-Finished Carbon Steel Bars and Shafting

C. Cadweld connectors - AISI C 1026 or AISI C 1018

D. Unistruts - Hot-Rolled Carbon Steel Sheet and Strip, Structural Quality, ASTM A570, Grade A and steel, Cold-Rolled Sheet, Carbon, Structural, ASTM A611, Grade A.

E. High strength bolts - ASME SA-325, High Strength Bolts for Structural Steel Joints Including Suitable Nuts and Plane Hardened Washers.

F. Anchor bolts or studs - ASME SA-36, Structural Steel, ASME SA-105 (bar stock), Carbon Steel Forgings for Piping Components, ASME SA-193 (Grade B7), Alloy-Steel and Stainless Steel Bolting Materials for High Temperature Services, ASME SA-194 (Grade 7), Carbon and Alloy-Steel Nuts for Bolts for High Pressure and High Temperature Service.

Tolerances for erection of penetration assemblies are specified as follows and in the event of conflict shall prevail over tolerances listed in BC-TOP-1, Section 1.3.8:

A. Penetration assemblies

1. Paragraph 3.8.1.6.4.1, listings A.2, 3, and 5 also control the tolerance requirements for penetrations.

2. A 30-inch long template curved to the required radius does not show deviations of more than 3/4 inch when placed against the completed surface of the shell within a single plate section.

3. Alignment of the axis of penetrations greater than 12-inch nominal pipe size, as erected, does not vary by more than 1° from the alignment shown. Alignment of the axis of penetrations 12 inch or smaller nominal pipe size as erected shall not vary by more than 2° from the alignment shown. Individual penetrations and penetrations in common reinforcing plates other than main steam and feedwater penetrations are located within ±1 inch of their design elevations and circumferential locations. Main steam and feedwater penetrations shall be located within ±1/2 inch of their design elevations and circumferential locations.

4. The location of penetrations in a common reinforcing late is within ±1/4 inch of the

dimensions shown on the design drawings relative to each other.

3.8.1.6.6 Structural and Miscellaneous Steel

Detailing, fabrication, and erection of the structural and miscellaneous steel are in accordance with the AISC specifications referenced in paragraph 3.8.1.2.2.

Mill test reports of structural and miscellaneous steel are obtained for all materials used with the exceptions of hand rails, toe plates, kick plates, stairs, ladders, and for nuts, bolts, and anchors including anchor bolts less than 1-1/4 inches diameter. Handrails, toe plates, etc., are not highly stressed but require certificates of compliance as documentation.

Materials conform to the following specific designations:

Material	ASTM Designations
Structural steel shapes, plates, and bars	A36, A516 Grade 70, A992
High strength structural steel shapes, plates, and bars	A441, A514, A588
Anchor bolts	A36, A307, A540, A449, A354 Grade BD
High strength bolts (steel connections)	A325, A354 Grade BD, A490, A540
Other bolts	A36, A307
Stainless steel plate	A167 or A240, type 304 with 0.05% maximum carbon or type 304L

Welding and the acceptance criteria for visual inspection of welding are in accordance with AWS Dl.1-72, Revision 1, 1973 with clarifications and changes identified in paragraphs 3.8.1.6.6.1, listing A.

3.8.1.6.6.1 Structural Steel Construction. For steel construction, procedures are as follows:

A. Welding and acceptance criteria for visual inspection of welding are per the Structural Welding Code (AWS Dl.1-72, Revision 1, 1973) with the following clarifications and changes:

   1. Weld joint classification is based upon suitability for service in accordance with the following categories:

      a. Category A joints are part of the main building frame and carry principal design loads.

      b. Category B joints are connections between main building frame and miscellaneous metal.

      c. Category C joints are not part of the main building frame, but rather provide auxiliary support or framing for systems, components, and equipment. These joints are within the miscellaneous metal category, and shall include, but are not limited to, pipe supports (beyond the scope of ASME codes), stairways, embedments, HVAC duct supports, instrument supports, and electrical raceway and supports.

d. Category D joints are not part of the building frame, or auxiliary support system, but rather perform a passive or inactive function. These joints are within the miscellaneous metal category and shall include, but are not limited to, doors, windows, hatch covers and frames, ledger angles, handrails, and gratings.

e. Category E joints are limited to welds, used in ductwork welding of thin-walled gauge steel, whose classification is not specifically covered by the Structural Welding Code.

2. The acceptance criteria for visual inspection of Category A, B, C, and D joints are per Nuclear Construction Issues Group Document, NCIG-01, Revision 2.

3. For Category E joints, Paragraph 3.1.4 is clarified as follows:

   a. Weld sizes specified in the drawings are considered nominal. Deviations of up to -1/32 inch for the entire weld length are considered as meeting the weld size requirement.

   b. The fillet leg dimension may not underrun the specified weld size by more than 1/16 inch for more than 10% of the weld length. For flange-to-web joints, the undersize may not be within two flange thicknesses of the weld end.

c. Fillet welds exceeding the specified size are acceptable, as long as the oversized weld does not interfere with mating parts and there is no evidence of excessive distortion.

d. Fillet weld lengths in excess of those shown on the design drawings are acceptable.

e. Where intermittent fillet welds are specified on the design drawings, a continuous weld of the same size is acceptable.

4. Paragraph 4.9.2 is replaced as follows:

All electrodes having low-hydrogen coverings conforming to AWS A5.1 are purchased in hermetically-sealed containers. If the hermetically-sealed container shows evidence of damage, the electrodes are dried prior to use. Immediately after the opening of the hermetically-sealed containers, electrodes are stored in ovens held at a temperature of 200F minimum. The E70XX electrodes that are not used within 12 hours, E80XX within 2 hours, E90XX within 1 hour, E100XX and E110XX within 1/2 hour after the opening of the hermetically-sealed container or removal of the electrodes from a drying or storage oven are redried for 8 hours at a temperature of 200F minimum prior to reissue. Electrodes which have been wet are not used. Heated rod cans are not required when rod is used within the specified time.

5. In Table 4.2, the governing thickness to determine preheat requirements for fillet welds shall be the weld throat thickness. The preheat for fillet welds is based on the weld throat dimension, and the justification is based on the following engineering analysis:

   a. The structural steels used at PVNGS that utilize the fillet weld throat approach to preheating the plain carbon steels (principally A36, A992, and A500) and are essentially nonhardenable. Preheat is important for plain carbon, nonhardenable steels to counteract high restraint and shrinkage strains. The fillet welds at PVNGS are not considered to be highly restrained. Since the shrinkage strain is proportional to the weld throat, it is a rational basis for preheating. This fillet weld throat approach to preheating is not used for high strength or alloy steels. High strength and alloy steels used at PVNGS are governed by other codes and specifications.

   b. The principal welding filler metal used for the structural steel is E7018, which produces a tough ductile deposit and has minimal preheat requirements due to its low hydrogen characteristic. The NRC has reviewed and approved a test report from PVNGS, qualification of an Alternative Electrode Control Program for AWS D1.1

(including the electrode control procedure WFMC-1, Revision 6), dated March 15, 1978, which reported on the control of E7018 electrodes. The test coupons used in that program were welded without preheat. Several coupons were 1-inch thick circular patch tests which represent the maximum restraint. As the circular patch test coupons welded without preheat were acceptable, fillet welding without preheat is justifiable. In addition to these tests, other procedure qualification test coupons have been welded without preheat. Any of these tests can serve to qualify deviations from the requirements of AWS D1.1, Table 4.2.

c. The inspection requirements of AWS D1.1 are supplemented with nondestructive examinations as appropriate to the design and function of the components.

6. For Category E joints, Paragraph 3.6.4 is replaced as follows:

   Undercut shall not exceed 50% of the material thickness.

7. For Category E joints, Paragraph 3.6.6 is replaced as follows:

   Overlap/rollover may not exceed 1/8 inch.

8. For Category E joints, Paragraph 3.6.1 is replaced as follows:

   The face of fillet welds may be slightly convex, flat, or slightly concave. The convexity height shall not exceed 1/8 inch. Concavity shall not reduce the weld throat beyond that required for weld size.

9. Paragraph 8.15.1.5 is replaced as follows:

   a. For Category E joints, the welds may contain a maximum of 5%, by surface area, unaligned, unclustered porosity.

10. Welding shall be performed only by welders or welding operators who have been qualified in accordance with AWS D1.1 1972, Revision 1, 1973, or ASME Section IX, Welding and Brazing Qualifications, 1974 Edition or later. The groove plate test in the 3G and 4G positions, or any 6G position pipe, shall qualify a welder to perform the following additional operations:

    a. Welding of handrails in all positions.

    b. To make fillet welds of any size, in all positions, on base metals in all thicknesses for structural tubing.

B. AISC, Specification for the Design, Fabrication and Erection of Structural Steel for Buildings, as referenced in paragraph 3.8.1.2.2, is used.

C. AISC, Specification for Structural Joints Using ASTM A325 or A490 Bolts, is used.

D. Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants (ANSI N45.2.5-1974) is used except as noted below:

1. Section 5.4, High Strength Bolting -- Used except AISC Specification for Structural Joints Using ASTM A325 or A490 Bolts shall govern the proper length of bolts.

2. Section 5.5, Welding -- Used with exceptions as noted in paragraph 3.8.1.6.6.1, listing A.

NOTE

Work accomplished prior to the adoption of NCIG-01 shall conform to the commitments established in the PVNGS FSAR prior to NCIG-01 adoption.

3.8.1.6.7 Quality Control

Quality control procedures are established and implemented during construction and inspection as specified in Chapter 17. The quality control procedures covering the fabrication, furnishing, and installation of each structural component provide inspection and documentation to assure that the codes and construction practices are met.

3.8.1.6.7.1 Control Tests for Concrete. Concrete for the containment structure is tested in accordance with ACI 301-72,

except as noted in paragraph 3.8.1.6.1. Concrete placement is accomplished in accordance with NRC Regulatory Guide 1.55 as discussed in section 1.8.

3.8.1.6.7.2 Control Tests for Reinforcing Steel. Reinforcing steel is tested in accordance with NRC Regulatory Guide 1.15. Control of mechanical splices for reinforcement utilizing filler metal and an enclosing sleeve (cadweld-type splices) is in accordance with NRC Regulatory Guide 1.10 with exceptions as noted in section 1.8.

3.8.1.6.7.3 Control Tests and Inspection of Prestressing System. The following quality control procedures are used:

A. Prestressing Wires

1. Each tendon is individually identified and traceable to the heat numbers of the wire utilized in its buildup. Chemical and physical test reports supporting the integrity of each heat of material are reviewed as a condition of acceptance.

2. Specimens are cut from each reel of wire and tension tested to assure compliance to specifications.

3. Wires are examined for quality prior to fabrication of the tendon.

B. Bearing Plates and Trumpets

1. Verify that the bearing plate material complies with that specified on the drawings. Compliance is evidenced by mill test reports traceable to the heat number by serial numbers permanently marked on each bearing plate.

2. A full scale ultimate tensile strength test on a representative tendon sample is conducted with the anchorage, bearing plate, and supporting concrete maintained at a temperature at least 30F below the lowest anticipated service temperature. This service temperature is 20F and the test is conducted at a maximum of -10F.

3. Plates are examined for workmanship and quality. Cracks, burrs, corrosion, and other defects are not acceptable.

C. Anchor Head

1. Raw material is accompanied by mill certificates and subjected to receiving inspection.

2. Parts are coated with a preservative prior to shipment.

D. Physical Tests

1. Load Test

Typical anchorage and tendon details are tested to show that the anchorage develops the minimum

guaranteed ultimate strength of the tendon and that the elongation of the assembly will not be less than specified.

2. Cyclic Test

   Failure must not result based on test results on reduced size anchorage assemblies subjected to 500 cycles of rapid loading from stress level 0.70 f_s' to stress level 0.75 f_s' and return to 0.70 f_s'. One complete cycle shall take place in 0.1 second.

3. Cold Environment Test

   Documentary evidence or certified testing at temperatures below the lowest anticipated service temperature shall substantiate that the anchorage assembly, including the bearing plate, is capable of transmitting the ultimate load of the tendon into the structure. Reference 1 is an example of accepted documentation for the cold environment test.

3.8.1.6.7.4 Quality Control Procedures for the Liner Plate. The nondestructive examination of the liner plate is in accordance with NRC Regulatory Guide 1.19 with exceptions noted in section 1.8.

The materials which are used in the liner plate system fabrication and construction are listed in table 3.8-1.

Properties and characteristics of the liner plate are given in table 3.8-5.

A. Liner and Thickened Plate

The liner plate is 1/4 inch thick. Thickened plates are used as penetration reinforcing plates and as part of the bracket and attachment assemblies. Thickened floor plate shall be ultrasonically inspected in accordance with ASME SA-435, except that inspection shall cover 100% of the plate area. Thickened plates over 5/8 inch in thickness require Charpy V-notch impact tests in accordance with ASTM A593. Testing is specified at 30F below service temperature and the average energy requirement for 3 specimens shall be greater than 15 ft-lbs while the minimum requirement for any one specimen shall be greater than 10 ft-lbs. Structural steel members and electrical ground rods are not classified as thickened plate.

B. Penetration Nozzles

Nozzles over 5/8 inch in thickness require the same Charpy V-notch impact tests as for thickened plates in paragraph 3.8.1.6.7.4, listing A. except see note c of table 3.8-1 for minimum requirements of ASME SA-333, Grades 1 and 6.

C. Welding Materials

Welding materials used to join various parts of the liner plate system are described in paragraph 3.8.1.6.4.

The quality assurance procedures that assure the suitability of the steel plate material for field-welded brackets and attachments that are not continuous through the liner plate are discussed as follows:

A. The liner plate shall be ultrasonically examined for delaminations in an area that extends an additional liner plate thickness from the attachment weld. Any delaminated plates are repaired.

B. The strength in the through the thickness direction is taken as one-half of that in the transverse direction unless tests are performed to justify higher values.

Ultrasonic examination shall be required only for plate 3/8 inch and greater thickness.

3.8.1.6.7.5 Quality Control Procedures for the Containment Liner Plate Attachments. The quality control procedures associated with penetrations, attachments, and hardware are incorporated in the quality control procedures for the liner plate.

3.8.1.6.7.6 Quality Control Procedures for Structural and Miscellaneous Steel. Quality control procedures for structural

and miscellaneous steel and the associated structural welding conform to the requirements specified in paragraph 3.8.1.6.6.

3.8.1.7 Testing and Inservice Surveillance Requirements

3.8.1.7.1 Structural Integrity Pressure Test

Following construction, the containment is proof-tested at 115% of the design pressure. During this test, deflection measurements and concrete crack inspections are made to determine that the actual structural response is within the limits predicted by the design analyses.

The test procedure complies with the requirements of NRC Regulatory Guide 1.18 except as noted in section 1.8. Section 9 of BC-TOP-5-A also describes test results obtained using a typical procedure as well as those obtained from early tests where a substantial amount of strain information was collected.

3.8.1.7.2 Long-Term Surveillance

The long-term surveillance program consists of evaluating the general condition of the post-tensioning system. Data on wire corrosion level and tendon lift-off forces are obtained and analyzed. The surveillance tendons and surveillance frequency are designated by the engineer as explained in BC-TOP-5-A, Section 9.3. Except as noted in section 1.8, the surveillance program complies with ASME Section IX, Subsection IWL, 1992 Edition with the 1992 Addenda, as modified and supplemented by 10 CFR 50.55a.

The inservice inspection program for the containment liner plate and exterior concrete surface consist of visual examinations, tracking, monitoring, reporting, and repair/replacement/rework of applicable degraded conditions. The inservice inspection program for the containment liner plate and exterior concrete surface complies with ASME Section XI, Subsection IWE and IWL, 1992 Edition with the 1992 Addenda, as modified and supplemented by 10 CFR 50.55a. The surveillance and inservice inspection programs provide assurances of the continuing ability of the structure to meet the design functions as stated in paragraph 3.8.1.5.

3.8.2 STEEL CONTAINMENT

As described in subsection 3.8.1, the containment is a prestressed, reinforced concrete structure; therefore, this section does not apply.

3.8.3 CONCRETE AND STEEL INTERNAL STRUCTURES OF STEEL OR CONCRETE CONTAINMENTS

3.8.3.1 Description of the Internal Structures

The internal structures located in the containment consist of the reactor supports, steam generator supports, reactor coolant pipe restraints, primary shield wall and reactor cavity, secondary shield walls, pressurizer supports, refueling pool walls, and the operating and intermediate floors.

3.8.3.1.1 Reactor Vessel Supports

The reactor vessel is supported by four columns under the cold leg nozzles discussed in section 5.4.14 which interface with anchor bolts embedded in the primary shield. Lateral supports are provided for the reactor vessel to resist the horizontal loads. These lateral supports transmit the loads to the reactor cavity wall, which houses the reactor. In addition, shear keys at the lower part of the reactor vessel fit into the keyways, located in the base plate, of the column supports. These keyways (which are described in section 5.4.14) transmit the horizontal loads to the cavity wall through shear bars attached to the bottom of the base plate. Both the lateral supports and shear keys are designed to allow movement due to thermal growth of the reactor vessel in the radial and vertical directions. Details of the lateral and vertical reactor vessel supports are shown in engineering drawings 13-C-ZCS-600 and -601.

3.8.3.1.2 Steam Generator Supports

The steam generator is mounted on thick, heavily reinforced, concrete supports. The loads are transmitted to the supports by means of high-strength bolts, bearing plates, and shear keys. The supports, in turn, transmit these loads to the containment basemat. The upper part of the steam generator is restrained by means of shear keys and snubbers that are attached to the refueling pool walls and secondary shield walls. The steam generator supports are shown in engineering drawings 13-C-ZCS-605 and –606.

3.8.3.1.3 Reactor Coolant Pump Supports and Stops

The reactor coolant pumps are supported by four vertical columns, four horizontal columns, and two horizontal snubber supports. The horizontal columns and snubbers and a portion of the vertical columns are considered to be part of the NSSS as discussed in section 5.4.14. The vertical columns transmit the vertical loads to the containment basemat. The horizontal columns and the snubber supports, attached to the secondary shield wall, transmit the lateral loads to the refueling pool walls and to the secondary shield walls. All of the columns are hinged to permit radial (defined as an axis passing through the center of the reactor and the pump) movement of the pumps due to thermal growth.

Additionally, one stop is provided for each reactor coolant pump. This stop is a horizontal column designed to resist lateral loads in the radial direction due to a postulated LOCA. The resisted loads are transmitted to the secondary shield walls. Details of the reactor pump supports and stop are shown in engineering drawings 13-C-ZCS-602 and –603.

3.8.3.1.4 Pressurizer Supports

The pressurizer vessel is located in a pressurizer compartment which is supported by concrete beams at elevation 110 feet. The pressurizer compartment has a floor space approximately 18 feet square and a height of 50 feet. It is attached to one of the secondary shield structures and is covered by a three-section removable reinforced concrete missile shield at the top of the

compartment. The pressurizer support skirt, which is described in section 5.4.14, is attached to the concrete beams by anchor bolts. The beams and anchor bolts are designed for vertical and lateral loads as well as for moments due to dead loads, thermal loads, seismic loads, and loads due to surge line and other pipeline breaks.

In addition, the pressurizer is restrained near the top by means of keys which fit into keyways. Four keyway supports are located 90° apart and are designed to transmit the lateral loads due to seismic excitation and due to sub-compartment pressures by pipe breaks to the pressurizer compartment walls. These keyways are also designed to permit vertical and radial movement of the pressurizer due to thermal growth. Details of the pressurizer supports are shown in engineering drawing 13-C-ZCS-604.

3.8.3.1.5 Reactor Coolant System Pipe Restraints

The RCS restraints are provided to restrict the displacement of the reactor coolant piping. Section 3.1.4 states that dynamic effects associated with postulated pipe ruptures of primary coolant loop piping in PWRs may be excluded from the design basis when analysis demonstrates the probability of rupturing piping is extremely low. The reactions from the restraints are transmitted to the basemat or various heavily reinforced members which transmit the loads to the basemat or to the primary or secondary shield walls.

All the restraints are provided with a gap to permit movement of the pipes due to thermal growth and seismic displacements.

3.8.3.1.6 Primary Shield Wall and Reactor Cavity

The primary shield is a heavily reinforced concrete structure that houses the reactor, provides the primary radiation shielding, and is an integral part of the internal structures. It is anchored to the containment basemat through the use of cadwelds welded to both sides of the thickened liner plate.

The massive primary shield walls provide a support for the refueling pool walls above the reactor cavity. In plan, the primary shield walls form a monolithic ring, housing the reactor vessel. Penetrations in the primary shield walls are provided for the primary loop and cavity ventilation system.

Details of the primary shield walls are shown in engineering drawings 13-C-ZCS-345 through -348.

3.8.3.1.7 Refueling Canal

The refueling canal is a reinforced concrete structure that is flooded during the reactor refueling operation. The pool walls are partially supported by the primary shield and partially by the containment basemat.

The refueling canal is lined with stainless steel plate and is connected with the spent fuel pool, in the fuel handling building, through the fuel transfer tube.

3.8.3.1.8 Fuel Transfer Tube

A detailed description of the fuel transfer tube is provided in paragraph 3.8.1.1.3.5.

3.8.3.1.9 Secondary Shield Walls

The secondary shield is a heavily reinforced concrete structure enclosing (together with the refueling pool walls) the steam generators. The massive secondary shield walls are anchored into the basemat of the containment in a manner similar to the primary shield walls, in order to allow for load transfer to the foundation. Each of the two enclosed secondary shield compartments houses a steam generator and two reactor coolant pumps.

Steel embedments in the secondary shield walls transmit loads from various equipment, pipe supports, operating and intermediate floors, and platforms to the walls.

Details of the secondary shield walls are shown in engineering drawings 13-C-ZCS-366 and -358.

3.8.3.1.10 Operating and Intermediate Floors

The floors inside the containment consist of both concrete slab construction and steel grating supported by structural steel framing. The steel framing is supported by perimeter steel columns just inside the exterior shell. The internal structure, including attachments, is separated from the liner plate and its attachments by a nominal 3-inch gap for seismic displacement allowances. Smaller gaps may be permitted, based

on an engineering evaluation, on a case-by-case basis. The steel grating is vertically supported by ledger angles welded to the containment liner plate but is free to move horizontally.

Details of the operating floor are shown in engineering drawings 13-C-ZCS-306 and -307.

3.8.3.2 Applicable Codes, Standards, and Specifications

3.8.3.2.1 Codes and Standard Specifications

The codes and standard specifications listed below apply to internal structures. Later editions of certain baseline standards as noted below are acceptable provided they are identified in applicable design calculations or specifications for fabrication, construction, testing, or inspection.

- American Concrete Institute, Building Code Requirements for Reinforced Concrete (ACI 318-71, or later edition)
- American Institute for Steel Construction, Specification for the Design, Fabrication and Erection of Structural Steel for Buildings, adopted February 12, 1969 and Supplement Nos. 1, 2, and 3, or later edition
- American Institute for Steel Construction, Specification for Structural Joints Using ASTM A325 or A490 Bolts Approved by Research Council on Riveted and Bolted Structural Joints of the Engineering Foundation, May 8, 1974, or later

- American Welding Society, Structural Welding Code (AWSD1.1-72, Revision 1, 1973 or later edition) except as noted in paragraph 3.8.1.6.6.1, listing A
- American Welding Society, Structural Welding Code Sheet Steel (AWS D1.3-1989) In addition to AWS D1.1 may be used for welding of structures inside containment.
- Crane Manufacturers Association of America Inc. CMAA Specification No. 70, 1971
- American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel (B&PV) Code
  - Section II, 1974 Edition and Addenda through Winter 1974
  - Section III, Division 1, 1974 Edition and Addenda through Winter 1974
  - Section V, 1974 Edition and Addenda through Summer 1974
  - Section VIII, Division 1, 1974 Edition and Addenda through Winter 1975
  - Section IX, 1974 Edition and Addenda through Winter 1974
- American National Standards Institute (ANSI), Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants (ANSI N45.2.5-1974) except

as noted in paragraph 3.8.1.6.1.2, listings A and H, and paragraph 3.8.1.6.6.1, listing D.

3.8.3.2.2 General Design Criteria and Industry Standards

General design criteria and industry standards applicable to internal structures are listed below:

- NRC Regulatory Guides (applicable revisions and dates are provided in section 1.8)
  - Regulatory Guide 1.10, Mechanical (Cadweld) Splices in Reinforcing Bars of Category I Concrete Structures
  - Regulatory Guide 1.15, Testing of Reinforcing Bars for Category I Concrete Structures
  - Regulatory Guide 1.29, Seismic Design

  Classification
  - Regulatory Guide 1.46, Protection Against Pipe Whip Inside Containment
  - Regulatory Guide 1.55, Concrete Placement in Category I Structures
  - Regulatory Guide 1.60, Design Response Spectra for Seismic Design of Nuclear Power Plants
  - Regulatory Guide 1.61, Damping Values for Seismic Design of Nuclear Power Plants
  - Regulatory Guide 1.69, Concrete Radiation Shields for Nuclear Power Plants

Exceptions to and interpretations of these regulatory guides are given in section 1.8.

- Industry Standards
  - Nationally recognized industry standards, such as those published by ASTM, are used whenever possible to describe material properties, testing procedures, fabrication, and construction methods.

3.8.3.2.3 Project Design and Construction Specifications

Project design and construction specifications are provided in paragraph 3.8.1.2.4.

3.8.3.3 Loads and Load Combinations

The internal structures are designed for loads and loading combinations described in paragraphs 3.8.3.3.1 through 3.8.3.3.3. The loading combinations involving extreme wind, tornado, or flood forces are not applicable to the containment internal structures.

3.8.3.3.1 Loads, Definitions, and Nomenclature

3.8.3.3.1.1 Normal Loads. Normal loads are those loads to be encountered during normal plant operation and shutdown. They include the following:

D = Dead loads or their related internal moments and forces, including any permanent equipment loads and hydrostatic loads

L = Live loads or their related internal moments and forces, including any movable equipment loads and other loads which vary with intensity and occurrence, such as soil pressure

T_o = Thermal effects and loads during normal operating or shutdown conditions, based on the most critical transient or steady state condition

R_o = Pipe reactions during normal operating or shutdown conditions, based on the most critical transient or steady state condition

3.8.3.3.1.2 Severe Environmental Loads. Severe environmental loads are those loads that could infrequently be encountered during the plant life. Included in this category are:

E = Loads generated by the operating basis earthquake (OBE)

W = Loads generated by the design wind specified for the plant (not applicable to subsection 3.8.3)

3.8.3.3.1.3 Extreme Environmental Loads. Extreme environmental loads are those loads which are credible but are highly improbable. They include:

E' = Loads generated by the safe shutdown earthquake (SSE)

W_t = Loads generated by the design basis tornado specified for the plant. They include loads due to the tornado wind pressure, loads due to the tornado-created

differential pressures, and loads due to the tornado-generated missiles (not applicable to subsection 3.8.3)

3.8.3.3.1.4 Abnormal Loads. Abnormal loads are those loads generated by a postulated high energy pipe break accident within a building and/or compartment thereof. Included in this category are the following:

P_a = Pressure equivalent static load within or across a compartment and/or building, generated by the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load

T_a = Thermal loads under thermal conditions generated by the postulated break and including T_o

R_a = Pipe reactions under thermal conditions generated by the postulated break and including R_o

Y_r = Equivalent static load on the structure generated by the reaction on the broken high energy pipe during the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load

Y_j = Jet impingement equivalent static load on a structure generated by the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load

Y_m = Missile impact equivalent static load on a structure generated by or during the postulated break, as from pipe whipping, and including an appropriate dynamic load factor to account for the dynamic nature of the load

In determining an appropriate equivalent static load for Y_r, Y_j, and Y_m, elasto-plastic behavior may be assumed with appropriate ductility ratios provided excessive deflections will not result in loss of function of any safety-related system.

3.8.3.3.1.5 Other Definitions. Additional pertinent definitions are as follows:

S = For concrete structures, S is the required section strength based on the working stress design methods and the allowable stresses defined in Section 8.10 of ACI 318-71.

For structural steel, S is the required section strength based on the elastic design methods and the allowable stresses defined in Part 1 of the AISC

Specification for the Design, Fabrication and Erection of Structural Steel for Buildings, February 12, 1969.

The 33% increase in allowable stresses for concrete and steel due to seismic or wind loadings is not permitted.

U = For concrete structures, U is the section strength required to resist design loads and is based on methods described in ACI 318-71.

Y = For structural steel, Y is the section strength required to resist design loads and is based on plastic design methods described in Part 2 of AISC Specification for the Design, Fabrication and Erection of Structural Steel for Buildings, February 12, 1969.

3.8.3.3.2 Load Combinations for Concrete Structures

The following presents a set of load combinations and allowable design limits for Seismic Category I concrete structures. To assure that the structural integrity will be maintained, limits on the resulting stresses and the required section strength capacities are defined for service loads, including earthquake (OBE) and wind loads, and for factored loads, including earthquake (OBE or SSE), tornado, and pipe break effects and various combinations thereof.

A. Load Combinations for Service Load Conditions

Either the working stress design (WSD) method or the strength design method will be used.

(1) If the WSD method is used, the following load combinations are considered:

1. S = D + L

2. S = D + L + E

3. S = D + L + W (not applicable to subsubsection 3.8.3)

If thermal stresses due to T_o and R_o are present, the following combinations are also considered:

1a. $1.3S = D + L + T_o + R_o$

2a. $1.3S = D + L + T_o + R_o + E$

3a. $1.3S = D + L + T_o + R_o + W$ (not applicable to subsection 3.8.3)

Cases of L having its full value or being completely absent are both checked.

(2) If the strength design method is used, the following load combinations are considered:

1. $U = 1.4\ D + 1.7\ L$

2. $U = 1.4\ D + 1.7\ L +1.9\ E$

3. $U = 1.4\ D + 1.7\ L + 1.7\ W$ (not applicable to subsection 3.8.3)

If thermal stresses due to T_o and R_o are present, the following combinations are also considered:

1b. $U = (0.75)\ (1.4\ D + 1.7\ L + 1.7\ T_o + 1.7\ R_o)$

2b. $U = (0.75)\ (1.4\ D + 1.7\ L + 1.9\ E + 1.7\ T_o + 1.7\ Ro)$

3b. $U = (0.75)\ (1.4\ D + 1.7\ L + 1.7\ W + 1.7\ T_o + 1.7\ R_o)$ (not applicable to subsection 3.8.3)

Cases of L having its full value or being completely absent are both checked and the following combinations are also satisfied:

1c. $U = 1.2\ D + 1.9\ E$

2c. $U = 1.2\ D + 1.7\ W$ (not applicable to subsection 3.8.3)

Where soil and/or hydrostatic pressures are present, in addition to all the above combinations where they have been included in L and D, respectively, the requirements of Sections 9.3.4 and 9.3.5 of ACI 318-71 will also be satisfied.

B. Load Combinations for Factored Load Conditions

For these conditions, which represent extreme environmental, abnormal, abnormal/severe environmental and abnormal/extreme environmental conditions, respectively, the strength design method is used and the following load combinations are considered:

1. $U = D + L + T_o + R_o + E'$

2. $U = D + L + T_o + R_o + W_t$ (not applicable to subsection 3.8.3)

3. $U = D + L + T_a + R_a + 1.5\ P_a$

4. $U = D + L + T_a + R_a + 1.25\ P_a + 1.0\ (Y_r + Y_j + Y_m) + 1.25\ E$

5. $U = D + L + T_a + R_a + 1.0\ P_a + 1.0\ (Y_r + Y_j + Y_m) + 1.0\ E'$

In load combinations 3, 4, and 5, the maximum values of P_a, T_a, R_a, Y_j, Y_r, and Y_m, including an appropriate dynamic load

factor, are considered unless a time-history analysis is performed to justify otherwise. Combinations 2, 4, and 5 will be satisfied first without the tornado missile load in 2 and without Y_r, Y_j, and Y_m in 4 and 5. When considering these loads, however, local section strength capacities may be exceeded under these concentrated loads, provided there will be no loss of function of any safety-related system.

Cases of L having its full value or being completely absent are both checked.

3.8.3.3.3 Load Combinations for Steel Structures

The following presents a set of load combinations and allowable design limits for Seismic Category I steel structures. To assure that the structural integrity will be maintained, limits on the resulting stresses and the required section strength capacities are considered for service loads, including OBE and wind loads, and for factored loads, including OBE or SSE, tornado, and pipe break effects and various combinations thereof.

A. Load Combinations for Service Load Conditions

Either the elastic working stress design methods of Part 1 or the plastic design methods of Part 2 of AISC, will be used.

(1) If the elastic working stress design methods are used, the following load combinations are considered.

1. S = D + L

2. $S = D + L + E$

3. $S = D + L + W$ (not applicable to subsection 3.8.3)

If thermal stresses due to T_o and R_o are present, the following combinations are also considered:

1a. $1.5\ S = D + L + T_o + R_o$

2a. $1.5\ S = D + L + T_o + R_o + E$

3a. $1.5\ S = D + L + T_o + R_o + W$ (not applicable to subsection 3.8.3)

Cases of L having its full value or being completely absent are both checked.

(2) If plastic design methods are used, the following load combinations are considered:

1. $Y = 1.7\ D + 1.7\ L$

2. $Y = 1.7\ D + 1.7\ L + 1.7\ E$

3. $Y = 1.7\ D + 1.7\ L + 1.7\ W$ (not applicable to subsection 3.8.3)

If thermal stresses due to T_o and R_o are present, the following combinations are also considered:

1b. $Y = 1.3\ (D + L + T_o + R_o)$

2b. $Y = 1.3\ (D + L + E + T_o + R_o)$

3b. $Y = 1.3\ (D + L + W + T_o + R_o)$ (not applicable to subsection 3.8.3)

Cases of L having its full value or being completely absent are both checked.

B. Load Combinations for Factored Load Conditions

The following load combinations are considered:

(1) If elastic working stress design methods are used, the applicable load combinations are:

1. $1.6\ S = D + L + T_o + R_o + E'$

2. $1.6\ S = D + L + T_o + R_o + W_t$ (not applicable to subsection 3.8.3)

3. $1.6\ S = D + L + T_a + R_a + P_a$

4. $1.6\ S = D + L + T_a + R_a + P_a + 1.0\ (Y_j + Y_r + Y_m) + E$

5. $1.7\ S = D + L + T_a + R_a + P_a + 1.0\ (Y_j + Y_r + Y_m) + E'$

For combinations 4 and 5 of this paragraph, the plastic section modulus of steel shapes will be used in computing the required section strengths.

(2) If plastic design methods are used, the applicable load combinations are:

1. $0.90\ Y = D + L + T_o + R_o + E'$

2. $0.90\ Y = D + L + T_o + R_o + W_t$ (not applicable to subsection 3.8.3)

3. $0.90\ Y = D + L + T_a + R_a + 1.5\ P_a$

4. $0.90\ Y = D + L + T_a + R_a + 1.25\ P_a + 1.0\ (Y_j + Y_r + Y_m) + 1.25\ E$

5. $0.90\ Y = D + L + T_a + R_a + 1.0\ P_a + 1.0\ (Y_j + Y_r + Y_m) + 1.0\ E'$

For elastic and plastic design method combinations 1 and 2, thermal loads can be neglected when it can be shown that they are secondary and self-limiting in nature and where the material is ductile.

In combinations 3, 4, and 5, the maximum values of P_a, T_a, R_a, Y_j, Y_r, and Y_m, including an appropriate dynamic load factor, are used unless a time-history analysis is performed to justify otherwise.

Combinations 2, 4, and 5 will be first satisfied without the tornado missile load in 2 and without Y_r, Y_j, and Y_m in 4 and 5. When considering these loads, however, local section strengths may be exceeded under the effect of these concentrated loads, provided there will be no loss of function of any safety-related system.

3.8.3.3.4 Procedures for Determination of the Effect of Missile Impact on Concrete and Steel Structures

Missile barriers, whether concrete or steel, are designed with sufficient strength and thickness to stop the postulated missiles and to prevent generation of secondary missiles or spalling that may damage safety-related systems. To accomplish

this objective, prediction of local and overall damage due to the missile impact is necessary.

Local damage prediction, in the immediate vicinity of the impacted area, includes estimation of the depth of penetration and whether secondary missiles might be generated by spalling in case of concrete targets. Overall damage prediction includes estimation of the structural response of the target to the missile impact, including structural stability and deformations.

In general, missiles are characterized by impact velocity, missile mass, and impact area. Procedures used in determining these parameters are discussed in section 3.5.

3.8.3.3.4.1 Local Damage Prediction. Estimated missile penetration, perforation, and spalling effects are investigated using the procedures outlined in BC-TOP-9-A.

3.8.3.3.4.2 Overall Damage Prediction. The response of a structure to missile impact depends largely on the location of impact (midspan of a slab or near the support), on the dynamic properties of the target and missile, and on the kinetic energy of the missile.

Energy losses due to missile deformation, local penetration, and type of impact are accounted for. The techniques given in appendix 3C are used to determine an analytical approach, ductility factors, strength increase due to high strain rates, and methods for determining yield displacement.

3.8.3.4 Design and Analysis Procedures

Design of the interior structure evolves around four basic systems: the reactor coolant system, the main steam system, the engineered safeguards system, and the fuel handling system supply.

The structures that house or support the basic systems are designed to sustain the factored loads described in paragraph 3.8.3.3.

The design bases to be applied are given as follows:

A. Operating loads, seismic loads, and the thermal deformations at the levels indicated in paragraph 3.8.3.3.

B. Loads and deformations resulting from a LOCA and its associated effects.

C. Environmental effects resulting from a postulated high-energy line break such as temperature, pressure, humidity, or flooding. The magnitude of thrust forces and pressure buildup resulting from a pipe break is determined from appropriate blowdown values.

D. Jet impingement equivalent static loads on a structure generated by a postulated high energy line break.

E. Missile impact equivalent static loads on a structure generated by or during a postulated high energy line break, like pipe whipping.

F. Missiles as described in section 3.5.

The containment interior structure is designed to provide structural supporting elements for the entire NSSS, as well as required shielding. Basic supporting components are designed using both reinforced concrete and structural steel as appropriate. Design aspects are integrated with the design criteria of the nuclear steam supply system vendor and include particular attention to the combined thermal and dynamic effects particularly evident during earthquake conditions. Thrusts are taken by rigid members and by shock suppressors. Design loads and loading combinations for the interior structure are listed and described in paragraph 3.8.3.3.

The main considerations in establishing the structural design criteria for the internal structures are to provide a structure that will withstand the differential pressure within the reactor cavity and across the secondary shield walls in the event of an accident, and to minimize the effects of the pipe rupture force and seismic loadings utilizing supports and restraints. Loads and deformations resulting from a LOCA and its associated effects on any one of the basic systems are restricted so that propagation of the failure to any other system is prevented.

In addition, a failure in one loop of the NSSS is restricted, so that propagation of the failure to the other loop is prevented. Localized concrete yielding is permitted, when it is demonstrated that the yield capacity of the component is not affected, and that this small localized yielding does not generate missiles that could damage the structure. Full

recognition is given to the time increments associated with these postulated failure conditions. The walls are also designed to provide adequate protection for potential missile generation that could damage the containment liner.

The effect of radiation-generated heat on the internal structures was considered in the design of the primary and secondary shield walls. The shield wall thicknesses were determined on the basis of the radiation shielding requirements and, therefore, are greater than those required for structural purposes. This additional thickness provides a reserve strength greater than required to offset minor damages to the structures due to a LOCA. Since high temperatures are damaging to concrete, a thorough ventilation at a constant temperature is maintained within the containment to cool the area surrounding the shield walls and to prevent any appreciable loss of structural strength due to gamma and neutron heating.

The final design of the interior structure and equipment supports is reviewed to assure that they can withstand applicable pressure loads, jet impingement forces, pipe reactions, and earthquake loads without loss of function. The deflections or deformations of the structures and supports are checked to ensure that the functions of the containment and safety feature systems are not impaired.

The computer programs employed in the analysis of the various internal structure components perform linear, elastic analysis. The information contained in the computer runs includes forces, shears, moments, reactions, and displacements as a result of

various loading conditions considered. Table 3.8-6 lists the computer programs used for analysis. The verification of the computer programs is shown in appendix 3B.

Seismic analyses for the interior structures conform to the appropriate procedures outlined in section 3.7.

The mathematical model used includes equipment of significant mass values as discrete masses at the appropriate elevation. The seismic loads are determined using the procedures of the design response spectrum technique of analysis. Bending moments and forces resulting from appropriate earthquake loads are combined according to the load combinations described in paragraph 3.8.3.3. The equipment seismic shear is resisted by the anchorage system, anchor bolts, and by additional shear studs.

Strength design methods given in the ACI 318 Code are used for concrete and the AISC Code is used for steel. The internal structures are provided with connections capable of transmitting axial and lateral loads to the containment base slab.

The proportioning of reinforcing steel in concrete structures is based upon the specified codes of practice and it is distributed according to common detailing methods. Likewise, the selection of structural steel sections and the methods of fabrication and connections are in accordance with engineering codes and accepted industry practices.

Table 3.8-6

METHODS AND COMPUTER PROGRAMS FOR USE ON CATEGORY I STRUCTURES OTHER THAN CONTAINMENT

Code No.	Name	Documentation Traceability	Remarks
None	Classical Methods	Roark, Formulas for Stress and Strain, McGraw-Hill M. Heteny, Beams on Elastic Foundation, The University of Michigan Press, 1946 AISC, Steel Construction Manual, 1969 Davis, H., "Thermal Consid-eration in Design of Con-crete Shield," ASCE Pro-ceedings, Sept. 1958	The classical methods are for use in analyses of beams, plates, frames and shells. They are given in the standard text book and reference handbooks as used in universities and engineering practice.
CE299	FOSIN	Bechtel Power Corporation (BPC)	Time-history response with frequency dependent soil springs.
CE800	SAP	BPC	General static and dynamic analy-ses using finite-element.
CE802	SPECTRA	BPC	Development and plotting of response spectra.
CE970	LUCON	BPC	Impedance functions for layered soils.
CE029	GTSTRUDL	BPC	General static and dynamic analyses using finite elements

3.8.3.4.1 Reactor Coolant System Equipment Supports

The steel and concrete supports for the reactor, the reactor coolant pumps, the steam generators, safety injection tanks, the pressurizer, and the reactor drain tank are designed for dead loads, seismic loads, and nozzle reaction loads. These loads include the maximum forces on a support due to accident loads (e.g., pipe rupture) with a dynamic load factor, operating loads, and seismic loads. The directions of the seismic forces are chosen to give the largest load at each support.

The loads are combined using the maximum seismic forces and the maximum accident forces simultaneously. This combination ensures the worst possible design condition that could occur for each support.

The RCS equipment supports are designed using conventional design techniques.

A combination of hot gaps, keyways, and snubbers is provided between the above mentioned equipment and their supports to ensure that minimal thermal loads from the expansion of the equipment are transmitted to the supports.

3.8.3.4.2 Primary Shield Wall and Reactor Cavity

For the hypothetical LOCA condition, the cavity wall is designed to withstand jet impingement forces and internal pressurization combined with seismic and LOCA loads on the reactor vessel and coolant pipeline without gross damage to the cavity structure.

The reactor cavity is designed to withstand an internal pressure load and the reactor support loads due to a LOCA. A three-dimensional, finite-element model is used for the analysis of the portion of the primary shield wall affected by the asymmetric loadings (accident pressure and support reaction due to LOCA). The pressure loading is applied statically using an appropriate dynamic load factor. Peak differential pressures for each compartment as determined by the nodal analysis described in paragraph 6.2.1.2.2.1 are used. The applied pressures ranged between 99.8 and 8 psid. The reactor support loadings are determined by C-E using the support stiffnesses provided by Bechtel. These LOCA loads are combined with the accident pressure, dead load, seismic, etc., using the load combinations in paragraph 3.8.3.3. The rebar is designed using the OPTCON computer code (see appendix 3B). A summary of the reinforcing requirements is contained in table 3.8-7. The maximum stress level in the rebar under the worst loading combination is limited to 90% of the yield strength of the rebar.

For the normal operating condition, the reactor cavity is designed to withstand the stresses due to dead loads, live loads, and seismic loads. Under this condition, the stresses in the concrete and the reinforcing steel are significantly below working stress levels. In the stress analysis, flexure tensile cracking is permitted but is controlled by the bonded reinforcing steel.

3.8.3.4.3 Secondary Shield Wall and Steam Generator Compartments

The secondary shield walls and the refueling pool walls enclosing the steam generator compartments are designed for the effects of a LOCA condition. Specifically, accident pressures with the normal operating loads of dead, live, thermal, and seismic in the design of the steam generator compartment walls. A three-dimensional, finite-element model is used for the analysis of the secondary shield wall and internal structure. Peak pressures as determined by the nodal analysis described in paragraph 6.2.1.2.2.2 are applied statically with an appropriate dynamic load factor. The magnitude of these pressures varies between 29.4 and 5.0 psid due to any of the postulated pipe breaks listed in subsection 6.2.1.

The equipment support LOCA loadings (steam generator and reactor coolant pumps) are determined by C-E using the support stiffnesses provided by Bechtel. These asymmetric loads are conservatively applied in the analysis. The maximum support loads from all load cases for one steam generator and two reactor coolant pumps are applied simultaneously in one steam generator compartment to determine the moments and forces in the secondary shield wall. All forces are applied in a direction that would cause axial tension in the wall. This is a conservative approach since not all supports have maximums occurring under the same loading condition or accident. These LOCA loads are combined together with the dead and live loads, etc., using the load combinations listed in paragraph 3.8.3.3.

The reinforcing steel is sized using the OPTCON computer code. The reinforcing requirements are shown in table 3.8-7.

The compartments are also designed for jet forces on localized areas of the walls resulting from the impingement of escaping fluid. In addition, the affect of pipe rupture loadings at various restraints on the walls has been considered with local analysis of the walls.

3.8.3.4.4 Refueling Canal

For the refueling condition, the walls are designed for the maximum hydrostatic head due to 47.5 feet of water and including the effect of hydrodynamic pressure due to OBE and SSE. The steam generator compartment pressure loads due to postulated pipe rupture and hydrostatic head are not considered to occur simultaneously.

3.8.3.4.5 Pressurizer Compartment

The pressurizer compartment is located outside of the secondary shield structure; therefore, the LOCA load due to the rupture of a reactor coolant pipe is not considered in the design of the pressurizer compartment. Instead, the pipe rupture loads due to various pipelines within the pressurizer compartment are used for the design.

The design basis and approach for such pipe rupture loads are similar to that of the primary shield wall as described in paragraph 3.8.3.4.2.

Other major loading conditions considered in the pressurizer compartment design are:

- Reactions from the pressurizer support for operating conditions
- Seismic load due to equipment and structure itself
- Construction load for erection of pressurizer

3.8.3.4.6 Floors

Concrete floor slabs and peripheral structural steel beams supporting the slabs are designed for dead load, live load, equipment load, laydown load for refueling, and pressure differential across floor slab due to LOCA or MSLB. The slabs and the supporting beams are designed by conventional methods. Grating floors are designed for dead load, live load, laydown load for refueling, and pressure differential across floor due to LOCA or MSLB: structural steel framings are designed for equipment load and piping loads in addition to loads designed for grating floors.

3.8.3.4.7 Polar Crane Support Design

The polar crane support consists of single span steel girders which span between the polar crane support brackets. The runway rail is attached to the top of the girders. The top flange is curved on the inside to accommodate a seismic lug attached to the polar crane girders. The seismic lug serves a dual purpose. It limits the seismic motion of the crane, and it also acts as a retainer which prevents any dislodging of the

crane during a seismic event. The crane being derailed during a seismic event will not affect the safe shutdown of the plant. See figure 3.8-4.

The steel runway girders are designed, fabricated, and tested per AISC standards. The details are shown in engineering drawing 13-C-ZCS-520.

3.8.3.5 Structural Acceptance Criteria

The limiting values of stress, strain, and gross deformations are established by the following criteria:

A. To maintain the structural integrity when subjected to the worst load combinations

B. To prevent structural deformations from displacing the equipment to the extent that the equipment suffers a loss of function

The allowable stresses are those specified in the applicable codes. The stress contributions due to earthquakes are included in the load combinations described in paragraph 3.8.3.3.

Table 7 summarizes the governing load interactions and maximum capacity of principal reinforced concrete members. Table 3.8-8 summarizes the governing combined stress ratios from the beam/column interaction equation for principal structural steel members. Table 3.8-9 summarizes the ductility ratios for pipe whip restraints.

a. Refer to paragraph 3.8.3.3.3, listing B(2) for description of load combination number.

3.8.3.6 Materials, Quality Control, and Special Construction Techniques

The following basic materials are used in the construction of internal structures:

A.	Concrete		f'_c, psi	= 5000 or greater

Note: Cement with standard chemical composition per ASTM C150 was used for the steam generator replacement project.

B.	Reinforcing steel Deformed bars	ASTM A615 Grade 60	f_y, psi	= 60,000 minimum
C.	Structural and miscellaneous steel			
	Rolled shapes, bars, and plates	ASTM A36	f_y, psi	= 36,000 minimum
		ASTM A588 Grade 50	f_y, psi	= 42,000 to 50,000 (varies depending on material thickness)
		ASTM A572	f_y, psi	= 42,000 minimum
	Structural Steel Shapes	ASTM A992	f_y, psi	= 50,000 minimum
	Forgings	ASTM A237 Class C	f_y, psi	= 58,000 to 60,000 (varies depending on material thickness)
		ASTM A336 Class F5A	f_y, psi	= 50,000
	Crane rails	AISC (Bethlehem)		171 lb/yd

3.8.3.6 (cont'd)

High-strength bolts	ASTM A325	f_y, psi	= 81,000 to 92,000 (varies depending on diameter of bolts)
	ASTM A354 Grade BD	f_y, psi	= 115,000 to 130,000 (varies depending on diameter of bolts)
	ASTM A490	f_y, psi	= 130,000 minimum
	A449	f_y, psi	= 58,000 to 92,000 (varies depending on diameter of bolts)
	A540	f_y, psi	= 105,000 to 150,000 (varies depending on the diameter, grade, and class of material)
	ASTM A193, Grade B7	f_t, psi	= 75,000 to 105,000 (varies based on bolt diameter)
Other bolts	ASTM A307	f_y, psi	= 60,000 minimum

3.8.3.6 (cont'd)

Stainless steel plate, sheet and strip	ASTM A167 or ASTM A240, Type 304 with 0.05% maximum carbon or type 304L	f_y, psi = 25,000
Stainless steel bars and shapes	ASTM A276, or A479 type 304L with 0.05% maximum carbon	f_y, psi = 25,000 f_y, psi = 25,000 minimum
Anchors, Stiffeners and other non-exposed carbon steel	ASTM A36	f_y, psi = 36,000 minimum
Stainless steel bolts	ASTM A320 Grade C	f_y, psi = 30,000
Unistrut	ASTM A570 Grade C	f_y, psi = 33,000
Shear studs	ASTM A108	f_y, psi = 50,000
Square/rectangular structural tubes	ASTM A500 Grade B	f_y, psi = 46,000
Structural pipe	ASTM A53 Grade B	f_y, psi = 35,000

Third coat - Epoxy

3.8.3.6.1 Stainless Steel Liner Plate

The refueling canal is lined with welded stainless steel plate conforming to the requirements of ASTM A167 or A240, type 304 with 0.05% maximum carbon or type 304L. This material covers all attachments exposed on the water side, as well as the liner plate, used for the construction of the refueling canal liner.

Stainless steel welding procedures and performance qualification tests are qualified in accordance with ASME B&PV Code, Section IX. Filler material for austenitic stainless steel welds are types 308 and 308L. Types 309 and 309L welding materials are used for welding carbon or low-alloy steel to austenitic stainless steel.

Stainless steel liner plate shall be formed cold. The minimum radius at corners shall be 1 inch. Erection tolerances of the stainless steel liner plate are as follows:

- Finished concrete floor surfaces and embedded metal in the concrete floor surfaces that receive the liner plate sections will be within 1/4 inch of the established surface level alignment shown. Embedded

metal will be flush with adjacent concrete surfaces and there will be no sharp breaks in the concrete surface.

- Variation from plumb: maximum deviations in the lines and surfaces of walls shall be 1/2 inch per 10 feet, but not more than 1-1/2 inches in the full height.
- Variation from level: maximum deviation from level shall be 1/2 inch per 10 feet, 5/8 inch per 20 feet, and 1 inch per 40 feet or more.
- Variation from lines: maximum deviation from lines in plan shall be 1/2 inch per 20 feet and 1 inch per
- 40 feet or more.
- Variation from squareness at floor plate level: maximum deviation for squareness based on the difference between the diagonal lengths shall be 1/2 inch.
- Variation for centerline locations: maximum deviation for location of embeds, sleeves, or anchor plates shall be 1/2 inch.
- Floor plates warping: no limits are applied to the floor plates with regard to warping due to temperature changes.
- Wall openings (including recessed frame around openings) for bulkhead gate shall meet the following erection tolerances prior to placement of concrete:
  - Variation of each side from the plumb: 1/2 inch

- Variation of bottom from level: 1/4 inch per 5 feet with 1/2 inch maximum
- Out of plane tolerance: 1/2 inch

Other materials and quality control procedures are described in paragraph 3.8.1.6.

3.8.3.7 Testing and Inservice Surveillance Requirements

A formal program of testing and inservice surveillance is not planned for the internal structures. The internal structures are not directly related to the functioning of the containment concept. Hence, no testing or surveillance is required.

3.8.4 OTHER CATEGORY I STRUCTURES

3.8.4.1 Description of the Structures

Seismic Category I structures other than the containment and its internal structures are listed below:

- Auxiliary building
- Fuel building
- Control building
- Diesel generator building
- Main steam support structure
- Essential spray ponds
- Condensate storage tank
- Refueling water tank

- Diesel generator fuel oil tanks

3.8.4.1.1 Auxiliary Building

The auxiliary building is a multi-story, reinforced concrete structure located adjacent to the containment structure but physically separated from it. The auxiliary building has approximate dimensions of 129 feet wide by 197 feet long. It has a four-level basement extending about 60 feet below grade. The building rises to about 60 feet above grade.

The auxiliary building primarily houses the engineered safety feature (ESF) systems for the safe shutdown of the reactor that include the following systems:

- Safety injection system
- Containment spray system
- Containment combustible gas control system
- Containment isolation system

Building plans and sections are shown in engineering drawings 13-P-OOB-002 through –011.

3.8.4.1.2 Fuel Building

The fuel building is 88 by 124 feet in plan and is a reinforced concrete structure whose roof is 94 feet above grade. It is physically separated from adjoining structures and has an independent foundation. The fuel building roof has been modified by addition of a permanent hatch to facilitate

modification of the Cask Handling Crane. When not in use, the opening is sealed with a steel plate. The building contains the new fuel storage area and spent fuel pool. The walls and the floor of the spent fuel pool are lined with stainless steel plates for leaktightness.

The new and spent fuel storage is described in section 9.1.

The fuel building has a single failure proof overhead crane capable of handling such heavy loads as a fuel cask. Travel of this crane over the main body of the spent fuel pool is prevented by design. Interlocks are provided to prevent the crane from moving over the new fuel area. A new fuel handling crane, running on rails mounted over the operating floor, is provided to handle the new fuel assemblies.

A spent fuel handling machine, running on rails mounted on the operating floor, is provided to handle spent fuel assemblies.

An aluminum honeycomb energy absorption pad, mounted on the wall in the cask decontamination pit, is provided to prevent any damage to the west wall of the spent fuel pool from fuel cask positioning.

Building plans and elevations are shown in engineering drawings 13-P-OOB-002 through -011.

3.8.4.1.3 Control Building

The control building is approximately 86 by 114 feet. It is a four-story reinforced concrete structure with a full basement below ground. The building rises to about 80 feet above grade.

It is physically separated from the auxiliary and radwaste buildings.

Facilities such as the control room, computer room, upper and lower cable spreading rooms and battery rooms form the essential features of this building.

Building plans and sections are shown in engineering drawings 13-P-OOB-002 through -011.

3.8.4.1.4 Diesel Generator Building

The diesel generator building is a reinforced concrete, box-type structure located adjacent to the control building and separated by a 6-inch space. Plan dimensions, established by equipment layout and space, are approximately 60 by 80 feet.

The building has a maximum height of approximately 48 feet above grade. The diesel generator building houses two identical diesel generators whose foundations are physically separated from each other and from the building foundation.

Building plans and sections are shown in engineering drawings 13-P-OOB-002 through -011.

3.8.4.1.5 Main Steam Support Structure

The main steam support structure is a box-type, reinforced concrete structure with two chambers shown in engineering drawings 13-P-OOB-002 through -011. The inside dimensions of each chamber are 64 feet 6 inches in height and 18 feet 3 inches in width. The length of each chamber varies from 33 to 35 feet. The main steam support structure design

strength and vent capabilities will be based on the thermal and pressure loads of a nonmechanistic break area equivalent to one full flow opening of a main steam line. Pipe whip and jet impingement loads associated with this break will not be postulated.

3.8.4.1.6 Essential Spray Ponds

The ultimate heat sink for each unit will consist of two adjacent reinforced concrete essential spray ponds. The ponds have vertical walls which extend approximately 8 feet above the adjacent finish grade. Each pond has interior plan dimensions of 345 by 172 feet and a depth of 15.5 feet which includes 1.1 feet of freeboard to contain the water during seismic or wind-wave action. Each pond has an intake structure to feed the cooling loop and a pond inlet for the return line. The ponds are interconnected to allow transfer of water from one pond to the other. Spray headers installed in the ponds are used to cool the water.

Plan and details of the ponds are shown in engineering drawing 13-C-SPS-375.

3.8.4.1.7 Condensate Storage Tank

The condensate storage tank is a reinforced concrete structure (46 feet 6 inches internal diameter, 52 feet 0 inch in height, and a capacity of 520,000 gallons, see Table 9.2-21) located approximately 175 feet northerly of the center of the containment structure. The condensate storage tank has

cylindrical walls of 21 inches nominal thickness which provide suitable missile protection to prevent penetration by the tornado missiles postulated in section 3.5. This precludes loss of the contained fluid for missile impacts on the tank exterior walls. The adjacent pump structure provides similar missile protection for the condensate transfer pumps and includes a reinforced concrete roof. The condensate storage tank has a Seismic Category I stainless steel wall and basemat liner and a non-Seismic Category I stainless steel roof liner. The roof is not designed to be tornado missile resistant. The concrete and stainless steel wall liner together will withstand the structural loads including the hydrostatic pressure of the condensate. The welded stainless steel liner attached to the inside surface of the tank also ensures the leaktight integrity of the structure.

3.8.4.1.8 Refueling Water Tank

The refueling water tank is a reinforced concrete structure (46 feet 6 inches internal diameter, 68 feet 0 inch in height, and a rated capacity of 750,000 gallons) located near the fuel building. The refueling water tank has cylindrical walls of 21 inches nominal thickness and the construction is the same as that of the condensate storage tank. The refueling water tank has a Seismic Category I stainless steel wall and basemat liner and a non-Seismic Category I stainless steel roof liner. The concrete will withstand the structural loads including the hydrostatic pressure of the refueling water without reliance upon the stainless steel liner. The welded stainless steel

liner attached to the inside surface of the tank ensures the leaktight integrity of the structure.

3.8.4.1.9 Diesel Generator Fuel Oil Tanks

The station has two diesel generator fuel oil tanks per unit, each tank has a nominal capacity of 83,000 gallons. The size of each horizontal tank is approximately 13 feet in diameter by 86 feet long. The tanks are located underground about 35 feet from the diesel generator building. The tanks have approximately 10 feet of earth cover for missile protection.

3.8.4.2 Applicable Codes, Standards, and Specifications

Other Seismic Category I structures are designed in accordance with the codes, standards, and specifications listed in paragraph 3.8.3.2

3.8.4.3 Loads and Load Combinations

Other Category I structures are designed for the loads listed in paragraph 3.8.3.3.1 and for the load combinations listed in paragraph 3.8.3.3.2.

3.8.4.4 Design and Analysis Procedures

The design and analyses procedures are similar to those discussed in paragraph 3.8.3.4 for the containment internals except that a three-dimensional, finite-element model was not used.

The behavior of the turbine and radwaste buildings was checked under the extreme environmental (tornado/SSE) loads to verify that a collapse would not occur.

The effects of a postulated collapse of the corridor building were analyzed to verify that the integrity of the auxiliary and control buildings would not be impaired.

3.8.4.5 Structural Acceptance Criteria

The limiting values of stress, strain, and gross deformations are established by the following criteria:

- Maintain the structural integrity when subjected to the worst load combinations
- Prevent structural deformation from disturbing the Seismic Category I equipment to the extent that it suffers a loss of function

The allowable stresses are those specified in the applicable codes. The stress contributions due to earthquake loading are included in the load combinations described in paragraph 3.8.3.3.

Structural deformations were not found to be a controlling criterion in the design of other Seismic Category I structures, listed in paragraph 3.8.4.1.

DESIGN OF

CATEGORY I STRUCTURES

The following table summarizes: (1) the governing load interactions and maximum capacity of principal reinforced concrete members (see category A), and (2) the governing combined stress ratios from the beam/column interaction equation for principal structural steel members (see category B).

Structure	Table Number Reference	
	Category A	Category B
Auxiliary building	3.8-10	3.8-11
Fuel building	3.8-12	3.8-13
Control building	3.8-14	3.8-15
Diesel generator building	3.8-16	3.8-17
Main steam support structure	3.8-18	3.8-19

a. Refer to paragraph 3.8.3.3.3, listing A(1) for description of load combination number.

b. Refer to paragraph 3.8.3.3.3, listing B(1) for description of load combination number.

3.8.4.6 Materials, Quality Control, and Special Construction Techniques

The materials, quality control, and special construction techniques are the same as those given for the containment internals in paragraph 3.8.3.6 except for the design compressive strength of concrete. For Seismic Category I structures other than the containment and its internals, the design compressive strengths are 5000 psi for the roofs and 4000 psi for the remaining structural elements. In addition, alternate interior coating system materials which are appropriate for service outside of containment may be substituted for those listed in paragraph 3.8.3.6, listing D.

3.8.4.7 Testing and Inservice Surveillance Requirements

Testing and inservice surveillance are not required for Seismic Category I structures other than the containment structure. No formal program of testing and inservice surveillance is planned.

3.8.5 FOUNDATIONS AND CONCRETE SUPPORTS

3.8.5.1 Description of the Foundations and Supports

3.8.5.1.1 Containment

The containment building foundation is a conventional reinforced concrete mat approximately 10 feet 6 inches thick. The basemat is circular in plan with an approximate diameter of 161 feet. A circular pit and instrumentation cavity extend below the basemat, and a continuous tendon gallery at the

periphery is provided for access for installation of vertical tendons. The gallery is structurally connected below the basemat and serves as a working space for post-tensioning of tendons of the containment shell and dome, and for inspection purposes. Refer to engineering drawings 13-C-ZCS-102 and -104 for configuration of the cavities and physical features. A steel liner plate with a leak chase system covers the entire interior basemat. A concrete slab 2 feet 9 inches thick is cast in place on top of the liner plate to protect the liner against damage during erection and maintenance and to reduce the thermal effects in the basemat. The added concrete slab also provides the foundation for some small equipment and steel columns so that their anchorage does not have to penetrate the liner plate underneath.

3.8.5.1.2 Other Seismic Category I Structures

A continuous reinforced concrete slab is used as foundation for each of the other Seismic Category I structures. Foundations of Seismic Category I structures are separated from one another and from other structures, either by using an expansion joint or by providing an adequate structural gap in between. The size and thickness of foundations vary with each individual Seismic Category I structure.

3.8.5.2 Applicable Codes, Standards, and Specifications

Refer to paragraph 3.8.1.2 for the containment and to paragraph 3.8.3.2 for other Seismic Category I structures.

3.8.5.3 Loads and Load Combinations

Containment foundation loads and loading combinations are discussed in paragraph 3.8.1.3.

Foundation loads and loading combinations for other Seismic Category I structures are discussed in paragraph 3.8.4.3.

Procedures for determining lateral earth pressure loadings for all Category I foundations are presented in appendix 3H.

No special measures are required in the design and construction of foundations for Category I structures to alleviate the effects of ground subsidence. As discussed in paragraph 2.5.4 1.1, subsidence, if any, will be negligible.

3.8.5.4 Design and Analysis Procedures

3.8.5.4.1 Containment

The analysis and design of the containment basemat meets the requirements of ASME Section III, Division 2, Article CC-3000, and is supplemented by BC-TOP-5-A.

The basemat is designed to sustain design loads of the containment and interior structures. The basemat is analyzed as a slab on an elastic foundation as delineated in the computer model for the SAP program. The loadings are dead load, live load, internal pressure, thermal, post-tensioning, and earthquake loads. The earthquake loads are those resulting from the entire structure taken as a whole. The basemat is designed for moments, shears, and forces resulting from

credible combinations of loads. The effect of LOCA and SSE are considered in the design in an appropriate manner.

For the discussion of the design loadings and method of analyses employed in design of the basemat, refer to paragraph 3.8.1.3. Additional discussions of the basemat are covered in BC-TOP-5-A, Sections 6 and 7.

3.8.5.4.2 Other Seismic Category I Structures

The basic techniques for analyzing the foundations of Seismic Category I structures are by the conventional methods, involving simplified assumptions found in the theory of concrete structures practice, such as two-way slab design and flat-slab design. Stresses resulting from local moments, torques, and concentrated reactions, and from uniform loading, are computed by these methods. These methods are further discussed in paragraph 3.8.3.4.

3.8.5.5 Structural Acceptance Criteria

The foundations of Seismic Category I buildings are designed to meet the same structural acceptance criteria as the buildings themselves. These criteria are discussed in paragraphs 3.8.1.5, 3.8.3.5, and 3.8.4.5. The limiting conditions for the foundation medium, together with a comparison of actual capacity and estimated structure loads, are found in paragraphs 2.5.4.10 and 2.5.4.11. Computed factors of safety against overturning, sliding, and flotation for Category I structures are given in table 3.8-20.

3.8.5.6 Materials, Quality Control, and Special Construction Techniques

The foundations and concrete supports are constructed of concrete using proven methods common to heavy industrial construction. The design compressive strength of concrete for the containment foundation is 5000 psi as described in paragraph 3.8.1.6.1. The design compressive strength of concrete for other Category I structure foundations and supports is 4000 psi. The test frequency of compressive strength for concrete shall comply with paragraph 3.8.3.2.1. For further discussion, refer to paragraph 3.8.3.6.

Table 3.8-20

COMPUTED FACTORS OF SAFETY

Structure	Overturning		Sliding		Flotation
	OBE	SSE	OBE	SSE	
Auxiliary	3200	830	2.2	1.3	4.7
Containment	3400	1200	1.7	1.2	4.5
Control	1500	420	1.6	1.2	4.8
Diesel generator	1200	400	2.2	1.1	NA[a]
Fuel	1600	400	1.9	1.1	NA
Main steam support	340	91	1.6	1.1	NA
Condensate storage and refueling water tanks	500	150	1.7	1.4	NA

a. Not applicable

3.8.5.7 Testing and Inservice Surveillance Requirements

Testing and inservice surveillance are not required and are not planned for foundations of structures or for concrete supports.

1. Metropolitan Edison Company, Jersey Central Power and Light, Three-Mile Island Nuclear Station, Unit 1, Final Safety Analysis Report, "Low Temperature Behavior of WCS 2.0 MEP/170-W Post Tensioning System," Docket No. 50-289, Part F, Appendix 5-B.

3.9 MECHANICAL SYSTEMS AND COMPONENTS

3.9.1 SPECIAL TOPICS FOR MECHANICAL COMPONENTS

3.9.1.1 Design Transients

The Palo Verde program specified in Technical Specification 5.5.5, Component Cyclic or Transient Limit, provides controls to track the UFSSAR Section 3.9.1.1 cyclic and transient occurrences to ensure that components are maintained within the design limits. The controls to track cyclic and transient occurrences are implemented by either counting the occurrences or by accounting for the occurrences in an assessment that ensures that components are maintained within the design limits. (LDCR 10-F031).

Prior to any transient cycles reaching their maximum allowable or UFSAR limits, a corrective action document shall be initiated to develop and implement corrective actions. Corrective actions to be considered are identified in Section A2.1 of the license renewal application FSAR supplement, which will be incorporate into the UFSAR after issuance of the renewed operating licenses. Corrective actions are to be taken prior to design limits being exceeded. Any corrective action document initiated shall also identify that ASME Section XI fatigue-related analyses, such as certain crack growth and stability analyses that are dependent on the number of occurrences of design transients, may also be impacted. The evaluation of corrective actions must also address these fatigue-related analyses and may require additional or separate corrective actions in accordance with any applicable ASME Section XI requirements

3.9.1.1.1 Design Transients for NSSS Scope

The following information identifies the transient used in the design and fatigue analysis of NSSS ASME code Class 1 components, reactor internals and component supports. Cyclic data fir the desugb if ASME Code Class 2 and 3 components, as applicable, are discussed in Section 3.9.3. All transients are classified with respect to the component operating condition categories identified as normal, upset, emergencym, faulted, and testing as defined in the ASME Code, Section III. The transients specified below represent conservative estimates for design purposes only and do not purport to be accurate representations of actual transients, or necessarily reflect actual operating procedures; nevertheless, all envisaged actual transients are accounted for, and the number and severity of the design transients exceeds those which may be anticipated during the 40 year life of the plant.

Pressure and temperature fluctuations resulting from the normal, upset, emergency and faulted transients were computed by means of computer simyulations of the reactor coolant system, pressurizer, and steam generators. Design transients were detailed in the equipment specifications. The component designer then used the specification curves as the basis for design and fatigue analysis.

In support of the design of each Code Class 1 component, a fatigue analysis of the combined effects of mechanical and thermal loads was performed in accordance with the requirements of Section III of the ASME Code. The purpose of the analysis was to demonstrate that fatigue failure would not occur when

the components are subjected to typical dynamic events which may occur at the power plant.

The fatigue analysis is based upon a series of dynamic events depicted in the respective component specifications. Associated with each dynamic event is a mechanical, thermal-hydraulic transient presentation along with an assumed number of occurrences for the event. The presentation is generally simple and straightforward, since it is meant to envelope the actual plant response. The intent is to present material for purposes of design.

Similarly, the characterization of a given dynamic event with a specific name is unimportant. Any plant dynamic occurrence with consequences which fall within the envelopes associated with one of these dynamic events is by definition represented by that dynamic event. The fundamental concept is to ensure that the consequences of the normal and upset conditions which are expected to occur in the power plant are enveloped by one or more of the dynamic event portrayals in the component specifications. The number of occurrences selected for each dynamic event is conservative, so that in the aggregate, a 40 year useful life will be provided by this design process.

Design load combinations for ASME Code Class 1, 2, and 3 components are given in subsection 3.9.3. Design loading combinations for reactor internals structures are presented in section 3.9.5.2.

The principal design bases of the reactor coolant system (RCS) and reactor internals structures are given in Section 5.2 and section 3.9.5, respectively.

Table 3.9.1-1 summarizes the transients used in the stress analysis of NSSS Code Class 1 components. Additional specific component transients for the reactor coolant pumps, steam generators, reactor coolant piping, and the pressurizer are provided in Sections 5.4.1, 5.4.2, 5.4.3, and 5.4.10 respectively. The basis for the transients is indicated, and the number of occurrences specified is to provide a system/component design that will not be limited by expected cyclic operation over the life of the plant. The number of occurrences is generally based on a once/day, once/week, once/month, etc., type of evaluation. It is expected that the frequency of cyclic transients will be greater than design at the beginning of plant life and significantly less than design after the first year of operation with cumulative occurrences less than design values. System integrity is further assured by using conservative methods of predicting the range of pressure and temperature for the transients. The list of transients is intended to include startup and shutdown operations, inservice hydrostatic tests, emergency and recovery operations, switching operations, and seismic events. An explanatory discussion of each transient is also given. The applicable operating condition category or service limit as designated by the ASME Code Section III is also indicated in each case.

The transients listed include allowance for less severe transients, such as rod withdrawal incident or boron dilution incident. The number of transients listed are believed to be far in excess of any number or severity that can be anticipated to occur during the life of the facility.

Pressure and thermal stress variations associated with the design transients are considered in the design of supports, valves, and piping within the reactor coolant pressure boundary (RCPB).

In addition to the design transients listed above and included in the fatigue analysis, the loadings produced by the OBE and DBE were also applied in the design of components and support structures of the RCS. The OBE and DBE are classified as upset and faulted condition events respectively. For the number of cycles pertaining to the OBE, refer to section 3.7.3.2.

3.9.1.1.2 Design Transients for Non-NSSS Scope

Design transients for Class 1 piping systems outside NSSS scope are provided in table 3.9-1.

3.9.1.2 Computer Programs Used in Stress Analyses

Refer to section 3.9.1.2.2 and 3.9.1.2.3 for computer programs used on equipment under the C-E scope of supply. Computer codes employed for the design of the Ansaldo Replacement Steam Generators are also listed. The following section 3.9.1.2.1 refers to computer programs used on systems and components not in the C-E or Ansaldo scope of supply.

3.9.1.2.1 Non-NSSS Systems and Components

Analysis of piping systems other than reactor coolant system (RCS) main loops is performed by using the following computer programs which are described below:

TABLE 3.9.1-1
TRANSIENTS USED IN STRESS ANALYSIS OF NSSS
CODE CLASS 1 COMPONENTS
(Sheet 1 of 3)

Normal Conditions

Occurrence	Conditions
Heatup and cooldown cycles	500 heatup and cooldown cycles during the design life of the components in the system. The rate of heating and cooling is $\leq$100F/hr between 70F and 565F except for the pressurizer which has a rate of $\leq$200F/hr between 70F and 653F. The heatup and cooldown rate of the system is administratively limited to assure that these limits will not be exceeded. This condition is based on a normal plant cycle of one heatup and cooldown per month rounded up to the next highest hundred.
Power changes	15,000 power change cycles over the range of 15% to 100% of full load at a rate of 5% of full load per minute either increasing or decreasing.
Normal cyclic variations	10^6 step changes of ±100 lb/in^2 and ±10F (±20F for surge line) when at operating conditions. This condition is selected based on 1 million-cycles approximating an infinite number of cycles so that the limiting stress is the endurance limit. Grouped together in these cycles are: pressure variations associated with fluctuation in pressurizer pressure between the setpoint for actuation of the backup heaters and the opening of the spray valves; temperature variations associated with the CEA controller deadband; and 2,000 step power changes of ±10% of full load assuming 1 cycle per week for 50 weeks of the year.

TABLE 3.9.1-1
TRANSIENTS USED IN STRESS ANALYSIS OF NSSS
CODE CLASS 1 COMPONENTS
(Sheet 2 of 3)

Upset Conditions

Occurrence	Conditions
Reactor trip, turbine trip, loss of reactor coolant flow	480 cycles are used to envelope all anticipated upset transients, (one occurrence per month for the life of the plant) which includes any combination of reactor trips, equipment malfunctions, or a total loss of reactor coolant flow (for the steam generators, the 480 cycles are limited by the following: Reactor Trip = 160 cycles; Loss of Reactor Coolant Flow = 120 cycles; Loss of Lead/Turbine Trip = 200 cycles). For design purposes, conservative temperature/pressure time histories are provided in the design specification for each Class 1 component, which reflects its unique response during these events. Further thermal transient information is specified for the nozzles on these components, when they experience additional transients due to changing flow conditions.
OBE condition	See Section 3.7.3.2 for the procedures used to determine the number of earthquake cycles during the seismic event.

Faulted Condition

1. The concurrent loading produced by normal operation at full power, plus the design basis earthquake, plus loss-of-coolant accident (pipe rupture) are used to determine the faulted plant loading condition.
2. Loss of Secondary Pressure: One cycle of a postulated loss of secondary pressure due to a complete double ended severance of one steam generator or feedwater nozzle, but not simultaneously. These are not considered credible events in forming the design basis of the reactor coolant system. However, they are included to demonstrate that the reactor coolant system components will not fail structurally in the unlikely event that one of these events occur.

TABLE 3.9.1-1
TRANSIENTS USED IN STRESS ANALYSIS OF NSSS
CODE CLASS 1 COMPONENTS
(Sheet 3 of 3)

Test Conditions

Occurrence	Conditions
Primary system hydrostatic	10 primary side cycles from 15 psia to 3,125 psia at a temperature between 120F to 400F. These cycles are based on one initial hydrostatic test plus a major repair every 4 years for 36 years which includes equipment failure and normal plant cycles. The secondary side of the steam generator is at atmospheric pressure during this test.
Primary system leak	200 cycles from 15 psia to 2250 psia at a temperature between 120F to 400F. These cycles are based on a normal plant maintenance operation involving 5 shutdowns per year for 40 years.

3.9.1.2.1.1 ME 101 Program. ME 101 is a finite-element computer program which performs linear elastic analysis of piping systems using standard beam theory techniques. The input data format is specifically designed for pipe stress engineering and the English system of units is used. A thorough checking of the input has been coordinated in the program. In addition, modifications aimed at achieving an improved model are performed automatically.

ME 101 is used for the static and seismic analysis of the piping systems. Static analysis considers one or more of the following: thermal expansion, dead weight, uniformly distributed loads, and externally applied forces, moments, displacements, and rotations. Seismic analysis is based on standard normal mode techniques and uses response spectrum data. Two methods of eigenvalue solution are available. The determinant search or subspace iteration subroutines consider all data points as mass points. Kinematic reduction and householder QR subroutines consider masses only at specified data points in designated directions.

Responses of the various modes are combined using the square-root-sum-of-the-squares (SRSS) rule. Further, the responses of x-, y-, and z-earthquakes are combined using the SRSS rule. In a response spectrum seismic analysis, if some or all of the modes are closely spaced, ME 101 combines the various modes based upon the grouping method per Equation 4 of Regulatory Guide 1.92.

Table 3.9-1

DESIGN TRANSIENTS FOR CLASS 1 PIPING OUTSIDE THE COMBUSTION ENGINEERING SCOPE OF SUPPLY (Sheet 1 of 21)

I. TRANSIENTS FOR THE REACTOR COOLANT SYSTEM

A. Events Initiated Within the Reactor Coolant System

1. Normal Events

Event	Occurrences
a. System (excluding pressurizer) heatup from 70F to hot standby conditions at a rate of 100F/hr. Pressurizer heatup from 70F to 653F at a rate of 200F/hr	500*
b. 5%/minute power ramp increase, from 15% to 100% power	15,000
c. 5%/minute power ramp decrease, from 100% to 15% power	15,000
d. System (excluding pressurizer) cooldown from hot standby conditions to 70F at a rate of 100F/hr. Pressurizer cooldown from 653F to 70F at a rate of 200F/hr	500*
e. Startup of one reactor coolant pump at hot standby conditions	1000
f. Coastdown of one reactor coolant pump at hot standby conditions	1000

Table 3.9-1

DESIGN TRANSIENTS FOR CLASS 1 PIPING OUTSIDE THE COMBUSTION ENGINEERING SCOPE OF SUPPLY (Sheet 2 of 21)

A. Events Initiated Within the Reactor Coolant System (Continued)

2. Upset Events	Occurrences
a. Coastdown of one reactor coolant pump at 100% power (no reactor trip)	10
b. Startup of one reactor coolant pump at 50% power	10
c. Inadvertent control element assembly drop, at 100% power	40
d. Inadvertent control element assembly withdrawal from 0% power	40
e. Depressurization by spurious actuation of pressurizer spray control valve(s) at 100% power (normal and auxiliary spray valves are considered)	40
f. Pressurization by spurious actuation of all pressurizer heaters at 100% power	10
g. Loss of an electrical bus supplying two reactor coolant pumps at 100% power	40

a. Seismic event up to and including the safe shutdown earthquake (system operating mode dependent upon design application for worst case conditions)	1
III. TRANSIENTS FOR THE SAFETY INJECTION SYSTEM	
A. Events Initiated Within the Safety Injection System	
Plant operation is divided into five categories; namely, normal, upset, emergency, faulted and test conditions, as defined in Article NB-3000, Section III, Division I, Subsection NB. Events occurring within each of these categories are listed below.	

Table 3.9-1

DESIGN TRANSIENTS FOR CLASS 1 PIPING OUTSIDE THE COMBUSTION ENGINEERING SCOPE OF SUPPLY (Sheet 18 of 21)

A. Events Initiated Within the Safety Injection System (Continued)

1. Normal (Condition I) Events	Occurrences
a. Startup of safety injection system from standby to injection to short-term recirculation to long term recirculation to shutdown cooling to standby	10 (Note 4)
b. Startup of SDC system from standby to shutdown cooling (RCS >200F) to shutdown cooling (RCS <200F) to standby	500 (Note 1)
c. Standby to HPSI pump test to standby	500 (Note 3)
d. Standby to LPSI pump test to standby	500 (Note 3)
e. Standby to SI cold leg injection check valve stroke test to standby (using charging pumps)	160 (Note 2)
f. Standby to SI hot leg injection check valve stroke test to standby (using the HPSI pump)	30

5. Test Events	Occurrences
a. Standby to preoperational hydrostatic test to standby	10
b. Standby to inservice hydrostatic test to standby	10

NOTES

(1) SIS event III-A-2 is caused by RCS event III-A-4, namely, RCS cooldown from hot standby to standby at a rate not to exceed 100F/hour. CESSAR Section 5.0 gives the frequency of occurrences for this event.

(2) Based on the test being conducted quarterly.

(3) Based on the test being conducted monthly.

(4) SIS event III-A-1, totaling 10 occurrences, is caused by the following RCS events:

Table 3.9-1

DESIGN TRANSIENTS FOR CLASS 1 PIPING OUTSIDE THE COMBUSTION ENGINEERING SCOPE OF SUPPLY (Sheet 21 of 21)

A. Events Initiated Within the Safety Injection System (Continued)

NOTES (Continued)

a) III-C-1 - RCS depressurization due to inadvertent actuation of one pressurizer safety valve at 100% power (5 occurrences)

b) III-D-1 - Control element assembly ejection at 0% power (1 occurrence)

c) 111-D-3 - Major loss of coolant accident (1 occurrence)

d) IV-D-1 - Major rupture in the main feedwater piping (1 occurrence)

e) IV-D-2 - Major rupture of the auxiliary feedwater piping (1 occurrence)

f) V-D-2 - Major rupture of the main steam piping (1 occurrence)

* The reactor vessel studs shall be limited to 250 occurrences

For verification, ME 101 results have been compared against the following:

A. ME 632, Computer Program, Seismic Analysis of Piping Systems, VERB MOD8, 1976 Bechtel International Corporation, San Francisco, California

B. Pressure Vessel and Piping 1972 Computer Programs Verification, The American Society of Mechanical Engineers

C. Hand calculations

3.9.1.2.1.2 ME 210 Program, Local Stress in Cylindrical Shells Due to External Loading. The ME 210 computes the local stresses in cylindrical shells that result from external loadings. The program is based on Welding Research Council Bulletin 107, August 1965. The program has been verified based upon hand calculations.

3.9.1.2.1.3 ME 632 Program. ME 632 performs stress analysis of three-dimensional piping systems. The effects of thermal expansion, uniform load of the pipe, pipe contents and insulation, concentrated loads, movements of the piping system supports, and other external loads, such as wind and snow, may be considered. The input data format is specifically designed for pipe stress engineering, and the English system of units is used. A thorough checking of the input has been coordinated in the program.

A response spectrum analysis is performed to analyze the effect of earthquake forces on the piping system. Time-history analysis is performed for transient effects of water hammer,

steam hammer, or other impulsive type dynamic loading are also handled by the program.

For verification, ME 632 results have been compared against the following:

A. TPIPE, Computer Program for Analysis of Piping Systems, Pregnoff, Matheu & Beebe, Inc., San Francisco, California

B. Pressure Vessel and Piping 1972 Computer Programs Verification, The American Society of Mechanical Engineers, 1972

3.9.1.2.1.4 ME 643-1, ME 643-2, and ME 643-3 Program. The purpose of this program is to determine the temperature and stress distributions within a body as a function of time when subjected to thermal and/or mechanical loads. The program is valid for axisymmetric or plane structures and typically is used for gross or local discontinuity analysis as described in Paragraphs NB-3213.2 and NB-3213.3 of the ASME Code, Section III.

The program consists of three parts, each of which can be used separately. The first part, ME 643-1, calculates steady-state or transient temperature distributions due to temperature or heat flux inputs. The method used is the finite-element technique coupled with a step-by-step time integration procedure.

The program adopts a stepwise description of environmental temperatures and heat transfer coefficients if they are time dependent. Transient temperature distributions are calculated

from the specified initial temperature and the step function heat inputs. ME 643-1 is for plane and axisymmetrical structures.

The second part of the program, ME 643-2, is built on the displacement method of the matrix theory of structures which calculates the displacements and stresses within the solids with orthotropic, temperature-dependent, nonlinear material properties. ME 643-2 is also used for plane and axisymmetrical structures.

The third part of the program, ME 643-3, calculates the steady-state or transient temperature distribution due to temperature or heat flux inputs. The output of this program gives the code-required parameters; i.e., Δt_1, Δt_2, T_a and T_b, where Δt_1 is the linear thermal gradient, Δt_2 is the nonlinear thermal gradient, and T_a and T_b are the average temperature on side a and b of a gross discontinuity. ME 643-3 is for straight pipe only.

The user has the option of saving the results from part 1 on an external tape. After reviewing the printout, the user can specify the transient states for the stress evaluations; part 2 then picks up the necessary information from the tape and performs the calculations.

The program was verified by comparing the results of ME 643-1-2-3 program with the solution of an identical problem obtained by hand calculation. The results of these calculations agreed.

3.9.1.2.1.5 ME 913 Program. The ME 913 program consists of numerical calculations of stress intensity levels for Class 1 nuclear power piping components to validate their design adequacy.

The program determines the stress intensity levels of Class 1 nuclear power piping components for Equations 9 through 14 of Subarticle NB-3650, Analysis of Piping Components of Section III, ASME Boiler and Pressure Vessel (B&PV) Code.

Prior to running this program, the user analyzes the piping system using flexibility analysis program ME 101 and heat transfer program ME 643. The inputs to this program are the following:

A. Design pressure and temperature

B. Specified conditions

C. Design cycles

D. Piping configuration

E. Piping and piping component properties

F. Moment reactions due to:

   1. Thermal expansion loads

   2. Weight loads

   3. Earthquake loads

   4. Anchor movements

G. The thermal response of the piping system due to the specified transients: Δt_1, Δt_1, T_a and T_b values for the selected points in the system

The verification of ME 913 is performed in two phases:

A. Phase I: Comparison of Results Between ASME Sample Problem (1) and ME 913

A comparison of stresses for ME 913 and ASME sample problem is shown in table 3.9-2. The results obtained from ME 913 are different from those of the ASME sample problem but the difference is acceptable due to the high conservatism built into ME 913. The higher stresses calculated by ME 913 are due to the change of stress indices in the 1974 version as compared with the sample problem which adopts the 1971 version of ASME Section III.

B. Phase II: Hand Calculated Verification of the Computer Output

The main feedwater piping system inside the containment on the Grand Gulf project was analyzed using the ME 913 program. A comparison of the tabulated stresses shown in table 3.9-3 indicates almost identical results.

The comparison between ME 913 outputs and hand calculated results demonstrates the correct application of code equations. The slight numerical difference is mainly due to round-off errors in the desk calculator multiplications as compared with the numerical accuracy of the digital computer.

Table 3.9-2

COMPARISON OF RESULTS BETWEEN ME 913 AND ASME SAMPLE PROBLEM

Components	Programs	Equations						
		Eq 9 Stress[(a)]	Eq 10 Stress	Eq 11 Stress	Eq 12 Stress	Eq 13 Stress	Eq 14 Stress	Total Usage Factor
Girth butt weld	ME 913	25,950	63,112	111,833	6,563	49,526	55,917	0.0555
(Location 19)	Sample Problem	23,400	52,549	80,677	(b)	(b)	40,338	0.0126
Butt weld tee	ME 913	24,600	65,567	128,920	39,536	23,152	135,937	0.2511
(Location 10)	Sample Problem	23,400	65,596	128,950	39,564	23,155	135,977	0.3699

a. All stresses are in psi.

b. Because S_n , calculated by Equation 10, is less than $3S_m$, (52,800 psi for type 304 at 400F), Equations 12 and 13 are satisfied.

3.9.1.2.1.6 ME 912 Program. ME 912 is a quasi-two-dimensional pipe thermal transient analysis program. It calculates axial and radial pipe-wall thermal transients at piping locations specified by the user. ME 912 allows nonuniform initial temperature distribution and time dependent temperature inputs. The program results give the code-required parameters; i.e., ΔT_1, ΔT_2, T_a and T_b where ΔT_1 is the linear thermal gradient, ΔT_2 is the nonlinear thermal gradient, and T_a and T_b are the average temperatures on side a and b of a gross discontinuity.

The program was verified by comparing the results of ME 912 with the solution of an identical problem obtained by hand calculation.

3.9.1.2.1.7 ME 916 Program. The ME 916 program calculates nuclear Class 1 and 2 piping stresses at lug type integral attachments. The program has been verified based upon hand calculations.

3.9.1.2.1.8 ANSYS. The ANSYS computer program is a large-scale general purpose computer program. Analysis capabilities include static and dynamic; elastic, plastic, creep and swelling; small and large deflections; steady-state and transient heat transfer and fluid flow. The program has been verified by comparison with known theoretical solutions, experimental results, and by other calculated solutions.

Table 3.9-3

HAND-CALCULATED RESULTS COMPARED WITH ME 913 OUTPUTS

Components	Programs	Equations						
		Eq 9 Stress[a]	Eq 10 Stress	Eq 11 Stress	Eq 12 Stress	Eq 13 Stress	Eq 14 Stress	Total Usage Factor
Tee	ME 913 outputs	23,650	87,446	154,318	27,805	20,433	164,256	0.7745
(Location 115)	Hand-calculated results	23,646	87,358	154,270	27,789	20,419	164,220	(b)

a. All stresses are in psi.

b. The total usage factor in hand calculated column is left empty because of large involvements in hand computations.

3.9.1.2.1.9 WAVENET. WAVENET provides solutions of the plane wave equation in complex networks of ducts or pipes containing a homogeneous compressible fluid. A series of simple criteria were established to enable the program verification by hand calculations.

3.9.1.2.1.10 PIPERUP. The PIPERUP computer program performs nonlinear elastic-plastic analysis of three dimensional piping systems subjected to concentrated static or dynamic time-history forcing functions. The program solutions have been verified by test results, closed form solutions, and/or independent computer programs.

3.9.1.2.1.11 General Frame Analysis Program. This program solves two-dimensional structural frames. It is used for the analysis of pipe supports and their supporting structures. This program has been verified using hand calculations and by comparison to results from the computer program STRUDL.

3.9.1.2.1.12 Bechtel Structural Analysis Program (BSAP). For program description and verification, refer to appendix 3B, section 3B.12.

3.9.1.2.1.13 TMRPIPE. The TMRPIPE program consists of numerical calculations of stress intensity levels for Class 1 nuclear piping components to validate their design adequacy. The program determines stress intensity levels of Class 1 nuclear piping components for Equations 9 through 14 of Subarticle NB-3650, Analysis of Piping components of Section III, ASME B&PV Code. This part of TMRPIPE has been

verified against the ASME sample problem for Class 1 analysis. Another option of the program calculates the steady-state or transient temperature distribution due to temperature or heat flux inputs. The output of this option gives the required code parameters; i.e., ΔT_1, ΔT_2, T_a and T_b defined in paragraph 3.9.1.2.1.4.

The output of the temperature distribution option of TMRPIPE has been verified with the solution of an identical problem obtained by hand calculation.

3.9.1.2.1.14 NE458 (RELAP5). The RELAP5 program is an advanced thermal hydraulics program intended for the analysis of complex transients in nuclear reactors and piping networks. Equations of conservation of mass, energy, and momentum are solved in one dimension for steam and/or water flow. The equations assume a non-homogenous mixture of steam and liquid, and non-equilibrium between phases can be modeled. The effects of non-condensable gas on steam/liquid flow are considered in the equations. Models are available to simulate pump, valve, and heat exchanger components, as well as complex control systems. RELAP5 is expressly written for the analysis of both small and large break reactor loss-of-coolant accidents, but can be used to analyze many power plant operational transients. The program is frequently coupled with the post-processor REPIPE or NE457 (R5FORCE) to generate hydrodynamic loads on power plant piping. Bechtel maintains the verification and validation for this program.

3.9.1.2.1.15 NE457(R5FORCE). The R5FORCE program is a post-processor to RELAP5. R5FORCE uses hydrodynamic output and fluid state point qualities from the RELAP5 program output to comput piping and hydraulic force/time histories for input into various structural and stress analysis codes such as ME101. The hydraulic response of power plant piping to postulated transients is calculated using the programs in combination. Bechtel maintains the verification and validation for this program.

3.9.1.2.1.16 FAPPS™ (ME150). FAPPS™ (Frame Analysis Program for Pipe Supports) is an interactive frame analysis program specifically developed for the analysis and design of pipe support frames, associated welds, base plates, embedments and local effects such as punching shear, web crippling and local flange bending; all in one run. The program performs the code check for AISC, ASME III Subsection NF codes for normal, upset, emergency and faulted load conditions. FAPPS™ accommodates unique project criteria, standard baseplates and embedments. FAPPS™ auto-generates the input for about 30 standard frame configurations. FAPPS™ allows an automatic input of loadings from ME101 or external file. FAPPS™ allows use of various load sets to allow algebraic, absolute and/or SRSS combination of results due to each vector within a load set as well as each load set that is to be combined in one load set. The program provides margin factors for structural members, welds, base plates with anchors and embedments. Bechtel maintains the verification and validation reports for this program.

3.9.1.2.1.17 BASEPLATE (ME035). ME035 is a non-linear base plate analysis program intended for analyzing/designing base plates for pipe supports. ME035 is a combination of pre-processor, SAP and post-processor. It has capability of analyzing flexible base plates on a geometrically non-linear foundation. The pre-processor performs geometry calculations to generate the finite element model and data sets for SAP. The SAP performs analysis execution. Post processing reformats the results into report tables. ME035 has a library of standard attachments, accepts any non-standard attachments as well as multiple attachments. It accommodates welded and/or bolted conditions of the base plate. Bechtel maintains the verification and validation for this program.

3.9.1.2.1.18 PIPESTRESS Program

PIPESTRESS is a finite-element computer program which performs linear elastic analysis of piping systems. The input data is entered in a free format style, which is internally converted to fixed format for performing the actual analyses. This process is transparent to the user. PIPESTRESS is specifically designed for pipe stress engineering, and is capable of producing reports to aid the analyst in documenting the stress analyses performed. Either the metric or English system of units can be used. PIPESTRESS also has a restart option. A thorough checking of the input has been coordinated in the program.

PIPESTRESS is used for the static, response spectrum, and/or dynamic analysis of piping systems. Static analysis considers one or more of the following: thermal expansion, dead weight,

uniformly distributed loads, and externally applied forces, moments, displacements, and rotations.

In a response spectrum analysis, digitized acceleration versus frequency inputs are analyzed. Results for the various modes are combined using the square root-sum-of-the-squares (SRSS) rule. If some or all of the modes are closely spaced, PIPESTRESS has the capability of combining the various modes based upon the requirements of Regulatory Guide 1.92.

Piping systems may be subject to loadings that vary rapidly in time. In PIPESTRESS, dynamic time history analysis results may be determined for two types of loadings - forces acting at mass points, or accelerations acting at support levels. In most cases, an envelope of the instantaneous system response is required. Usually, this envelope must be combined with solutions for other loadings. In some cases, detailed information for instantaneous response is required. The PIPESTRESS package is capable of calculating either instantaneous or enveloped system response.

In either case, the mathematical model used to describe these types of problems is a system of ordinary, linear second order differential equations. The solution to two forms of these equations has been programmed into PIPESTRESS. The first form is the most general form, which calculates the external forces at piping system nodes due to vector forcing functions (e.g., pipe break loadings). The second form is a special case used for determining the primary (inertial) portion of the solution for support movement loadings, typically for earthquakes.

Finally, PIPESTRESS has the capability of combining the results of static, response spectrum, and time history load case results in any number of ways (i.e., absolute sum, algebraic sum, positive and negative envelopes, SRSS, etc.), and presenting the detailed stress and support load results in report form.

For verification, PIPESTRESS is supplied with a suite of test cases that are executed as part of any installation process.

3.9.1.2.2 Computer Programs Used in Stress Analyses for C-E Scope of Supply

3.9.1.2.2.1 Reactor Coolant System

The following paragraphs provide a summary of the applicable computer programs used in the structural analyses for ASME Code Class 1 systems, components, and supports in the CESSAR scope. The summaries include individual descriptions and applicability data. The computer codes employed in these analyses have been verified in conformance with design control methods, consistent with Chapter 17.

3.9.1.2.2.1.1 ICES/STRUDL-II. The ICES/STRUDL-II computer program provides the ability to specify characteristics of framed structure and three-dimensional solid structure problems, perform static and dynamic analyses, and reduce and combine results.

Analytic procedures in the pertinent portions of ICES/STRUDL-II apply to framed structures. Framed structures are two- or three-dimensional structures composed of slender, linear

members that can be represented by properties along a centroidal axis. Such a structure is modeled with joints, including support joints, and members connecting the joints. A variety of force conditions on members or joints can be specified. The member stiffness matrix is computed from beam theory. The total stiffness matrix of the modeled structures is obtained by appropriately combining the individual member stiffness.

The stiffness analysis method of solution treats the joint displacements as unknowns. The solution procedure provides results for joints and members. Joint results include displacements and reactions and joint loads as calculated from member end forces. Member results are member end forces and distortions. The assumptions governing the beam element representation of the structure are as follows: linear, elastic, homogeneous, and isotopic behavior, small deformation, plane sections remain plane, and no coupling of axial, torque, and bending.

The program is used to define the dynamic characteristics of the structural models used in the dynamic seismic analyses of the reactor coolant system components. The natural frequencies and mode shapes of the structural models and the influence coefficients which relate member end forces and moments and support reactions to unit displacements are calculated. The influence coefficients are calculated for each dynamic degree-of-freedom of each mass point and for each degree-of-freedom of each support point at which relative motion is imposed. In addition, stiffness coefficients are calculated which relate the forces corresponding to those joint

degrees-of-freedom for which mass is specified to the imposed displacements corresponding to those (support) joint degrees-of-freedom at which relative motion will be specified during subsequent seismic response calculations. As appropriate, these data are stored for later use in response spectra or time-history seismic response calculations.

ICES/STRUDL-II is a program which is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation. The version of the program in use at C-E was developed by the McDonnell Automation Company/Engineering Computer International and is run on the IBM-360 computer system. STRUDL is described in more detail in Reference 1.

3.9.1.2.2.1.2 MARC. The MARC program is a general purpose nonlinear finite element program with structural and heat transfer capabilities. It is described in detail in Reference 2.

MARC is used for stress analysis of regions of vessels, piping or supports which may deform plastically under prescribed loadings. It is also used for elastic analyses of complex geometries where the graphics capability enables a well defined solution. The thermal capabilities of MARC are used for complex geometries where simplification of input and graphical output are preferred.

MARC is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification

of the C-E version has been performed to supplement the public documentation.

3.9.1.2.2.1.3 LION. LION is a finite difference heat transfer program for computing temperature distributions in a three dimensional field. It is described in detail in Reference 3.

LION is used for solution of heat conduction in structural elements, forced convection, free convection and radiation problems. The computed temperature distributions are used as input to the stress analysis programs.

LION is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation.

3.9.1.2.2.1.4 TMCALC. The C-E program TMCALC solves the differential equations of motion for a singly or multiply excited multi-degree-of-freedom linear structural system. The program accepts separate, independent, time-varying inputs at each boundary point in the system at which motions due to a seismic event may be imposed, or where a load forcing function may be imposed. The input excitations are provided in digitized form and are assumed to vary linearly between input time steps. The solution of the equations of motion in normal mode coordinates employs a closed form integration process.

The output from TMCALC consists of digitized time history records of the absolute accelerations and relative

displacements for each mass point and boundary point dynamic degree-of-freedom of the structural system.

The program is used to calculate the dynamic response of structural models used in the dynamic seismic analysis of the reactor coolant system major components, and in the dynamic analysis of linear structural systems subjected to time varying load forcing functions, such as thrust from postulated pipe ruptures.

To demonstrate the applicability and validity of the TMCALC program, the solutions to test problems were obtained and shown to be substantially identical to the results obtained by hand calculations. Details of verification are found in Appendix 3.9A.

3.9.1.2.2.1.5 FORCE. The computer code program FORCE calculates the internal forces and moments at designated locations in a piecewise linear structural system, at each time step, due to the time history of relative displacements of the system mass points and boundary points. The program also selects the maximum value of each component of force or moment at each designated location, and the times at which they occur, over the entire duration of the specified dynamic event. The program forms appropriate linear combinations of the relative displacements at each time step and performs a complete loads analysis of the deformed shape of the structure at each time step over the entire duration of the specified dynamic event.

The program is used to calculate the time dependent reactions in structural models subjected to dynamic excitation which are analyzed by the TMCALC and DAGS programs.

To demonstrate the validity of the FORCE program, results for test cases were obtained and shown to be substantially identical to those obtained for an equivalent analysis using the public domain program ICES/STRUDL-II. Details of verification are found in Appendix 3.9A.

3.9.1.2.2.1.6 AXEL. The AXEL program allows the solution of axisymmetric problems using either triangular or general isoparametric finite elements. The isoparametric element is an 8-noded quadrilateral where the midside nodes can be used to model second order curved boundaries and to provide increased accuracy in regions of high stress. The program was verified by comparison of numerous classical examples with results from AXEL. Details of verification are found in Appendix 3.9A.

3.9.1.2.2.1.7 DAGS. The computer program DAGS (Dynamic Analysis of Gapped Structure) performs a piecewise linear direct integration solution of the coupled equations of motion of a three dimensional structure which may have clearances or gaps between the structure and any of its supports or restraints (boundary gaps) or between points within the structure (internal gaps). The contacted boundary points may be oriented in any selected direction and may respond rigidly, elastically, or plastically. The structure may be subjected to applied dynamic loads or boundary motions.

The DAGS program is used to calculate the dynamic response of piecewise linear structural systems subjected to time varying load forcing functions resulting from postulated LOCA conditions.

To demonstrate the applicability and validity of the DAGS program, the solutions to an extensive series of tests problems were obtained and shown to be substantially identical to results obtained by hand calculations or alternate computer solutions. Details of verification are found in Appendix 3.9A.

3.9.1.2.2.1.8 NFATIG. NFATIG is a digital computer program used to analyze nuclear Class 1 piping components in accordance with the ASME Code Section III NB-3650[4]. Input to this program consists of a geometry, material properties, and the various indices for a given section of piping, the loadings and number of cycles of each, the material fatigue curve, and allowable Sm stresses. The output includes the stresses Sn and Salt, and the usage factor for each load set as well as the cumulative usage factor for all cases. NFTIG also incorporates the capability to calculate the stress indices for various standard piping component shapes including tangents, elbows, tees, branches, tapered joints, fillet welds, and reducers.

The NFATIG program was developed in 1973 and updated as required in accordance with subsequent revisions of Section III, ASME Code.

Verification of NFATIG was by example problems and comparison with hand calculations. Details of verification are found in Appendix 3.9A.

3.9.1.2.2.1.9 Bottom Head Penetration Reinforcement Program. This program calculates reinforcement available and reinforcement required for penetrations in hemispherical heads.

The technique described in paragraph NB-3332 of the ASME Code, Section III is used.

This program is used to perform preliminary sizing and reinforcement calculations for hemispherical heads in the reactor vessel. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.10 Flange Fatigue Program. This program computes the redundant reactions, forces, moments, stresses, and fatigue usage factors in a reactor vessel head, head flange, closure studs, vessel flange, and upper vessel wall for pressure and thermal loadings. Classical shell equations are used in the interaction analysis.

This program is used to perform the fatigue analysis of the reactor vessel closure head and vessel flange assembly. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.11 Nozzle Fatigue Program. This program computes the redundant reactions forces, moments, and fatigue usage factors for nozzles in cylindrical shells.

This program is used to perform the fatigue analysis of reactor vessel nozzles and steam generator feedwater nozzle. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.12 Edge Coefficients Program. This code calculates the coefficients for edge deformations of conical

cylinders and tapered cylinders when subjected to axisymmetric unit shears and moments applied at the edges.

This program is used to perform the fatigue analysis of reactor vessel wall transition. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.13 Generalized 4 x 4 Program. This program computes the redundant reactions, forces, moments, stresses, and fatigue usage factors for the reactor vessel wall at the transition from a thick to thinner section and at the bottom head juncture.

This program is used to perform fatigue analysis of reactor vessel bottom head juncture. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.14 ANSYS. Large-scale, general-purpose, finite element program for linear and nonlinear structural and thermal analysis. This program is in the public domain. Additional descriptive information on this code is provided in section 3.9.1.2.3.3.

This program is used for numerous applications for all components in the areas of structural, fatigue, thermal and eigenvalue analysis. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.15 Mare Island Computer Program. This program is used for flexibility analysis of the main loop piping and components. This program is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation. MEC-21 is described in more detail in Reference 4.

3.9.1.2.2.1.16 The Structural Analysis for Partial Penetration Nozzles, Heater Tube Plug Welds, and the Water Level Boundary of the Pressurizer Shell Program. This program computes various analytical parameters, primary plus secondary stresses and stress intensities, peak stresses and stress intensities, and the cyclic fatigue analysis with usage factors at cuts of interest. This program is utilized to satisfy the requirements of Section III, of the ASME Code.

This program is used in the fatigue analysis of partial penetration nozzles in the pressurizer and piping. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.17 Seal-Shell II Code. This code computes stresses and deformations of axisymmetric shells for pressure and thermal loads.

This program is used in the fatigue analysis of various nozzles in the pressurizer, piping, and steam generator. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.18 Primary Structure Interaction Program. This code calculates redundant loads, stresses, and fatigue usage factors in the primary head, tubesheet, secondary shell, and stay cylinder for pressure and thermal loadings.

This program is used in the fatigue analysis of the steam generator primary structure. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.19 Tube-To-Tubesheet Weld Program. This code performs a three body interaction analysis of the tube-to-tubesheet weld juncture. The code calculates primary, secondary, and peak stresses and computes range of stress and fatigue usage factors.

This program is used in the fatigue analysis of steam generator tube-to-tubesheet weld. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.20 Support Skirt Loading Program. This code calculates the stresses in the conical support skirt of the steam generator for external loads.

This program is used in the structural analysis of steam generator support skirt. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.21 Principal Stress Program. This code sums stresses for three load conditions and computes principal

stress intensity, stress intensity range, and fatigue usage factor.

This program is used in the fatigue analysis of steam generator components. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.22 OUTRND Program. This code calculates the bending stresses in an out-of-round cylinder subjected to internal pressure. The application of this code is limited to evaluation of secondary shell out-of-round deviation exceeding the ASME Code allowables.

This program is used for fabrication deviations on steam generator shells. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.23 Nozzle Load Resolution Program. A special purpose code, used to calculate stresses in nozzles produced by piping loads in combination with internal pressure.

This program is used in the fatigue analysis of steam generator nozzles. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.24 Zipper, CDC Timesharing Zipper, Siddon Program. These codes are used to determine the neutral axis in bending for the bolted flange of the steam generator support skirt.

These programs are used in the structural analysis of the steam generator support skirt. Program was verified by comparisons

of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.25 CHAT Program. A general purpose finite difference heat transfer program. This program is used for steady state and transient thermal analysis.

This program is used in numerous thermal relaxation analysis for all components. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.26 CEFLASH-4A. A code used to calculate transient conditions resulting from a flow line rupture in a water/steam flow system. The program is used to calculate steam generator internal loadings following a postulated main steam line break.

This program is used in a steam line break accident structural analysis. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.27 CRIBE. A one dimensional, two phase thermal hydraulic code, utilizing a momentum integral model of the secondary flow. This code was used to establish the recirculation ratio and fluid mass inventories as a function of power level. The code is in the public domain and further verification is not required.

This program is used for determining steam generator performance. Program was verified by comparisons of program results and hand calculated solutions of classical problems.

3.9.1.2.2.1.28 RANGE. This program was used for the steam generator analysis. It takes six stress components given as output by ANSYS and computes the maximum stress intensity range for axisymmetric shells and nozzles.

The program has been verified by comparison of program results with hand calculated solutions of classical problems.

3.9.1.2.2.1.29 RANGETS. This special purpose program has been used for evaluation of the stress intensity range for the steam generator tubesheet, considering the procedure of ASME III, Appendix A-8000.

This program has built-in the curve of Fig. A-8142-1 (stress multiplier K vs. biaxiality ratio β). The program requires also as input the hole pattern geometry (pitch, ligament). Stress results from ANSYS are used to evaluate β, get K, then calculate the stress range.

The program has been verified by comparison of program results with hand calculated solutions of classical problems.

3.9.1.2.2.1.30 FATIGTS. This program is used in the fatigue analysis of the steam generator tubesheet.

This program has built-in the curves of Figs. A-8142-3 to 5 (stress multipliers Y1, Y2 vs. ligament efficiency and angle ϕ). The program requires also as input the hole pattern geometry (pitch, ligament) and the Young modulus. Stress results from ANSYS are used to evaluate the peak stress intensity at different angles, based on Y1, Y2 values read on the curves. Also the fatigue curve of Table I-9.1 of ASME III

89 Edition (related to Fig. I-9.1 UTS < 80 ksi) is built into the program, to allow for the fatigue evaluation. The program has been verified by comparison of program results with hand calculated solutions of classical problems.

3.9.1.2.2.1.31 Head PR Program

This program calculates reinforcement available and reinforcement required for penetrations in hemispherical heads. The technique in paragraph NB-3332 of ASME Code, Section III is used. This program is used to perform preliminary sizing and reinforcement calculations for hemispherical heads in the reactor vessel. Program was verified by comparison of program results and hand calculated solutions of classical problem.

3.9.1.2.2.1.32 AFP2D Program

This program utilizes the thermal stresses of two dimensional axisymmetric structure resulting from ANSYS code run. This program combines thermal stresses calculated for transient load steps with stresses due to pressure and external mechanical loads, calculates primary plus secondary stresses, peak stresses and their ranges of stress intensities and fatigue usage factors.

Program was verified by comparison of the results from the program run and the hand-calculation for a test problem.

3.9.1.2.2.1.33 AFPOST Program

This program utilizes the thermal stresses of two and three dimensional structural resulting from ANSYS code run. This program combines thermal stresses calculated for transient load

steps with stresses due to pressure and external mechanical loads, calculates primary plus secondary stresses, peak stresses and their ranges of stress intensities and fatigue usage factors.

Program was verified by comparison of the results from the program run and the hand-calculation for a test problem.

3.9.1.2.2.1.34 TEMPOST Program

TEMPOST is a post processor for temperature data generated by the ANSYS finite element program. The program is used to examine thermal gradients at defined cuts and bodies in the ANSYS model. A mean temperature, equivalent linear gradient and nonlinear or skin gradients are calculated from model temperatures. The program was verified by comparison of results from the program run and hand calculations.

3.9.1.2.2.1.35 APP-GP Program

APP-GP applies the procedures of Appendix G of the ASME Code, Section III and the supplemental procedures in Welding Research Council Bulletin 175 to evaluate non-ductile fracture in pressure vessels. The program calculates the allowable internal pressure as a function of crack size. RT_{NDT}, and thermal conditions which are input by the user. Program was verified by comparison of program results and hand calculated solutions of classical problem.

3.9.1.2.3 Reactor Internals, Fuel and CEDMS

The following computer programs are used in the static and dynamic analyses of reactor internals, fuel, and CEDMs.

3.9.1.2.3.1 ICES/STRUDL-II. The ICES/STRUDL-II computer program provides the ability to specify characteristics of programs, framed structures and three-dimensional solid structures; perform analyses, static and dynamic, and reduce and combine results.

Analytic procedures in the pertinent portions of ICES/STRUDL-II apply to framed structures. Framed structures are two or three dimensional structures composed of slender, linear members and/or plate elements. Such a structure is modeled with joints (including support joints) and members connecting the joints. A variety of force conditions on members or joints can be specified. The member stiffness matrix is computed from beam and/or plate theory. The total stiffness matrix of the modeled structure is obtained by appropriately combining the individual member stiffnesses.

The stiffness analysis method of solution treats the joint displacements as unknowns. The solution procedure provides results for joints and members. Joint results include displacements and reactions and joint loads as calculated from member end forces. Member results are member end forces and distortions. The assumptions governing the element representation of the structure are as follows: linear, elastic, homogenous, and isotropic behavior, small deformations, plane sections remain plane, and no coupling of

axial, torque, and bending. Further description is provided in reference (1).

The ICES/STRUDL-II code is used for the Normal Operations thermal stress analysis of the lower support structure grid beams, and for the stiffness evaluation and stress analysis of the bottom plates and the instrument nozzle support plate.

ICES/STRUDLL-II is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation.

3.9.1.2.3.2 MRI/STARDYNE. The MRI/STARDYNE program uses the finite-element method for the static and dynamic analysis of two and three dimensional solid structures subjected to any arbitrary static or dynamic loading or base acceleration. In addition, initial displacements and velocities may be considered. The physical structure to be analyzed is modeled with finite elements that are interconnected by nodes. Each element is constrained to deform in accordance with an assumed displacement field that is required to satisfy continuity across element interfaces. The displacement shapes are evaluated at nodal points. The equations relating the nodal point displacements and their associated forces are called the element stiffness relations and are a function of the element geometry and its mechanical properties. The stiffness relations for an element are developed on the basis of the theorem of minimum potential energy. Masses and external forces are assigned to the nodes. The general solution

procedure of the program is to formulate the total following equations:

$$[K] \cdot \{\delta\} = \{P\} \qquad (1)$$

$$\omega^2[m]\{q\} - [K]\{q\} = 0 \qquad (2)$$

where:

$\{\delta\}$ = the nodal displacement vector

$\{P\}$ = the applied nodal forces

$[m]$ = the mass matrix

ω = the natural frequencies

$\{q\}$ = the normal modes

Equation (1) applies during a static analysis which yields the nodal displacements and finite elements internal forces. Equation (2) applies during an eigenvalue/eigenvector analysis, which yields the natural frequencies and normal modes of the structural system. Using the natural frequencies and normal modes together with related mass and stiffness characteristics of the structure, appropriate equations of motion may be evaluated to determine structural response to a predescribed dynamic load.

The finite elements used to date in CE analyses are the elastic beam, plate and ground support spring members. The assumptions governing their use are as follows: small deformation, linear-elastic behavior, plane sections remain plane, no coupling of axial, torque and bending, geometric and elastic properties constant along length of element.

Further description is provided in reference (5).

The MRI/STARDYNE code is used in the analysis of reactor internals. The program is used to obtain the mode shapes, frequencies and response of the internals to predescribed static and dynamic loading. The structural components are modeled with beam and plate elements. Ground support spring elements are used, at times, to represent the effects of surrounding structures. The geometric and elastic properties of these elements are calculated such that they are dynamically equivalent to the original structures. The response analysis is then conducted using both modal response spectra and modal time history techniques. Both methods are compatible with the program.

The program is also used to perform a static finite element analysis of the lower support structure to determine its structural stiffness.

MRI/STARDYNE is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation.

3.9.1.2.3.3 ANSYS. ANSYS is a general purpose nonlinear finite element program with structural and heat transfer capabilities. It is described in reference (6).

ANSYS is used to perform detailed stress analyses of the fuel assembly due to combined lateral and vertical dynamic loads resulting from postulated seismic and loss-of-coolant-accident conditions.

Static finite element analyses of reactor internal structures such as flanges, expansion compensating ring and core shroud are performed with ANSYS to determine vertical and lateral stiffnesses and thermal stresses.

ANSYS is a proprietary code in the public domain. The developers, Swanson Analysis Systems, Incorporated have published an ANSYS verification manual with numerous examples of its usage.

3.9.1.2.3.4 ASHSD. The ASHSD program uses a finite-element technique for the dynamic analysis of complex axisymmetric structures subjected to any arbitrary static or dynamic loading or base acceleration. The three-dimensional axisymmetric continuum is represented as an axisymmetric thin shell. The axisymmetric shell is discretized as a series of frustums of cones.

Hamilton's variational principle is used to derive the equations of motion for these discrete structures. This leads to a mass matrix, stiffness matrix, and load vectors which are all consistent with the assumed displacement field. To minimize computer storage and execution time, the non-diagonal "consistent" mass matrix is diagonalized by adding off-diagonal terms to the appropriate diagonal terms. These equations of motion are solved numerically in the time by a direct step-by-step integration procedure.

The assumptions governing the axisymmetric thin shell finite element representation of the structure are those consistent with linear orthotropic thin elastic shell theory. Further description is provided in reference (7).

ASHSD is used to obtain the dynamic response of the core support barrel under Normal Operating Conditions and due to a LOCA. An axisymmetric thin shell model of the structure is developed. The spatial Fourier series components of the time varying normal operating hydraulic pressure or LOCA loads are applied to the modeled structure. The program yields the dynamic shell and beam mode response of the structural system.

ASHSD has been verified by demonstration that its solutions are substantially identical to those obtained by hand calculations or from accepted experimental tests or analytical results. The details of these comparisons may be found in references (7) and (8).

3.9.1.2.3.5 CESHOCK. The computer program CESHOCK solves for the response of structures which can be represented by lumped-mass and spring systems and are subjected to a variety of arbitrary type loadings. This is done by numerically solving the differential equations of motion of an n^{th} degree of freedom system using the Runge-Kutta-Gill technique. The equations of motion can represent an axially responding system or a laterally responding system; i.e., an axial motion, or a coupled lateral and rotational motion. The program is designed to handle a large number of options for describing load environments and includes such transient conditions as time-dependent forces and moments, initial displacements and rotations, and initial velocities. Options are also available for describing steady-state loads, preloads, accelerations, gaps, nonlinear elements, hydrodynamic mass, friction, and hysteresis.

The output from the code consists of minimum and maximum values of translational and angular accelerations, forces, shears, and moments for the problem time range. In addition, the above quantities are presented for all printout times requested. Plots can also be obtained for displacements, velocities and accelerations as desired. Further description is provided in Reference (9).

The CESHOCK program is used to obtain the transient response of the reactor vessel internals and fuel assemblies due to LOCA and seismic loads.

Lateral and vertical lumped-mass and spring models of the internals are formulated. Various types of springs; linear, compression only, tension only, or nonlinear springs are used to represent the structural components. Thus, judicious use of load-deflection characteristics enables effects of components impacting to be predicted. Transient loading appropriate to the horizontal and vertical directions is applied at mass points and a dynamic response (displacements and internals forces) is obtained.

CESHOCK has been verified by demonstration that its solutions are substantially identical to those obtained by hand calculations or from accepted analytical results via an independent computer code. The details of these comparisons may be found in References (8) and (9).

3.9.1.2.3.6 SAMMSOR/DYNASOR. SAMMSOR/DYNASOR provides the ability to perform nonlinear dynamic analyses of shell structures represented by axisymmetric finite-elements and subjected to arbitrarily varying load configurations.

The program employs the matrix displacement method of structural analysis, utilizing a curved shell element. Geometrically nonlinear dynamic analyses can be conducted using this code.

Stiffness and mass matrices for shells of revolution are generated utilizing the SAMMSOR part of this code. This program accepts a description of the structure in terms of the coordinates and slopes of the nodes, and the properties of the elements joining the nodes. Utilizing the element properties, the structural stiffness and mass matrices are generated for as many as twenty harmonics and stored on magnetic tape. The DYNASOR portion of the program utilizes the output tape generated by SAMMSOR as input data for the respective analyses.

The equations of motion of the shell are solved in DYNASOR using Houbolt's numerical procedure with the nonlinear terms being moved to the right-hand side of the equilibrium equations and treated as generalized pseudo-loads. The displacements and stress resultants can be determined for both symmetrical and asymmetrical loading conditions. Asymmetrical dynamic buckling can be investigated using this program. Solutions can be obtained for highly nonlinear problems utilizing as many as five circumferential Fourier harmonics. Further description is provided in references (10) and (11).

This program is used to analyze the dynamic buckling characteristic of the core support barrel during a LOCA hot-leg break. The program's nonlinear characteristics provide this capability.

A finite element model of the CSB is formulated which is consistent with the computer program. Taking into account the initial deviation of the structure and the shell mode which is most likely to give the minimum critical pressure, the time-dependent pressure load is applied to the barrel. The maximum displacement occurring in the barrel is obtained.

SAMMSOR/DYNASOR has been verified by demonstration that its solutions are substantially identical to those obtained by hand calculations, accepted experimental test or analytical results, and results obtained with a similar independently written program in the public domain. The details of these comparisons may be found in reference (8).

3.9.1.2.3.7 MODSK. MODSK is a CE computer program which solves for the natural frequencies and mode shapes of a structural system. The natural frequencies and mode shapes are extracted from the system of equations:

$$(K - W_n^2 M)\,\phi_n = 0$$

where

K = model stiffness matrix

M = model mass matrix

W_n = natural circular frequency for the n^{th} mode

ϕ_n = normal mode shape matrix for the n^{th} mode

The solution to the general eigenvalue problem is obtained using the dual Jacobi rotation method.

The MODSK code is used in the analyses of reactor internals to obtain frequencies and mode shapes, and damping parameters. The results of these analyses are incorporated into overall reactor vessel internals models, which calculates dynamic response due to seismic and LOCA conditions.

The MODSK program was developed by CE and is used on the CDC 7600 computer. To demonstrate the validity of the MODSK program, results from lateral and vertical test problems were obtained and shown to be substantially identical to those obtained from an equivalent analysis using the public domain program ANSYS (Refer to section 3.9.1.2.3.3).

3.9.1.2.3.8 SAPIV. The SAP IV computer code is a structural analysis program capable of analyzing two and three dimensional linear complex structures subjected to any arbitrary static and dynamic loading or base acceleration. The analysis technique is based on the finite element displacement method. The structure to be analyzed can be represented using bars, beams, plates, membranes and three dimensional finite elements.

Structural stiffness and load vectors are assembled from the element matrices which are derived assuming various displacement functions within each element whereas lumped mass matrices are used to represent inertia characteristics of the structure. In the static analysis, the assembled equations of equilibrium are solved by using a linear equation solver. Dynamic analysis capabilities include modal analysis, modal superposition and direct integration methods of computing dynamic response and response spectrum techniques.

SAPIV has been applied to the eigenvalue and response spectra analyses of spent fuel storage racks and lifting rig structures.

The SAPIV code is used in the computation of dynamic response of control element drive mechanisms under mechanical and seismic loads. Both modal analysis and response spectrum capabilities of the code are used to find the natural frequencies and mode shapes and the dynamic loads in CEDM components.

SAPIV is in the public domain and has had sufficient use to justify its applicability and validity. Extensive verification of the C-E version has been performed to supplement the public documentation.

3.9.1.2.3.9 CEFLASH-4B. The CEFLASH-4B computer code (Reference 15) predicts the reactor pressure vessel pressure and flow distribution during the subcooled and saturated portion of the blowdown period of a Loss-of-Coolant-Accident (LOCA). The equations for conservation of mass, energy and momentum along with a representation of the equation of state are solved simultaneously in a node and flow path network representation of the primary reactor coolant system.

CEFLASH-4B provides transient pressures, flow rates and densities throughout the primary system following a postulated pipe break in the reactor coolant system.

The CEFLASH-4B computer code is a modified version of the CEFLASH-4A code (References 16-18). The CEFLASH-4A computer code has been approved by the NRC (References 19 and 20). The

capability of CEFLASH-4B to predict experimental blowdown data is presented in Reference 15.

3.9.1.2.3.10 LOAD 2. LOAD 2 calculates the applied forces of the axial internals model which is contained within water control volumes using results from the CEFLASH-4B blowdown loads analysis as input. The fluid momentum equation is applied to each volume and a resultant force is calculated. Each force is then apportioned to the various structural nodes contained within the volume. Use of the fluid momentum equation takes into account pressure forces, fluid friction, water weight, and momentum changes within each volume. The resultant forces are combined with the reactor vessel motions obtained from the reactor coolant system analysis before the structural responses are determined. The LOAD 2 code has been verified by demonstrating that its solutions are substantially identical to those obtained from hand calculations.

3.9.1.3 Experimental Stress Analyses

3.9.1.3.1 NSSS Items

Requirements for experimental stress analysis have not been imposed on any equipment in the CESSAR scope.

3.9.1.3.2 Non-NSSS Items

Most stress analyses have been computer simulated. Experimental stress analysis has not generally been performed on non-C-E scope components. However, experimental stress analysis has been utilized on the following components:

A. Essential Air Cooling Units, Auxiliary Building Pump Rooms

   Two units of different sizes were tested to verify the analytical method.

B. Essential Ducting

   The experimental analysis of essential HVAC ducting was performed on 17 groups of various sized ducts. These samples were subjected to pressure loading, equivalent seismic loads, and live loads (e.g., a concentrated weight was applied along the duct to simulate the live load of a man walking on the duct).

The test loads causing failure were compared to the theoretical load to failure in order to justify the design procedure.

3.9.1.4 Consideration for the Evaluation of the Faulted Condition

3.9.1.4.1 Seismic Category I NSSS Items

Analyses of the reactor coolant system components (reactor vessel, steam generator, reactor coolant pump, pressurizer, and reactor coolant piping) and their supports have been performed in accordance with the methods described in CESSAR Section 3.9.1.4.1. However, due to analyses submitted on the CESSAR docket under the requirements of 10CFR50, Appendix A, Criterion 4, loads resulting from postulated pipe breaks of the RCS MAIN Loop piping are no longer required for consideration. For each component and support member, the calculated loads, in combination with the seismic loads, are below the loads specified for design and the stresses (pipe rupture in combination with SSE) are below those listed in Table 3.9.3-2.

No components or supports of the reactor coolant system main loop for PVNGS were designed using the inelastic methods defined in Section III of the ASME Code as plastic instability or limit analysis methods.

The reactor vessel lower key horizontal supports include load limiting devices in accordance with section 5.4.14.2(e). These load limiters are designed to remain elastic for all normal, upset, and SSE loadings, and elastic system analyses are used to establish or confirm the loads specified for design of the

components and supports for these conditions. For loads resulting from postulated pipe breaks, the load limiter devices are designed to deflect plastically, and nonlinear system analyses are used accordingly for proper calculation of the distribution of the loads among the system of supports.

Figure 3.9-1 illustrates the performance requirements specified for the reactor vessel lower support key load limiters. The dashed lines represent the stiffness and load ranges evaluated in the overall system analyses. All test data points were within the envelope indicated by the solid lines. All testing was performed on samples extracted from the heat specific material used in construction.

Twenty-one tests were run at various temperatures and at crush velocities representative of performance requirements. The test results were within the specified load deflection limits.

3.9.1.4.2 Seismic Category I Non-NSSS Items

Dynamic loads for components loaded in the elastic range are calculated using dynamic load factors, time-history analysis, or any other method that assumes elastic behavior of the component. A component is assumed to be in the elastic range if yielding across a section does not occur. The limits of the elastic range are defined in Paragraph F-1323 of Appendix F for code components. Local yielding due to stress concentration is assumed not to affect the validity of the assumptions of elastic behavior. The stress allowables of Appendix F for elastically analyzed components are used for code components. For noncode components, allowables are based on tests or

accepted material standards consistent with those in Appendix F for elastically analyzed components.

3.9.1.4.3 Control Element Drive Mechanisms

The pressure boundary portions of the control element drive mechanisms (CEDMs), including the nozzle attached to the reactor vessel head, have been analyzed in accordance with the methods described in section 3.9.1.4.3.1 below. The calculated moments and/or stresses for both pipe rupture only and for the combined effects of pipe rupture and the SSE are below those allowed by Section III of the ASME B&PV Code for service level D.

The capability of the control element drive mechanisms (CEDMs) to withstand the effects of design basis pipe breaks in combination with safe shutdown seismic (SSE) loadings is evaluated by analysis. This dynamic loading is experienced by the CEDMs via the motion of the reactor vessel head. The reactor vessel head/CEDM motions due to pipe rupture and seismic loadings are calculated as described in sections 3.7.2 and 3.9.1.4.1.

3.9.1.4.3.1 Method of Analysis

Prior to implementation of leak before-break, studies on other C-E plants (Reference 1) indicated that the reactor vessel asymmetric load aspects of a hypothetical main coolant loop guillotine break produce motions which result in stresses which exceed the ASME Code Level D allowable stresses for elastic calculation. Elastic plastic dynamic analyses have demonstrated for those plants that the structural integrity of

the CEDMs is not impaired by these loadings and that the ASME Code Level D allowable limits for elastic plastic calculation are not exceeded. In order to demonstrate that the integrity of the CEDMs were not impaired by main coolant loop pipe break and SSE loads, elastic plastic dynamic analyses of the CEDM's were originally performed.

In the elastic plastic analysis, the motions of the RV were input to the finite element model of the CEDM. Moments and deformation were computed as a function of time during the event. The moment to cause plastic instability of the most severely loaded section was computed by elastic plastic static analysis. The actual moments during the dynamic event were then compared to the plastic instability moment in order to evaluate integrity.

1. "Reactor Coolant System Asymmetric Loads Evaluation Program Final Report", Combustion Engineering, Inc., July 1, 1980.

3.9.1.4.3.2 Models

Dynamic analysis finite element models were prepared for CEDMs near the center of the RV head and near the outer edge. The models were made up of beam type elements.

The model for the calculation of the plastic instability load was made up of shell elements in order to consider the effects of ovalization of the cylindrical section. The nozzle at the RV head is usually the most severely loaded section.

3.9.1.4.3.3 Material Properties

The material properties necessary for elastic plastic analysis were developed by the C-E Metallurgical and Materials Laboratory. These properties are available for all of the materials at all of the temperatures that the CEDM normally experiences.

3.9.1.4.3.4 Loading

The effects of pipe break and SSE are transmitted to the CEDM by the motion of the reactor vessel head resulting from the analyses of sections 3.7.2 and 3.9.1.4.1.

A response spectrum is calculated for the motion of the reactor vessel head resulting from the primary system dynamic analysis for pipe break loads. This response spectrum is combined with the SSE response spectrum by taking the square root of the sum of the squares (RSS) of the ordinates of the two spectra. An artificial time history of motion is then developed from the combined acceleration spectrum and used as the input to the dynamic CEDM analysis.

Acceleration spectra resulting from pipe rupture at the RV inlet nozzle, the RV outlet nozzle, and at the steam generator inlet nozzle will be compared in order to determine the most severe loading condition. If one loading condition can be identified as the most severe case, only that loading condition will be used in the dynamic CEDM analysis. Other loadings will also be used if they are not clearly enveloped by the most severe one.

3.9.1.4.3.5 Response

The models, material properties and RV head motion history are used in the MARC finite element program (Section 3.9.1.2.2.1.2) for analysis. The ANSYS program (3.9.1.2.2.1.14) may also be used. The results of the dynamic analysis include moments, strains, stresses and deformation as a function of time. These results are presented graphically for critical regions of the CEDM. The same material properties will be used in the static analysis for the plastic instability moment.

3.9.1.4.3.6 Evaluation

3.9.1.4.3.6.1 Acceptance Criteria

The CEDMs are not required to operate for safe shutdown after a loss of coolant event resulting from the design basis pipe breaks. In order to comply with existing ECCS analysis methods, however, the integrity of the CEDMs must be maintained and leakage must be prevented. The ASME Boiler and Pressure Vessel Code Section III Division 1 Appendix F lists a number of criteria which assure that the pressure boundary will not be violated. These criteria include an instability limit for comparison to elastic plastic analysis results. The integrity of the pressure boundary is assured if the applied loads do not exceed 70% of the plastic instability load.

3.9.1.4.3.6.2 Evaluation of Integrity

The results of each dynamic analysis are compared to the results of the static plastic instability moment analysis.

Integrity of the CEDMs is assured if the acceptance criteria are satisfied.

3.9.1.4.3.7 CEDMs Evaluation

Evaluations of the CEDMs for loadings were performed. Linear response spectrum analyses specific to the current plant configuration were used for both seismic and BLPB excitations to calculate response loads in the CEDM nozzles and CEDM components. A three-dimensional beam finite element ANSYS 5.5 model, with all spatial degrees of freedom, was developed and used for these analyses. This model uses a sufficient number of nodes to accurately represent the dynamic characteristics of the nozzle components and to provide a detailed load response distribution throughout the CEDM structure. The mathematical model was used for dead weight, seismic and BLPB analyses.

The seismic and BLPB loads were applied to the CEDM with the longest nozzle length (37.63 inches) and the shortest nozzle length (8.31 inches). The longest nozzle produces conservative results for seismic loads, while the shortest nozzle produces conservative results for BLPB loads. However, the governing load for the Faulted Condition combined loadings are the seismic loads; therefore stresses evaluated for the CEDM with the longest nozzle are limiting, and these results are applicable and conservative for all CEDM locations.

Seismic loads were generated by performing response spectrum analyses of the mathematical model using response spectra at the RV closure head from the RCS seismic analysis. The OBE analysis was performed using structural damping of 2.5% for the first mode and 2% for all other modes, conforming to RG 1.61

and test results without introducing over-conservatism. Although RG 1.61 allows 4% damping for welded steel structures for the SSE event, 2% damping was used in the CEDM SSE analysis. For the seismic analyses, each set of spectra for three orthogonal directions were broadened by ±15%. Since the effect of closely spaced modes for the CEDM structure is insignificant, modal responses were combined using the SRSS rule. The values of structural responses to each of three orthogonal components of motion were combined using the SRSS rule.

For BLPB analysis, input response spectra were generated from RV closure head acceleration response time histories from the BLPB analysis of the RCS. Damping of 4% was used to generate the RV closure head response spectra due to BLPB. The values of structural responses to each of three orthogonal components of motion were combined using the SRSS rule.

It was demonstrated that CEDM loads due to Service Levels A, B and D are within the allowable limits and that CEDM stresses for Service Levels A and B are addressed, CEDM and RV head thermal stresses are acceptable.

It was also demonstrated that during seismic and BLPB, the maximum displacement at the top of the CEDMs is within acceptable limits, that CEDMs retain their ability to scram within the 3 second time period, that the CEDMs will not impact, and that the RSPTs remain operable.

3.9.1.4.4 Emergency Core Cooling System Piping

The emergency core cooling system (ECCS) piping, inside containment, is comprised of the high- and low-pressure piping of the safety injection system.

The capability of the ECCS piping to withstand the effects of design basis pipe breaks is evaluated by analysis. The capability of the ECCS piping to withstand the combined effects of pipe break and SSE seismic loadings is also evaluated. Pipe rupture loadings are experienced by the ECCS piping via the motion of the primary system piping and the SSE loadings are experienced by the ECCS piping via the motion of the primary system piping and the ECCS piping supports.

The primary piping motions due to pipe rupture loadings are calculated as described in section 3.9.1.4.1. Each ECCS pipeline is evaluated by dynamic elastic or dynamic elastic/plastic analysis for these primary piping motions.

The effects of primary system pipe breaks are transmitted to the ECCS piping by the motion of the primary piping. For the evaluation of pipe break loads, the displacement time-history of the primary piping (at the ECCS injection nozzle) is applied directly to each dynamic ECCS pipeline analysis.

The analysis results in motions and stresses in the piping. The analysis also results in pipe support motions and loading.

For ECCS piping attached to the broken primary pipe, pressure boundary integrity is assumed by meeting the faulted condition limits found in Appendix F of ASME B&PV Code, Section III, Division 1.

For ECCS piping attached to the unbroken loops of the primary pipes, function ability can be assumed:

A. by meeting the level B (upset condition) limits of ASME B&PV Code, Section III, Division 1 with fatigue considerations excluded, or

B. by meeting the criteria found in GE Topical Report "Functional Capability Criteria for Essential Mark II Piping," NGDO-21985 dated September 1978 (refer to NRC memorandum for R. L. Tedesco, Assistant Director for Licensing, from J. P. Knight, Assistant Director for Components and Structures Engineering, dated July 17, 1980), or

C. by demonstrating that the deformations of the piping do not significantly affect ECCS flow.

3.9.2 DYNAMIC SYSTEM ANALYSIS AND TESTING

3.9.2.1 Piping Vibration Thermal Expansion and Dynamic Effects

Safety-related piping systems are designed in accordance with the ASME Code, Section III. Each system is designed to maintain dynamic effects within acceptable limits. A preoperational test program is implemented as required by NB-3622.3, NC-3622.3, and ND-3622.3 of Section III of the ASME B&PV Code to verify that the piping and piping restraints will withstand dynamic effects due to transients such as pump trips and valve trips, and that piping vibrations are within acceptable levels.

The preoperational test program for the Class 1, 2, and 3 piping systems is to simulate actual operating modes to demonstrate that the appurtenances comprising these systems meet functional design requirements and that piping vibrations are within acceptable levels.

Piping systems are checked in three sequential series of tests and inspections. Construction acceptance, the first step, entails inspection of components for correct installation. During this phase, pipe and equipment supports are checked for correct assembly and setting. The cold locations of RCS components, such as steam generators and reactor coolant pumps, are recorded.

During the second step of testing, plant heatup, the plant is heated to normal operating temperatures. During the heatup, systems are observed periodically to verify proper expansion and expansion data is recorded at the end of heatup.

During the third step of testing, performance testing, systems are operated and performance of critical pumps, valves, controls, and auxiliary equipment is checked. This phase of testing includes transient tests such as reactor trip or turbine trip and relief valve testing. During this phase of testing, the piping and piping restraints are observed for acceptable dynamic response. System tests include critical valve operation during transient system modes.

Vibratory dynamic loadings can be placed in two categories: transient-induced vibrations and steady-state vibrations. The first is a dynamic system response to a transient, time-

dependent forcing function, such as fast valve closure, while the second is a constant vibration, usually flow-induced.

A. Transient Response

1. Dynamic events falling in this category are anticipated operational occurrences. The systems and the transients to be included in the preoperational test program will be identified in test procedures.

2. For these transients, a time-dependent dynamic analysis is performed on the system. The stresses thus obtained are combined with system stresses resulting from other operating conditions in accordance with the criteria provided in subsections 3.9.1 and 3.9.3.

   Details of the program, including the criteria for evaluation of data gained, are provided in the test procedures.

B. Steady-State Vibration

1. System vibration resulting from flow disturbances fall into this category. Positive displacement pumps may cause such flow variation and vibrations.

   In these situations, pipe supports are spaced so the natural frequency of the piping system is at least 50% higher than the pulsation frequency of the pumps. Pulsation dampeners are also provided

on the suction and discharge sides of the pumps to reduce the pressure pulsations.

2. Since the exact nature of the flow disturbance is not known prior to pump operation, no analysis is performed. If excessive system vibration is evidenced during initial operation, appropriate measures will be taken to reduce the vibration.

3.9.2.2 Seismic Qualification Testing of Safety-Related Mechanical Equipment

3.9.2.2.1 Safety-Related Mechanical Equipment in the C-E Scope of Supply

The operability of all active safety related mechanical equipment within CE's scope of supply is demonstrated by analysis and/or testing. The methods and procedures used and the results of tests and analyses that confirm implementation of the design criteria for safety-related mechanical equipment, including supports, are provided in section 3.9.3.2.

3.9.2.2.2 Safety-Related Mechanical Equipment Not in the C-E Scope of Supply

The criteria used to decide whether dynamic testing or analysis will be used to qualify Seismic Category I mechanical equipment are as follows (refer to section 3.10):

A. Analysis Without Testing

1. Structural analysis without testing will be used if structural integrity alone can assure the

intended design function. Equipment which falls into this category includes:

- Piping
- Ductwork
- Tanks and vessels
- Heat exchangers
- Filters

The seismic analysis of piping is described in section 3.7.

2. Rotational analysis without testing will be used to qualify heavy rotating machinery items where it must be verified that deformations due to seismic loadings will not cause binding of the rotating element to the extent that the component cannot perform its required safety function.

   The seismic qualification of pumps is discussed more fully in paragraph 3.9.3.2. The procedure discussed therein applies with some variations to other items in this category.

B. Dynamic Testing

Dynamic testing is used for components with mechanisms that must change position or maintain position in order to perform their required safety function and which, because of their complexity, do not lend themselves to analysis. Such components include:

- Electric motor valve operators

- Valve limit switches
- Similar appurtenances for other active mechanical equipment

The seismic qualification of Seismic Category I electrical equipment is discussed in section 3.10.

C. Combinations of Analysis with Testing

A combination of analysis, static testing, and dynamic testing is used for seismic qualification of active valves whereby:

1. The manufacturer determines the first natural frequency of the valve assembly by analysis.
2. It is verified by static test that deformation due to seismic loadings will not cause binding of internal valve parts, which prevents valve operations within specified time limits.
3. The motor operator and other electrical appurtenances are qualified by dynamic testing.

The seismic qualification of active valves is discussed in paragraph 3.9.3.2.

The acceptance criteria which are used are as follows:

1. Tests, when used, demonstrate that the component is not prevented from performing its required safety function during and after the test.
2. Analysis, when used, verifies that stresses do not exceed the allowables specified in tables 3.9-4, 3.9-5, 3.9-6, 3.9-7, 3.9-9, and

3.9-11 for the loading combinations shown in tables 3.9-8, 3.9-10, and 3.9-12 and that deformations do not exceed those that will permit the component to perform its design intended function.

3.9.2.3 Dynamic Response Analysis of Reactor Internals Under Operational Flow Transients and Steady-State Conditions

3.9.2.3.1 Introduction

The flow-induced vibration of the reactor internals components during normal operation can be characterized as a forced response to both deterministic (periodic and transient) and random pressure fluctuations in the coolant. Methods have been developed to predict the various components of the hydraulic forcing function and the response of the reactor internals to such excitation.

This analytical methodology is summarized in Figure 3.9.2-1. The method separates the response calculations into two groups in accordance with the physical nature of the loading; i.e., deterministic or random. Methods for developing the deterministic component of the hydraulic forcing function are discussed in section 3.9.2.3.2, while those relating to the random component are discussed in section 3.9.2.3.3. Where complex flow path configurations or wide variations in pressure distribution are involved, the hydraulic forcing functions are formulated using a test-analysis combination method utilizing data obtained from plant tests and/or scaled model tests.

The response of the reactor internals components (to include Core Support Barrel Assembly, Upper Guide Structure Assembly and Lower Support Structure Assembly) to the normal operating hydraulic loads are calculated by finite-element techniques. The mathematical models used in these response analyses are described in section 3.9.2.3.4. The methods used in calculating the structural responses are discussed in section 3.9.2.3.5.

3.9.2.3.2 Periodic Forcing Function

3.9.2.3.2.1 Core Support Barrel Assembly

An analysis based on an idealized hydrodynamic model is employed to obtain the relationship between reactor coolant pump pulsations in the inlet ducts and the periodic pressure fluctuations on the core support barrel. A detailed description of this model and subsequent solution are given in References 7-13. The model represents the annulus of coolant between the core support barrel and the reactor vessel. In deriving the governing hydrodynamic differential equation for the above model, the fluid is taken to be compressible and inviscide. Linearized versions of the equations of motion and continuity are used. The excitation on the hydraulic model is harmonic with the frequencies of excitation corresponding to pump rotational speeds and blade passing frequencies. The result of the hydraulic analysis is a system of equations which define the forced response, natural frequencies and natural modes of the hydrodynamic model. The forced response equations define the spatial distributions of pressure on the core support barrel system as a function of time.

3.9.2.3.2.2 Upper Guide Structure

The dynamic force on the upper guide structure assembly is due to flow induced forces on the tube bank. The periodic components of these forces are caused by pressure pulsations at harmonics of the pump rotor and blade passing frequencies, and vortex shedding due to crossflow over the tubes.

A series of tests on full size tubes at reactor pressure and temperature indicated no evidence of periodic vortex shedding at the Reynolds Number and turbulence levels expected in the tube bank (Ref. 23). Thus, the only significant periodic force is that due to pump pulsations. Data from this same test series was utilized to determine the magnitude of these pulsations at the pump rotor, twice the rotor, blade passing, and twice blade passing frequencies.

3.9.2.3.2.3 Lower Support Structure Assembly

The ICI nozzles and the skewed beam supports for the ICI support plate are excited by periodic and/or random, flow induced forces.

The periodic component of this loading is due to pump related pressure fluctuations and vortex shedding due to crossflow. High turbulence intensity caused by jetting through the flow skirt makes it unlikely that regular vortex shedding will occur (Refs. 18, 19). If it were assumed to occur, the maximum shedding frequency would be well below the lowest structural frequency for both the ICI support nozzles and skewed beams. The magnitude and frequency of this periodic force are accounted for based on data in the literature for crossflow

over both vertical (Ref. 17, 22) and skewed (Ref. 21) isolated tubes.

Derivation of pump frequency related loads is accomplished by assuming that these periodic pressure variations are propagated undiminished through the flow skirt from the lower portion of the core barrel - reactor vessel annulus. The magnitude of these pulsations is based on a combination of analytical predictions, based on Reference 7, and data from previous precritical programs (Refs. 9, 10).

3.9.2.3.3 Random Forcing Function

3.9.2.3.3.1 Core Support Barrel Assembly

The random hydraulic forcing function is developed by analytical and experimental methods. An analytical expression is developed to define the turbulent pressure fluctuation for fully developed flow (Ref. 12). This expression is modified, based upon the result of scale model testing (Refs. 15 and 16), to account for the fact that flow in the downcomer is not fully developed. Based upon tests results, an expression is developed to define the spatial dependency of the turbulent pressure fluctuations. In addition, experimentally adjusted analytical expressions are developed to define the peak value of the pressure spectral density associated with the turbulence and the maximum area of coherence, in terms of the boundary layer displacement, across which the random pressure fluctuations are in phase (Refs. 11, 12, 13). The transient behavior of the random fluctuations during loop startup and shutdown is assumed to be identical to that of the periodic excitations.

3.9.2.3.3.2 Upper Guide Structure

Results of the full size tube tests (Ref. 23) showed that at normal operating conditions the shroud tubes are excited by upstream and wake produced turbulent buffeting (Ref. 23, 24, 25). The forcing function for this type of loading can be represented as a band limited white noise power spectrum (Ref. 23). The magnitude of this spectrum is computed based on data from these tests. The resultant velocity dependent force is combined with static drag loads to compute the amplitude response and stress levels.

3.9.2.3.3.3 Lower Support Structure Assembly

The ICI nozzles and ICI support plate support beams are both subject to turbulent buffeting by the flow skirt jets. The outermost ICI nozzles and beams receive full impact of the jets before the jets decay due to fluid entrainment and the presence of inner tube rows. The force spectrum of these jets is assumed to be represented as wide band white noise. The magnitude of this spectrum is based on data in the literature for impingement of turbulent jets (Ref. 20, 26). This velocity dependent magnitude is applied to each tube, assuming no change in jet characteristics, between the outermost and inner tubes. The approach velocity for each tube is calculated from an analytical expression based on experimental data on the velocity distribution in the lower portion of the reactor vessel-core barrel annulus and the flow skirt.

3.9.2.3.4 Mathematical Models

A finite element analysis is performed on each of the reactor internals components using mathematical models. These models are designed to provide the most efficient analysis under the most significant loading condition to which each structure is exposed. The core support barrel assembly is modeled as a shell using the ASHSD computer code (Ref. 29) (Figure 3.9.2-2). The structure is fixed at the upper flange to determine the beam modes and frequencies. The shell modes and frequencies are found by considering the upper flange fixed and the lower flange pinned. These analyses include hydrodynamic mass effects. All significant mode shapes and frequencies are used in combination to perform the normal operating deterministic response analysis. A simplified finite-element model of the barrel assembly is generated on the STARDYNE computer code (Ref. 30) for use in the random response analysis.

The control element shroud tubes in the upper guide structure assembly are modeled as beams supported at the ends by plate elements. The end plates are in turn supported by spring elements which represent the stiffness of additional surrounding structure. A typical model of this configuration is shown in Figure 3.9.2-3. The STARDYNE computer code (Ref. 30) is employed to allow the same models to be utilized for modal analysis as well as deterministic and random response analysis.

The lower support structure assembly is modeled in several ways. Beam and plate elements are assembled in a comparatively coarse mesh to model the entire Instrument Nozzle Assembly

(Figure 3.9.2-4). This representation of the structure is used on the STARDYNE computer code (Ref. 30) to determine the modes, frequencies and response actions of the assembly as a system. The reaction points in this model are taken at the bottom plate level of the LSS Assembly. Typical ICI nozzles (Figure 3.9.2-5) and Skewed Beams (Figure 3.9.2-6) are modeled as fine mesh beam elements reacted at the support points by spring elements representing the surrounding structure flexibility. These component models are used on the STARDYNE computer code (Ref. 30) to provide the individual structural modes, frequencies and responses within the system. The results of both individual and system analysis are combined to provide the total response.

3.9.2.3.5 Response Analysis

3.9.2.3.5.1 Deterministic Response

The normal mode method (Reference 27) is used to obtain the structural response of the reactor internals to the deterministic forcing functions developed in section 3.9.2.3.2. The method is applied to the appropriate finite-element models described in section 3.9.2.3.4. Generalized masses based on mode shapes and the mass matrices from the finite-element computer programs are calculated for each component's modes of vibration. Modal force participation factors are based on the mode shapes and the predicted periodic forcing functions are calculated for each mode and forcing function. The generalized coordinate response for each mode is then obtained through solution of the corresponding set of independent second order single-degree of freedom equations. Utilizing displacement and

stress mode shapes from the finite-element computer programs, the modal responses of the reactor internals are obtained by means of the appropriate coordinate transformations. Response to any specific forcing function is obtained through summation of the component modes for that forcing function.

3.9.2.3.5.2 Random Response

The normal mode method (Ref. 27) is used to obtain the structural response of the reactor internals subjected to random forcing functions. The random forcing functions are assumed to be of both the band limited and wide band white noise varieties as described in section 3.9.2.3.3. Experimental and analytical expressions are used to define the force power spectral density associated with flow related turbulence and jet impact. The appropriate mathematical models described in section 3.9.2.3.4 are used in the STARDYNE computer code (Ref. 28). This code computes the response RMS displacements, loads and stresses in a multi-degree-of-freedom linear elastic structural model subjected to stationary random dynamic loadings, such as those described in section 3.9.2.3.3.

The largest response of the Core Support Barrel is expected to be in the "beam" mode. The simplified finite-element model of this structure, described in section 3.9.2.3.4, is used to compute these displacements.

The Upper Guide Structure and Lower Support Structure will not respond to random excitation as complete assemblies but rather will experience local disturbances of individual components within the assemblies. The modal analyses from the finite-element models of these components, (Figures 3.9.2-3,

3.9.2-4 and 3.9.2-6) already used for deterministic analysis, are once again utilized to determine the random responses via the normal mode procedure.

3.9.2.4 Preoperational Flow-Induced Vibration Testing of Reactor Internals

PVNGS Unit 1 is the proto-type System 80 plant for the purposes of the precritical vibration monitoring program (PVMP). PVNGS Units 2 and 3 are nonprototype plants.

In accordance with NRC Regulatory Guide 1.20, a preoperation vibration monitoring program has been developed for the prototype System 80 plant. The first System 80 unit that will go on-line will be the lead plant and will be used as the System 80 prototype. Subsequent System 80 plants will fall under a non-prototype designation as defined in Regulatory Guide 1.20. Precritical program guidelines on these plants are as defined in Regulatory Guide 1.20 for non prototype plants. The precritical test program described in this section is a prototype program.

Precritical test programs have been run on previous CE plants (References 9, 10 and 31). The System 80 program utilizes the experience from these earlier plants. The System 80 program includes predictions, measurements and evaluation of the core support barrel, lower support structure and upper guide structure assemblies consistent with the guidelines reflected by Regulatory Guide 1.20. The developed program will be incorporated into the precritical testing of the lead System 80 plant. The program is made up of four distinct, yet closely

interrelated phases. These phases are designed to satisfy the guidelines of Regulatory Guide 1.20 and are described below.

3.9.2.4.1 Vibration Analysis Phase

Analytical and test-analysis methods are used to estimate the normal operating steady state and transient forcing functions. Dynamic response of the reactor internals components are then analytically determined for those forcing functions which correspond to preoperational and initial startup test and normal operating conditions. The methods employed in these analyses are described in sections 3.9.2.3.1 through 3.9.2.3.5. The final results of this phase of the program will be issued in a prediction report prior to the initiation of the second phase of the PVMP program. Included in the prediction report will be theoretical estimates of the forcing functions and associated structural responses, definitions of criteria, and the bases for the establishment of the criteria.

3.9.2.4.2 Vibration Measurement Phase

This experimental program will incorporate internal and external accelerometers, pressure transducers and strain gages, which will permit the recording of time-dependent accelerations, pressures and strains at specific locations. The type, number and position of the instrumentation is based upon the results of the phase one analysis and will be summarized in the instrumentation report to be issued prior to startup of the prototype plant. Measurements will be made during precritical testing. A general outline of the measurement program instrumentation is shown in Figures 3.9.2-7

to 3.9.2-9. Data collection will be done on a time history basis for subsequent reduction using methods of random data analysis (Ref. 32). Testing will be of sufficient duration to assure satisfaction of the NRC Regulatory Guide 1.20 requirement.

3.9.2.4.3 Inspection Phase

A visual inspection program, including photographic documentation, will be undertaken in accordance with Regulatory Guide 1.20 at the start and conclusion of the vibration measurement phase. Critical locations identified in phase one will all be inspected to establish the effects of vibration. These locations will include contact and potential contact surfaces between all major load bearing reactor internal components, lateral, vertical and torsional restraints, locking and bolting components.

3.9.2.4.4 Evaluation & Documentation Phase

A final report will be issued to summarize the results of the experimental PVMP program. This report (see section 3.9.2.6) will include a comparison between the measured and analytically determined responses and excitation to demonstrate the validity of the analytical techniques. An evaluation of the PVMP results with respect to design and test criteria will also be made to determine the margins associated with normal steady-state and anticipated transient operation.

3.9.2.5 Dynamic System Analysis of the Reactor Internals Under Faulted Condition

The analysis of reactor internals has been performed in accordance with the methods described in CESSAR Section 3.9.2.5. The calculated stresses are below the allowable stresses for faulted conditions of the ASME B&PV Code, Section III, Appendix F. (See Table 3.9.27A)

Dynamic analyses are performed to determine blowdown loads and structural responses of the reactor internals and fuel to postulated LOCA loadings and to verify the adequacy of their design. A brief description of these methods is provided below.

The LOCA maximum stress intensities in the reactor internals will be determined using the combinations of lateral and vertical LOCA time-dependent loadings which result in maximum stress intensities. The maximum LOCA stresses and the maximum stresses resulting from the SSE will then be combined using the root sum square method to obtain the total stress intensities.

3.9.2.5.1 Dynamic Analysis Forcing Functions

The hydrodynamic forcing functions during a postulated LOCA consist of transient pressure, flow rate, and density distributions throughout the primary reactor coolant system.

3.9.2.5.1.1 Hydraulic Pressure Loads

The transient pressure, flow rate and density distributions are computed for the subcooled and saturated portions of the blowdown period during a LOCA. The computer code utilized is

based on a node-flowpath concept in which control volumes (nodes) are connected in any desired manner by flow areas (flowpaths). A complex node-flow path network is used to model the Reactor Coolant System (RCS). The modeling procedure has been compared to a large scale experimental blowdown test with excellent agreement.

The laws of conservation of mass, energy and momentum along with a representation of the equation of state are solved simultaneously. The hydraulic transient of the reactor is coupled to the thermal response of the core by analytically solving the one dimensional radial heat conduction equation in each core node.

Pre-blowdown steady state conditions in the RCS are established through the use of specified input quantities.

The blowdown loads model uses a nonequilibrium critical flow correlation for computing the subcooled and saturated critical fluid discharge through the break.

3.9.2.5.1.2 Drag Loads

A break in the primary coolant system will result in large local pressure differences across various reactor vessel internal components and an acceleration of the local fluid velocity in various regions. The acceleration of the local fluid velocity can result in higher component drag loads than occur during steady state reactor operation.

3.9.2.5.1.3 Core Loads

The total instantaneous load across the core is given by the summation of the pressure forces acting in the direction of the pressure gradient and the drag forces acting parallel to the flow. The loads are obtained using a control volume approach utilizing an integrated fluid momentum equation. The drag forces are represented by the fluid shear term in this equation and consist of both frictional and form drag.

3.9.2.5.1.4 Control Element Tube Loads

During normal operation, the reactor coolant flows axially through the core into the upper guide structure. Within the upper guide structure, the coolant flow changes direction so that it exits radially through the hot leg nozzles. During a LOCA, the transverse flow of the coolant across the control element shroud tube gives rise to loads which induce deflections in these shrouds.

The transverse drag forces were determined from flow model experiments which were geometrically and dynamically similar to the full scale upper guide structure design. The measured experimental model forces were scaled up to represent the actual forces on the System 80 upper guide structure using the computed transient flow rate and density information.

3.9.2.5.1.5 Results of Blowdown Loads Analysis

Analysis was performed of a postulated pipe break at the reactor vessel inlet nozzle. The transient pressure differences throughout the vessel are evaluated and used in the

structural response calculation described below. The pressure difference across the core is also evaluated for the break.

A postulated pipe break occurring at the reactor vessel outlet nozzle was also analyzed. The pressure difference throughout the vessel is calculated. The decompression in the annulus is symmetric early in the transient because the pressure wave must travel through the core barrel internals to reach the lower plenum from where the wave propagates uniformly up through the downcomer. The axial pressure difference across the core was also calculated.

3.9.2.5.2 Structural Response Analyses

The dynamic LOCA analyses of the reactor internals and core determine the shell, beam and rigid body motions of the internals, using established computerized structural response techniques. The analyses consist basically of three parts. In the first part, the time-dependent shell response of the core support barrel to the transient loading is calculated using the finite-element computer code, ASHSD (section 3.9.1.2.3.4). The second part of the analysis evaluates the buckling potential of the core support barrel for hot leg break conditions using the finite-element computer code, SAMMSOR-DYNASOR (section 3.9.1.2.3.6). In the third part, the non-linear dynamic time history responses of the reactor internals and core to vertical and horizontal loads resulting from hot and cold leg breaks are determined with the CESHOCK code (paragraph 3.9.1.2.3.5).

3.9.2.5.2.1 Shell Response of the Core Support Barrel (CSB)

A cold leg break causes a pressure transient on the core support barrel that varies circumferentially as well as longitudinally. The ASHSD finite element computer code is used to analyze the shell response of the CSB to the pressure transient from a cold leg break.

The CSB is modeled as a series of shell elements joined at their nodal point circles as shown in Figure 3.9.2-2. The length of the elements in each model is selected to be a fraction of the shell attenuation length.

A damped equation of motion is formulated for each degree of freedom of the system. Four degrees of freedom, radial displacement, circumferential displacement, vertical displacement, and meridional rotation are considered in the analysis. The differential equations of motion are solved numerically using a step-by-step integration procedure.

The circumferential variation of the pressure time-history is considered by representing the pressure as a Fourier expansion. The pressure at each node in the model is determined by linear interpolation. Thus a complete spatial time load distribution compatible with the ASHSD computer program is obtained. Each load harmonic is considered separately by ASHSD. The results for each harmonic are then added to obtain the nodal displacements, resultant shell forces and shell stresses as a function of time.

3.9.2.5.2.2 Dynamic Stability Analysis of CSB

A hot leg break causes net external radial pressure on the core support barrel. A stability analysis of the CSB is performed using the finite-element computer code, SAMMSOR-DYNASOR. The effects of an initially imperfect shape based on the out-of-roundness tolerances are included in the analysis.

The CSB is modeled as a series of shell elements, as shown in Figure 3.9.2-10. Stiffness and mass matrices for the barrel are generated utilizing the SAMMSOR part of the code. The equations of motion of the shell are solved in DYNASOR using the Houbolt numerical procedure.

An initial imperfection is applied to the core support barrel by means of a pseudoload for each circumferential harmonic considered. The actual pressure transient loading generated by the outlet break is uniform circumferentially but varies longitudinally. The response is obtained for each of the imperfection harmonics.

Appendix F, Section III of the ASME Boiler and Pressure Vessel Code requires that permissible dynamic external pressure loads be limited to 75% of the dynamic instability pressure loads, or alternately, the dynamic instability load must be greater than 1.33 times the actual loads. Consequently, this analysis is repeated with the imperfection applied in the critical harmonic and the pressure loading is increased beyond 1.33 times the actual loads in order to demonstrate the stability of the core support barrel.

3.9.2.5.2.3 Dynamic System Analysis of the Reactor Internals

Dynamic analyses are performed to determine the structural response of the reactor internals to postulated asymmetric LOCA loading (including reactor vessel motion effects) and to verify the adequacy of their structural design. The postulated pipe breaks result in horizontal and vertical forcing functions which cause the internals to respond to both beam and shell modes.

Detailed structural mathematical models of the reactor internals are developed based on the geometrical design. These models are constructed in terms of lumped masses connected by beam or bar elements, and include non-linear effects such as impacting and friction. The models are developed for input to the CESHOCK code which solves the differential equations of motion for lumped parameter models by a direct step-by-step numerical integration procedure. The model definitions employ the procedures established in Combustion Engineering Topical Report CENPD-42 and, in addition, include hydrodynamic coupling effects and a detailed representation of the core support barrel to upper guide structure to reactor vessel interfaces. Separate models are formulated for the horizontal (Figure 3.9.2-11) and vertical (Figure 3.9.2-12) directions to more efficiently account for structural and response differences in those directions.

A revised horizontal model is used for the analysis of BLPB effects (Figure 3.9.2-11A).

The models for the horizontal directions are developed in terms of lumped masses connected by beam elements. The stiffness

values for the beam elements are generally evaluated using beam characteristic equations. The lumped-mass weights are based upon the mass distribution of the internals structures. Local masses such as plates and snubber blocks are included at appropriate nodes. The effect of the surrounding water on the dynamics of the internals for horizontal motion is accounted for by hydrodynamically coupling the components separated by a narrow annulus - the vessel, core barrel, and core shroud. The clearance between the core support barrel and the reactor vessel snubbers, as well as the clearance between the core shroud, guide lugs and the fuel alignment plate is simulated by non-linear springs which account for the loads generated when impacting occurs. A representation of the core is included in the internals models which provides appropriate inertial and impact feedback effects on the internals response.

The vertical model stiffness values are generally calculated using bar characteristic equations. Non-linear couplings are included between components to account for structural interactions such as those between the fuel and core support plate, and between the core support barrel and upper guide structure upper flanges. Pre-loads, which are caused by the combined action of applied external forces, dead weights, and holddowns are also included. Friction elements are used to simulate the coupling between the fuel rods and spacer grids.

A reduced model of the reactor vessel internals (Fig. 3.9.2-13) is developed for incorporation into the reactor coolant system model. The detailed non-linear horizontal and vertical internals (plus core) models are condensed and combined into a three-dimensional model compatible with the reactor coolant

system model and the computer programs through which the latter model is analyzed. The purpose of this reduced internals model is to account for the effects of the internals LOCA loads on the reactor vessel support motion and the structural loading interaction between the internals and the vessel. The reduced internals model is developed so as to produce reactor vessel support motions and loadings equivalent to those produced by the detailed internals models.

The dynamic responses of the reactor internals to the postulated pipe breaks are determined with the CESHOCK code utilizing the detailed models. Horizontal and vertical analyses are performed for both hot and cold leg breaks to determine the lateral and axial responses of the internals to the simultaneous internal fluid forces and vessel motion excitation.

The vertical excitation of the internals is calculated by the LOAD2 computer code (section 3.9.1.2.3.10) using a control volume method of analysis. In this method, the reactor internals are subsectioned and enclosed within volumes of solid plus fluid. The momentum equation is then applied to each volume, and a resultant force is calculated which is assigned to the structural node within the volume. This method takes into consideration pressure, fluid friction, momentum changes, and gravitational forces acting on each volume. The resulting load time histories are in a form consistent for CESHOCK code input.

In order to achieve an initial (prior to the pipe break) equilibrium, the initial static deflections and gaps are

calculated. The resulting initial conditions and load time histories are input to the CESHOCK code and the dynamic response of the model is calculated.

The horizontal input excitation resulting from a cold leg break are the core support barrel force time history and the vessel motion time history determined from the reactor coolant system analysis. The core support barrel forces are obtained by representing the asymmetric pressure distribution time history as a Fourier expansion. The two terms (sin θ and cos θ) which excite the beam mode of vibration are then integrated over the core support barrel and transformed into nodal force time histories.

The horizontal input excitation resulting from a hot leg break are the CEA shroud crossflow load time histories and the vessel motion time history determined from the reactor coolant system analysis. The forces applied to the shroud mass points are determined directly from the blowdown pressure time history and include the drag force and forces due to the pressure differential on the shrouds.

The results from these analyses consist of time dependent member forces, and nodal displacements, velocities, and accelerations. The load and displacement responses are used in the detailed stress analyses of the internals.

3.9.2.5.2.3.1 Dynamic System BLPB Analysis of the Reactor Internals

Dynamic BLPB analyses are performed to determine the structural responses of the reactor internals considering the effects of

the steam generator and value added fuel. The methodology used is the same as described in Section 3.9.2.5.2.3 except that the horizontal direction reactor internals model uses a single grouping to represent all of the fuel assemblies. This is done because the BLPB responses of the core boundary in the internals evaluation are low and no impacting of the peripheral assemblies occurs. The fuel assembly deflected shapes at times of peak relative displacement, shear and bending moments are determined using the results of a detailed core analysis of the shortest (7 assemblies) row across the core.

3.9.2.6 Correlations of Reactor Internals Vibration Tests with the Analytical Results

Comparison of analytical predictions with data obtained from precritical program will be addressed in an evaluation report, to be submitted shortly after completion of testing.

Table 3.9-4

DESIGN STRESS LIMITS FOR CLASS 2 AND 3 VESSELS, PUMPS, AND VALVES

(Sheet 1 of 2)

Component \ Plant Condition	Design[(a)] and Normal	Upset[(a)]	Emergency[(a)]	Faulted[(a)]
ASME Code Class 2 and 3 vessels	ASME Section VIII Division 1	$\sigma_m \leq 1.1S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.65S$	$\sigma_m \leq 1.5S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.80S$	$\sigma_m \leq 2.0S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 2.4S$
ASME Code Class 2 and 3 inactive pumps	ASME Section III NC-3400 or ND-3400	$\sigma_m \leq 1.1S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.65S$ $P_{max} \leq 1.1$ PD	$\sigma_m \leq 1.5S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.80S$ $P_{max} \leq 1.2$ PD	$\sigma_m \leq 2.0S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 2.4S$ $P_{max} \leq 1.5$ PD
ASME Code Class 2 and 3 active pumps	ASME Section III NC-3400 or ND-3400	$\sigma_m \leq 1.0S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.5S$ $P_{max} \leq 1.1$ PD	$\sigma_m \leq 1.1S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.65S$ $P_{max} \leq 1.2$ PD	$\sigma_m \leq 1.2S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.8S$ $P_{max} \leq 1.5$ PD
ASME Code Class 2 and 3 active and inactive valves (See notes 1 to 5 and 7)	Valve bodies shall conform to the requirements of ASME Section III NC-3500 or ND-3500	$\sigma_m \leq 1.1S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.65S$ $P_{max} \leq 1.1$ PD or rated pressure (see note 6)	$\sigma_m \leq 1.5S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 1.80S$ $P_{max} \leq 1.2$ PD or rated pressure (see note 6)	$\sigma_m \leq 2.0S$ $(\sigma_m$ or $\sigma_L) + \sigma_b \leq 2.4S$ $P_{max} \leq 1.5$ PD or rated pressure (see note 6 and 7)

a. Stress limits are found in the applicable code cases as discussed in UFSAR section 1.8, Regulatory Guide 1.48 Response B.

Table 3.9-4
DESIGN STRESS LIMITS FOR CLASS 2 AND 3 VESSELS, PUMPS, AND VALVES
(Sheet 2 of 2)

Definitions

σ_m = general membrane stress. This stress is equal to the average stress across the solid section under consideration. It excludes discontinuities and concentrations and is produced only by mechanical loads.

σ_L = local membrane stress. This stress is the same as σ_m except that it includes the effect of discontinuities.

σ_b = bending stress. This stress is equal to the linearly varying portion of the stress across the solid section under consideration. It excludes discontinuities and concentrations and is caused by mechanical loads only.

S = allowable stress values given in Tables I-7.1, I-7.2 and I-7.3 of Appendix I of the Section III Code. The allowable stress shall correspond to the highest metal temperature at the section under consideration during the condition under consideration.

P_{max} = maximum pressure resulting from upset, emergency, or faulted conditions.

The term "stress" in above definitions means maximum normal stress.

Notes pertaining to ASME Code Class 2 and 3 valves (active and inactive)

1. Valve nozzle (piping load) stress analysis is not required when both of the following conditions are satisfied by calculation:
   a. Section modulus and area of a plane, normal to the flow, through the region of valve body crotch is at least 10% greater than the piping connected (or joined) to the valve body inlet and outlet nozzles.
   b. Code allowable stress, S, for valve body material is equal to or greater than the code allowable stress, S, of connected piping material.

   If the valve body material allowable stress is less than that of the connected piping, the valve section modulus and area as calculated in a. above shall be multiplied by the ratio of S_{pipe}/S_{valve}. If unable to comply with this requirement, the design by analysis procedure of NB-3545.2 is an acceptable alternate method.
2. Casting quality factor of 1.0 shall be used.
3. These stress limits are applicable to the pressure retaining boundary, and include the effects of loads transmitted by the extended structures, when applicable.
4. Design requirements listed in this table are not applicable to valve discs, stems, seat rings, or other parts of valves that are contained within the confines of the body and bonnet, or otherwise are not part of the pressure boundary.
5. These rules do not apply to Class 2 and 3 safety relief valves. Safety relief valves will be designed in accordance with ASME Section III requirements.
6. Maximum pressure should not exceed the rated pressure of valve at the applicable plant conditions.
7. The PVNGS 120 day response to NRC Generic Letter 96-06, was transmitted to the NRC under APS Letter 102-03855-JML/AKK/JRP dated January 28, 1997. This response stated that the as built penetration configurations which do not have installed relief valves were evaluated and accepted by the NRC during initial PVNGS licensing and documented by reference in the PVNGS Safety Evaluation Report. PVNGS response to a request for additional information from the NRC provided, under APS Letter 102-04130-JML/SAB/RMW, dated June 4, 1998, detailed information on the methodology utilized to predict the response of the containment penetrations to thermally induced over-pressurization due to a LOCA. This response identified the use of ASME B&PV Code, Section III, Division 1-1974 Edition with Winter 1975 Addenda, Appendix F-1000 in the evaluation of the containment penetration piping and valve components as well as the reduction of fastener torque in the body to bonnet joint for some of the containment isolation valves. The maximum internal pressure that the valves are allowed to withstand was determined based on the elastic faulted stress method of ASME Code Section III, Division 1 – 1974 Edition, with Winter 1975 Addenda, paragraphs NB-3221, NB-3545.2 and Appendix F-1000, Subsection F1323.1(b).

E' = SSE
P_a = Accident pressure load
R_a = Pipe reactions due to postulated break
Y_r = Pipe whip load
Y_j = Jet impingement load
Y_m = Missile impact load

3.9.3 ASME CODE CLASS 1, 2, AND 3 COMPONENTS, COMPONENT SUPPORTS, AND CORE SUPPORT STRUCTURE.

Refer to section 3.9.3.5 and 3.9.3.6 for components in the C-E scope of supply, except that the following valves are added to the list of NSSS Seismic I Active Valves in Table 3.9.3-3, sheet 7 of 8:

Valve No.	System Name (Safety Function)	Line Size	Valve Type	ASME Section III Code Class	Actuator Type
CH 501	Volume Control Tank Discharge Isolation (Close)	4	Gate	2	Motor
CH 536	RWT Gravity Feed to Charging Pump Suction (Open)	4	Gate	3	Motor

The subsections 3.9.3.1 through 3.9.3.4 apply to all components not in the C-E scope of supply.

For plant conditions and loading combinations, the requirements of Regulatory Guide 1.48 are met except as noted in section 1.8.

3.9.3.1 Loading Combinations, Design Transients, and Stress Limits

Non-NSSS ASME Class 2 and 3 components and supports and ASME Class 1 piping are designed to an appropriate combination of plant conditions and design loadings. The plant conditions are design, normal, upset, emergency, faulted, and thermal conditions. The design loadings are pressure, temperature, dead weight, seismic, and dynamic loads.

The plant conditions and design loading combinations for ASME Code Class 1 piping outside the C-E scope of supply are indicated in table 3.9-8. Stress limits for Class 1 supports, bolting, and piping outside the C-E scope of supply are indicated in tables 3.9-9, 3.9-7, and 3.9-4, respectively.

The plant conditions and design loading combinations for ASME Code Class 2 and 3 components and supports outside the C-E scope of supply are indicated in table 3.9-10. Stress limits for Class 2 and 3 supports, bolting, piping and vessels, pumps, and valves are indicated in tables 3.9-11, 3.9-7, 3.9-6, and 3.9-4, respectively.

The methodology used for combining responses meets the requirements of NUREG-0408, Revision 1.

Piping components in essential ASME Code Class 1, 2, and 3 piping systems designed to level C or D service limits were shown to retain functionability for emergency and faulted plant conditions by meeting the screening criteria found in GE Topical Report, "Functional Capability Criteria for Essential Mark II Piping," (NEDO-21985), dated September 1978 (reference NRC memorandum to R. L. Tedesco, Assistant Director for Licensing, from J. P. Knight, Assistant Director for Components and Structures Engineering, dated July 17, 1980).

3.9.3.1.1 Design Load Combinations and the Associated Operating Plant Condition

3.9.3.1.1.1 Design and Normal Conditions. The design and normal conditions are as defined in NB-3112 and NB-3113 of ASME B&PV Code, Section III.

3.9.3.1.1.2 Upset Condition. Loads that are considered in upset plant operating conditions (defined in ASME Section III as those having a high probability of occurrence) include the following:

- Operating pressure
- Operating temperature
- Deadweight
- Open relief valve thrust
- Transient pressure effects
  - Fast valve closure
  - Closed relief valve discharges
- Earthquake (OBE)

Although the occurrence of an earthquake cannot be considered highly probable, the number of cycles associated with a seismic event are considered with the low stress allowables of the upset plant condition.

It should be noted that two different types of relief valves are categorized, open discharge and closed discharge, as described in paragraph 3.9.3.3.

The open discharge relief valve has a continuous blowdown thrust that can occur for a period of tens of seconds to minutes. The associated piping must be designed for this thrust. Since the maximum stress due to the relief valve thrust occurs over a significant period of time, coincident earthquake and relief stresses are assumed.

The case, however, for a closed discharge system is much different. During the long-term blowdown following the establishment of steady-state flow, the reactions on the discharge piping, relief valve, and inlet piping are balanced and no stresses are introduced as a result of relief valve blowdown. The time duration for the stresses induced during the transient preceding steady-state flow is approximately 500 milliseconds. After this period of time, the effects from valve blowdowns are damped out.

The results of time-history dynamic analysis, using very conservative damping ratios (0.5%), show that 3 to 10 stress cycles occur before steady-state blowdown.

It may be argued that an earthquake can cause a plant trip and consequential relief valve actuation. However, the probability of the maximum stresses from these transients (in a time sense) occurring at the same location, at the same instant in time and in place, is extremely low.

Further, the number of cycles (3 to 10) during which both are occurring also is extremely low.

Therefore, it is concluded that the combination of loads resulting from the OBE and the transient induced by relief valve actuation in a closed discharge system is not an upset plant condition. The same argument is made for the fast valve closure event. An example of this is the trip of the main steam turbine stop valves.

3.9.3.1.1.3 Emergency Conditions. Load combinations falling into this category are of low probability of occurrence.

Therefore, a higher design stress is allowed since the number of cycles is low. The coincident effects of OBE and transient pressures (discussed under upset) are evaluated as an emergency plant condition.

3.9.3.1.1.4 Faulted Condition. For the faulted condition, ASME piping, vessels, pumps, and valves are analyzed to the three design loading combinations shown in tables 3.9-8 and 3.9-10.

3.9.3.1.2 Design Stress Limits

3.9.3.1.2.1 ASME Code Class 2 and 3 Components. Stress limits on valves, pumps, and vessels are given in table 3.9-4.

3.9.3.1.2.2 ASME Code Class 2 and 3 Piping. Stress limits on piping are given in the subsequent listing:

A. Normal Conditions

Calculated stresses due to sustained loads and thermal expansion shall conform to the requirements of ASME Section III, NC-3600 or ND-3600. For calculated stresses due to occasional loads, the following shall be used.

B. Upset Conditions

The sum of stresses produced by loading combinations shown in table 3.9-10 for upset condition shall not exceed 1.2 times the allowable stress values given in Tables I-7.1, 1-7.2, and 1-7.3 of Appendix I of the ASME Code Section III or ND-3600. Under upset

conditions, Equation 9 of NC-3650 or ND-3650 shall be met (permissible pressure $\leq$1.1p).

C. Emergency Conditions

The sum of the stresses produced by the loading combinations shown in table 3.9-10 for emergency conditions shall not exceed 1.8 times the allowable stress values given in Tables I-7.1, I-7.2, and I-7.3 of Appendix I of the ASME Code, Section III. Under emergency conditions, Equation 9 of NC-3650 or ND-3650 shall be met using a stress limit of 1.8 S_h. Equations 8, 10, and 11 shall not be considered.

The permissible pressure shall not exceed 1.5 times the design pressure (P) calculated in accordance with Equation 4 of NC-3641.1.

D. Faulted Conditions (Code Case 1606)

The sum of the stresses produced by the loading combinations shown in table 3.9-10 for faulted condition shall not exceed 2.4 times the allowable stress values given in Tables I-7.1, I-7.2, and I-7.3 of ASME Code, Section III, Appendix I. Under faulted conditions, Equation 9 of NC-3650 shall be met using a stress limit of 2.4 S_h. Equations 8, 10, and 11 shall not be considered.

The permissible pressure shall not exceed 2.0 times the design pressure (P) calculated in accordance with Equation 4 of NC-3641.1.

3.9.3.1.2.3 ASME Code Class 1 Piping. Stress limits on ASME Code Class 1 piping not provided by C-E are given in table 3.9-5.

3.9.3.2 Pump and Valve Operability Assurance

3.9.3.2.1 Non-C-E-Supplied Active ASME Code Class 2 and 3 Pumps and Class 1, 2, and 3 Valves.

3.9.3.2.1.1 Pumps. Non-C-E-supplied, safety-related active pumps are subjected to in-shop tests which include hydrostatic tests of casing to 150% of the design pressure, and performance tests to determine total developed head, minimum and maximum head, net positive suction head (NPSH) requirements except as noted below, and other pump/motor characteristics. Where applicable, bearing temperature and vibration are monitored during the performance tests. For the diesel fuel oil transfer pumps, the NPSH data were developed by actual developmental testing of pumps of the same size. For the essential spray pond pumps, submergence is the relative parameter used to satisfy the NPSH requirement.

In addition to the required testing, the pumps are designed and supplied in accordance with the following specified criteria:

A. In order to ensure that the active pump will not be damaged during the seismic event, test or analysis is required to show that the lowest natural frequency of the pump is greater than 33 Hz. If the natural frequency is found to be above 33 Hz, the pump will be considered essentially rigid. This frequency is considered sufficiently high to avoid problems with

amplification between the component and structure for all seismic areas. A static shaft deflection analysis of the rotor is performed. The natural frequency of the support is determined and used in conjunction with the project seismic response spectra. The deflection determined from the static shaft analysis is compared to the allowable rotor clearances.

If the natural frequency is found to be below 33 Hz, an analysis is performed to determine the amplified input accelerations necessary to perform the static analysis. The static deflection analyses are performed using the adjusted accelerations.

B. The maximum seismic nozzle loads are also considered in an analysis of the pump supports to assure that unacceptable system misalignment cannot occur.

C. To complete the seismic qualification procedures, the pump motor and appurtenances vital to the operation of the pump are independently qualified for operation during the maximum seismic event in accordance with IEEE Standard 344-1975. If the testing option is chosen, sine-beat or sweep testing for the electrical equipment is justified by satisfying one or more of the following requirements to demonstrate that multifrequency response is negligible or the sine-beat or sine-sweep input is of sufficient magnitude to conservatively account for this effect:

1. The equipment response is basically due to one mode.

2. The sine-beat response spectra envelops the floor response spectra in the region of significant response.

3. The floor response spectra consists of one dominant mode and has a narrow peak at this frequency.

The degree of coupling in the equipment, in general, determines if a single or multiaxis test is required. Multiaxis testing is required if there is considerable cross-coupling. If coupling is very light, then single-axis testing is justified. Or, if the degree of coupling can be determined, then single-axis testing can be used with the input sufficiently increased to include the effect of coupling on the response of the equipment.

From this, it is concluded that the safety-related pump/motor assemblies will not be damaged and will continue operating under SSE loadings, and will perform their intended functions. These proposed requirements take into account the complex characteristics of the pump and are sufficient to demonstrate and assure the seismic operability of the active pumps. Results of these analyses are contained in the following paragraphs. For the results of pump motor seismic operability analyses refer to section 3.10.

3.9.3.2.1.1.1 Essential Cooling Water Pumps. A structural integrity and operability analysis of the essential cooling water pump (Ingersoll-Rand Model 16 x 23 S pump) was performed.

The components analyzed are those that comprise the pressure boundary, the rotating member, and the attachment of the pump/motor to the floor.

Tables 3.9-13 and 3.9-14 list the most important stresses and deflections. The upset condition was not analyzed as the emergency condition was more significant. The calculated stresses were within the allowable stress limits.

Two sets of figures for the shaft deflections are listed in table 3.9-14. The first numbers are the maximum sums of weight, g loads, and hydraulic loads, all assumed to act in the same direction. The numbers in parentheses represent expected normal or maximum deflections based on the following considerations: the normal deflection at the coupling, in reality, becomes zero when the pump and motor is aligned in the field; the shaft deflection relative values are reduced when the pump rotor is aligned. The impeller to casing ring clearance is equalized for 360 degrees during pump alignment and the bearing housing is pinned to the casing to prevent movement. The shaft deflection at the casing ring cannot exceed one-half of the ring clearance. Beyond this point, the casing ring acts as a bearing, during which time a hydrodynamic film is generated, maintaining a finite clearance between the rotor and casing.

Holddown bolting and shear pin loads are analyzed using a computer program to calculate the reactions at the pump/supporting structure interface. These reactions are then used to determine bolt stresses, shear pin stress, and the stresses in the pump casing feet.

The reactions are obtained by applying the external forces and moments along with the deadweight, seismic accelerations, driving torque, and, using the principles of statics, individual forces are determined. Maximum values are summed for a conservative analysis.

The program was checked by an independent reviewer and verified by a hand calculation.

Nozzle flange stresses are analyzed using a computer program to calculate the longitudinal hub stress, radial flange stress, and tangential flange stress in accordance with the ASME B&PV

Code, Section III, Subsection NA, Appendix XI and Subsection NC, Paragraph 3647.1.

This procedure incorporates the contribution of the external nozzle loads and internal pressure in the form of an equivalent pressure.

The program was checked by an independent reviewer and verified by hand calculation.

The natural frequency of vibration of the pump-motor assembly is shown to be above 33 Hz based on the detailed analysis of two directly comparable pumps. This detailed analysis is based on multidegree of freedom mathematical model and a structural mechanics computer program. The numerical value of the important parameters that determine the natural frequency of vibration are listed in table 3.9-15 for the essential cooling water pump.

Based on this comparison of the parameters, the natural frequency of vibration of the 16X23S pump-motor assembly will be above 33 Hz.

Past inservice experience with other pumps of this type indicates that the pump is capable of operating in a safe manner. The pump meets the performance criteria for structural integrity and operability in accordance with the design specification.

3.9.3.2.1.1.2 Essential Chilled Water Pumps. A structural integrity and operability analysis of the essential chilled water pump (Ingersoll-Rand Model 4X10AN) was performed.

The fundamental frequency of pump-motor-support frame is demonstrated to be above 33 Hz. Accordingly, a static analysis was performed.

The components analyzed are those that comprise the pressure boundary, the rotating member, and the attachment of the pump/motor to the floor.

Table 3.9-16 lists the most important stresses. Shaft deflections are calculated as 0.0012 inch under normal loading and 0.0023 inch with a 3g static load imposed. These deflections are less than the minimum clearance of 0.0085 inch between impeller and casing wear ring.

The ANSYS computer program was used to perform the structural analysis.

The nozzle flanges were analyzed in accordance with ASME B&PV Code, Section III, Subsection NA, Appendix XI, Article NC-3647. Internal pressure, axial force and bending moments are used. Visual factor is 0.8 as per ASME Table 1-7.1, footnote 4.

The stuffing box extension is a Class 3 component, and ASME B&PV Code, Division 1, ND-3325-2 (b), 1977 Edition was applied for analyzing the flange thickness. An Ingersoll-Rand verified computer program EAS-1-13 was used to calculate the maximum reaction at each pedestal bolt.

The pump was modeled and analyzed using the ANSYS computer program to determine the natural frequencies and mode shapes for the pump and motor assembly.

The pump stand, pump, and shaft were modeled as beams with distributed mass. Mass elements were added in the pump and motor areas to account for the total mass of these items.

The shaft was conservatively considered unsupported at the stuffing box and no credit was taken for the effects of the grouting. The actual grouting effects would stiffen the bedplate and raise the natural frequency, so this model is conservative.

A reduced modal analysis was performed. No rotational dynamic degrees of freedom were specified since the mode shapes at the lower natural frequencies are dominated by translation rather than rotation.

A static analysis with a 1g vertical acceleration was made first, followed by a natural frequencies and mode shapes run.

The first vibration mode has a natural frequency of 48.5 Hz. This mode is characterized by lateral displacement of the whole pump.

Natural frequencies for this pump assembly are sufficiently high such that the pump assembly may be treated as a rigid component for seismic analyses.

3.9.3.2.1.1.3 Condensate Transfer Pumps. The condensate transfer pump is a horizontal, single-stage, end-suction, frame-mounted-type unit, Ingersoll-Rand Model 2X10AN. The driver is an electric motor, with a nominal rating of 5 hp at

1750 revolutions per minute. The motor is coupled directly to the pump using a flexible type steel coupling. Both pump and motor are mounted on a common bedplate.

The fundamental frequency of pump-motor-support frame is demonstrated to be above 33 Hz. Static analysis techniques are therefore employed in evaluating the structural integrity and operability.

Pressure vessel and support structure components are analyzed in accordance with applicable methods and allowable stresses of the ASME B&PV Code, Section III.

A. Pressure Boundary

The pump casing and cover are analyzed by ASME Code design procedures to assure that the casting thicknesses of the parts are equal to or above the minimum requirements.

Material is SA-351 CF8M, for which the allowable stress is 17,500 psi. A casting quality factor of 0.8 is used. Stresses evaluated are the result of combined membrane and bending loads. The allowable stresses for the various operating modes, therefore, are:

Normal	(1.5)	(0.8)	(17,500)	=	21,000	psi
OBE	(1.65)	(0.8)	(17,500)	=	23,100	psi
SSE	(1.8)	(0.8)	(17,500)	=	25,200	psi

Pressure bolting is also analyzed for both the main flange and the shaft seal gland. Bolting material is SA-193 Grade B7, for which the allowable stress is 25,000 psi under normal load conditions. Seismic loads

do not contribute significantly to the stresses in these bolts.

B. Nozzle Flanges

The pump casing flanges are analyzed in accordance with the procedures of Section III, Subsection NA, Appendix XI, Subarticle NC-3647. Internal pressure and externally applied axial force and bending moments are applied. Allowable stresses are the same as those defined for the casing. Detailed calculations are performed using a verified computer program which utilizes the equations given in the Code procedures. Nozzle loads are given in table 3.9-17.

C. Anchor Bolts

Anchor bolts are used along the edges of the bedplate to fasten the entire pump assembly to the floor. The loads and stresses are analyzed. No credit is taken for restraining effects of the grout which is to be used at the final installation.

D. Shaft

The natural frequency of the shaft is determined, to assure that there is a safe margin above 33 Hz.

To assure that operability requirements are satisfied, the shaft deflection at the impeller under the maximum anticipated seismic load and radial thrust (hydraulic) load is determined and compared to the minimum running clearances designed into the pump.

Table 3.9-17
PRIMARY LOADS ON CONDENSATE TRANSFER PUMP NOZZLES

Plant Condition	Suction and Discharge Nozzles	
	Moment, M (Lb-In.)	Force, F (Lb-In.)
Primary		
Normal, N_n	1,800	150
Upset, N_u	2,270	190
Emergency, N_e (DBE)	2,570	215
Faulted, N_f (SSE)	5,440	450
Primary and Secondary		
	6,030	500

Notes:

1. Attached piping for both nozzles is 3 inches Schedule 40.

2. All forces F_x, F_y and F_z and all moments M_x, M_y, and M_z act concurrently.

   Magnitudes: $F_x = F_y = F_z = F$ $M_x = M_y = M_z = M$

Seismic Loading

OBE: 1.0g

SSE: 1.6g

Notes:

1. Analysis established that the pumps are rigid equipment; hence, the listed values are for zero period acceleration (ZPA), floor-mounted devices.
2. The seismic components are applied in the two horizontal and the vertical direction simultaneously.

CONDENSATE TRANSFER PUMPS
DETAILED STRESS ANALYSES (Sheet 4 of 4)

Part	Load Case	Stress	Calculated (psi)	Allowable (psi)
Shaft	-	Torsional	469	7,500
Shaft natural frequency		10,713 rpm		
Running speed		1,750 rpm		
Pump rotor deflection at wear rings (SSE)			0.0038 in.	
Radial clearance at wear rings			0.008 in.	
Drive Motor				
First critical of shaft/rotor assembly is			155.3 Hz	
Maximum rotor deflection (SSE)			0.0036 in.	
Radial clearance			0.0148 in.	

E. Results

The lowest natural frequency of the pump-driver-bedplate assembly was established by analysis to be 61.3 Hz.

The wall thickness of the casing is found to be well above the required minimum, by code. When seismic acceleration and externally applied nozzle loads were superimposed on the pressure load, stresses are still found to be within prescribed limits.

Pump and motor holddown bolts, anchor bolts, and the most highly loaded portions of the bedplate were also analyzed and deemed acceptable.

Operability considerations addressed were shaft natural frequency and the running clearances within the pump. The first critical was found to be well above running speed, and maximum deflection at the impeller ring fits will be less than the running clearance provided.

Results of the detailed stress analyses are given in table 3.9-18.

3.9.3.2.1.1.4 Fuel Pool Cooling Pumps. The 8X17A horizontal centrifugal pump is used for fuel pool cooling. The pump is of the single-stage, end-suction volute type and is driven by a Westinghouse motor of 100 hp at 1180 revolutions per minute.

The first natural frequency of the assembly has been demonstrated to be 59 Hz, and the pump is thus a rigid structure.

The analysis is done according to ASME B&PV Code, Section III, Subsection NA, Appendix XI, Article NC-3647.

Flange material is ASME SA-351 CF8M, and the visual qualification factor is 0.8. The material allowable stresses are 19,800 psi, 21,780 psi, and 23,760 psi for the three load cases, respectively.

The reaction of each pedestal bolt is conservatively calculated. Since there is one pin to each foot, the pin will take up twice the bolt shear load. Stresses of the bolting and foot are calculated and compared.

Results of detailed stress analyses are given in table 3.9-19.

3.9.3.2.1.1.5 Auxiliary Feedwater Turbine-Driven Pump. A seismic, stress, and deflection analysis of the auxiliary feedwater turbine-driven pump (Bingham-Willamette Model 4 x 6 x 10-1/2 MSD 8 stage) was performed. The components analyzed are those that comprise the pressure boundary, the rotating member, the pump/turbine sole plate, and attachments to the floor. The turbine driver was analyzed separately.

Table 3.9-20 lists the more important stresses and deflections.

A dynamic model of the pump was developed and a computer frequency analysis made. The frequency analysis of the assembly shows that the pump and bedplate are rigid. The turbine was analyzed separately and found to be flexible.

A static analysis was made of the assembly, with 1.5 times the peak of the response spectra curve applied to the turbine center of gravity to account for the effect of the turbine on the bedplate and pump.

The pump and turbine nozzle loads, normal loads, and seismic loads are imposed on the same model used for the frequency analysis and a stress and deflection analysis of the pump and plate was made.

The pump nozzle discontinuity stresses are calculated by the method of the ASME Code, ND-3652, where the pump casing/discharge nozzle intersection is treated as an equivalent tee in a conservative manner. The pump suction nozzle is treated as an equivalent tee.

The pump discharge and suction flanges are treated by the method of the ASME Code, ND-3647, for the normal loads and external forces and moments caused by weight and thermal. Seismic loads were also considered.

The pump rotor/shaft was analyzed separately in accordance with the design specification.

The computer analysis for the frequencies is performed by use of the ICES-STRUDL computer program operating on an IBM 370/158 computer. Certain assumptions are made in developing the model.

These assumptions are made such that the model would be more flexible than the actual assembly. Thus, the frequencies predicted by the model will be lower than the actual frequencies.

Some of these assumptions are:

A. The bedplate is assumed to be supported only at the foundation bolts. This is true for upward forces, but for downward forces the bedplate channel flanges are continuously supported.

B. The turbine could help restrain the pump in the direction parallel to the shaft centerline by transmitting forces through the coupling. This is not included in the model since the coupling connection is not positive in that direction. This is also not desirable since this would impose thrust loads on the pump and turbine bearings.

The local flexibility of the turbine is not included in the model, but the effect of the turbine upon the pump/bedplate is included.

To account for the turbine flexibility, 1.5 x the peak of the spectra curve loads are applied for the turbine frame only. The turbine sole plate is rigid.

The turbine (Terry Turbine Model Number G5-2N) is analyzed separately. A similar turbine assembly has been shake tested and the results of this test are used for seismic qualification of the auxiliary feedwater pump turbine. The turbine tested was the same model turbine but differed in the configuration of the mounting plate.

A supplementary analysis was performed to qualify parts not subject to heat. Table 3.9-21 itemizes the type of qualification. Results of the seismic test were reviewed and an analysis made of deviations observed during testing. Minor modifications were incorporated into the turbine design as a result of seismic testing. It was concluded that turbine seismic operability was satisfactorily demonstrated.

3.9.3.2.1.1.6 Auxiliary Feedwater Motor-Driven Pump. A seismic, stress, and deflection analysis of the auxiliary

feedwater motor-driven pump (Bingham-Willamette Model 4 x 6 x 10-1/2 MSD 8 stage) was performed.

Table 3.9-22 lists the more important stresses and deflections.

A dynamic model of the pump was developed and a computer frequency analysis made. The lowest frequency of the pump was shown to be 40 Hz, and thus it can be treated statically.

The nozzle loads, seismic loads, and normal loads were imposed on the computer model and a stress and deflection analysis of the entire assembly was made.

The nozzle discontinuity stresses were calculated by the method of the ASME Code, ND-3652, where the pump casing/discharge nozzle intersection is treated as an equivalent tee in a conservative manner. The suction nozzle was treated as an equivalent tee.

The discharge and suction flanges were treated by the method of the ASME Code, ND-3647, for the normal loads and external forces and moments caused by weight and thermal. Seismic loads were also considered.

The pump rotor/shaft was analyzed separately in accordance with the design specification.

The motor holddown bolt stresses for the upset/emergency case are 5406 psi tensile and 7270 psi shear compared with allowable stresses of 16,368 psi tensile and 10,000 psi shear.

a. These are faulted case stresses and allowable.

The computer analysis for the frequency analysis was performed by use of the ICES-STRUDL computer operating on an IBM 370/158 computer. Certain assumptions were made in developing the model. These assumptions were made such that the model would be more flexible than the actual assembly. Thus, the frequencies predicted by the model will be lower than the actual frequencies.

Some of these assumptions are:

A. The bedplate is assumed to be supported only at the foundation bolts. This is true for upward forces but for downward forces the bedplate channel flanges are continuously supported.

B. The motor could help restrain the pump in the direction parallel to the shaft centerline by transmitting forces through the coupling. This is not included in the model since the coupling connection is not positive in that direction. This is also not desirable since this would impose thrust loads on the pump and motor bearings.

3.9.3.2.1.1.7 Diesel Fuel Oil Transfer Pump. A static analysis shows the pump to have a natural frequency greater than 33 Hz. Accordingly, a 3g horizontal and vertical seismic load is applied. Calculated values of stresses and deflections are listed in table 3.9-23.

Discharge pipe	0.234	0.3125
Retainer	0.105	0.25

Calculations are performed for this pump in the dry condition. This is considered the most severe condition since the affect of the fluid would be to dampen or cushion the acceleration forces. One exception is taken to this; the radial thrust force is taken into consideration for impeller calculations.

The affect that various loadings have relative to the analysis are discussed below.

The only operating load considered critical, other than seismic conditions, is radial thrust. This force affects the deflection of the rotor and impeller.

As the discharge pipe is fixed to the coverplate, the nozzle loads are not transmitted to the pump or the support. They do have an effect on the coverplate, the discharge pipe weld and on the anchor bolts. The effects are investigated in this analysis using the maximum loading combinations for a faulted condition.

The calculated stresses in this report have been compared to the working stress limits as specified by the ASME Code, Section III. A study of the cross-section of the pump suggests that seismic forces would have little or no effect. This is due to the general compactness and relative mass of the component parts. Horizontal and vertical forces are assumed to act through the center of gravity of the pump being analyzed. For calculation purposes, the center of gravity can be considered to be located on the axes of the pump, with little or no effect on the final results.

Temperature is not considered to have any critical effect. The allowable stresses for the materials of construction are based

on values shown in Section III of the Code for a design temperature of 200F.

The calculated rotor and impeller deflections are compared to the value of the corresponding deflection which would cause rubbing or interference of the pump's operation. The calculated bearing load will be compared to the design bearing load.

3.9.3.2.1.1.8 Essential Spray Pond Pump. A structural integrity and operability analysis of the essential spray pond pump (Bingham-Willamette Model Number 24 x 38 BVTM) was performed.

A dynamic computer model of the pump was developed and the masses lumped at appropriate places. The ANSYS structural program was employed for the study and the lowest natural frequency of the system was found to be 32.26 Hz. Hence, a seismic analysis was conducted using the SSE spectra from which the stresses and deflections were obtained. The same computer model was used to conduct static analyses for nozzle loads and dead weight. The pump structure was analyzed for 150 psi internal pressure loading. The faulted condition combining these load cases is the critical condition. The component stresses for individual load cases are added algebraically to obtain the maximum stress values. These stresses are found to be within the specified allowables. Table 3.9-24 lists a summary of the stresses.

The effect of hydraulic thrust on the suction bell, impeller, bowl, and shaft has been included to obtain maximum stresses in these components. The highest temperature of 200F that the

pumped fluid attains is considered and, accordingly, the allowables at that temperature are used for the analysis.

The SSE response spectrum (acceleration vs. frequency) for the floor-mounted device was applied in X, Y, and Z directions individually and the stresses in each element of the computer model for the first six mode shapes obtained through computer runs. For each excitation (in X, Y, and Z directions) the individual element stresses due to modal responses are obtained by using the SRSS method. The total stresses are obtained by summing the SRSS stresses due to individual X, Y, and Z excitations. These stress values are used to analyze the faulted condition.

Appendix 1, by the specified factor of 1.8 for faulted condition.

3.9.3.2.1.2 Valves. Refer to section 3.9.3.6 for testing criteria of NSSS and containment spray system. Non-C-E scope safety-related active valves, 2 inches and larger nominal pipe size, are listed in table 3.9-25. Combustion Engineering scope safety-related active valves, 2 inches and larger nominal pipe size, which are plant specific to PVNGS and not provided in section 3.9.3.6, are listed in table 3.9-26. Safety-related active valves are subjected to the following tests: hydrostatic test in accordance with ASME Section III requirements, main seat leakage tests, functional tests that verify that the valve will open and close within the specified time limits when subjected to the maximum expected differential pressure, and operability qualification of motor operators for the environmental conditions over the installed life (i.e.,

Table 3.9-24
ESSENTIAL SPRAY POND PUMP - SUMMARY OF
MAXIMUM STRESSES AND ALLOWABLES

Item	Max Stress[a] (psi)	Allowable Stress[a] (psi)
Suction bell	12,114	33,660

Shaft keys	17,461	52,434
Driver stand	2,615	31,500

a. The allowable stresses given above are obtained by multiplying the values given in ASME Section III, Division 1, Appendix 1, by the specified factor of 1.8 for faulted condition.

aging, radiation, accident environment simulation, etc.) in accordance with the general format and qualification procedure of IEEE 382-1972, IEEE 323-1974, and IEEE 344-1975. Normal and abnormal conditions to which the valves are subjected are discussed in section 3.11.

Periodic inservice testing is performed to verify and assure the functional ability of the valve. These tests enhance reliability of the valve for the design life of the plant. Note that the lists of active valves in Tables 3.9-25, 3.9-26, and 3.9-27 are not necessarily identical to the list of valves in the Pump and Valve Inservice Testing Program, because these lists serve different purposes. Refer to UFSAR Section 3.9.6.2 for additional information on inservice testing of valves.

The valves are designed using either stress analysis (described by ASME Section III) or standard design rules for minimum wall thickness requirements. On active valves with extended top works, an analysis is also performed for static equivalent SSE loads applied at the center of gravity of the extended structure.

The maximum stress limits allowed in the analyses are those recommended by the ASME for the particular ASME class of valve analyzed.

In addition to these tests and analyses, the operability of the valve during an SSE is demonstrated by satisfying the following criteria:

A. The active valves with extended top works are designed to have a first natural frequency greater than 33 Hz. This may be shown by test or analysis. Valves with a

first natural frequency less than 33 Hz are discussed below.

B. The structural integrity of the valve is qualified by requirements that the nozzle loads due to the SSE (emergency or faulted plant condition) are considered as a normal load for the active valve, including supports when required to operate after SSE.

C. The motor operators and other electrical appurtenances necessary for operation are qualified for operability during SSE as described in section 3.10.

D. The complete valve assembly is qualified by test or analysis or both for operability during the SSE. The valve assembly is only qualified by analysis in cases where structural integrity alone is sufficient to assure operability.

For the seismic operability test, the valve is mounted in a manner that conservatively represents a typical plant installation. The valve includes the actuator and appurtenances normally attached to the valve when in service.

The extended top works of the valve are subjected to a statically applied equivalent seismic load of 1.6g horizontally and vertically for floor-mounted valves and 3g horizontally and vertically for line-mounted valves. Vertical load in the static test may be excluded when it is not a contributing factor.

b. For application of the single failure rule to check valves, refer to Section 3.1.30.

The load is applied at the center of gravity of the operator in the direction of the weakest axis of the yoke. The design pressure of the valve is simultaneously applied to the valve during the static load tests.

The valve is then operated while the equivalent seismic static load is applied; i.e., from the normal operating status to the faulted operating status. The valve must perform its safety-related function within the specified operating time limits. Three minutes testing is required.

If the frequency of the valve, by test or analysis, is less than 33 Hz, a dynamic analysis of the valve is performed to determine the equivalent acceleration, considering the natural frequency of the valve and the frequency content of the applicable plant floor response spectra. The equivalent acceleration is then used in the static analysis and the valve seismic operability test.

The seismic operability test applies only to valves with overhanging structures; i.e., the motor operator. The valves are tested with appropriate external loads and seismic excitation as a unit and qualified using input motion which develops test response spectra equal to or greater than the required floor response spectra. The testing is conducted on a representative number of valves. Valves from each of the primary safety-related design types; e.g., motor-operated control valve, are tested. Valve sizes that envelop the range of sizes in service are qualified by the tests and the results are used to qualify all valve sizes within the envelope.

Stress and deformation analyses are used to support the interpolation.

Valves without extended structural features that are safety-related but can be classified as not having an overhanging structure, such as check valves, are considered below. Refer to table 3.9-27 for safety-related check valves 2 inches and larger. Check valves are characteristically simple in design. The effects from seismic accelerations or the maximum applied nozzle loads on their operation are negligible. The check valve design is compact and there are no extended structures or masses whose motion can cause distortions that can restrict operation of the valve. The nozzle loads due to maximum seismic excitation will not affect the functional ability of the valve since the valve disc is designed to be isolated from the casing wall. The clearance supplied around the disc by the design will prevent the disc from becoming bound or restricted due to any casing distortions caused by nozzle loads. Therefore, the design of these valves is assured, using standard design or analysis methods, and the ability of the valve to operate is assured by the design features. In addition to these design considerations, the valve also undergoes the following tests and analyses:

- Stress analysis as a part of the piping system including the SSE loads
- In-shop hydrostatic test
- In-shop seat leakage test

- Periodic in situ valve exercising and inspection to assure the functional ability of the valve

3.9.3.2.1.2.1 Anchor/Darling Gate Valves -- Limitorque Actuators. Natural frequency of each valve assembly (valve plus actuator) was determined by a multimass finite-element model analysis to be greater than 33 Hz. A static stress analysis was performed using a static seismic loading of 3g. The maximum stresses and deflections were calculated. A static operability test was conducted on a representative group of valves to verify operability during a safe shutdown earthquake condition. The Limitorque motor actuators were environmentally and seismically qualified by the manufacturer, Limitorque. Nonmetallic parts of the valve, such as packing and gaskets, were environmentally qualified by analysis.

3.9.3.2.1.2.2 Anchor/Darling Main Steam and Feedwater Isolation Valves. A hydraulic actuator for the main steam and feedwater isolation valves was subject to seismic testing.

Testing was performed using a shake table. Nonmetallic components, such as seals, and electrical equipment were subjected to irradiation and temperature aging prior to the seismic test program.

3.9.3.2.1.2.3 Dresser Globe Valves -- Rotork Actuators. Natural frequency of each valve assembly (valve plus actuator) was determined by a one degree of freedom, mass-spring model analysis to be greater than 33 Hz. A static stress analysis was performed using a static seismic loading of 3g. The maximum stresses and deformations were calculated. A static operability test was conducted on a representative group of valves to verify operability during a safe shutdown earthquake condition. The Rotork motor actuators were environmentally qualified by the manufacturer, Rotork. Nonmetallic parts of the valve, such as packing and gaskets, were environmentally qualified by analysis.

3.9.3.2.1.2.4 Henry Pratt Butterfly Valves -- Limitorque Actuators. A type test was performed on these valve sizes, and the other valve sizes are qualified by comparison and analysis. The valves tested were subject to leakage test, cold cycling, static seismic loading, hot cycling, and dynamic seismic testing. The valve actuators were qualified separately by the manufacturer, Limitorque.

3.9.3.2.1.2.5 Anchor/Darling Gate Valves -- Parker-Hannifin, Miller Fluid Power, and Chicago Fluid Power Pneumatic Actuators. Natural frequency of each valve assembly (valve plus actuator) was determined by a multimass, finite-element model analysis. The qualification of these valves was performed either by static or dynamic analysis based on the valve assembly's natural frequency. The stress analysis was performed using a seismic loading of 3g. The maximum stresses and deflections were calculated. A static operability test was

conducted on a representative group of valves to verify operability during a safe shutdown earthquake condition. The pneumatic actuator Class 1E parts (limit switches-Namco, solenoid valves-Asco and Valcor) were qualified separately by the individual suppliers. Environmental qualification of the air cylinder consisted of identifying and analyzing the non-metallic degradable parts which, if they failed, would prevent the actuator from closing the valve. Nonmetallic parts of the valve, such as packing and gaskets, were environmentally qualified by analysis.

3.9.3.2.1.2.6 Henry Pratt Butterfly Valves -- Bettis Pneumatic Actuators. The containment purge isolation valves were qualified by analysis. The valve actuator type test was performed and qualified separately by the manufacturer, GH Bettis Corporation. The test valve assembly (valve plus actuator) was subjected to operability testing; e.g., leakage, cold cyclic, hot cyclic temperature-pressure, seismic, and vibration testing.

3.9.3.2.2 C-E-Supplied Active ASME Code Class 2 and 3 Pumps and Class 1, 2, and 3 Valves

Refer to section 3.9.3.6 and Table 3.9.3-3 as augmented for PVNGS specific equipment.

3.9.3.2.2.1 Pumps for PVNGS Specific Equipment.

Active Components	Active Safety Function
Containment spray pumps	Operate

3.9.3.2.2.1.1 Containment Spray Pumps. Operability of the containment spray (CS) pumps under faulted conditions has been demonstrated by analyses of the assemblies and by analyses and tests of the motors in accordance with the recommendations of Regulatory Guide 1.48.

A. Structural Integrity[2]

Component		Calculated (psi)	Allowable (psi)
Casing foot attachment		15,913	28,050
Casing discharge nozzle attachment		7,849	28,050
Casing suction nozzle attachment		17,800	28,050
Main flange bolting		22,225	37,500
Foot		20,720	24,300
Foot weld		20,054	24,300
Anchor bolting	Tension	17,143	40,000
	Shear	6,202	15,390
Support head		1,029	18,900
Motor attachment bolting		9,845	37,500

B. Operational Deflection[2]

Description	Calculated (in.)	Allowable (in.)
Rotor/stator deflection (motor air gap)	0.0020	0.0500
Impeller/ring deflection	0.0055	0.0115
Shaft/cover deflection at mechanical seal	0.0023	0.0100

C. Operability was demonstrated under the following loads[2]

CS Pump

Horizontal seismic, (g)	1.1
Vertical seismic, (g)	1.1
Design pressure (psig)	710
Suction nozzle resultant force, (lb)	10,607
Suction nozzle resultant bending moment, (ft-lb)	50,000
Discharge nozzle resultant force, (lb)	6,500
Discharge nozzle resultant bending moment, (ft-lb)	16,000

To complete the operability demonstration, the motors were qualified to IEEE 323-1974 and IEEE 344-1975[3].

CH-757	CVCS (Open)	3	Packless diaphragm	2	Manual

3.9.3.3 Design and Installation Criteria, Pressure-Relieving Devices

Pressure vessels are protected by pressure-relieving devices to meet applicable code requirements such as ASME Code, Section III, Section VIII, and ANSI B31.1.

The design of pressure-relieving devices generally can be grouped in two categories, open and closed systems.

A. Open System

An example of an open system is a relief valve discharge elbow open to the atmosphere.

1. Main Steam Lines and Relief Valve System

Each main steam line is designed to withstand the maximum possible discharge flow from any one relief valve and also from the full steam generator capacity with all valves discharging simultaneously. A stress analysis is performed to determine the effects on the main steam lines, assuming that all steam generator relief valves discharge concurrently. The design of a safety and relief valve system shall include consideration of all components of the system; safety or relief valve, upstream piping or header, downstream or vent piping, system support, and structures or buildings to which the supports are attached.

The most severe load combination is considered as follows: internal pressure, dead weight, seismic, thermal, and reaction forces of blowing valves including entrainment.

The maximum allowable internal pressure in the main steam piping or header at the safety valve inlet nozzle is 110% of the steam generator shell design pressure as specified by the ASME Code.

Relief valve connections will be spaced on the header so that there is no local interaction.

Reaction force and moment effects on the steam header, supports, and connecting nozzles for each valve blowing, and for combinations of valves blowing, shall be considered. The steady blowdown load is not transmitted to the header but is carried by the structure, using a piston type design.

The reaction force of the flowing valve is obtained from the valve manufacturer; however, the manufacturer's reaction force is verified by the total hydraulic reaction force analysis for a discharging jet of fluid, comprised of a pressure area contribution and fluid momentum contribution, referring to the outlet plane of the flow geometry.

Dynamic amplification of the reaction force is considered using a dynamic load factor of 2.0. Amplification load factor is defined as the ratio of the dynamic deflection at any time to the deflection which would have resulted from the static application of the load.

Stress analysis of the safety and relief valve system is conducted including evaluation of the header local stresses due to reaction moment when

applicable. The stresses are categorized according to the appropriate code.

Material thicknesses are selected to accommodate expected loads and maintain stresses within allowable limits.

B. Closed System

1. Pressurizer and Relief Valve Systems

The pressurizer in the RCS is provided with four spring-loaded ASME Code, Section III, Class 1 safety valves connected to the top of the pressurizer for overpressure protection and transient pressure control and is designed in accordance with ASME B&PV Code, Section III, Class 1. These valves discharge through a closed piping system to the reactor drain tank, where the steam is condensed and cooled by mixing with water. The system arrangement is shown schematically in engineering drawings 01, 02, 03-M-RCP-001, -002 and –003.

The transient force is included in the analysis to assure that the pressurizer nozzle, the safety valve, and the connecting piping (Safety Class 1) will not fail when the valve operates.

2. Hydraulic Forces

The pressurizer safety valve discharge piping system is a closed system so that no sustained reaction force from a free discharging jet of fluid can exist. However, transient hydraulic forces can be imposed at various points in the piping system from

the time a safety valve begins to pop open until steady flow is completely developed. In order to evaluate these transient forces, an analytical model is developed which incorporates technology applied from existing analyses of the blowdown during LOCA. The analytical model and its application is estimated to be a conservative representation of the transient forces.

3. Load Combinations

   One of the most important considerations related to the mechanical design and analysis is the identification and calculation of the loads and load combinations imposed on the system. The following is considered in determining the most severe combinations: internal pressure; dead weight; seismic, thermal, transient hydraulic forces in closed piping system.

4. Internal Pressure

   The maximum design pressure in relief lines has been incorporated in the stress analysis of pressure-relieving devices.

5. Safety Valve Flow

   The rated flow of the safety valves is based on the total relieving capacity required to prevent pressurizer pressure from exceeding the maximum stated in item 4 above. However, based on ASME Code, the rated flow of a safety valve is no more than 90% of the actual flow-relieving capacity. In

the development of the hydraulic forces on the discharge piping, maximum flow capacity is applied.

6. Thermal

   The design of the safety valve system considers the differential thermal growth and expansion loads, as well as the local effects of reinforcing and supports. The design also considers the differential thermal growth and expansion loads existing after any combination of safety valves (one valve to all valves) operates, raising the temperature of the discharge piping.

7. Safety Valve Cycling

   Pressurizer safety valves are full-life, pop-type valves, and are essentially full-flow devices, with no capability for flow modulation. In actual pressure transients, the steam relief flow required to prevent overpressure is a varying quantity, from zero to the full rated capacity of the safety valves. As a result, the valves will be required to open and close a number of times during the transient. Since each opening and closing produces a reaction force, consideration is given to the effect of multiple valve operations on the piping system, including supports. For design purposes, it is assumed that each safety valve will experience 80 occurrences of valve operation transients and each occurrence will include 20 cycles of individual safety valve operations, for a 40-year plant life.

C. Supports

The following support system criteria apply:

1. A support is provided on the discharge piping as close as possible to each safety valve discharge nozzle so that forces and moments will not jeopardize the integrity of the valves, the inlet lines to the valves, or the nozzles on the pressurizer.

2. Each straight leg of discharge piping has a support to take the force along that leg. Where the support is not on the leg itself, it is as near as possible on an adjacent leg.

3. Where a large portion of the system lies in a plane, the piping is supported normal to that plane even though static calculations do not identify a direct force requiring restraint in that direction. Dynamic analyses of these systems have shown that out-of-plane motions can occur.

4. Either hydraulic snubbers or rigid supports may be applied, consistent with the requirements for thermal expansion and seismic support.

D. Stress Analysis

Open discharge systems are analyzed using a static method of analysis. To ensure consideration of the effects of fast valve opening, a dynamic load factor (DLF) of 2.0 is applied to the steady-state forces and moments. This method of analysis is conservative, and follows the guidance of Regulatory Guide 1.67. Closed

discharge systems are dynamically analyzed considering the transient hydraulic forces imposed on the structural piping system. If a static analysis is performed on closed discharge systems, additional justification will be provided.

3.9.3.4 Component Supports

3.9.3.4.1 NSSS Supports

Supports for ASME Section III Code Class 1 components in the CESSAR scope are specified for design in accordance with the loads and loading combinations discussed in section 3.9.3.5.

In addition to the normal operating and seismic supports, component stops are employed to limit displacements for postulated pipe breaks. Where a component stop is designed solely to control movement following a postulated pipe break, only the design loading combination (d) of section 3.9.3.5 is specified.

Component supports which are loaded during normal operation, seismic and following a pipe break are specified for design for loading combinations (a) through (d) of section 3.9.3.5. Component stops which are loaded only following a pipe break are specified for design for loading combination (d). Design stress limits applied in evaluating loading combinations (a), (b), and (c) of section 3.9.3.5 are consistent with the ASME Code, section III. The design stress limits applied in evaluating loading combination (d) of section 3.9.3.5 are in accordance with the ASME Code, Section III. Loads in compression members are limited to 2/3 of the critical buckling load.

To insure that pipe restraints and component stops do function independently of the normal support system, the motions of the intact pipe due to all normal and upset plant conditions and vibratory motion of the SSE are calculated and used to specify a minimum clearance between the pipe and the restraint. Wherever possible, gaps between pipes and restraints are maximized to avoid possible contact during plant operation. Where a particular location requires minimizing a gap, special features are provided to permit adjustment of the gap size during hot functional testing in order to decrease the uncertainty in the calculated pipe motion in the vicinity of the restraint.

3.9.3.4.2 Non-NSSS Supports

Refer to subsection 3.6.2 for a description of supports required to absorb loads due to the dynamic effects of piping ruptures.

Loading combinations, design transients, and stress limits for the design of Code Class 1, 2, and 3 component supports are provided in paragraph 3.9.3.1. The analysis for such supports complies with Subsection NF of Section III of the ASME B&PV Code as indicated within the design specification.

Supports for active pumps and valves are included in the overall design and qualification of the component. Refer to subsection 3.9.3 for test and analysis of components and supports for active components.

3.9.3.5 Loading Combinations, Design Transients, and Stress Limits for CE Scope

ASME Section III Code Class 1, components, supports and piping in the CESSAR licensing scope are limited to the reactor coolant system main loop and the pressurizer. The loading combinations specified for the design of CESSAR Code Class 1 components, supports, and piping are categorized as normal, upset, emergency and faulted. The following specific loading combinations are specified for design:

A. The concurrent loadings associated with the normal plant conditions of dead weight, pressure and the thermal and expansion effects during startup, hot standby, power operation and normal shutdown to cold shutdown conditions.

B. The concurrent loadings associated with either the normal plant condition or the upset plant condition and the vibratory motion of the Operational Basis Earthquake (OBE).

C. The concurrent loadings associated with the plant emergency condition.

D. The concurrent loadings associated with the normal plant condition, the vibratory motion of the SSE, and the dynamic system loadings associated with the plant faulted condition (postulated pipe rupture). The SSE and pipe rupture loadings are combined by the SRSS method or a more conservative method.

The specific design transient specified for design are discussed in section 3.9.1.1.

3.9.3.5.1 ASME Code Class 1 Components and Supports

Design transients for ASME Code Class 1 components, supports and piping are discussed in subsection 3.9.1. Loading combinations for ASME Code Class 1 components are described in Table 3.9.3-1. Stress limits for ASME Code Class I components, supports and piping are described in Table 3.9.3-2. The operating pressures of Code Class 1 active valves are limited to the pressures taken from the applicable primary pressure class pressure-temperature rating of the ASME Code, Section III, for the maximum temperature for the applicable condition.

3.9.3.5.2 Reactor Internals Structures

Design transients for reactor internals structures are discussed in section 3.9.1.1. Loading combinations and stress limits are presented in section 3.9.5.

3.9.3.5.3 ASME Code Class 2 and 3 Components and Supports

Loading combinations applicable to Code Class 2 and 3 components and supports are described in Table 3.9.3-1. System operating conditions due to the design transients defined in Table 3.9.1-1, as well as any other auxiliary system specific conditions, are reviewed to determine the appropriate operating parameters to be used in the design of Code Class 2 and 3 components.

3.9.3.5.3.1 <u>Tanks, Heat Exchangers, and Filters</u>

Pressure vessels supplied for the auxiliary systems are:

A. Letdown heat exchanger

B. Shutdown cooling heat exchanger

C. Regenerative heat exchanger

D. Seal injection heat exchanger

E. Safety injection tanks

F. Volume control tank

G. Spray chemical storage tank

H. Equipment drain tank

I. Preholdup ion exchanger

J. Purification ion exchangers

K. Deborating ion exchanger

L. Purification filters

M. Seal injection filters

N. Reactor drain filter

O. Boric acid filter

Vessel assemblies, including supports, support attachment welds, and anchor bolts, are capable of withstanding specified horizontal and vertical seismic accelerations. The seismic accelerations are applied separately at the center of gravity acting in each of two orthogonal horizontal directions and either vertical direction. The stresses or reaction loads at a given point, due to the three separate analyses, are combined by the SRSS method to define a total seismic design condition. The design allowable nozzle forces and moments act in directions that yield the highest stress which combined with the seismic loads, as determined above, and other concurrent loads.

For Class 2 and 3 pressure retaining parts under the concurrent loadings of the OBE and normal operation (upset conditions), the primary membrane stress is less than 1.1S, and the primary membrance plus bending stress is less than 1.65S. No emergency condition that has been identified for the applicable components is more severe than the upset condition; therefore, no appropriate stress criteria are provided. Under the concurrent loadings of the normal operating condition and the SSE, the primary membrane stress is less than 2.0S, and the primary membrane plus bending stress is less than 2.4S. Where:

S = Allowable value of ASME Code, Section III.

Vessel components not subject to fluid pressure, such as supports, attachment welds, and anchor bolts, were designed to the stress criteria of ASME Code, Section III for the loading conditions defined above.

In cases where the natural frequency could not be increased to avoid amplification of the floor response of the postulated seismic input for a specific plant, the components were modeled as multi-mass systems, and their modal frequencies and maximum reactions were determined from the floor response spectra for the plant, using the ICES STRUDL II computer program. The maximum damping values used were 2% for OBE and 3% for SSE. The design point reactions due to each modal loading were combined by the STRUDL computer program as the sum of the absolute values or by root sum square of the modal reactions, as appropriate per recommendation of Regulatory Guide 1.92.

3.9.3.5.3.2 Valves

ASME Class 2 and 3 valves are designed by analysis to standard rules. Valve operating pressures are consistent with the recommendations of Regulatory Guide 1.48. For active valves, the design pressure rating is not exceeded, for nonactive valves the ratio of 1.1 Pr for upset and emergency conditions is not exceeded and 1.2 Pr for faulted conditions is not exceeded. Loading combinations are in accordance with Table 3.9.3-1. Stress limits are in accordance with Table 3.9.3-2 for active values and ASME Section III paragraphs NC 3522 or ND 3522 for non-active values.

3.9.3.5.3.3 Pumps

Pumps supplied for the Auxiliary Systems are:

A. Boric Acid Makeup (non-active) Code Class 3

B. Reactor Drain (non-active) Code Class 3

C. Spray Chemical Addition (active) Code Class 2 (abandoned in place)

D. Charging (active) Code Class 2

E. High Pressure Safety Injection (active) (Safeguard) Code Class 2

F. Low Pressure Safety Injection (active) (Safeguard) Code Class 2

G. Containment Spray (active) (Safeguard) Code Class 2

The design result and associated design stress limits applied in the design of ASME Code Class 2 and 3 pumps are in accordance with the ASME Code, Section III, respectively. The

results are supplemented in a manner consistent with Regulatory Guide 1.48, May 1973, as described herein.

Pump assemblies, including supports, support attachment welds, and bolts, are capable of withstanding specified horizontal and vertical seismic accelerations. The seismic accelerations are applied separately at the center of gravity acting in each of two orthogonal horizontal directions and either vertical direction. The stresses or reaction loads at a given point, due to the three separate analyses, are combined by the SRSS method to define a total seismic design condition. The design allowable nozzle forces and moments act in directions that yield the highest stress when combined with the seismic loads, as determined above, and other concurrent loads.

For Class 2 and 3 pressure retaining parts of non active pumps under the concurrent loadings of the OBE and normal operating (upset conditions), the primary membrane stress is less than 1.1S, and the primary membrane plus bending stress is less than 1.65S. No emergency condition that has been identified for the applicable components is more severe than the upset condition; therefore, no appropriate stress criteria are provided. Under the concurrent loadings of the normal operating conditions and the SSE (faulted conditions), the primary membrane stress is less than 2.0S, and the primary membrane plus bending stress is less than 2.4S. Where:

S = Allowable value of ASME Code, Section III.

For Class 2 and 3 pressure retaining parts of active pumps, the primary membrane stress is limited to the allowable stress value S, and primary membrane plus bending stress is limited to

1.5 S for each of the loading combinations associated with the upset, emergency and faulted plant operating conditions.

The stress criteria of the ASME Code, Section III are applied in the design of component supports to the same Code Class as the pressure boundary involved within the jurisdictional boundaries defined in the code for the loading conditions defined above. Those steel support structures which are considered to be an extension of the building structure, but supplied with the pump assembly (i.e., bedplates), are designed to the stress criteria of the AISC Manual of Steel Construction.

In addition, the Safeguard Pump assemblies are required to be capable of withstanding the following thermal transients:

A. HPSI and LPSI, suction temperature increases from 40°F to 300°F in 10 seconds. After each temperature change the end point is assumed to hold until temperature equilibrium is attained. Temperature returns to 40°F in several days. This transient would be applied a minimum of 10 times during the design life of the pump.

B. LPSI shutdown cooling operation applied for 500 cycles as follows:

   1. Suction temperature increases from 70°F to 350°F in about 1 minute.

   2. Suction temperature decrease from 350°F to 70°F in several hours.

3.9.3.6 Pump and Valve Operability Assurance for CE Scope

3.9.3.6.1 NSSS Active ASME Code Class 2 and 3 Pumps and Class 1, 2 and 3 Valves

3.9.3.6.1.1 Operability Assurance Program

Active pumps and valves are defined in Regulatory Guide 1.48 as components that require a mechanical motion in performing a safety function. The operability (i.e., performance of this mechanical motion) of active components during and after exposure to design bases events is confirmed per the recommendations of Regulatory Guide 1.48 by:

A. Designing each component to be capable of performing all safety functions during and following design bases events. The design specification includes applicable loading combinations, and conservative design limits for active components, consistent with the recommendations of Regulatory Guide 1.48. The specification requires that the manufacturer demonstrate operability by analysis or test (footnotes 6 and 11 of Regulatory Guide 1.48). The results are independently reviewed by the NSSS Supplier considering the effects of postulated failure modes on operability.

B. Analysis and/or test demonstrating the operability of each design under the most severe postulated loadings which are combined in a manner consistent with the recommendations of Regulatory Guide 1.48. Methods/results of operability demonstration programs are detailed in sections 3.9.3.6.1.2 and 3.9.3.6.1.3.

C. Inspection of each component to assure compliance of critical parameters with specifications and drawings. This inspection confirms that specified materials and processes were used, that wall thicknesses met code requirements, and that fits and finishes met the manufacturer's requirements based on design clearance requirements.

D. Shop testing of each component to verify "as built" conditions as defined in sections 3.9.3.6.1.2 and 3.9.3.6.1.3.

E. Startup and periodic inservice testing in accordance with ASME OM Code to demonstrate that the active pumps and valves are in operating condition throughout the life of the plant.

NSSS active pumps are listed below with a brief description of active safety function of each. NSSS active valves are listed in Table 3.9.3-3. CENPD-161-P-A (proprietary), April 1986.

Active Components	Active Safety Function
High-pressure safety injection pumps	Operate at flowrates to runout
Low-pressure safety injection pumps	Operate at flowrates to runout
Charging pumps	Operate

3.9.3.6.1.2 Operability Assurance Program Results for Active Pumps

3.9.3.6.1.2.1 High- and Low-Pressure Safety Injection Pumps. Operability of the high- and low-pressure safety injection (HPSI and LPSI) pumps under faulted conditions has been

demonstrated by analyses of the assemblies and by analyses and tests of the motors in accordance with the recommendations of Regulatory Guide 1.48.

For the HPSI pumps, the manufacturer has shown that allowable stresses are not exceeded, that clearances are acceptable and that shaft and pedestal bolt deflections do not cause stresses to exceed the normal values indicated by past experience for other pumps of the same type.

For the LPSI pumps, the manufacturer has shown that allowable stresses are not exceeded and that clearances remain acceptable under faulted loadings.

Where necessary, lumped mass models are used with the computer programs to determine the natural frequencies and displacements. The models are conservative (i.e., simplifications tend to make them more flexible).

Operability was demonstrated under the following loads;

	HPSI Pump	LPSI Pump
Horizontal seismic, g's	1.1	1.1
Vertical seismic, g's	1.1	1.1
Design pressure, lb/in.^{2}	2050	710
Suction nozzle max, resultant force, lb	6713	22711
Suction nozzle max, resultant moment, ft-lb	12990	59225
Discharge nozzle max, resultant force, lb	2500	6611
Discharge nozzle max, resultant moment, ft-lb	2500	33237

To verify "as built" conditions the HPSI and LPSI pumps were hydrostatically tested in accordance with the ASME Boiler and Pressure Vessel Code, Section III to confirm acceptability of structural integrity of pressure retaining parts, tested for seal leakage, and tested for performance and NPSH characteristics in accordance with the Hydraulic Institute

Standard to verify operation within specified parameters. The motors were built as Class IE and were tested in accordance with IEEE Standard 112A-1964 to verify operation within specified parameters. Additionally, the motors were qualified to IEEE Standard 323-1974 and IEEE Standard 344-1975 to assure operability during and following design basis events.

3.9.3.6.1.2.2 Charging Pumps. The charging pumps have a relatively complex geometry, which is difficult to analyze. Therefore, a simplified analysis and type test were used to confirm the charging pump functionality during and following a DBE.

A sinusoidal test with simultaneous 1.5 g horizontal and vertical accelerations was conducted. The test on the pump assembly, including its supports, showed no significant natural frequencies in the 1 to 33 Hz range. The fundamental linear natural frequency of the rotating parts of the pump was shown to be greater than 73 Hz. The base of the test pump had a fundamental natural frequency above 33 Hz. Therefore, the System 80 pumps are rigid to postulated seismic input.

The test pump was vibration tested with 2410 psig internal pressure, 1825-pound axial force and 610 ft-lb moment on the suction nozzle, and 1650-pound axial force and 550 ft-lb moment on the discharge nozzle. Simultaneous 1.5g accelerations is applied to the horizontal and vertical axes by driving the assembly in a 45 degree plane. The test was run with the horizontal input parallel to the motor axis. It was repeated with the horizontal input directed 90, 180, and then 270 degrees from the direction for the first test.

The pump was subjected to two sinusoidal sweeps at 1/2 octave per minute in each direction with 1.0g peak accelerations, limited to 12-inch double amplitude, from 1 to 35 Hz. One of the sweeps in each direction was with the pump operating and one with the pump idle. The test shows that no resonances applicable to functionality are in the range of concern, and the unit is therefore rigid to the postulated seismic input. The assembly, both operating and non-operating, was exposed to a 1.5g horizontal and vertical 30-second sinusoidal dwell at 2.5, 10, 12.25, 20, 23.8 and 33 Hz. The pump was shown to operate normally, and no evidence of damage or deterioration to critical parts exists. The 1.5g horizontal and vertical accelerations exceed the applicable response spectra. The successful test on these pumps demonstrates that the System 80 pumps operate during and following the postulated seismic event.

To verify "as built" conditions the charging pumps were hydrostatically tested in accordance with the ASME Boiler and Pressure Vessel Code, Section III to confirm acceptability of structural integrity of pressure retaining parts, tested for seal leakage, and tested for performance and NPSH characteristics in accordance with the Hydraulic Institute Standards to verify operation within specified parameters. The motors were built as Class IE and were tested in accordance with IEEE Standard 112A-1964 to verify operation within specified parameters. Additionally, the motors were qualified to IEEE Standard 323-1974 and IEEE Standard 344-1975 to assure functionality during and following design basis events.

3.9.3.6.1.3 Operability Assurance Program for Active Valves

Safety related active valves must perform their mechanical motion in times of an accident. The qualification program assures that these valves will operate during a seismic event. Qualification tests and/or analyses are conducted for all active valves.

Class 1, 2 and 3 valves are designed/analyzed according to the rules of the ASME Boiler and Pressure Vessel Code, Section III, Section NB-3500, NC-3500, and ND-3500 respectively.

Procurement specifications for safety related active valves stipulate that vendor shall submit either detailed calculations and/or test data to demonstrate operability when subjected to the specification loading and stress criteria (normal through faulted conditions). The decision to accept actual or prototype test data, or analysis for operability assurance is made during the normal design and procurement process. The decision to test is based on (1) whether the component is amenable to analysis, (2) whether proven analytical methods are available, and (3) whether applicable prototype test data is available. If analysis or prototype test data is not sufficient, testing is conducted to qualify the component or to verify the analytical technique.

Where appropriate, valve stem deflection calculations are performed to determine deflections due to short term seismic and other applicable loadings. Deflections so determined are compared to allowable clearances. It must be noted that seismic events are of short duration; thus, contact (if it occurs) does not demonstrate that operability is adversely

affected. Cases where contact occurs are reviewed on a case by case basis to determine acceptability.

The operability of active Code Class 1, 2 and 3 components is assured through an extensive program of design verification, qualification testing and thorough surveillance of the manufacturing, assembly and shop testing of each active component. Each aspect of the design related to pressure boundary integrity and operability is either tested or verified by calculations. Procedures for testing are developed by component manufacturers and reviewed and approved by the NSSS supplier before the tests are conducted. The design analyses of the component take into consideration environmental conditions including loadings developed from seismic, operational effects, and pipe loads. Where necessary and feasible, the conclusions of these analyses are confirmed by test.

On all active valves, an analysis of the extended structure is also performed for static equivalent seismic SSE loads supplied at the center of gravity of the extended structure. The maximum stress limits allowed in these analyses show that structural integrity is within the limits developed and accepted by the ASME Code.

The safety-related valves are subjected to a series of tests prior to service and during the plant life. Prior to installation, the following tests are performed; shell hydrostatic test to ASME Sections III requirements, backseat and main seat leakage tests, disc hydrostatic test, functional tests to verify that the valve will open and close within the specified time limits, operability qualification of motor

operators for the environmental conditions over the installed life (i.e., aging, radiation, accident environment simulation, etc.) according to IEEE 382. Cold hydro qualification tests, hot functional qualification tests, periodic inservice inspections, and periodic inservices operation are performed in-situ to verify and assure the functional ability of the valves. These tests ensure the reliability of the valve for the design life of the plant. The valves are designed using either stress analyses or the pressure containing minimum wall thickness requirements.

All the active valves shall be designed to have a first natural frequency which is greater than 33 Hz. This is shown by suitable test or analysis.

The above outlines in general the methods used to assure valve operability. Each vendor's specific program is described in Section 3.9.3.2.

In addition to the above, the following specific operability assurances are provided for the various type valves:

3.9.3.6.1.3.1 Pneumatically Operated Valves

Pneumatic operated valves are furnished by several vendors in CE System 80 Nuclear Power Plants. Methods of operability demonstration are discussed in general and discussed in detail in Section 3.9.3.2.1.2 subject to the vendor(s) utilized. Spring actuation of the valve is the required active safety function. Loss of electric power or supply air will result in venting of the actuator and return of the valve to the safe position. Each vendor provides their own method to demonstrate valve operability. The operability for these valves is

demonstrated by analysis, test or by a combination of analysis and test. The vendor considers concurrent loads including seismic, design pressure and pipe loads.

The three-way solenoid valve was qualified by test to IEEE-382-1972, IEEE-323-1974 and IEEE-344-1975. Testing included thermal aging, radiation aging, wear aging, vibration endurance, seismic event simulation, and loss of coolant accident. All test results provided satisfactory evidence of air solenoid valve operability.

Limit switches, used to determine valve position, were qualified by testing to IEEE-323-1974, IEEE-344-1975 and IEEE-382-1972. Switches were successfully performance tested for aging simulation, wear aging, radiation exposure, seismic qualification, and design basis event environmental conditions. For valves outside of containment and utilizing EA-170 limit switches, the switches were seismically qualified to IEEE-344-1975 and were tested to sustain radiation dosages up to 2×10^8 rads.

3.9.3.6.1.3.2 Motor Operated Valves

Motor operated valves are qualified by analysis as a minimum as described above. The analysis for each valve assembly considers the effects of seismic loads, design pressure, and piping reaction forces to provide assurance of operability.

To provide full qualification of the motor operated valve actuator, environmental and seismic qualification tests were conducted to simulate the following conditions:

A. Inside Containment (LOCA)

B. Outside Containment

C. Seismic Qualification

D. Steam Line Break Accident

Mid-size valve actuators were subjected to complete environmental qualification consisting of inside containment and outside containment. Each qualification exposed the actuator to thermal and mechanical aging, radiation aging, seismic aging, environmental transient profile test, and steam line break. For the steam line break test an actuator was subjected to a very high superheated temperature to demonstrate that the electrical components of the actuator never exceeded the saturated temperature corresponding to the ambient pressure for the short duration of the test. This short term test proves the existing qualification envelopes the steam line break for superheated temperatures as high as 492°F for a few minutes.

The qualification of the mid-size valve actuator was used to generically qualify all sizes of mid-size valve actuator operators for the environmental test conditions in accordance with IEEE-382-1972. All sizes are constructed of the same materials with components designed to equivalent stress levels, and to the same clearances and tolerances with the only difference being in physical size which varies corresponding to the differences in unit rating.

All the qualifications were conducted per IEEE 382-1972 and meet the requirements of IEEE 323-1974 and IEEE 344-1975 as they apply to valve motor actuators. Further, since the actuators performed satisfactorily without maintenance

throughout the various qualifications, the valve actuators are fully qualified for use in CE Nuclear Power Generating Plants.

3.9.3.6.1.3.3 Pressurizer Safety Valves

Pressurizer Safety valves are 6 x 8 valves. Operability has been successfully demonstrated by a combination of dynamic testing and analysis or by static testing. Operability was successfully demonstrated with a 6g seismic load by one vendor or with a 7.1g seismic load by another vendor. Dynamic testing has demonstrated that the natural frequency of both valves was greater than 33 Hz. A summary of the test programs follows:

A. Vendor A Safety Valves

1. Natural Frequency Demonstration

   Vibration input was in a single, horizontal direction. It was established by previous experience that the horizontal direction was more significant than the vertical direction, and that there was no material difference between the various horizontal directions. The frequency of vibration was increased from 5 to 75 Hz at a rate of 1 octave per minute. Accelerometers were mounted on the valve assembly. The actual natural frequency under test conditions was 38 Hz.

2. Operability Demonstration

   A series of tests demonstrated that the valve would fully open and reseat during and after a seismic acceleration. Vibration input ranged from 3 to 6g and 10 to 33 Hz. The tests were performed using

saturated steam. In addition, analysis was used to establish the significance of nozzle loading. The results indicated that deformation was significantly less than the internal clearances. This loading was therefore neglected in the seismic operability tests.

B. Vendor B Safety Valves

1. Natural Frequency Demonstration

A resonance survey was performed along three orthogonal axes with one axis being the centerline of the outlet port. (Valve mounted on inlet port.) No resonant frequencies were detected in the range of 1-50 Hz on any axis.

2. Operability Demonstration

A series of tests demonstrated that the valve would fully open and reseat during and after applying the following loading combinations: Static seismic loads up to 7.1g were applied to the valve in the direction of least bending stiffness. In addition the maximum permissible piping loads were applied concurrently. The tests were performed using saturated steam. Valve operation was satisfactory.

C. EPRI Testing of Safety Valves

One manufacturer's valve was tested in the EPRI Test Program under full pressure and full flow conditions. This testing has demonstrated that stable valve operation under these conditions is dependent upon the inlet pipe configuration, built up back pressure range

and blowdown setting. Prior to plant startup the inlet pipe configuration and built up back pressure range for each specific plant will be examined by CE and the applicable valve vendor. If necessary, the valves will be adjusted to provide blowdown settings which will result in stable valve operation. These blowdown settings will be recommended by the vendor and approved by CE. These adjustments will be based on the results obtained in the EPRI Test Program. Required adjustments to the valve to assure operability will be documented in the plant specific FSAR.

3.9.3.6.1.3.4 Check Valves. The check valves are characteristically simple in design and their operation will not be affected by seismic accelerations or the maximum applied nozzle loads. The check valve design is compact and there are no extended structures or masses whose motion could cause distortions which could restrict operation of the valve. The nozzle loads due to maximum seismic excitation will not affect the functional ability of the valve since the valve disc is designed to be isolated from the casing wall. The clearance supplied by the design around the disc will prevent the disc from becoming bound or restricted due to any casing distortions caused by nozzle load. Therefore, the design of these valves is such that once the structural integrity of the valve is assured using standard design or analysis methods, the ability of the valve to operate is assured by the design features. In addition to these design considerations, the valve will also undergo, (1) stress analysis including the SSE loads,

MECHANICAL SYSTEMS AND COMPONENTS

TABLE 3.9.3-1

LOADING COMBINATIONS ASME CODE CLASS 1, 2, AND 3 NSSS COMPONENTS

Condition	Design Loading[a] Combination
Design	PD
Normal[b]	PO+DW
Upset[b]	PO+DW+OBE
Emergency	PO+DW+DE
Faulted	PO+DW+SSE+DF

A) Legend:

PD = Design pressure

PO = Operating pressure

DW = Dead weight

OBE = Operating Basis earthquake

SSE = Safe shutdown earthquake

DE = Dynamic system loadings associated with the emergency condition

DF = Dynamic system loadings associated with a postulated pipe rupture (LOCA) for ASME Code Class 1 NSSS components. See the Applicant's SAR for the effects of postulated piping terminal end breaks for ASME Code Class 2 and 3 components.

B) As required by ASME Code Section III, other loads, such as thermal transient, thermal gradient, and anchor point displacement portions of the OBE require consideration in addition to the primary stress producing loads listed.

TABLE 3.9.3-2
STRESS LIMITS FOR ASME CODE CLASS 1
NSSS COMPONENTS, PIPING, AND COMPONENT SUPPORTS

	COMPONENT AND PIPING STRESS LIMITS (a)	COMPONENT SUPPORT STRESS LIMITS (c)
Design	NB-3221, NB-3231 and NB-3652	NF-3221 or NF-3231, and NF-3280
Normal	NB-3222, NB-3232 and NB-3653	NF-3222 or NF-3231, and NF-3280
Upset	NB-3223, NB-3233 and NB-3654	NF-3223 or NF-3231, and NF-3280
Emergency	NB-3224, NB-3234 and NB-3655	NF-3224 or NF-3231, and NF-3280
Faulted	NB-3225, NB-3235 and NB-3656 (d)	NF-3225 or NF-3231 (b)

a) Stress limits listed are used as required by ASME Section III, and applicable addenda for all components except active components. Active components are designed to the stress limits of NB-3221 and NB-3231 for Design Conditions and the stress limits of NB-3222 and NB-3232 for all other conditions for active components.

b) For faulted condition loadings, bolts in the load path connecting two members of an NF support for Class 1 components are designed in accordance with Appendix XVII of the ASME Code for friction type connections with tensile stresses limited to the lesser of 0.7 Su or Sy.

c) Stress limits used are as required by ASME Section III and applicable addenda and modified by Regulatory Guide 1.124 and 1.130. Component standard supports may be designed to the limits of NF-3260.

d) The deformation resulting from the application of a moment in excess of the maximum Level D moment, determined on an elastic basis, (56.7 x 106 in-lb) permitted by NB 3656 of Section III of the ASME Code has been calculated to demonstrate piping functionability following postulated pipe rupture. The calculated deformation is shown in Figure 3.9.3-1.

NOTE:

1. (Operate) is defined as valve being capable of both opening and closing.
2. (Close) is defined as valve being capable of moving to or maintaining a closed position.
3. (Open) is defined as valve being capable of moving to or maintaining an open position.
4. For application of the single failure rule to check valves, refer to Section 3.1.30.

(2) in-shop hydrostatic tests, (3) in-shop seat leakage test, and (4) periodic in-situ valve exercising and inspection to assure the functional ability of the valve.

3.9.4 CONTROL ROD DRIVE SYSTEMS

3.9.4.1 Descriptive Information of CEDM

The control element drive mechanisms (CEDMs) are magnetic jack type drives used to vertically position and indicate the position of the full-strength control element assemblies (FSCEAs) and the part-strength control element assemblies (PSCEAs) in the core. Each CEDM is capable of withdrawing, inserting, holding, or tripping the FSCEA/PSCEA from any point within its 153 inch stroke in response to operation signals.

The CEDM is designed to function during and after all normal plant transients. The FSCEA drop time for 90% insertion is 4.0 seconds maximum. The drop time is defined as the interval between the time power is removed from the CEDM coils to the time the FSCEA has reached 90% of its fully inserted position. This maximum drop time does not apply to the PSCEAs which are not considered for SDM. The CEDM pressure boundary components have a design life of 40 years. The CEDM is designed to operate without maintenance for a minimum of 1-1/2 years and without replacing components for a minimum of 3 years. The CEDM is designed to function normally during and after being subjected to the operating basis earthquake loads. The CEDM will allow for tripping of the FSCEA/PSCEA during and after a safe shutdown earthquake.

The design and construction of the CEDM pressure housing fulfill the requirements of the ASME boiler and Pressure Vessel

Code, Section III, for Class 1 vessels. The CEDM pressure housings are part of the reactor coolant pressure boundary, and they are designed to meet stress requirements consistent with those of the vessel. The pressure housings are capable of withstanding, throughout the design life, all normal operating loads, which include the steady-state and transient operating conditions specified for the vessel. Mechanical excitations are also defined and included as a normal operating load. The CEDM pressure housings are service rated at 2500 lb/in.^{2} at 650°F. The loading combinations and stress limit categories are presented in Table 3.9.4-1 and are consistent with those defined in the ASME code.

The design duty requirements for the CEDM is a total cumulative CEA travel of 100,000 feet operation without loss of function.

The test programs performed in support of the CEDM design are described in Section 3.9.4.4.

3.9.4.1.1 Control Element Drive Mechanism Design Description

The CEDMs are mounted on nozzles on top of the reactor vessel closure head. The CEDMs consist of the upper and lower CEDM pressure housings, motor assembly, coil stack assembly, reed switch assemblies, and extension shaft assembly. A typical CEDM outline drawing is shown in Figure 3.9.4-1. The drive power is supplied by the coil stack assembly, which is positioned around the CEDM housing. Two position indicating reed switch assemblies are supported by the upper pressure housing shroud, which encloses the upper pressure housing assembly.

The lifting operation consists of a series of magnetically operated step movements. Two sets of mechanical latches are utilized engaging a notched extension shaft. To prevent excessive latch wear, a means has been provided to unload the latches during the engaging operations. The magnetic force is obtained from large dc magnet coils mounted on the outside of the lower pressure housing.

Power for the electromagnets is obtained from two separate supplies. A control programmer actuates the stepping cycle and moves the FSCEA/PSCEA by a forward oreverse stepping sequence. Control element drive mechanism hold is obtained by energizing deenergized. The FSCEAs/PSCEAs are tripped upon interruption of electrical power to all coils. Each CEDM is connected to the FSCEAs/PSCEAs by an extension shaft. The weight of the CEDMs and the FSCEAs/PSCEAs is carried by the pressure vessel head. Installation, removal, and maintenance of the CEDM is possible with the reactor vessel head in place; however, the CEDM is inaccessible during operation of the plant.

The axial position of a FSCEA/PSCEA in the core is indicated by three independent signals. One counts the CEDM steps electronically, and the other two consist of magnetically actuated reed switches located at regular intervals along the CEDM. These signals are designed to indicate FSCEA/PSCEA position to within $\pm$ 2-½ inches of the true location. This accuracy requirement is based on ensuring that the axial alignment between FSCEAs/PSCEAs is maintained within acceptable limits. Refer to UFSAR Sections 7.5.1.1.4 and 7.7.1.3.2.3 for a more complete description of the three position signals.

The materials in contact with the reactor coolant used in the CEDM are listed in Section 4.5.1.

3.9.4.1.1.1 CEDM Pressure Housing

The CEDM pressure housing consists of the motor housing assembly and the upper pressure housing assembly. The motor housing assembly is attached to the reactor vessel head nozzle by means of a threaded joint and seal welded. Once the motor housing assembly is seal welded to the head nozzle, it need not be removed since all servicing of the CEDM is performed from the top of the housing. The upper pressure housing is threaded into the top of the motor housing assembly and seal welded. The upper pressure housing encloses the CEDM extension shaft and contains a vent.

3.9.4.1.1.2 Motor Assembly

The motor assembly is an integral unit which fits into the motor housing and provides the linear motion to the CEA. The motor assembly consists of a latch guide tube, upper latches and lower latches.

Both upper latches and lower latches are used to perform the stepping of the CEA and by proper sequencing perform a load transfer function to minimize latch and extension shaft wear. The upper latch also performs the holding when CEA motion is not required. Engagement of the extension shaft occurs when the appropriate set of magnetic coils is energized. This moves sliding magnets which cam a two-bar linkage moving the latches inward. The upper latches move vertically 7/16" while the lower latches move vertically 3/8" to perform both the load

transfer and stepping action. Total CEA motion per cycle is limited to 3/4".

3.9.4.1.1.3 Coil Stack Assembly

The coil stack assembly for the CEDM consists of four large DC magnet coils mounted on the outside of the motor housing assembly. The coils supply magnetic force to actuate mechanical latches for engaging and driving the CEA extension shaft. Power for the magnetic coils is supplied from two separate supplies. A CEDM control system actuates the stepping cycle and obtains the correct CEA position by a forward or reverse stepping sequence. CEDM hold is obtained by energizing the upper latch coil at a reduced current while all other coils are deenergized. The CEAs are tripped upon interruption of electrical power to all coils. Electrical pulses from the magnetic coil power programmer provide one of the means for transmitting CEA position indication.

A conduit assembly containing the lead wires for the coil stack assembly is located at the side of the upper pressure housing shroud.

3.9.4.1.1.4 Reed Switch Assembly

Two reed switch assemblies provide separate means for transmitting CEA position indication. Reed switches and voltage divider networks are used to provide two independent output voltages proportional to the CEA position. The reed switch assemblies are positioned so as to utilize the permanent magnet in the top of the extension shaft. The permanent magnet actuates the reed switches as it passes by them. The reed

switch assemblies are provided with accessible electrical connectors at the top of the upper pressure housing.

3.9.4.1.1.5 Extension Shaft Assembly

The extension shaft assemblies are used to link the CEDMs to the CEAs. The extension shaft assembly is a 304 stainless steel rod with a permanent magnet assembly at the top for actuating reed switches in the reed switch assembly, a center section called the drive shaft and a lower end with a coupling device for connection to the CEA.

The drive shaft is a long tube made of 304 stainless steel. It is threaded and pinned to the extension shaft. The drive shaft has circumferential notches in 3/4" increments along the shaft to provide the means of engagement to the control element drive mechanism.

The magnet assembly, located in the top of the extension shaft assembly, consists of a housing, magnet and plug. The magnet is made of two cylindrical Alnico-5 magnets. This magnet assembly is used to actuate the reed switch position indication and is contained in a housing which is plugged at the bottom of the housing.

3.9.4.1.2 Description of the CEDM Motor Operation

Withdrawal or insertion of the CEA is accomplished by programming current to the various coils. There are three programmed conditions for each coil; high voltage for initial gap closure, low voltage for maintaining the gap closed and zero voltage to allow opening of the gap.

3.9.4.1.2.1 Operating Sequence for the Double Stepping Mechanism

The initial condition is the hold mode. In this condition, the upper latch coil is energized at low voltage.

Withdrawal

1. The upper lift coil is energized causing the 7/16" upper lift gap to close lifting the CEA.
2. The lower latch coil is energized causing the lower latches to engage the drive shaft with 1/32" clearance.
3. The upper lift coil is deenergized allowing the upper latches to drop 7/16" and the drive shaft to lower 1/32" placing the load on the lower latches.
4. The upper latch coil is deenergized disengaging the upper latches.
5. The lower lift coil is energized lifting the drive shaft 3/8".
6. The upper latch coil is energized engaging the upper latches in the drive shaft with 1/32" clearance.
7. The lower lift coil is deenergized allowing the lower latches to drop 3/8" and causing the drive shaft to drop 1/32" applying the load on the upper latches.
8. The lower latch coil is deenergized disengaging the lower latches from the drive shaft.

Insertion

1. The lower latch coil is energized causing the lower latches to engage the drive shaft.
2. The lower lift coil is energized lifting the lower latches 3/8" and lifting the drive shaft 1/32" thus applying the load to the lower latches.
3. The upper latch coil is deenergized causing the upper latches to disengage the drive shaft.
4. The upper lift coil is energized, moving the deenergized upper latch assembly up 7/16".
5. The upper latch coil is energized engaging the latches with clearance, 11/32".
6. The lower lift coil is deenergized, allowing the lower latches to drop with the drive shaft, 3/8. The drive shaft will move down 11/32" stopping on the upper latch assembly which is energized and in its up position.
7. The lower latch coil is deenergized disengaging the lower latches.
8. The upper lift coil is deenergized lowering the upper latch assembly with the drive shaft 7/16".

3.9.4.2 Applicable CEDM Design Specifications

The pressure boundary components are designed and fabricated in accordance with the requirements for Class 1 vessels per the applicable Edition and Addendums of Section III of the ASME Boiler and Pressure Vessel Code. The pressure boundary material complies with the requirements of Section III and IX

of the ASME Boiler and Pressure Vessel Code and Code Case N-4-11.

The adequacy of the design of the non pressure boundary components have been verified by prototype accelerated life testing as discussed in Section 3.9.4.4.

The reed switch position transmitter assembly of the CEDM is designed to comply with IEEE 323-1974, standard for "Qualification of Class I Electrical Equipment for Nuclear Power Generating Stations," and IEEE 344-1975, "Recommended Practice Seismic Qualification of Class I Electric Equipment for Nuclear Power Generating Stations." The electrical components are external to the pressure boundary and are non-pressurized.

The test program to verify the CEDM design is discussed in Section 3.9.4.4.

3.9.4.3 Design loads, Stress Limits, and Allowable Deformations

The CEDM stress analyses consider the following loads:

A. Reactor coolant pressure and temperature

B. Reactor operating transient conditions

C. Dynamic stresses produced by seismic loading

D. Dynamic stresses produced by mechanical excitations

E. Loads produced by the operation and tripping of the mechanism

F. Loads produced by loss-of-coolant accident.

The methods used to demonstrate that the CEDMs operate properly under seismic conditions are presented in Section 3.7.3.14.

The design and fabrication of the CEDM pressure boundary components fulfills the requirements of the ASME Code, Section III, for Class I vessels. The pressure housings are capable of withstanding throughout the design life all the steady state and transient operating conditions specified in Table 3.9.4-1.

The adequacy of the design of the CEDM pressure boundary and non-pressure boundary components has been verified by prototype accelerated life testing as discussed in Section 3.9.4.4.

Clearances for thermal growth and for dimensional tolerances were investigated, and tests have proven that adequate clearances are provided for proper operation of the CEDM.

The latch locations are set by a master gage, and settings are verified by testing at reactor conditions.

A weldable seal closure, per Section III of the ASME Code, is provided for the vent valve in case of leakage.

The motor housing fasteners are mechanically positively captured, and all threaded connections are preloaded before capturing.

The coil stack assembly can be installed or removed simply by lowering or lifting the stack, relative to the CEDM pressure housing, for ease of coil replacement or maintenance.

3.9.4.4 CEDM Performance Assurance Program

3.9.4.4.1 CEDM Testing

3.9.4.4.1.1 Prototype Accelerated Life Tests

The PVNGS (System 80) CEDM is similar to and based on magnetic jack mechanisms used at other reactors such as Maine Yankee (Docket No. 50-309), Calvert Cliffs (Docket 50-317), as well as 150-inch core reactors such as Arkansas Nuclear One Unit 2 (Docket No. 50-368) and San Onofre Units 2 & 3 (Docket Nos. 50-361/362).

The significant differences between the System 80 drives and previous CEDMs are:

(1) The elimination of the pulldown coil and (2) the use of the lift coils to perform both a load transfer function and stepping action. The elimination of the pulldown coil required installation of a coil spring to ensure positive resetting of the latch assemblies. In addition, the drive shaft was modified by placing the teeth on 3/4" centerline in place of the 3/8" spacing of previous drive shafts to allow load transfer and stepping with the same coil. The safety release mechanism uses the same materials and clearances as on all previous magnetic jack mechanisms. The following describes accelerated life tests on both a pre-System 80 mechanism as well as on a prototype System 80 CEDM. Both programs provide design verification for the PVNGS CEDM.

A pre-System 80 prototype CEDM was subjected to an accelerated life test accumulating a minimum of 157,000 feet of travel on all CEDM components. In addition, the latch guide tube

bearings in the motor assembly saw an additional 50,000 feet of operation.

The prototype mechanism was installed on a test facility which was operated at a nominal temperature of 600°F and 2250 psi. After 50,000 feet of operation lifting 230 pounds at 40 inches per minute, the motor was removed from the test motor housing and the bearing surfaces inspected. During this inspection it was found that excessive wear existed on the upper gripper magnet and upper gripper housing bearings.

The gripper housing magnet bearing configuration was revised and replacement parts with this revision were incorporated into the prototype mechanism. This configuration was reinstalled into the test facility and the mechanism operated as before for an additional 157,000 feet of travel. The replacement parts showed a wear of only .001 inches while the latch guide tube bearings had a total wear of .012". The mechanism at disassembly was still operational with no abnormalities. This test constituted operation equivalent to 1.5 to 2.0 times the design duty requirements of the mechanism.

A prototype System 80 CEDM was assembled and installed in a test loop, where the accelerated wear test was conducted at 615°F and 2250 psi. The total weight attached to the CEDM was 450 pounds and this was moved at a nominal speed of 30 inches per minute. A total of thirty-four thousand (34,000) feet of travel was then completed without difficulty. Included in that test were 300 full height gravity scrams.

The mechanism motor was removed from the test facility and disassembled for inspection. The latch guide tube bearings

showed a maximum diametrical wear of .003" with negligible wear on the gripper housing to gripper magnetic bearings. Alignment tabs, which maintain orientation of the gripper with the latch guide tube, showed extensive wear but had not caused mechanism malfunctions. These alignment tabs were replaced in production units with an improved design.

Upon completion of the accelerated wear test, 300 full height light weight drops were completed utilizing a 75 lb. test weight. The maximum CEA drop time to 90% insertion was 2.93 seconds which met the 4.0 second criteria. All release times were less than .3 seconds with normal releases completed in less than .200 seconds.

3.9.4.4.1.2 First Production Test.

A qualification test program was completed on the first production C-E magnetic jack CEDM. During the course of this program, over 4000 feet of travel was accumulated and 30 full height gravity drops were made without mechanism malfunction or measurable wear on operating parts. The program included the following:

A. Operation at 40 in./min lifting 230 pounds (dry) at ambient temperature and 2300 psig pressure for 800 feet.

B. Six full-height 230 pounds dry weight gravity drops at ambient temperature.

C. Operation at simulated reactor operating condition at 40 in/min lifting 230 pounds for 1700 feet.

D. Six full-height drops at simulated reactor operating conditions with 230 pounds of weight.

E. An operational test at ambient temperature and 2300 psig pressure, lifting 335 pounds at 200 in/min. for 500 feet.

F. Six full-height drops of the 335 pound weight.

G. Operation at simulated reactor conditions for 1700 feet at 20 in/min, lifting 335 pounds.

H. Operation at ambient temperature and 2300 psig for 1100 feet and 20 full-height drops with an attached dry weight of 130 pounds.

The mechanism operated without malfunction throughout the test program and, upon final inspection, no measurable wear was found.

3.9.5 REACTOR PRESSURE VESSEL INTERNALS

3.9.5.1 <u>Design Arrangements</u>

The components of the reactor internals are divided into two major parts consisting of the core support structure and the upper guide structure assembly. The flow skirt, although functioning as an integral part of the coolant flow path, is separate from the internals and is affixed to the bottom head of the pressure vessel. The arrangement of these components is shown in Figure 3.9.5-1.

3.9.5.1.1 Core Support Structure

The major structural member of the reactor internals is the core support structure. The core support structure consists of the core support barrel and the lower support structure. The material for the assembly is Type 304 stainless steel.

TABLE 3.9.4-1

STRESS LIMITS FOR CEDM PRESSURE HOUSINGS

Operating Condition	Stress Categories and Limits of Stress Intensities[(a)]
1. Normal (level A) & Upset(Level B) : Normal Operating Loading plus Normal Operating & Upset Plant Transients plus Operating Basis Earthquake Forces.	Article NB-3222 (Normal/Level A) Article NB-3223 (Upset/Level B).
2. Faulted (Level D): Normal Operating Loadings plus Faulted Plant Transients plus Safe Shutdown Earthquake (SSE) and Branchline pipe breakloads.	Article NB-3225 (Faulted/Level D)
3. Testing: Testing Plant Transients	Article NB-3226

For the above listed operating conditions, the following limits regarding function apply:

1. Normal & Upset: The CEDMs are designed to function normally during and after exposure to these conditions.

2. Faulted: The deflections of the CEDM shall be limited, so that the CEAs can be inserted after exposure to these conditions.

a. References listed in Table 3.9.4-1 are taken from Section III, Subsection NB of the ASME Boiler and Pressure Vessel Code 1998 Edition through 2000 Addenda. Note that the ASME code replaced Normal with Level A; Upset with Level B; and Faulted with Level D.

The core support structure is supported at its upper end by the upper flange of the core support barrel, which rests on a ledge in the reactor vessel. Alignment is accomplished by means of four equally spaced keys in the flange, which fit into the keyways in the vessel lodge and closure head. The lower flange of the core support barrel supports, secures, and positions the lower support structure and is attached to the lower support structure by means of a welded flexural connection. The lower support structure provides support for the core by means of support beams that transmit the load to the core support barrel lower flange. The locating pins in the beams provide orientation for the lower ends of the fuel assemblies. The core shroud, which provides a flow path for the coolant and lateral support for the fuel assemblies, is also supported and positioned by the lower support structure. The lower end of the core support barrel is restricted from excessive radial and torsional movement by six snubbers which interface with the pressure vessel wall.

3.9.5.1.1.1 Core Support Barrel

The core support barrel is a right circular cylinder including a heavy external ring flange at the top end and an internal ring flange at the lower end. The core support barrel is supported from a ledge on the pressure vessel. The core support barrel, in turn, supports the lower support structure upon which the fuel assemblies rest. Press-fitted into the flange of the core support barrel are four alignment keys located 90 degrees apart. The reactor vessel, closure head, and upper guide structure assembly flange are slotted in

locations corresponding to the alignment key locations to provide alignment between these components in the vessel flange region. The core support barrel assembly is shown in Figure 3.9.5-2.

The upper section of the barrel contains two outlet nozzles that interface with internal projections on the vessel nozzles to minimize leakage of coolant from inlet to outlet.

Since the weight of the core support barrel is supported at its upper end, it is possible that coolant flow could induce vibrations in the structure. Therefore, amplitude limiting devices, or snubbers, are installed on the outside of the core support barrel near the bottom end. The snubbers consist of six equally-spaced lugs around the circumference of the barrel and act as a tongue-and-groove assembly with the mating lugs on the pressure vessel. Minimizing the clearance between the two mating pieces limits the amplitude of vibration. During assembly, as the internals are lowered into the pressure vessel, the pressure vessel lugs engage the core support barrel lugs in an axial direction. Radial and axial expansion of the core support barrel are accommodated, but lateral movement of the core support barrel is restricted. The pressure vessel lugs have bolted, captured Inconel X shims. The core support barrel lug mating surfaces are hardfaced with Stellite to minimize wear. The shims are machined during initial installation to provide minimum clearance. The snubber assembly is shown in Figure 3.9.5-3.

3.9.5.1.1.2 Lower Support Structure and Instrument Nozzle Assembly

The lower support structure and ICI nozzle assembly position and support the fuel assemblies, core shroud, and ICI nozzles. The structure is a welded assembly consisting of a short cylinder, support beams, a bottom plate, ICI nozzles, and an ICI nozzle support plate. The lowest support structure is made up of a short cylindrical section enclosing an assemblage of grid beams arranged in egg-crate fashion. The outer ends of these beams are welded to the cylinder. Fuel assembly locating pins are attached to the beams. The bottoms of the parallel beams in one direction are welded to an array of plates which contain flow holes to provide proper flow distribution. These plates also provide support for the ICI nozzles and, through support columns, the ICI nozzle support plate. The cylinder guides the main coolant flow and limits the core shroud bypass flow by means of holes located near the base of the cylinder. The ICI nozzle support plate provides lateral support for the nozzles. This plate is provided with flow holes for the requisite flow distribution. The lower support structure and ICI nozzle assembly is shown in Figure 3.9.5-4.

3.9.5.1.1.3 Core Shroud

The core shroud provides an envelope for the core and limits the amount of coolant bypass flow. The shroud consists of a welded vertical assembly of plates designed to channel the coolant through the core. Circumferential rings and a top and bottom end plate provide lateral support. The rings are attached to the vertical plates by means of welded ribs which

extend the full length of the core shroud. A small gap is provided between the core shroud outer perimeter and the core support barrel in order to provide upward coolant flow in the annulus, thereby minimizing thermal stresses in the core shroud. The core shroud is shown in Figure 3.9.5-5. Four hardfaced alignment lugs, spaced 90 degrees apart, protrude vertically from the top of the core shroud and engage in corresponding hardfaced slots in the upper guide structure fuel alignment plate to ensure proper alignment between the upper guide structure assembly, core shroud, and lower support structure.

3.9.5.1.2 Upper Guide Structure Assembly

The UGS assembly aligns and laterally supports the upper end of the fuel assemblies, maintains the control element spacing, holds down the fuel assemblies during operation, prevents fuel assemblies from being lifted out of position during a severe accident condition and protects the control elements from the effects of coolant cross flow in the upper plenum. The upper guide structure (UGS) assembly is handled as one unit during installation and refueling.

The UGS assembly consists of the UGS support barrel assembly and the CEA shroud assembly (Figure 3.9.5-6). The UGS support barrel assembly consists of UGS support barrel fuel alignment plate, UGS base plate and control element shroud tubes. The UGS support barrel consists of a right circular cylinder welded to a ring flange at the upper end and to a circular plate (UGS base plate) at the lower end. The flange, which is the supporting member for the entire UGS assembly, seats on its

upper side against the pressure vessel head during operation. The lower side of the flange is supported by the holddown ring, which seats on the core support barrel upper flange. The UGS flange and the holddown ring engage the core support barrel alignment keys by means of four accurately machined and located keyways equally spaced at 90 degree intervals. This system of keys and slots provides an accurate means of aligning the core with the closure head and thereby with the CEA drive mechanisms. The fuel alignment plate is positioned below the UGS base plate by cylindrical control element shroud tubes. These tubes are attached to the UGS base plate and the fuel alignment plate by rolling the tubes into the plates and welding. The fuel alignment plate is designed to align the lower ends of the control element shroud tubes which in turn locate the upper ends of the fuel assemblies. The fuel alignment plate also has four equally spaced slots on its outer edge which engage with Stellite hardfaced lugs protruding from the core shroud to provide alignment. The control element shroud tubes bear the upward force on the fuel assembly holddown devices. This force is transmitted from the alignment plate through the control element shroud tubes to the UGS barrel base plate.

The CEA shroud assembly limits cross flow and provides separation of the CEA assemblies. The assembly consists of an assemblage of large vertical tubes connected by vertical plates in a grid pattern. The shroud assembly is mounted on the UGS base plate and is held in position by eight tie rod tube assemblies which are threaded into the UGS base plate at their lower end. The tie rods are bolted against plates located at

the top of the CEA shroud assembly and are pretensioned. Guides for the CEA extension shafts are provided by the Guide Structure Support System. The tubes and connecting plates are furnished with multiple holes to permit hydraulic communication. Lateral movement of the vertical tube and plate assembly is minimized by four snubbers symmetrically located between this assembly and the top of the UGS support barrel.

The holddown ring provides axial force on the flanges of the upper guide structure assembly and the core support structure in order to prevent movement of the structures under hydraulic forces. The holddown ring is designed to accommodate the differential thermal expansion between the pressure vessel and the internals in the vessel ledge region.

3.9.5.1.3 Flow Skirt

The Inconnel flow skirt is a right circular cylinder, perforated with flow holes, and reinforced with two stiffening rings. The flow skirt is used to reduce inequalities in core inlet flow distributions and to prevent formation of large vortices in the lower plenum. The skirt is supported by nine equally spaced machined sections that are welded to the bottom head of the pressure vessel.

3.9.5.1.4 In-Core Instrumentation Support System

The complete in-core neutron flux monitoring system includes self-powered in-core detector assemblies, supporting structures and guide paths, an external movable detector drive system and an amplifier system to process detector signals. The self-powered in-core detector assemblies and the amplifier system

are described in Section 7.7. The external movable detector drive system and the instrumentation supporting structures and guide paths are described in this section and shown in Figure 3.9.5-7.

The support system begins outside the pressure vessel, penetrates the bottom of the vessel boundary and terminates in the upper end of the fuel assembly. Each in-core instrument is guided over its full length by the external guidance conduit, the pressure vessel nozzles, the lower support structure ICI nozzles and the instrument guide tube of the fuel assembly. Figure 3.9.5-4 shows the in-core instrument support structure. The in-core instrumentation support system routes the instruments so that detectors are located in selected fuel assemblies throughout the core. An equal instrument length exists for all locations. The guide tube routing outside the reactor vessel is a simple 180° bend to the seal table. The pressure boundaries for the individual instruments are at the out-of-reactor seal table, where the external electrical connections to the in-core instruments are made (Figure 3.9.5-7).

The in-core instrument assemblies contain a movable detector guide tube to allow insertion of a miniature movable flux detector. The assemblies have an integral seal plug which forms a seal at the instrument seal table and through which the signal cables and movable guide tube pass. Static O-ring seals are used to seal against operating pressure.

The movable detector drive system consists of two drive machines, two transfer machines, two drive cables with detectors and the interconnecting tubing. Because the two

halves of the system are identical with only several connections between them (leak detection and gas purge), only half of the system is described below.

A fission chamber is used as the moveable flux detection device. The detector signal cable is wound with an edgewise helical steel wrap to form the drive cable. This cable construction allows a hobbed wheel in the drive machine to drive the cable in either direction. The drive machine consists of a cable reel, a drive motor, gear reducer, hobbed drive wheel and a shaft position encoder. The detector may be positioned from the control room by use of the plant computer or a separate control box.

The detector may be shifted from any location to any other location in less than eight minutes. The detectors are shifted by the transfer machine which is mounted above the seal table. The machine consists of a geared drive motor, multiple position Geneva positioning mechanism, inlet and outlet tubes and miscellaneous limit and interlock switches. External commands control the motor to position the mechanism so that the inlet path is lined up with the correct outlet path. The transfer machine also has connections for inert gas blanketing and for guide tube leak detection. The gas connection allows an inert gas supply to blanket the transfer machine and movable detector guide tubes during machine operation.

The leak detector alarm system is a float switch mounted in a chamber which is fed from both transfer machines. Any leak which might occur in a movable detector guide tube flows to the transfer machine and then to the transfer machine sump, which exists to the leak detector. A solenoid valve past the leak

detector allows remote drainage of the leak detector sensing line.

3.9.5.2 Design Loading Conditions

The following loading conditions are considered in the design of the reactor internals.

A. Normal operating temperature differences

B. Normal operating pressure differences

C. Flow loads

D. Weights, reactions and superimposed loads

E. Vibration loads

F. Shock loads (including operating basis and safe shutdown earthquakes)

G. Anticipated transient loadings not requiring forced shutdown

H. Handling loads (not combined with other loads above)

I. Loads resulting from postulated loss-of coolant accidents

3.9.5.3 Design Loading Categories

The design loading conditions are categorized as follows:

3.9.5.3.1 Normal Operating and Upset

This category includes the combinations of design loadings consisting of normal operating temperature and pressure differences, loads due to flow, weights, reactions,

superimposed loads, vibration, shock loads including operating basis earthquake, and transient loads not requiring shutdown.

3.9.5.3.2 Faulted

This category consists of the loading combinations of Section 3.9.5.3.1 with the exception that the safe shutdown earthquake (in place of the operating basis earthquake) and the blowdown loads resulting from the loss-of-coolant accident are included.

3.9.5.4 Design Bases

3.9.5.4.1 Reactor Internals

The stress limits to which the reactor internals are designed are listed in Table 3.9-27A.

No emergency condition has been identified for the applicable components, therefore no stress criteria are provided.

The operating categories and stress limits are defined in the applicable section of the Section III of the ASME Boiler and Pressure Vessel Code.

The maximum stresses resulting from the LOCA and the SSE are combined to obtain the total stress intensities.

To properly perform their functions, the reactor internal structures are designed to meet the deformation limits listed below:

A. Under design loadings plus operating basis earthquake forces, deflection will be limited so that the control element assemblies (CEAs) can function and adequate core cooling is preserved.

B. Under normal operating loadings, plus SSE forces, plus pipe rupture loadings resulting from a break equivalent to a maximum of 0.5 square foot, deflections are limited so that the core will be held in place, adequate core cooling is preserved, and all CEAs can be inserted. Those deflections which would influence CEA movement are limited to less than 80% of the deflections required to prevent CEA insertion.

C. Under normal operating loadings, plus SSE forces, plus the maximum pipe rupture loadings resulting from the design basis pipe breaks, deflections are limited so that the core will be held in place and adequate core cooling is preserved. CEA insertion is not required for a safe and orderly shutdown for break sizes greater than 0.5 square foot, in accordance with the Safety Analysis described in 6.3.3.

The allowable deformation limits are listed in the following tabulation. Allowable limits are established as 80% of the loss-of-function deflection limits.

Location	Allowable Deflection (in)
Fuel lower end fitting, lower support structure	2.600 (Disengagement)
Fuel upper end fitting, upper guide structure	1.216 (Disengagement)
CEA Shroud (lateral)	0.209 (CEA Insertion)

In the design of critical reactor vessel internals components which are subject to fatigue, the stress analysis is performed utilizing the design fatigue curve of Figure I-9-2 of Section III of the ASME Boiler and Pressure Vessel Code. A cumulative usage factor of less than one is used as the limiting criterion.

As indicated in the preceding Sections, the stress and fatigue limits for reactor internals components are obtained from the ASME Code. Allowable deformation limits are established as 80% of the loss-of-function deflection limits. These limits provide adequate safety factors assuring that so long as calculated stresses, usage factors, or deformations do not exceed these limits, the design is conservative.

TABLE 3.9-27A

STRESS LIMITS FOR REACTOR INTERNALS

Operating Category	Limits of Stress Intensities[a]
Normal and Upset	Figure NG 3221.1 including notes.
Faulted	Appendix F, Rules for Evaluating Faulted Conditions, Section F-1380 and Table F-1322.2-1 including notes.

(a) References listed are taken from Section III of the ASME Boiler and Pressure Vessel Code. Only the stress-intensity criteria given by the ASME code are applicable to the reactor internal components.

3.9.6 INSERVICE TESTING OF PUMPS AND VALVES

The inservice testing program for Code Class 1, 2, and 3 pumps and valves will be conducted in accordance with the requirements of the ASME OM Code. This program will be implemented to assess operational readiness during preservice and inservice inspection.

3.9.6.1 Inservice Testing of Pumps

Inservice testing of pumps is limited by ASME OM Code to those pumps that are required to perform a specific function in shutting down a reactor or in mitigating the consequences of an accident, and are provided with an emergency power source. A list of the applicable Code Class 2 and 3 pumps is given in table 3.9-28. The required hydraulic and mechanical parameters will be measured by the methods and with the frequency prescribed in ASME OM Code.

3.9.6.2 Inservice Testing of Valves

Code Class 2 and 3 valves will be categorized in accordance with ASME OM Code. The valves will be tested according to the requirements of Subsection ISTC for each valve category. Certain valves will be exempt from testing in accordance with ASME OM Code.

Additionally, the RCS pressure isolation valves listed in table 3.9-29 are subject to Technical Specification 3.4.15, RCS pressure isolation valve leakage requirements.

The Class 1 to Class 2 boundary will be considered the isolation point which must be protected by redundant isolation valves.

Where pressure isolation is provided by two valves, both will be leak tested. When three or more valves provide isolation, only two of the valves will be leak tested.

Table 3.9-28
ASME CODE CLASS 2 AND 3 PUMPS SUBJECT TO
TESTING FOR OPERATIONAL READINESS PER ASME OM CODE

Equipment Tag Number	Description
M-SIA(B)-P02	HP safety injection pump
M-SIA(B)-P01	LP safety injection pump
M-DFA(B)-P01	Diesel fuel oil transfer pump
M-AFB-P01	Auxiliary feedwater pump (motor-driven)
M-AFA-P01	Auxiliary feedwater pump (turbine-driven)
M-SIA(B)-P03	Containment spray pump
M-EWA(B)-P01	Essential cooling water pump
M-SPA(B)-P01	Essential spray pond pump
M-ECA(B)-P01	Essential chilled water pump
M-CHA(B)-P01	Charging pump
M-CHE-P01	Charging pump

APPENDIX 3.9A

APPENDIX 3.9A
COMPUTER CODE VERIFICATION

3.9A-1 INTRODUCTION

This Appendix provides documentary verification for those computer codes used in the analyses reported, which are not in the public domain.

Programs discussed in this Appendix include TMCALC, FORCE, NFATIG, DAGS, and AXEL.

3.9A-2 TMCALC

The C-E program TMCALC solves the differential equations of motion for a singly or multiply excited multi-degree-of-freedom linear structural system. The program accepts separate, independent, time-varying inputs at each boundary point in the system at which motions due to a seismic event may be imposed, or where a load forcing function may be imposed. The input excitations are provided in digitized form and are assumed to vary linear between input time steps. The solution of the equations of motion in normal mode coordinates employs a closed form integration process.

The inputs to TMCALC consist of:

A. Eigenvalues (natural frequencies) and eigenvectors (mode shapes).

B. A stiffness matrix which relates mass point degrees-of-freedom to boundary point degrees-of-freedom.

C. Mass and damping matrices.

D. Digitized time history records which define the excition in terms of motions at the boundary points of the structural system or forces at mass points.

The output from TMCALC consists of digitized time history records of the absolute accelerations and relative displacements for each mass point and boundary point dynamic degree-of-freedom of the structural system.

The program is used to calculate the dynamic response of structural models used in the dynamic seismic analysis of the reactor coolant system major components, and in the dynamic analysis of linear structural systems subjected to time varying load forcing functions, such as thrust from postulated pipe ruptures.

To demonstrate the applicability and validity of the TMCALC program, the solutions to test problems were obtained and shown to be substantially identical to the results obtained by hand calculations.

One such problem is shown here for the purposes of illustration. The satisfactory agreement between the program results and the theoretical solution indicates the reliability of TMCALC.

Figure 3.9A-1 is a lumped mass, shear beam representation of a uniform beam with the properties shown subjected to different, arbitrary motions at each of the two supports, as shown. The closed form solution to the equation of motion for this structure can be found using standard integration techniques (1). From this closed form solution of the

equations of motion of the multipliexcited system shown in Figure 3.9A-1 maximum values of relative displacement, velocity and acceleration were derived. These solutions are tabulated on Figure 3.9A-1 along with the corresponding results from program TMCALC. Differences can be seen to be less than 1%. The respective times at which these maxima occurred were identical.

3.9A-3 FORCE

The computer code program FORCE calculates the internal forces and moments at designated locations in a piecewise linear structural system, at each time step, due to the time history of relative displacements of the system mass points and boundary points. The program also selects the maximum value of each component of force or moment at each designated location, and the times at which they occur, over the entire duration of the specified dynamic event. The input to FORCE consists of the following:

A. A matrix of influence coefficients computed by the ICES/STRUDL-II[2] program which relate the displacements of the mass point and support point dynamic degrees-of-freedom to the reaction forces and moments or displacements at the designated locations.

B. The time history of the relative displacements of the mass point and support point dynamic degrees-of-freedom as calculated by the programs TMCALC or DAGS.

The program forms appropriate linear combinations of the relative displacements at each time step and performs a complete loads analysis of the deformed shape of the structure at each time step over the entire duration of the specified dynamic event.

The program is used to calculate the time dependent reactions in structural models subjected to dynamic excitation which are analyzed by the TMCALC and DAGS programs.

To demonstrate the validity of the FORCE program, results for test cases were obtained and shown to be substantially identical to those obtained for an equivalent analysis using the public domain program STRUDL(2). One such test case is shown here for purposes of illustration. Figure 3.9A-2 is a lumped mass multiple degree of freedom model of a uniform beam which has been defined to have mass and differential boundary excitation. The arbitrary differential support motion and mass point responses chosen for this example are tabulated on Figure 3.9A-2. The matrix of influence coefficients and the arbitrary mass point and differential support point motions are input to the program to calculate the support reactions and internal shear forces and bending moments indicated in Figure 3.9A-2. These results and those found by performing a stiffness analysis using the STRUDL(2) program are tabulated on Figure 3.9A-2. Results can be seen to be substantially identical.

3.9A-4 AXEL

The AXEL program allows the solution of axisymmetric problems using either triangular or general isoparametric finite elements. The isoparametric element is an 8-noded quadrilateral where the midside nodes can be used to model second order curved boundaries and to provide increased accuracy in regions of high stress. The AXEL program has been run at C-E since 1971 on the IBM 360 computer. The program was verified by comparison of numerous classical examples with results from AXEL. Two such cases are presented here for information.

COMPARISON #1

Two finite element models of a thick cylinder (inner radius = 1 inch, thickness = 4 inches, outer radius = 5 inches) are shown in Figure 3.9A-3. The internal pressure is 20 ksi and the axial pressure is zero. Lame is credited with the classical solution to this problem in the year 1852[3].

In the table below, the deflections and stresses reported are those at the center line of the disc.

	Model			% of Classical	
Radius	A	B	Classical	A	B
1" δ R(mils)	0.921	0.919	0.924	99	99
1" σ R(KSI)	-13.6	-18.5	-20.0	68	92
1" σ T	23.5	21.9	21.7	104	101
1" $\sigma_1 - \sigma_3$	37.1	40.4	41.7	89	97
3" σ R	0.359	0.360	0.359	100	100
3" σ R	-1.5	-1.5	-1.5	100	100
3" σ T	3.1	3.2	3.1	100	103

3" $\sigma_1 - \sigma_3$	4.6	4.7	4.6	100	102
5" δ R	0.277	0.278	0.277	100	100
5" σ R	-0.1	0	0	-	-
5" $\sigma_1 - \sigma_3$	1.7	1.6	1.6	100	100
5" $\sigma_1 - \sigma_3$	1.7	1.6	1.6	106	100

The two different models are presented to demonstrate the accuracy of the program independent of the details of modeling assumptions. It can be seen that there is excellent agreement between the classical text book solution and the program results.

COMPARISON #2

The gross dimensions are identical to the previous case, but the models are subject to a linear radial gradient of 100°F/inch, Figure 3.9A-4. Axial displacement is suppressed (σ_2 = 0) as shown in Figure 3.9A-5. Classical work in this area is attributed to Duhamel (1838) and Lorenz (1907).[3]

Deflection and stresses reported are at the center line of the disc.

	Model			% of Classical	
Radius	A	B	Classical	A	B
1" σ R(MILS)	2.65	2.67	2.69	99	99
1" σ R(KSI)	3.4	3.4	0	-	-
1" σ 2	0	1.9	0.9	-	-
1" σ T	56.6	62.9	62.9	90	100
1" $\sigma_1 - \sigma_3$	56.6	61.0	62.9	90	97
3" δ R	6.17	6.16	6.15	100	100
3" σ 2	-50.4	-50.5	-50.5	100	100
3" σ T	-2.9	-3.0	-3.0	-	-

5" $\sigma_1 - \sigma_3$	102.3	101.6	102.0	100	100

Again, two models are presented to allow independent evaluation of the code, and excellent agreement with the classical solution is observed.

3.9A-5 DESCRIPTION OF COMPUTER CODE DAGS

The computer program DAGS (Dynamic Analysis of Gapped Structure) performs a piecewise linear direct integration solution of the coupled equations of motion of a three dimensional structure which may have clearances or gaps between the structure and any of its supports or restraints (boundary gaps) or between points within the structure (internal gaps). The contacted boundary points may be oriented in any selected direction and may respond rigidly, elastically, or plastically. The structure may be subjected to applied dynamic loads or boundary motions.

3.9A-5-1 Formulation of Equations

The general matrix form of the undamped coupled equations of motion can be written as:[1]

$$M\ddot{X} + KX = F \qquad (1)$$

or in expanded form

$$\begin{matrix} M_m & 0 \\ 0 & 0 \end{matrix} \begin{matrix} \ddot{X}_m \\ \ddot{X}_s \end{matrix} + \begin{matrix} K_{mm} & K_{ms} \\ K_{sm} & K_{ss} \end{matrix} \begin{matrix} X_m \\ X_s \end{matrix} = \begin{matrix} F_m \\ F_s \end{matrix} \qquad (2)$$

Where:

K = the stiffness matrix of the system, condensed in a manner to retain only degrees of freedom at which mass is lumped (subscript m), and those massless boundary degrees of freedom which move with the system until they contact an external boundary point (subscript s).

M_m = a diagonal submatrix of the lumped masses of the system.

X_m = vector of displacements of the mass degrees of freedom of the system.

X_s = vector of displacements of the boundary degrees of freedom of the system.

F_m = vector of external loads applied to the mass degrees of freedom.

F_s = vector of reaction forces applied to the boundary degrees of freedom by the boundaries which they may contact.

For each boundary degree of freedom, either the reaction force is known to be zero because the degree of freedom is not in contact with the boundary, or the position is known to be equal in magnitude to the specified gap distance necessary for contact. For each boundary degree of freedom in Equation (2), the corresponding element in either the X_s or F_s vector is known. Consequently, Equation (2) are rearranged and written as:

$$\begin{bmatrix} M_m & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} \ddot{X}_m \\ \ddot{X}_s \end{Bmatrix} + \begin{bmatrix} K_{mm} & K_{ms} \\ \overline{K}_{sm} & \overline{K}_{ss} \end{bmatrix} \begin{Bmatrix} X_m \\ \overline{X}_s \end{Bmatrix} = \begin{Bmatrix} F_m \\ \overline{F}_s \end{Bmatrix} \qquad (3)$$

Where:

$\overline{X}_s$ = vector of known quantities.

$\overline{F}_s$ = vector of unknown quantities.

The first of equations (3) is written as

$$M_m \ddot{X}_m + \overline{K}_{mm} X_m = P \qquad (4)$$

where: $P = F_m - \overline{K}_{ms} X_s$ is a vector of known quantities.

Equation (4) are solved in the coupled form using the Newmark β Method[(4)] with β = 1/6 which assumes that acceleration varies linearly between integration points.

At each point in time at which Equation (4) are solved for X_m, the second of Equations (3) are solved for all boundary point unknowns F_s. The status of each boundary degree of freedom is then checked and the stiffness matrix is rearranged if necessary to reflect a change in the configuration of the structure, such as opening or closing of a gap. Time steps are adjusted by the program to insure that an integration is performed at the time of configuration change.

The stiffness matrix can be similarly manipulated to account for elasticity or bilinearity in the boundaries, contact between two internal joints, boundary excitation, and

combinations of any or all of these features. In all cases, the basic configuration changes take place as described above.

3.9A-5-2 Description of Program

The DAGS program is used to calculate the dynamic response of piecewise linear structural systems subjected to time varying load forcing functions resulting from postulated LOCA conditions. The program was developed by C-E in 1974 for use of the CDC 7600 computer.

The input to the DAGS program consists of:

A. A symmetric stiffness matrix condensed as described in Equation (2).

B. Mass and damping matrices.

C. Digitized time history records of each of the externally applied forcing functions.

The output from the program consists of digitized time history records of the displacements, velocities and accelerations of all mass degrees of freedom and the displacements and reaction forces for all boundary degrees of freedom.

To demonstrate the applicability and validity of the DAGS program, the solutions to an extensive series of test problems were obtained and shown to be substantially identical to results obtained by hand calculations or alternate computer solutions. Several such problems are shown here for the purposes of illustration. The satisfactory agreement between the program results and the alternate solution indicates the reliability of DAGS.

A. Figure 3.9A-6 is a lumped mass single degree of freedom system with the given properties, subjected to a suddenly applied constant force F_o. The massless boundary degree of freedom is initially a distance of 2 inches from a rigid stop. The solution of the equation of motion for this structure for maximum displacement and reaction force can be found by standard work-energy balance principles. This solution was performed by hand calculation and by the DAGS program. Both results are shown in Table 3.9A-1 and can be seen to be virtually identical.

B. Figure 3.9A-7 is a multiple degree of freedom lumped mass shear beam representation of a beam which may contact rigid, elastic or plastic boundaries and which has a gap between two internal joints. This structure is subjected to three simultaneous applied loads chosen to insure that all gaps close. The solution to the equations of motion for this structure was found using the computer program SHOCK[5] which is in the public domain. The resulting maximum responses are shown in Table 3.9A-2 along with the corresponding results from DAGS. These results can be seen to be in a very good agreement.

C. Figure 3.9A-8 is a three dimensional multiple degree of freedom space from representation of a reactor coolant pump and cold leg piping with a gap between the pump and a pump stop. The structure is subjected to a suddenly applied constant load simulating a

postulated guillotine rupture in the pump discharge piping. This system was analyzed by a version of the C-E computer program TMCALC which uses modal solution procedures but allows the presence of a single rigid stop. The results from the analyses using TMCALC and DAGS are shown in Tables 3.9A-3a and 3.9A-3b. Table 3.9A-3a shows the maximum mass point displacements, velocities, and accelerations and the reaction force at the stop. The support reactions and internal forces and moments shown in Table 3.9A-3b were obtained using C-E computer program FORCE and the digitized time history results from the TMCALC analysis and from the DAGS analysis. All results can be seen to be in excellent agreement.

3.9A-6 NFATIG

NFATIG is a digital computer program used to analyze nuclear Class 1 piping components in accordance with the ASME B&PV code Section III NB-3650(6). Input to this program consists of a geometry, material properties, and the various indices for a given section of piping, the loadings and number of cycles of each, the material fatigue curve, and allowable Sm stresses.

The output includes the stresses Sn and Salt, and the usage factor for each load set as well as the cumulative usage factor for all cases. NFATIG also incorporates the capability to calculate the stress indices for various standard piping component shapes including tangents, elbows, tees, branches, tapered joints, fillet welds, and reducers.

The NFATIG program was developed by C-E in 1973 for use on the CDC 7600 computer, and updated as required in accordance with subsequent revision of Section III Code.

Verification of NFATIG was by example problems and comparison with hand calculations. One such example is included below for demonstration of the accuracy of the program.

Example:

The stress indices for an elbow are given in Table NB-3683.2-1 as follows:

$$C_1 = \frac{2R - r}{2(R - r)}$$

$$C_2 = \frac{1.95}{(t\,R/r^2)\;2/3}$$

C_3 = 1.0

C_3 = 0.5

K_1 = K_2 = K_3 = 1.21 (weld corrected)

For the example problem of a hot leg elbow:

R = 63.

r = 23.3125

t = 4.125

Then:

C_1 = 1.2937

C_2 = 3.1889

NFATIG computes values of 1.294 and 3.190, respectively.

Equation (10) of NB-3653 is:

$$S_n = C_1 \frac{Po\,Do}{2t} + C_2 \frac{Do}{2I} Mi + \frac{1}{2(1-v)} E\alpha\,\Delta T_1 + C_3\,Eab\,(\alpha aTa - \alpha bTb)$$

For the example problem of a hot leg elbow, considering the Hydrostatic Test - Plant Heatup Load Set:

Do = 50.75 in. (piping spec.)

Po = (3125 - 200) = 2925 psid (system spec.)

Mx = 405.

My = 7.63

Mz = 2383584. (from MEC - 21 Flexibility analysis)

E = 29.9×10^6

v = 0.3

α = 6.07×10^{-6} (material spec.)

ΔT_1 = 127. (system spec.)

ΔT_2 = 77.

Ta = 6.0 (LION thermal gradient analysis)

T_b = 0

I = 6521.1 (calculated from geometry)

The computed NFATIG result is 54822. psi versus a value of 54818. calculated by hand, showing excellent agreement within round off accuracy.

Equation (11) of NB-3653 is:

$$Sp = K_1C_1 \frac{Po\,Do}{2T} + K_2C_2 \frac{Do}{2I} Mi + \frac{1}{2(1-v)} K_3\, E\alpha\, \Delta T_1 + K_3C_3\, Eab$$

$$(\alpha a\, Ta - \alpha b\, Tb) + \frac{1}{(1-v)} E\alpha\, \Delta T_2$$

The computed NFATIG result is 86298 psi versus a hand calculated value of 86283 psi, which again shown excellent agreement.

Now, since Sn < 3 Sm, Ke = 1.0 and by Equation (14) Salt equal 1/2 Sp. NFATIG computes Salt 43149 psi versus 43147 psi by hand.

The number of allowable fatigue cycles at this Salt magnitude is computed at 6945 cycles by NFATIG versus 6950 calculated by eye from Figures 1-90.

The individual usage factor for 5 cycles specified for this load set is computed at .00072 by NFATIG and .00072 by hand.

Additional verification examples exist to verify computation of primary stress intensity by Equation (9), inclusion of seismic induced pipe moments, computation of cumulative usage factor for several loads sets, and computation of stress indices for other shapes. The above example is provided as a typical case to verify the accuracy of the NFATIG program.

At node 1379, the max stress range occurs for the radial stress between LCs 0 & 1 and is -1.80E4.

The corresponding biaxiality ratio β is 0.248 and the stress multiplier factor is 1.06 (from fig. A-8142-1 of Ref. 7). The corresponding stress range results then Dσ = **19,058.**

At node 2935, the max stress range occurs for the tangential stress between LCs 1 & 5 and is -1.63E4.

The corresponding biaxiality ratio β is 0.425 and the stress multiplier factor is 1.03 (from fig. A-8142-1 of Ref. 7). The corresponding stress range results then Dσ = **16,754.**

TABLE 3.9A-5b
MAX STRESS INTENSITIES (OUTPUT of RANGETS)

NODE 1379
FIRST LOAD STEP = 0
SECOND LOAD STEP = 1
BETA = 0.24821E+00
KAPPA = 0.10604E+01
STRESS RANGE = **0.19067E+05**

NODE 2935
FIRST LOAD STEP = 1
SECOND LOAD STEP = 5
BETA = 0.42568E+00
KAPPA = 0.10289E+01
STRESS RANGE = **0.16737E+05**

Hand-calculated results (Table 3.9A-5a) match those obtained by running the RANGETS program (Table 3.9A-5b) except for the small differences caused by rounding off in hand calculations.

TABLE 3.9A-6a
HAND-CALCULATED FATIGUE USAGE FACTORS
(FROM STRESS COMPONENTS CALCULATED BY ANSYS, REF. 8)

Stress components – output of five LCs from ANSYS – are tabulated below. LCs 1 & 4 were imposed coincident to verify that the program performs correctly also when stress components are identical. The 5 LCs were grouped within two events, the first containing LCs 1, 2, 3, the second one LCs 3 and 4. The associated number of cycles were 500 and 100,000, respectively.

2	2	6100.7	3344.2	2	2	2532	1947.7

By performing hand-calculation following the sequence identified at points a) thru k) of Section 3.9A-9, the cumulative fatigue usage factors at selected locations/orientations of the nodes being analyzed result:

Node **1379** (two locations/orientations selected):

1. T/S angular orientation: **0°** - orientation through the hole: **40°**.

Max total stress range occurs between Event 1, LC 1 and Event 1, LC 2.

Max absolute value of the stress range is 36,048.
Corresponding S_{alt} is 18,024.
Number of allowable cycles is 145,480
Usage factor is 500/145480 = 0.0034.
Event 1 is eliminated. The 100,000 cycles of Event 2 remain.
Max absolute value of the stress range is 25,718.
Corresponding S_{alt} is 12,859.
Number of allowable cycles is 774,900
Usage factor is 0.129.
100,000 cycles of Event 2 eliminated. No other events remain.
The cumulative usage factor is then **0.1324.**

2. T/S angular orientation: 15° - orientation through the hole: 120°.

Max total stress range occurs between Event 1, LC 1 and Event 1, LC 2.

Max absolute value of the stress range is 52,490.
Corresponding S_{alt} is 26,245.

Number of allowable cycles is 33,344

TABLE 3.9A-6a (Cont'd)
HAND-CALCULATED FATIGUE USAGE FACTORS
(FROM STRESS COMPONENTS CALCULATED BY ANSYS, REF. 8)

Usage factor is 500/145,480 = 0.015.
Event 1 is eliminated. The 100,000 cycles of Event 2 remain.
Max absolute value of the stress range is 40,384.
Corresponding S_{alt} is 20,192.
Number of allowable cycles is 95,372.
Usage factor is 1.048.
Cycles of Event 2 eliminated. No other events remain.
The cumulative usage factor is then **1.063**.
Node **2935** (two orientations/locations selected):

1. T/S angular orientation: 0° - orientation through the hole: 0°.

   The max total stress range occurs either between Event 1, LC 1 and Event 2, LC 2 (or between Event 2, LC 1 and Event 2, LC 2, being LCs 1 and 4 imposed to be coincident).

   Max absolute value of the stress range is 27,724.
   Corresponding S_{alt} is 13,862.
   Number of allowable cycles is 443,090
   Usage factor is 500/443090 = 0.0011.
   Event 1 is eliminated. The 99,500 cycles of Event 2 remain.
   Max absolute value of the stress range is 27,724 (this cycle too).
   Corresponding S_{alt} is 13,862.
   Number of allowable cycles is 443,090
   Usage factor is 99,500/443,090 = 0.225.
   Cycles of Event 2 eliminated. No other events remain.
   The cumulative usage factor is then **0.226**

[If the first cycle reported above between (…..) was used, the first usage factor (for 100,000 cycles) would have resulted 0.226, whereas the second usage factor (for 500 cycles) would have resulted 0.0011 giving a cumulative usage factor of 0.227.]

TABLE 3.9A-6a (Cont'd)
HAND-CALCULATED FATIGUE USAGE FACTORS
(FROM STRESS COMPONENTS CALCULATED BY ANSYS, REF. 8)

1. T/S angular orientation: 15° - orientation through the hole: 180°.

   The max total stress range occurs between Event 1, LC 1 and Event 2, LC 2 (or between Event 2, LC 1 and Event 2, LC 2, being LCs 1 and 4 imposed to be coincident).

   Max absolute value of the stress range is 25,345.
   Corresponding S_{alt} is 12,673.
   Number of allowable cycles is 883,560.
   Usage factor is 500/883,560 = 0.001.
   Event 1 is eliminated. The 99,500 cycles of Event 2 remain.
   Max absolute value of the stress range is 25,345 (this cycle too).
   Corresponding S_{alt} is 12,673.
   Number of allowable cycles is 883,560.
   Usage factor is 99,500/883,560 = 0.112.
   Cycles of Event 2 eliminated. No other events remain.
   The cumulative usage factor is then **0.113**

   [If the first cycle reported above between (…..) was used, the first usage factor (for 100,000 cycles) would have resulted 0.113, whereas the second usage factor (for 500 cycles) would have resulted 0.001 giving a cumulative usage factor of 0.114.]

3.9A-7 RANGE

The RANGE program calculates the primary membrane plus bending stress range at two nodes of a stress line for "n" load cases (LCs), based on the rules of NB-3222-2 (Ref. 7). Specifically:

a) calculates the difference of the six membrane plus bending stress components between each LC and the other "n-1" LCs;

b) calculates the resulting stress intensity (S.I.) from the stress differences above;

c) for the two LCs which give the maximum S.I., results are recorded and printed.

As an example, for 6 LCs identified as "1", "2",..., "6", the difference between each stress component (membrane + bending) is computed according to the following scheme ("0" indicates the "zero-stress" case):

0-1	0-2	0-3	0-4	0-5	0-6
1-2	1-3	1-4	1-5	1-6	
2-3	2-4	2-5	2-6		
3-4	3-5	3-6			
4-5	4-6				
5-6					

For each of the 21 combinations, the maximum S.I. is computed starting from the difference between corresponding stress components (i.e., $\sigma_{x(0)} - \sigma_{x(1)}$, $\sigma_{y(0)} - \sigma_{y(1)}$, etc.).

For the two LCs giving the maximum S.I., results are recorded and printed.

The difference between hand-calculated numbers and output from RANGE are summarized in Tables 3.9A-4a and 3.9A-4b, respectively. The results can be observed to be perfectly coincident.

3.9A-8 RANGETS

RANGETS calculates the stress range at two nodes of a stress line in a perforated region of a tubesheet (T/S), analyzed according to the rules established in A-8000 (Ref. 7). The stress range is computed for "n" load cases (LCs) – including the "zero stress" – as per NB-3222-2 (Ref. 7), starting from the ANSYS (Ref. 8) output for a homogeneous T/S analysis.

Namely:

a) for each LC, the program calculates the radial and tangential stress components. The contribution due to the primary pressure inside the T/S holes is taken into account as defined in A-8000;

b) the difference between the radial and tangential stress components (membrane + bending + peak) for each LC (including the "zero stress") is calculated;

c) the maximum stress range ($D\sigma$) is selected, regardless the direction (either radial or tangential);

d) for the maximum $D\sigma$ identified at point c), the biaxiality ratio σ_r/σ_t is calculated;

e) the stress multiplier factor K is determined (from Figure A-8142-1) and the max S.I. is calculated multiplying the stress range of point c) by the K factor;

f) for each node of the stress line, and for each LC, operations c) thru e) are performed and results recorded and printed.

Following the rules of A-8000, the stress due to the internal pressure on tubes is evaluated as follows:

$S = (p-h-2 * t) * [h+2 (E_t/E)t]$

$\sigma_{rt} = \sigma_{\Theta t} = s * Pr$, where:

s = stress for unitary pressure, p = pitch, h = nominal width of ligament

t = tube thickness, Pr = internal pressure on tubes,

E_t = Young's modulus of tubes, E = Young's modulus of T/S,

σ_{rt} = radial stress due to internal pressure,

$\sigma_{\Theta t}$ = tangential stress due to internal pressure.

Total stresses are then evaluated with the following formulas:

$\sigma_r = (p/h) * \sigma_{ra} + \sigma_{rt}$

$\sigma_{\Theta} = (p/h) * \sigma_{\Theta a} + \sigma_{\Theta t}$

where:

σ_r = total radial stress, σ_{ra} = radial stress from ANSYS (Ref. 8),

σ_θ = total tangential stress, $\sigma_{\theta a}$ = tangential stress from ANSYS (Ref. 8).

The difference between hand-calculated results and output results as generated by RANGETS are summarized in Tables 3.9A-5a and 3.9A-5b, respectively, and show excellent agreement within round off accuracy.

3.9A-9 FATIGTS

The FATIGTS program calculates the maximum fatigue usage factor at two nodes of a stress line in a perforated region of a tubesheet (T/S), analyzed per rules of A-8000 (Ref. 7). The fatigue usage factors are calculated for "m" events of "n" load cases (LCs) each (including the "zero stress"), as per NB-3222-4 (Ref. 7). Stresses are calculated with ANSYS for a homogeneous T/S model. The stress intensity (S.I.) range is computed per rules of A-8142-2 (Ref. 7), at various angular orientations of the T/S and through the holes. Namely, FATIGTS includes three angular orientations along the T/S and ten orientations along the holes. The orientations along the T/S are 0°, 15° and 30°, whereas the orientations along the holes are evenly distributed between 0° and 90° per the T/S angular orientations at 0° and 30°; between 0° and 180° per the T/S angular orientation at 15°. The three angular orientations above cover all the T/S surface with an approximation of 7.5°.

Angular orientations refer to a coordinate system X-Y with the origin at the center of the T/S and the axes parallel and perpendicular to the tube-lane, respectively. Moreover, the Y-axis is located such that the distance between two adjacent tubes, measured along the Y-axis, corresponds to the nominal ligament. Angular orientations along the T/S holes are measured starting from the y-axis of a coordinate system with the origin at the center of the hole and the axes oriented according to Fig's A-8142-3, A-8142-4 and A-8142-5 of A-8000 (Ref. 7).

The fatigue usage factors at each node of a stress line and at each angular orientation as described above are computed as follows:

a) for each LC of a specified event, the radial and tangential stress components are evaluated per rules of A-8000. Contribution due to the primary pressure inside the T/S holes is taken into account;

b) radial and tangential components are multiplied by Y1 and Y2 (stress multipliers), derived from Fig's A-8142-3, A-8142-4, A-8142-5, as a function of the ratio between ligament and pitch to account for the effective angular orientations along the T/S and along the holes;

c) for each LC, the total stress obtained by summing the radial, the tangential and the pressure on the

surface where the stress is being computed (either primary or secondary) is evaluated;

d) the range of the total stress is then computed as a difference between each LC (including the "zero stress") and the others;

e) the (two) LCs, and the events to which they belong, producing the maximum range of point d) are identified;

f) the smaller – between the number of cycles associated at the events of point e) – is identified;

g) the corresponding S_{alt}, half of the maximum stress range of point e) is computed;

h) the fatigue usage factor produced by the two events identified at point e) is computed. The allowable number of cycles is derived from the fatigue curve for S_{alt} * (E/E_{act}), being E the Young's modulus of the fatigue curve used and E_{act} the actual Young's modulus at the location being examined;

i) the event to which corresponds the smaller number of cycles is then eliminated. The number of cycles of the other event is reduced by an equivalent amount of cycles;

j) calculations of points d) to i) above are repeated until all the events are eliminated;

k) the total fatigue usage factor is then computed by summing each single contribution computed at point h) for all the iterations required.

The stress contribution due to the tube internal pressure is computed as described in previous Section 3.9A-8 for the program RANGETS.

According to the rules of A-8000, the total stresses are:

$\sigma = Y1*\sigma_r + Y2*\sigma_\theta + Ps$, where:

σ = total stress,

$\sigma_r = (p/h) * \sigma_{ra} + \sigma_{rt}$,

$\sigma_\theta = (p/h) * \sigma_{\theta a} + \sigma_{\theta t}$,

Ps = pressure on the surface where the stress is being computed,

σ_{rt} = radial stress due to tubes internal pressure,

$\sigma_{\theta t}$ = tangential stress due to tubes internal pressure,

σ_r = total radial stress,

σ_{ra} = radial stress from ANSYS (Ref. 8),

σ_θ = total tangential stress,

$\sigma_{\theta a}$ = tangential stress from ANSYS (Ref. 8),

p = pitch; h = ligament,

Y1, Y2 = stress multipliers, from Tables A-8142-3, A-8142-4, A-8142-5 of Ref. 7.

The difference between hand-calculated results and output results as generated by FATIGTS are summarized in Tables 3.9A-6a and 3.9A-6b, respectively. Excellent matching can be observed, except for small differences caused by rounding off to hand calculations.

3.10 SEISMIC QUALIFICATION OF SEISMIC CATEGORY I INSTRUMENTATION AND ELECTRICAL EQUIPMENT

Refer to section 3.10.5 through 3.10.7 for the seismic qualification of Seismic Category I instrumentation and electrical equipment in the C-E scope of supply. The following sections 3.10.1 through 3.10.4 applies to Seismic Category I instrumentation and electrical equipment not in the C-E scope of supply.

3.10.1 SEISMIC QUALIFICATION CRITERIA

General Design Criterion 2 (GDC-2) of Appendix A to Code of Federal Regulations, 10CFR50 requires that "Structures, systems and components important to safety shall be designed to withstand the effects of earthquakes without loss of capability to perform their safety functions. The integrity of the safety-related Seismic Category I instrumentation of nuclear power plants must be assured in the event that earthquakes occur at nuclear plant sites. This assurance is provided by designing the plant to withstand the seismic responses that would be experienced during a postulated earthquake."

3.10.1.1 General

Seismic Category I instrumentation and electrical equipment are qualified to withstand the effects of the safe shutdown earthquake (SSE) and remain functional.

10CFR100 defines Safe Shutdown Earthquake as an earthquake which produces maximum vibratory ground motion for which structures, systems and components, important to safety, are designed to remain functional.

The parameters used to develop seismic loadings and criteria for Seismic Category I structures, systems, and components are described in section 3.7.

Seismic Category I instrumentation and electrical equipment important to safety are divided into three categories:

A. Equipment which has been designed and qualified to maintain its functional capability during and after an SSE

B. Equipment which has been qualified to remain functional after an SSE

C. Equipment which has been designed and qualified to maintain the pressure boundary integrity of the system of which it is a part during and after an SSE

The structural requirements for instrumentation equipment and systems that were qualified to maintain pressure boundary integrity are in accordance with ASME Section III.

3.10.1.2 Standby Power System and Category I Instrumentation and Electrical Equipment

In addition to the general qualifications of paragraph 3.10.1.1, the standby power system and Seismic Category I instrumentation and electrical equipment associated with engineered safety features are qualified to withstand seismic disturbances of the intensity of an SSE during post-accident operation.

3.10.2 METHODS AND PROCEDURES FOR QUALIFYING ELECTRICAL EQUIPMENT AND INSTRUMENTATION

3.10.2.1 Means of Qualification

IEEE Standard 344-1975, Recommended Practices for Seismic Qualification for Class IE Equipment (classified as Seismic Category I) for Nuclear Power Generating Stations, was used for all seismic qualifications.

The applicable seismic input data in the form of a specification was provided to the equipment supplier with appropriate response spectrum curves for the various floor elevations (or one curve that envelops all locations). The supplier was also provided with minimum acceptance criteria for all equipment and/or systems to determine their compliance with the seismic specifications.

An analysis of seismic design adequacy of equipment, including supports such as cable tray supports, battery racks, instrument racks, control consoles and switchgear, was performed according to the response spectrum techniques (see section 3.7).

3.10.2.2 Seismic Qualification

Seismic qualification plans were prepared by the equipment suppliers and submitted for review prior to qualification. Subsequent seismic qualifications were performed by the equipment suppliers.

The seismic qualification reports demonstrate the equipment's ability to perform its required function during and after (in accordance with paragraph 3.10.1.1) the time it would be

subjected to the force resulting from one SSE preceded by the effects of the equivalent of two operating basis earthquakes (OBEs).

Qualification and documentation procedures used for Seismic Category I equipment and/or systems meet the requirements of IEEE 344-1975 and Regulatory Guide 1.100 (refer to section 1.8).

The methods for seismic qualification are:

- Analysis
- Test
- Combination of analysis and test.

3.10.2.2.1 Analysis

Mathematical analyses without testing were acceptable only where it could be demonstrated that structural integrity alone ensured the intended design function. The procedures used were in accordance with Section 5 of IEEE 344-1975. Justification for the use of any static coefficient was provided by the supplier. In the case of electrical motors used as pump drivers where it was shown that the motors had no resonances in the frequency range below the high frequency asymptote (ZPA) of the required response spectrum (RRS), they were considered rigid and were analyzed statically without testing.

3.10.2.2.2 Testing

Seismic tests were performed by subjecting equipment to vibratory motions that conservatively simulated the Required

Response Spectra (RRS) or the required input motion (RIM) at the equipment mounting. The requirements of testing were in accordance with Section 6 of IEEE 344-1975. The tests were performed using one of the following techniques:

- Proof testing
- Fragility testing
- Device testing
- Assembly testing
- Generic testing

If the equipment was not tested to its ultimate capability (fragility testing), then proof or generic testing was acceptable based on limits imposed by system design requirements.

3.10.2.2.3 Test Methods

Test methods were in accordance with Section 6 of IEEE 344-1975 for qualification testing. Selection and justification for any static coefficients or test methods used was provided by the supplier (refer to paragraph 3.10.2.1).

3.10.2.2.4 Combined Analysis and Testing

When the equipment could not be qualified practically by analysis or testing because of its size and complexity, combined analysis and testing were utilized.

Combined analysis and testing methods were in accordance with Section 7 of IEEE 344-1975.

3.10.3 METHODS AND PROCEDURES OF ANALYSIS OR TESTING OF SUPPORTS OF ELECTRICAL EQUIPMENT AND INSTRUMENTATION

Analyses or tests were performed for all supports of electrical and instrumentation equipment to ensure their structural capability to withstand seismic excitation. The following bases were used in the design and analysis of cable tray supports and instrument tubing supports:

A. All cable tray supports and instrument tubing supports were designed by the response spectrum method.

B. Analysis and seismic restraint measures for tray supports and tubing supports were based on combined limiting values for static load, span length, and computed seismic response.

C. All Class 1E cable tray supports were designed to meet the requirements by dynamic analysis using the appropriate seismic response spectra generated for 20% damping during SSE loading. The damping value is expressed as a percentage of critical damping.

D. The Seismic Category I instrument tubing systems are supported such that the allowable stresses permitted by Section III of ASME Boiler and Pressure Vessel (B&PV) Code are not exceeded when the tubing is subjected to the loads specified in section 3.9 and Regulatory Guide 1.48 for Class 2 and 3 piping.

   For field-mounted instruments, the stress level in the mounting structure does not exceed the material allowable stress when subjected to the maximum

acceleration level of the mounting location. The weight of the instrument is included.

Supports were tested and/or analyzed with equipment installed. If the equipment was inoperative during the support test, the response at the equipment mounting location was monitored. In such a case, equipment was tested separately. Where it was necessary to test individual devices (e.g., relays or instruments) separate from the panels to which they are mounted, the accelerations of the panel at the device locations were checked to ensure that they were equal to or lower than the level to which the devices were qualified.

3.10.4 OPERATING LICENSE REVIEW

3.10.4.1 Qualification and Documentation Procedures

Qualification and documentation procedures for Seismic Category I equipment were in accordance with the recommendations contained in IEEE Standard 344-1975.

3.10.5 SEISMIC DESIGN OF CATEGORY I INSTRUMENTATION AND ELECTRICAL EQUIPMENT IN THE CE SCOPE OF SUPPLY

This section describes the seismic design criteria and analyses, tests, procedures, and acceptance criteria applied to seismic Category I instrumentation, electrical equipment, except for valve and pump motors, and their supports. The information applicable to instrumentation and control equipment is contained in Combustion Engineering's Topical Report CENPD-182 "Seismic Qualification of C-E Instrumentation

Equipment." Valve and pump motors are discussed in Section 3.9.2.2.

3.10.5.1 Seismic Qualification Criteria

Instrumentation and electrical equipment used for Post-Accident Monitoring (PAM), the Reactor Protective System (RPS), the Supplementary Protection System (SPS), the Engineered Safety Features Actuation System (ESFAS), the actuation devices for ESF Systems actuated components, and the emergency power system are designed as Seismic Category I requirements to ensure the ability to initiate required protective actions during, and following, a Safe Shutdown Earthquake (SSE); and to supply power, following an SSE, to components required to mitigate the consequences of events which require safety system operation. The criteria chosen, tests or analyses to be used, and the general methodology are discussed in CENPD-182.

3.10.6 METHODS AND PROCEDURES FOR QUALIFYING ELECTRICAL EQUIPMENT AND INSTRUMENTATION

Seismic Category I instrumentation and electrical equipment required to perform a safety action during a seismic event, after a seismic event, or both is qualified (with appropriate documentation) in accordance with the requirements of the equipment specifications. These requirements are consistent with the requirements of IEEE 344-1971 "IEEE Guide For Seismic Qualification of Class 1 Electrical Equipment for Nuclear Power Generating Stations" and the following additional requirements.

A. The appropriate seismic excitation for which the equipment must qualify will be determined based on location in the plant.

B. The equipment will be required to be designed against failure to perform its intended function during and after an earthquake of the intensity of the Safe Shutdown Earthquake.

C. The vendor is required to substantiate the adequacy of the design by analysis, or testing and/or operating experience depending on the type of equipment under consideration and its intended safety function. The choice of the qualification method will be approved by Combustion Engineering.

D. The quality assurance program as described in CENPD-210A "Description of the C-E Nuclear Steam Supply System Quality Assurance Program" illustrates the procedures used in assuring the implementation of the requirements by equipment suppliers.

The tests and analyses used to implement IEEE 344-1971 and the additional requirements are discussed in Combustion Engineering's Topical Report CENPD-182. The documentation of these tests and analyses will appear in Part Two of CENPD-182 as they are performed. See table 3.2-1 for Seismic Category I principal components. The test program will provide the following:

E. A test program is required to confirm the functional operability of all Seismic Category I electrical and

associated mechanical equipment and instrumentation during and after an earthquake of magnitude up to and including the SSE.

F. The characteristics of the required input motion shall be specified by one of the following:

1. response spectrum

2. power spectral density function

3. time history

Such characteristics, as derived for the structures or systems seismic analysis, shall be representative of the input motion at the equipment mounting locations.

G. Equipment shall be tested in the operational condition. Operability shall be verified during and after the testing.

*H. The actual input motion shall be characterized in the same manner as the required input motion, and the conservatism in amplitude and frequency content shall be demonstrated.

____

* Item H is supplemented as follows: In applying this item to the electrical equipment, the frequency spectrum used shall cover the range from 1 through 33 hz.

I. Seismic excitations generally have a broad frequency content. Random vibration input motion shall be used. However, single frequency input, such as sine beats, may be utilized provided one of the following conditions are met:

1. The characteristics of the required input motion indicate that the motion is dominated by one frequency (i.e., by structural filtering effects).

2. The anticipated response of the equipment is adequately represented by one mode.

3. The input has sufficient intensity and duration to excite all modes to the required magnitude, such that the testing response spectra will envelop the corresponding response spectra of the individual modes.

J. The input motion shall be applied to one vertical and one principal (or two orthogonal) horizontal axes simultaneously unless it can be demonstrated that the equipment response along the vertical direction is not sensitive to the vibratory motion along the horizontal direction, and vice versa. The time phasing of the inputs in the vertical and horizontal direction, and vice versa. The time phasing of the inputs in the vertical and horizontal directions will be such that a purely rectilinear resultant input is avoided. The acceptable alternative is to have vertical and horizontal inputs in-phase, and then repeated with inputs 180 degrees out-of-phase. In addition, the test

will be repeated with the equipment rotated 90 degrees horizontally.

K. The fixture design shall meet the following requirements:

   1. Simulate the actual service mounting

   2. Cause no dynamic coupling to the test item.

L. The in-situ application of vibratory devices to superimpose the seismic vibratory loadings on the complex active device for operability testing is acceptable when application is justifiable.

M. The test program may be based upon selectively testing a representative number of mechanical components according to type, load, level, size, etc. on a prototype basis.

3.10.7 METHODS AND PROCEDURES OF ANALYSIS OR TESTING OF SUPPORTS OF ELECTRICAL EQUIPMENT AND INSTRUMENTATION

To insure qualification for the required forces, acceleration requirements are included in equipment specifications as design parameters. Vendors will use this information as the basis for analysis or testing depending on the type, size, shape, or complexity of equipment to be qualified.

The equipment specification include, as a minimum, the following seismic requirements:

A. The appropriate seismic excitation for which the equipment must qualify will be determined based on location in the plant.

B. The equipment is required to perform its intended function during and after a Safe Shutdown Earthquake;

C. The vendor is required to substantiate the adequacy of the design by analysis, testing, past qualifications, or a combination of these depending on the type of equipment and its intended safety function; and

D. The quality assurance program used in assuring the implementation of the requirements of CENPD-182 are discussed in CENPD-210A.

The seismic qualification program, as described in CENPD-182 meets the specified requirements for seismic category I equipment.

E. Analyses or tests shall be performed for all supports of electrical and associated mechanical equipment and instrumentation to ensure their structural capability to withstand seismic excitation.

F. The analytical results will include the following:

   1. The required input motions to the mounted equipment shall be obtained and characterized in the manner as stated in Section 3.10.6 item F.

   2. The combined stresses of the support structures shall be within the allowable limits found in recognized mechanical handbooks.

G. Supports shall be tested with either equipment or dynamically equivalent models installed. If the equipment is not operating or not installed during the support test, the response at the equipment mounting

locations shall be monitored and characterized in the manner as stated in Section 3.10.6 item F. In such a case, equipment shall be tested separately and the actual input to the equipment shall be more conservative in amplitude and frequency content than the monitored response.

H. The requirements of Section 3.10.6 items F, H, I, J, and K are applicable when tests are conducted on the equipment supports.

Specifically, cabinet and support test requirements will be conducted as follows:

The design seismic environment of equipment located within support-structures (cabinets) will be determined by either test or analysis.

I. Testing will consist of one of the following procedures:

1. Fully Operational Cabinet Test

The cabinet, fully loaded with equipment, will be tested in its operating state. During testing, a sample of safety-related functions will be monitored. This test will demonstrate both structural integrity and functional operability.

2. Weighted Cabinet Test With Subsequent Equipment Tests

a. The cabinet will be tested with simulated equipment in place of the actual equipment. The simulated equipment will be equal in mass, mass distribution, and mounting to the actual

equipment such that the dynamic response of the weighted cabinet is equal to that of the fully loaded cabinet. During testing the motions present at the equipment mounting points will be recorded. This test will demonstrate the cabinet structural integrity and determine the local seismic environment of the actual equipment.

b. The actual equipment will be independently tested or analyzed to those motions determined by the weighted cabinet test. The equipment will be operational and all safety related functions will be monitored during the test. This test will demonstrate functional operability of the equipment.

3. <u>Equipment Test</u>

Equipment which is not mounted in a cabinet will be tested or analyzed in its operating state in a configuration which simulates its intended mounting.

J. For structures which can be modeled a dynamic analysis may be substituted for the weighted cabinet test to determine the motions at the enclosed equipment mounting points.

For both testing and analysis, the input motions to the cabinet shall be derived from the building motions at the cabinet's intended location.

This page intentionally left blank

3.11 ENVIRONMENTAL DESIGN OF ELECTRICAL EQUIPMENT

Environmental design criteria for the facilities conform to 10CFR50, Appendix A, General Design Criterion 4, Environmental and Missile Design Bases. Compatibility of safety-related equipment with environmental conditions is provided to fulfill the following design criteria:

A. For normal operation, systems and components required to mitigate the consequences of a design basis accident (DBA) or for safe shutdown are designed to remain functional during and after exposure to the following environmental conditions:

   1. Winter and summer design temperatures maintained at the equipment location during normal operation by the ventilating and cooling system described in section 9.4.

   2. Relative humidity conditions at the equipment location during normal operation.

   3. Pressure conditions at the equipment location during normal operation.

   4. Maximum expected integrated radiation exposures for 40 years at the equipment location during normal operation.

B. In addition to the normal operation environmental requirements given in listing A above, the safety-related systems and components required to mitigate the consequences of a DBA, or to attain a safe

shutdown of the reactor, are designed to remain functional after exposure to the environmental conditions anticipated following the specific DBA which they are intended to mitigate. Anticipated environmental conditions and requirements are as listed below:

1. Components inside containment -- The temperature, pressure, humidity, and chemical environment inside containment after a design basis loss-of-coolant accident (LOCA) or main steam line break (MSLB) accident.

2. Components inside containment which are required after a design basis LOCA -- In addition to the requirements set forth in listing B.1, the time integrated post-LOCA radiation doses.

3. Components outside containment -- The expected pressure temperature and humidity environmental conditions at the equipment location.

4. Components outside the containment that are required to mitigate the consequences of a design basis LOCA -- The expected integrated accident radiation doses at the equipment locations in addition to the requirements set forth in listing B.3. In computing such doses for equipment in contact with or in proximity to recirculation water, it is assumed that 50% of the core halogen inventory and 1% of the core solid fission product

inventory are in the recirculation water after a design basis LOCA. For equipment located remotely from recirculation water, the containment leakage plume or other appropriate accidental release is assumed. These other accidental releases may be from a fuel handling accident or waste gas decay tank rupture in the fuel building or radwaste building, respectively.

3.11.1 EQUIPMENT IDENTIFICATION AND ENVIRONMENTAL CONDITIONS

The Equipment Qualification Program provides assurance that certain safety-related (i.e. important to safety) electrical and post-accident monitoring equipment will function during the design conditions postulated for plant normal, abnormal operation, design basis accidents, and the post-accident duration, as outlined in subsections 3.11.A and 3.11.B.

Normal plant environmental conditions are defined as those temperature, pressure, humidity and radiation conditions that occur during normal plant operations, including anticipated operational occurrences. Normal conditions are those for which the plant is designed.

Anticipated operational occurrences, or abnormal plant conditions, are those transient conditions of normal operation which are expected to occur one or more times during the life of the plant and include, but are not limited to, the loss of all offsite power and the concurrent loss of non-essential HVAC systems.

The Equipment Qualification Program defines plant areas as either mild or harsh based upon their accident environments. Mild environmental parameters are the range of conditions upon which equipment design is based. Failures under mild environment conditions are not considered common mode failures and are typically random in nature. A mild environment is an environment that would at no time be significantly more severe than the environment that would occur during normal plant operation, including anticipated operational occurrences. The specific environmental qualification of equipment located in mild environment plant areas is established by the use of design/purchase specifications and maintenance/surveillance programs. Therefore, equipment located in mild environment plant areas is not within the scope of the environmental qualification program.

A harsh environment is defined as the environment in any plant area where there is a significant increase above the normal plant environmental conditions in one or more environmental parameters due to a design basis accident or high energy line break. Harsh plant conditions subject equipment to severe environmental stresses as compared to the range of conditions during the equipment design and specification process and may potentially result in common mode failures. Therefore, important to safety equipment located in harsh environment plant areas are within the scope of the environmental qualification program.

The harsh environmental parameters that occur during normal plant operation and postulated design basis accident conditions

are provided for the containment, auxiliary, and fuel buildings and the main steam support structure in Appendix A of the Equipment Qualification Program Manual. The environmental parameters in the appendix are given by EQ Zone. An EQ Zone consists of one or more rooms and/or plant areas grouped according to their similarity of environmental conditions. The values given for each zone represents the worst case for the room(s) within each zone.

3.11.2 QUALIFICATION TESTS AND ANALYSES

Qualification tests and analyses performed on instrumentation and electrical equipment located in a harsh environment fulfill the requirements of IEEE 323-1974. When data for safety-related equipment are available and proven analytical methods are known, environmental qualification may be based on analysis. If such analytical methods are not feasible, qualification is based on environmental testing.

The harsh environmental qualification design parameters are presented in Appendix A of the Equipment Qualification Program Manual.

3.11.2.1 Component Environmental Design and Qualification for Normal Operation

Environmentally qualified equipment is designed for 40 years of continuous operation in the most severe temperature, pressure, humidity, and radiation environment that exists at the equipment location during normal operation, assuming proper

routine preventive maintenance is performed, such as periodic replacement of seals and packing, and testing.

Appendix A of the Equipment Qualification Program Manual provides the design temperatures, pressures, and humidities for each harsh plant area in which the safety-related equipment is located, as well as the exposures to radiation and chemical spray.

The use of representative operating temperatures (based on actual field temperature monitoring) in lieu of design temperatures from Appendix A of the Equipment Qualification Program Manual in the calculation of qualified life of equipment is acceptable.

For most equipment, special qualification tests to verify operability at normal operating temperature, pressure, and humidity conditions are generally not required. Certification for this equipment is based on proven operating capability in similar environments in nuclear power plant applications. The preoperational and postoperational test programs for safety-related components further ensure that safety-related components will be available when required. The normal and accident integrated radiation doses are assumed to have cumulative effects. The integrated radiation dose during normal operation is discussed in paragraph 3.11.5.2.

The normal plant vibration of safety-related equipment conforms to the requirements of the following standards or requirements;

Equipment	Standard or Requirement
Diesel fuel oil transfer pumps	Hydraulic Institute Standard
Essential cooling water pump	Hydraulic Institute Standard
Fuel pool cooling pump	Hydraulic Institute Standard
Essential chilled water pump	Hydraulic Institute Standard
Condensate transfer pump	Hydraulic Institute Standard
Essential spray pond pump	Hydraulic Institute Standard
Auxiliary feedwater pump	Hydraulic Institute Standard
HVAC equipment	ASHRAE Systems Handbook
Diesel engine generators	DEMA Standard Practices for Low and Medium Speed Stationary Diesel and Gas Engines
Electric motors	NEMA MG-1

The absence of any significant plant vibration caused by piping vibration (interaction) with the above equipment is verified as discussed in subsection 3.9.2

3.11.2.2 Component Environmental Design and Qualification for Operation After a Design Basis Accident

Safety-related equipment is designed to remain functional in the most severe combination of temperature, pressure, humidity, and chemical spray environmental conditions that exist at the equipment location after a DBA. This equipment is also designed for the maximum calculated integrated radiation

exposure after the DBA, as discussed in subsection 3.11.5. The temperature, pressure, and humidity environment inside the containment after a DBA is discussed in detail in subsection 6.2.1. The containment spray characteristics are given in paragraph 6.2.2.1. The integrated post-accident radiation dose for harsh plant locations in which the equipment is located is given in Appendix A of the Equipment Qualification Program Manual. In addition, steam and feedwater line breaks outside the containment are analytically checked to ensure that no additional qualifications need be applied to components that could be affected by these breaks.

The requirements of the General Design Criteria, Appendix A to 10CFR50, are met as follows:

- Criterion 1 - Quality Standards and Records, refer to section 3.1.
- Criterion 4 - Environmental and Missile Design Basis, refer to section 3.1.
- Criterion 23 - Protection System Failure Modes, refer to sections 3.1.
- Criterion 50 - Containment Design Basis, refer to sections 3.1 and 6.2.

The requirements of Quality Assurance Criterion III, Appendix B to 10CFR50 were met in accordance with the design and procurement QA program.

The recommendations contained in the regulatory guides listed below, listings A through E, have been utilized as described in

section 1.8. Additional comments are included in listings F through I.

A. Regulatory Guide 1.30, Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment.

   Standard procedures and plans are utilized. Preconstruction verification is combined with receiving inspection when components are not stored.

B. Regulatory Guide 1.40, Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants.

   Regulatory Guide 1.40 is not applicable to PVNGS as there are no safety-related continuous-duty motors installed inside the containment.

C. Regulatory Guide 1.63, Electrical Penetration Assemblies in Containment Structures for Water-Cooled Nuclear Power Plants. Refer to section 8.3 for the discussion on this guide.

D. Regulatory Guide 1.73, Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants.

   Motor-operated valves used inside the containment are qualified for abnormal environmental conditions in accordance with the general format and qualification procedures of IEEE 323-1974, IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power

Generating Stations, and IEEE 382-1972, IEEE Trial-Use Guide for Type Test of Class 1 Electric Valve Operators for Nuclear Power Generating Stations.

E. Regulatory Guide 1.89, Rev 1, Environmental Qualification of Certain Electric Equipment Important to Safety for Nuclear Power Plants.
The qualification methods and documentation requirements of IEEE Standard 323-1974, IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations, are discussed in section 1.8.

F. Type tests to ensure acceptability for use in the containment post-accident environment are performed for each type of cable in accordance with IEEE Standard 383-1974, Standard for Type Tests for Class 1 Cables, Field Splices and Connections for Nuclear Power Generating Stations. Values of environmental parameters used in such tests are given in Appendix A of the Equipment Qualification Program Manual.

G. A total (normal plus accident) integrated dose of less than 10^4 rads will not affect the strength or properties of materials used;(1) hence, further qualification analyses and tests for components which will be exposed to less than 10^4 rads are not necessary. For higher integrated doses, components are qualified either by qualification testing or by evaluation of materials used. Reliable accumulated data on radiation effects,

such as is contained in reference 1, is used to analyze the dose effects on particular materials.

H. The sources used in calculating the radiation levels following a DBA are consistent with those set forth in reference 2 and Regulatory Guide 1.4. The non-NSSS safety-related equipment located inside the containment is designed to withstand the maximum integrated doses listed in Appendix A of the Equipment Qualification Program Manual during the life of the plant. Verification of suitability of materials used are verified by test for all electrical penetration assembly materials, for an integrated dose of at least 1.1×10^8 rads.

I. The materials used in the fabrication of mechanical and structural components inside the containment are selected so as to minimize corrosion and hydrogen generation resulting from contact with chemical spray solutions. Alternately, the components may be protected from contact with the spray. The use of aluminum and zinc is minimized in these components.

Copper is used as a pressure boundary material only in the containment fan cooler coils since its corrosion rate in the spray solution is acceptably low.(3) Gaskets, when used in piping systems, are composed of material compatible with the spray solution. Gasket materials on the fuel transfer tube and on the containment equipment and personnel hatches are selected

to be compatible with the spray solution. Other pressure boundary and structural materials used are stainless and carbon steel and concrete, which do not suffer significant degradation in the spray environment.[3]

3.11.3 QUALIFICATION TEST RESULTS

The results of qualification tests for the equipment covered in subsection 3.11.2 have been provided to the NRC by letters separate from the FSAR.

3.11.4 LOSS OF VENTILATION

The HVAC design to prevent loss of essential ventilation is described in sections 6.4 and 9.4. In general, for areas containing safety-related equipment, two separate environmental control systems are provided. One system operates during normal plant conditions. The second (essential) system operates during emergency conditions.

The following plant areas contain safety-related equipment:

A. Auxiliary Building

B. Main Steam Support Structure

C. Diesel Generator Building

D. Control Building

E. Fuel Building Exhaust

F. Containment

The safety-related equipment inside containment is qualified, as a minimum, to LOCA conditions as defined in Appendix A of the Equipment Qualification Program Manual. This qualification is more severe than any temperature, humidity, or radiation conditions expected during normal operation, shutdown, or standby. Two 100% capacity normal environmental control systems are provided in containment with automatic failover from the operating system to the standby system. In addition, the containment is equipped with temperature and humidity monitors which alarm in the control room.

The following plant areas contain temperature switches which alarm in the control room:

A. Auxiliary Building

   1. HPSI pump rooms
   2. LPSI pump rooms
   3. CSS pump rooms
   4. ECW pump rooms
   5. ESF electrical penetration areas
   6. CEDM control cabinet room

B. Main Steam Support Structure

   1. Motor-driven auxiliary feed pump room
   2. Turbine-driven auxiliary feed pump room

C. Diesel Generator Building

   1. DG rooms

2. DG control areas

D. Control Building

1. Essential DC equipment rooms

The following plant areas are monitored by a temperature switch (alarmed in the control room) in the exhaust duct or exhaust plenum of the normal environmental control system:

A. Control Building

1. ESF switchgear rooms

2. Essential DC equipment rooms

3. Essential battery rooms

4. Remote shutdown panel area

B. Fuel Building Exhaust Plenum

Temperature switches located in individual rooms alarm when abnormally high temperatures exist in the room. Administrative procedures require operating personnel to respond to these alarms. Operation of either the normal or essential environmental control system will ensure control of humidity below that for which the equipment is qualified. Therefore, only temperature switches are provided in each room.

Temperature switches located in the exhaust duct or exhaust plenum of the normal environmental control system monitor for abnormally high temperature in the control building and monitor for abnormally high/low temperature in the fuel building. The equipment located in the ESF switchgear rooms, essential battery rooms, and remote shutdown area does not constitute a

large heat load. It is expected, therefore, that temperature variations during periods of operations, standby, and shutdown would be slight, making individual room alarms unnecessary. The initial quantification of the Level I Probabilistic Risk Assessment (performed as part of the Individual Plant Examination requirements in response to Generic Letter 88-20) identified the loss of all ventilation to the essential DC equipment rooms, which results in the failure of the battery chargers and vital inverters due to high temperature, as a dominant scenario in the assessed Core Damage Frequency. Subsequent quantifications, accounting for the installed local temperature indicators and the high temperature alarm in the essential DC equipment rooms allowing for operator recovery of ventilation, result in a substantial decrease in the assessed Core Damage Frequency.

Per Regulatory Guide 1.47, whenever an essential environmental control system is bypassed or inoperable, this condition will be alarmed in the control room. Administrative procedures will require operating personnel to respond to these alarms and ensure that either an environmental control system is operating or, if all systems are shut down, that portable temperature monitoring equipment is installed near the affected safety-related equipment before the environmental conditions would adversely effect equipment qualification. Administrative procedures ensure that the environmental control systems in safety related areas are always maintained in operation during periods of plant shutdown or hot standby.

The normal and essential environmental control systems are designed to maintain the conditions listed in Appendix A of the Equipment Qualification Program Manual during normal plant operation and during shutdown or standby conditions. Either the normal or the essential environmental control system is capable of maintaining these environmental conditions.

In order to assure the function of the safety-related harsh area equipment during accident conditions, the equipment is qualified to perform its safety-related function in the environmental conditions listed in Appendix A of the Equipment Qualification Program Manual.

The main steam support structure above elevation 100 feet is open to natural circulation of outside air. All safety-related equipment in this area are qualified to the conditions listed in Appendix A of the Equipment Qualification Program Manual. This qualification is sufficient to ensure that the safety-related equipment in the main steam support structure will not be exposed to environmental conditions during normal operation, shutdown or standby for which it has not been qualified.

The remote shutdown panel area is located adjacent to the ESF switchgear, ESF equipment, and essential battery rooms and utilizes the same environmental control systems as these rooms.

Cable insulation design rating is 90°C.

The actual operating temperature of a cable is affected by its current flow under load, the normal and abnormal environmental temperature(s) and routing conditions. Cable ampacity analysis

have been performed to verify that cables installed in raceway within the Licensed Facility do not exceed the 90 degree C insulation rating.

3.11.5 ESTIMATED CHEMICAL AND RADIATION ENVIRONMENT

3.11.5.1 Chemical Environment

Engineered safety feature (ESF) systems located in a harsh environment are designed to perform their safety-related functions in the temperature, pressure, and humidity conditions described in Appendix A of the Equipment Qualification Program Manual and sections 6.2 and 6.3. In addition, components of ESF systems inside the containment are designed to perform their safety-related functions in long-term contact with boric acid recirculated through the emergency core cooling system and containment spray systems.

The containment atmosphere is maintained below 4 volume % hydrogen consistent with the recommendations of Regulatory Guide 1.7 as discussed in subsection 6.2.5.

3.11.5.2 Radiation Environment

ESF systems and components are designed to perform their safety-related functions after normal operational exposure plus an accident exposure. The normal operational exposure is based on the design source terms presented in chapter 11 and subsection 12.2.1 and the equipment and shielding configurations presented in section 12.3.

Post-accident ESF system and component radiation exposures are dependent on equipment location. In the containment and control room area, exposures are due to a hypothesized LOCA. Source terms and other accident parameters are presented in subsection 12.2.1 and chapter 15, and are consistent with the recommendations of Regulatory Guides 1.4, 1.7, and Standard Review Plan Section 6.5.2 NUREG 800 Rev. 1.

In the auxiliary building, exposures are based on the assumption that 50% of the core halogen inventory and 1% of the core solid fission products are recirculated in the sump water. For a postulated intact primary degraded core event, the exposures are based on the assumption that 100% of the core noble gases, 50% of the core halogen inventory, and 1% of the core solid fission products are recirculated in the low pressure safety injection (LPSI) piping. In addition, the post-LOCA total integrated doses for the auxiliary building, fuel building, and main steam support structure are the sum of the following doses:

1. Containment shine and penetration streaming.
2. Shine from equipment and piping in or near the electrical and mechanical penetration rooms.
3. Post-LOCA airborne dose due to containment airborne penetration leakage.
4. 40 year normal dose.

In the fuel handling building, exposures are based on a fuel handling accident and LOCA. Source terms and other accident parameters are presented in chapter 15.

Normal, accident, and design (normal plus accident) radiation exposures based on the above assumptions for harsh environment locations are presented in Appendix A of the Equipment Qualification Program Manual.

APPENDIX 3A

RESPONSES TO NRC REQUESTS FOR INFORMATION

CONTENTS

TABLES

FIGURES

ATTACHMENT

APPENDIX 3A

QUESTION 3A.1 (NRC Comment on section 3.8.3.5) (6/18/80) (3.8.3.5)

No input of allowable limits and factors of safety against structural failure.

RESPONSE: The response is given in amended paragraph 3.8.3.5.

QUESTION 3A.2 (NRC Question 460.2) (3.2.2)

Include sections for effluent radiation monitors and process radiation monitors in table 3.2-1 of the Final Safety Analysis Report (FSAR), which lists quality classification of structures, systems and components.

RESPONSE: The response is given in amended subsection 3.2.2 (table 3.2-1).

QUESTION 3A.3 (NRC Question 220.1) (3.4.2)

Provide information of underdrains and pressure-relieving systems if used in Palo Verde stations.

RESPONSE: There are no underdrains or pressure-relieving systems required for PVNGS.

QUESTION 3A.4 (NRC Question 220.2) (3.7.1)

Provide information on the strain levels of soil during an OBE and SSE, and the variations of soil strain with the depth and layering of the supporting soil media. Describe the procedure of using strain-dependent soil properties (damping and shear modulus) to model the soil-structure interaction system. To what extent the computer program SHAKE is used to develop

strain-corrected damping values for foundation materials and what is the theoretical basis for such use?

RESPONSE: The "effective strains"[a] for each layer of the soil media for SSE and OBE are shown in figures 3A-1 and 3A-2. The computer program SHAKE[b] was used to establish the strain-corrected values of shear moduli and damping values for each layer of soil during SSE and OBE. The curves relating shear moduli and damping values to shear strain are site specific. The strain-corrected values of shear moduli and damping values were then utilized to calculate the impedance functions for each foundation by means of a computer program LUCON[c]. The method for coupling soil impedance function with the structural model has been described in paragraph 3.7.2.4.

QUESTION 3A.5 (NRC Question 220.3) (3.7.2)

Explain how does each of the Category I structures (containment building, auxiliary building, control building, and fuel building) have different sets of natural frequencies for OBE and for SSE. Do the natural frequencies listed in tables 3.7-7 through 3.7-10 represent the structural modes only, or the soil- structure interaction modes as well?

RESPONSE: The response is given in amended paragraph 3.7.2.2.2

____

a. Effective strain is defined as 65% of the maximum strain in "SHAKE" (see reference 1 of section 3.7).

b. The theoretical basis of the SHAKE program is given in reference 1 of section 3.7.

c. The theoretical basis for the computer program LUCON is described in appendix 3B.8.

APPENDIX 3A

<u>QUESTION 3A.6</u> (NRC Question 220.4) (3.7.2)

Supply for each mode of vibration listed in tables 3.7-3 through 3.7-6 the mode shape and its corresponding participation factor.

<u>RESPONSE</u>: The response is given in amended paragraph 3.7.2.4.

<u>QUESTION 3A.7</u> (NRC Question 220.5) (3.7.2)

Perform a comparative study of results in structural responses obtained by two different approaches of soil modeling to soil-structure interaction analyses: the half-space method (lumped parameter, compliance function, or impedance function methods) and the finite boundary method (also known as the finite-element, shear beam, or one-dimensional shear wave methods). Quantities to be compared should include floor response spectra in typical Category I structures; e.g., at the basemat, operating floor, and an upper elevation of the containment building, and at the basement and an intermediate elevation of the auxiliary building. The input ground motion or control motion should be applied at the foundation level as required by Appendix A to 10CFR100.

RESPONSE: The response is given in amended paragraph 3.7.2.4.

<u>QUESTION 3A.8</u> (NRC Question 220.6) (3.7.3)

Provide specific number of earthquake cycles used in the design of subsystems of Palo Verde Stations. The Standard Review Plan 3.7.3 states that a postulation of one safe shutdown earthquake

and five operating basis earthquake with ten stress cycles per earthquake is acceptable.

RESPONSE: The response is given in paragraph 2.5.2.7 and amended paragraph 3.7.3.2.

<u>QUESTION 3A.9</u> (NRC Question 220.7) (3.7.3)

The criteria for combining responses to three components of earthquake motion have been stipulated in Regulatory Guide 1.92. The criteria suggested in NUREG/CR-0098 are for certain operating plants only and have not been approved for use in Palo Verde stations. The applicant should either provide justification to use the NUREG/CR-0098 criteria or commit to use Regulatory Guide 1.92 criteria for Palo Verde seismic analysis.

RESPONSE: The factor method of combining responses to three components of earthquake motion is equivalent to the square-root-of-the-sum-of-the-squares (SRSS) method discussed in Regulatory Guide 1.92. The results from the component factor method are usually more conservative than the results from the SRSS method. In no case is the component factor method outcome below the SRSS value by more than 1%. The validity of the component factor method is demonstrated in attachment 3A1.

Thus, it is concluded that use of the component factor method is a valid alternative to the SRSS approach.

QUESTION 3A.10 (NRC Question 220.8) (3.8.1)

The acceptance of the Topical Report BC-TOP-5A as reference to prestressed concrete nuclear reactor containment structures excludes its applicability to Subsection 3.8.1.6, Materials, Quality Control and Special Construction Techniques. Identify all deviations from PSAR commitments and all exceptions to accepted codes. Provide explanation and justification for these deviations and exceptions.

RESPONSE:

I. Exceptions to PSAR Sections 3.8.1.6 and 3.8.3 commitments are as follows:

A. PSAR Section 3.8.1.6.3 does not take any exceptions to obtaining mill test reports (MTRs) for materials.

FSAR paragraph 3.8.1.6.6 takes exceptions as stated.

B. PSAR Section 3.8.1.6.4 states that if loads are transferred through the thickness dimension of the liner plate, tests will be made to determine the through-thickness strength of the liner materials used in these locations. FSAR paragraph 3.8.1.6.4 and project specifications do not require any tests to be performed to determine the through-thickness strength of the liner materials.

Justification: Although no tests are required, the design was based on the code requirement

that the strength in the thickness direction of the plate is one-half of the nominal yield strength.

C. FSAR paragraph 3.8.1.6.6 lists additional materials which were not listed in the PSAR.

Additional steels were required by design due to their material properties or material availability.

D. PSAR Section 3.8.1.6.6.2.A takes no exceptions to Table 4.2 of AWS Dl.1-72. FSAR paragraph 3.8.1.6.6.1 takes exceptions as stated.

E. PSAR Section 3.8.3.4.1.7 states that the polar crane is provided with mechanical guides to the rails to prevent the crane from being derailed as a result of the SSE.

FSAR paragraph 3.8.3.4.7 takes exceptions as stated.

II. All exceptions to accepted codes or regulatory guides have been previously identified in the following paragraphs of the FSAR:

A. Paragraph 3.8.1.6.1.2 for exception to the ACI Code.

B. Paragraph 3.8.1.6.6.1 for exception to the AWS Code.

C. Section 1.8 for exceptions to the Regulatory Guides.

A review of these exceptions indicates mostly minor differences between the PVNGS criteria and accepted codes and regulatory guides. These differences in no

way affect the safety margin of the containment building.

QUESTION 3A.11 (NRC Question 220.9) (3.8.4)

Identify any deviation from PSAR design criteria of Category I structures and any exception to applicable accepted codes. Provide explanation and justification for these deviations and exceptions.

RESPONSE: There are no deviations or exceptions to applicable accepted codes mentioned in subsection 3.8.3 for the design of the following Category I structures: auxiliary building, control building, diesel generator building, fuel handling building, Category I tanks. (The containment building exceptions are discussed in Question 3A.10 (NRC Question 220.8).

QUESTION 3A.12 (NRC Question 220.10) (3.8.4)

Are there any concrete masonry walls used in any of the Category I structures of the Palo Verde plant? If "yes", provide answers to the following questions:

(a) Indicate the loads and load combinations to which the walls are designed to resist. If load factors other than one (1.0) have been employed, indicate their magnitudes.

(b) In addition to complying with the applicable requirements of the SRP Sections 3.5, 3.7, and 3.8, is there any other code, such as the "Uniform Building Code" or the "Building Code Requirements for Concrete

Masonry Structures" (proposed by the American Concrete Institute) which was or is being used to guide the design of these walls? Please identify and discuss any exceptions or deviations from the SRP requirements or the aforementioned codes.

(c) Indicate the method that you used to calculate the dynamic forces in masonry walls due to earthquake, i.e., whether it is a code method such as Uniform Building Code, or a dynamic analysis. Identify the code and its effective date if the code method has been used. Indicate the input motion if a dynamic analysis has been performed.

(d) How were the masonry walls and the piping/equipment supports attached to them designed? Provide enough (numerical) examples including details of reinforcement and attachments to illustrate the methods and procedures used to analyze and design the walls and the anchors needed for supporting piping/equipment (as applicable).

(e) Provide plan and elevation views of the plant structures showing the location of all masonry walls for your facility.

RESPONSE: The project has used nonbearing, non-shear carrying concrete masonry walls in two Category I structures; namely, the control building and the auxiliary building.

The control building has a concrete masonry partition wall for fire protection which divides the building into two

halves from elevation 74 feet to elevation 100 feet. There are seven concrete masonry partition walls at elevation 100 feet which form eight compartments to house various equipment. In addition, concrete masonry walls were used to provide fire protection for a cable raceway from elevation 120 feet to elevation 140 feet.

The auxiliary building has seven concrete masonry partition walls at elevation 140 feet.

(a) The subject concrete masonry walls are classified as non-Category I, however they are required to retain their structural integrity in the event of an earthquake. Therefore, the walls were originally designed for the following governing load-factored equations:

1) 1.4 D + 1.9 E

2) 1.0 D + 1.0 E'

where D = Dead load

E = Seismic loads due to operating basis earthquake (OBE)

E' = Seismic loads due to safe shutdown earthquake (SSE)

The original concrete masonry wall design was performed using ultimate strength design methods. Because the partition walls at control building elevations 74'-0" and 100'-0" have limited Category attachments, they have also been seismically evaluated in accordance with the working stress design

requirements described in NUREG-0800, Standard Review Plan (SRP), Revision 0, July 1981, Section 3.8.4, Appendix A. The following governing load combinations were considered for the working stress analysis:

1.0 D + 1.0 E

1.0 D + 1.0 E'

(b) The concrete and masonry walls were originally designed in accordance with NUREG-75/087, Standard Review Plan (SRP), November 1975, Sections 3.7 and 3.8, and using the following codes:

1) 1974 masonry codes and specifications by Masonry Industry Advancement Committee.

2) Building code requirements for reinforced concrete (ACI 318-77).

Through subsequent evaluations, it has been established that the masonry walls of the control building at elevations 74'-0" and 100'-0" also conform to the requirements of NUREG-0800, Standard Review Plan (SRP), Revision 0, July 1981, Section 3.8.4, Appendix A. In addition, these evaluations utilized the following codes:

1) Uniform Building Codes (UBC) - 1985.

2) Building code requirements for concrete masonry structures, ACI 531-79, Revised 1983.

3) Specifications for the design, fabrication and erection of structural steel for buildings, AISC Manual of Steel Construction, 8th edition.

It should be noted that SRP Section 3.5 does not apply since these walls are not missile barriers.

(c) Seismic acceleration values corresponding to the specifically calculated wall frequencies were used to generate equivalent static loads for the initial design of the masonry walls. The accelerations were obtained from the in-structure response spectrum curves generated by performing dynamic analysis of the respective building. Subsequent evaluations utilized the same analytical methods in addition to the time history response spectrum analysis of detailed FEM models representing various concrete masonry wall sections.

(d) Project requirements prohibit the attachment of Seismic Category I piping to masonry walls.

At a few locations conduits, instrumentation tubing, bracing for equipment supports and small electrical panels are attached to the masonry walls. Two-inch and smaller non-Seismic Category I fire protection lines are also attached. In general, these attachments are made by bolting through the masonry walls. Light-weight attachments, i.e., small diameter thin wall conduits, emergency lighting fixtures, and instrumentation lines, may be attached using expansion anchors. The attachments and their effects on the

integrity of the walls are evaluated using frequency-specific or peak seismic acceleration values obtained from the in-structure response spectrum curves and equivalent static load methodology. The time history and response spectrum analyses of the control building masonry walls at elevations 74'-0" and 100'-0" include the effects of the additional weight of the attachments. Records of the wall attachments are kept to assure that wall integrity is not jeopardized.

The calculated out-of-plane deflections on the masonry block walls due to seismic OBE and SSE loading conditions will have an insignificant effect on the performance of Seismic Category I components attached to those walls. These components will retain their structural integrity without loss of operability during and following an OBE or SSE event.

(e) Figures 3A-3 through 3A-6 show plan and elevation views of all masonry walls used in Category I structures for Palo Verde Nuclear Generating Station as well as reinforcement and attachment details.

QUESTION 3A.13 (NRC Question 450.1) (3.5.1.4)

Provide the locations of all safety-related equipment not contained within reinforced concrete buildings or structures. Provide the structural composition of all walls and roofs of buildings housing safety-related equipment, as well as the building locations. Discuss the sizes and directional orientations of any openings in these buildings.

RESPONSE: The following safety-related equipment is not enclosed within reinforced concrete buildings or structures:

- Roof levels of the refueling water tank (RWT) and condensate storage tank (CST) (structural steel lined with 1/4-inch stainless steel)
- The discharge duct from the fuel building and auxiliary building exhaust essential air filtration units and the radiation monitoring equipment located in it. These items are located on the fuel building roof.
- Piping from the RWT to the auxiliary building (buried below ground level)
- Piping from the condensate storage tank (CST) to the auxiliary feedwater pumps (buried below ground level or enclosed in concrete pipe tunnel)
- Diesel fuel oil storage tank and piping (buried below ground level)
- Piping from the essential spray pond to the auxiliary building (buried below ground level)
- Essential spray pond spray headers and nozzles

The locations of this equipment are shown in engineering drawing 13-P-OOB-001.

Refer to table 3.5-9 for the structural composition of the walls and roofs of buildings housing safety-related equipment. Any openings in the buildings through which a tornado-generated missile may enter and damage the

safety-related equipment are provided with one of the following missile barriers:

1. All exterior door openings are protected by missile-proof doors.
2. Thick steel plate missile shields.
3. Concrete missile shields.
4. The space within the opening is sufficiently occupied by piping and pipe supports to preclude missile penetration.

The roof of the main steam support structure is elevated from the top of the walls to allow the escape of steam in the event of a major pipe break. The roof is cantilevered beyond the wall to provide the necessary missile protection.

Missile protection is not required for the duct or radiation monitoring equipment located on the fuel building roof because:

a) The duct is on the discharge side of the AFUs; therefore the air in this duct has already been filtered. The amount of radiation released would remain the same.

b) If a tornado-generated missile did strike the duct, it would either tear it apart [see (a) above] or pierce it. The five missiles from UFSAR table 3.5-8 that must be considered all strike end-on. The blockage caused from any of these (maximum 12 inches wide x 60 inches long) is small compared to the 60-inch diameter duct.

The velocity through this duct without a blockage is only about 305 fpm (6000 cfm, 60-inch diameter duct). Because of this extremely low velocity, the airflow change caused by one of these five missiles is negligible. The other two missiles, the utility pole and the car, do not have to be considered because the fuel building roof is higher than 30 feet above grade level (UFSAR 3.5.1.4).

c) The radiation monitors can provide a "start" signal to these AFUs but this is a redundant function. Radiation monitor J-SQA-RU-31 provides a redundant FBEVAS. The AFUs may also be started by an SIAS to keep the elevations below 100 feet in the auxiliary building negative. There is also a manual "on" switch for the AFUs.

d) The Offsite Dose Calculation Manual (ODCM) allows for manual effluent monitoring if these radiation monitors are inoperable.

e) UFSAR chapter 3 does not show a fuel handling accident or LOCA combined with a tornado as a credible scenario.

QUESTION 3A.14 (NRC Question 450.2) (3.5.1.4)

Describe the protection of the control room air intakes and diesel generator exhaust pipes from tornado-generated missiles.

RESPONSE:

- The control room air intakes are enclosed within a box structure located within the control building (see figure 3A-7). The wall sections exposed to

tornado-generated missiles are designed to withstand such impact without adverse effect upon the system.

- The diesel generator exhaust pipes are enclosed within a 1- foot 9-inch thick vertical, concrete chimney which is designed to withstand tornado-generated missile impact. A thick, steel pipe sleeve, also capable of withstanding tornado-generated missile impact, provides protection for the exhaust piping at the vent opening at the top of the chimney.

QUESTION 3A.15 (NRC Question 210.1) (3.9.6)

There are several safety systems connected to the reactor coolant pressure boundary that have design pressure below the rated reactor coolant system (RCS) pressure. There are also some systems which are rated at full reactor pressure on the discharge side of pumps but have pump suction below RCS pressure. In order to protect these systems from RCS pressure, two or more isolation valves are placed in series to form the interface between the high-pressure RCS and the low-pressure systems. The leaktight integrity of these valves must be ensured by periodic leak testing to prevent exceeding the design pressure of the low-pressure systems, thus causing an intersystem LOCA.

Pressure isolation valves are required to be Category A or AC and to meet the appropriate requirements of the ASME OM Code except as discussed below.

Limiting conditions for operation (LCO) are required to be added to the technical specifications which will require corrective action; i.e., shutdown or system isolation when the final approved leakage limits are not met. Also surveillance requirements, which will state the acceptable peak rate testing frequency, shall be provided in the Technical Specifications.

Periodic leaktesting of each pressure isolation valve is required to be performed at least once per each refueling outage, after valve maintenance prior to return to service, and for systems rated at less than 50% of RCS design pressure each time the valve has moved from its fully closed position unless justification is given. The testing interval should average to be approximately 1 year. Leaktesting should also be performed after all disturbances to the valves are complete, prior to reaching power operation following a refueling outage, maintenance, and etc.

The staff's present position on leak rate limiting conditions for operation must be equal to or less than 1 gallon per minute for each valve (gpm) to ensure the integrity of the valve, demonstrate the adequacy of the redundant pressure isolation function and give an indication of valve degradation over a finite period of time. Significant increases over this limiting valve would be an indication of valve degradation from one test to another.

Leak rates higher than 1 gpm will be considered if the leak rate changes are below 1 gpm above the previous test leak rate or system design precludes measuring 1 gpm with sufficient

accuracy. These items will be reviewed on a case-by-case basis.

The Class 1 to Class 2 boundary will be considered the isolation point which must be protected by redundant isolation valves.

In cases where pressure isolation is provided by two valves, both will be independently leaktested. When three or more valves provide isolation, only two of the valves need to be leaktested.

Provide a list of all pressure isolation valves included in your testing program along with four sets of piping and instrument diagrams which describe your reactor coolant system pressure isolation valves. Also discuss in detail how your leaktesting program will conform to the above staff position.

RESPONSE: The response is given in amended paragraph 3.9.6.2.

QUESTION 3A.16 (NRC Question 410.1) (3.5.1.2)

Your evaluation of potential missile sources inside containment is not complete. The following concerns should be addressed:

a) Verify that secondary missiles, if any, generated by impact of the primary missiles identified in FSAR table 3.5-4 inside containment will not cause damage to essential systems required to assure a safe shutdown or result in unacceptable release of radioactivity.

b) Verify that a seismic event will not result in gravity missiles within the containment which could cause damage to

essential systems required to assure a safe shutdown or result in unacceptable releases of radioactivity.

RESPONSE: The response is given in amended paragraph 3.5.1.2.2.

QUESTION 3A.17 (NRC Question 410.2) (3.5.2)

In FSAR figures 3.5-4 through 3.5-7 you have identified those areas housing equipment, systems, and components required for safe reactor shutdown as missile targets. However, you have not considered areas housing radioactive fluid such as the radwaste building as missile targets. Verify that equipment, systems, and components containing radioactive fluid are protected against tornado missile damage, or assure that failure of unprotected components will not result in an unacceptable release of radioactivity.

RESPONSE: As noted in paragraphs 15.7.3.3, 15.7.3.4, and 15.7.3.5, failures of liquid and gaseous radwaste components do not cause unacceptable releases of radioactivity; therefore, missile protection is not required. Also see amended table 3.5-9.

QUESTION 3A.18 (NRC Question 410.3) (3.5.2)

Describe the protection provided for all essential ventilation system air intakes and exhausts against damage due to multiple tornado-generated missiles assuming missiles as identified in the tornado missile spectrum for the plant. Verify that safety-related equipment and spent fuel is not affected by tornado missile impact to these openings or that openings in

structures created by failures due to a tornado will not affect the function of safety related components or cause damage to spent fuel by allowing missile entry.

RESPONSE: Essential ventilation system openings with a potential for tornado-generated missiles to enter and damage safety-related equipment are provided with missile protection, as shown in table 3A-1. This prevents tornado-generated missiles from damaging safety-related equipment or spent fuel.

Table 3A-1

MISSILE PROTECTION OF ESSENTIAL

VENTILATION SYSTEM AIR INTAKES AND EXHAUSTS

Intake/Exhaust Point	Protective Feature
Fuel building exhaust	Steel plate prevents missile passage through penetration
Main steam support structure	Steel plate prevents missile passage through penetration
Auxiliary building	
• Hydrogen recombiner cooling air intake	Steel plate prevents missile passage through penetration
• Hydrogen recombiner cooling air exhaust	Steel plate prevents missile passage through penetration
Control building intake	Concrete intake plenum designed as labyrinth
Control building exhaust	Steel louvers
Diesel generator	
• Combustion air intake	Offset concrete baffles prevent missile entry
• Combustion air exhaust	Protected by a combination of concrete and guard piping
• Cooling air intake	Offset concreted baffles prevent missile entry
• Cooling air exhaust	Concrete plenum

QUESTION 3A.19 (NRC Question 410.4) (3.6.1)

Your analysis of the consequences of high and moderate energy pipe breaks outside containment is not complete. Provide the following additional information:

a. Verify that the high and moderate energy pipe break analysis outside containment is in accordance with the guidance of Branch Technical Position (BTP) ASB 3-1.

b. Reference is made in FSAR paragraph 3.6.1.3 to specific safety-related system failure modes and effects analyses. However, these tables do not identify the capability of individual systems to mitigate the consequences of pipe breaks assuming a single failure as identified in the criteria of BTP ASB 3-1. Include such a discussion in FSAR paragraph 3.6.1.3.

c. Provide layout drawings of safety-related areas outside containment showing the routing of high and moderate energy piping systems and their relative position to safety-related equipment and components. These drawings should identify postulated break and crack locations in high and moderate energy lines. Further, provide a table which identifies the means of protection (i.e., pipe whip restraint, jet impingement barrier, separation, floor drainage, etc.) for safety-related equipment from the effects of the postulated high and moderate energy pipe breaks.

d. Expand the discussion in FSAR subsection 3.6.1 to identify the design bases for the protection of individual safety-related equipment which has been identified in

part c) above. For example, the FSAR should describe the design bases for internal flood protection (expected leakage rate), jet impingement protection (force assumed from the blowdown), worst expected environment (temperature, pressure, and humidity), etc., which result from the bounding pipe breaks in the area of the auxiliary feedwater pumps.

RESPONSE:

a. Extent of compliance with BTP ASB 3-1 (follows format of BTP ASB 3-1):

   1. In compliance.

   2a. In compliance.

   2b(1). In compliance.

   2b(2). In compliance.

   2c(1). The design of PVNGS fluid system piping in the penetration area either:

      (1) Meets the stress limits of BTP MEM 3-1 Sec. B.1.b or B.2.b, or,

      (2) Is not essential to shut down the reactor or mitigate the consequences of the postulated piping failure (at the terminal end) without offsite power.

   2c(2). Not applicable to PVNGS

   2c(3). Terminal ends of the piping are considered to originate at the penetration sleeve inside and outside containment.

2c(4). In compliance.

2d(1). In compliance.

2d(2). In compliance.

2d(3). Not applicable to PVNGS.

2d(4). In compliance.

3a. In compliance.

3b(1). In compliance.

3b(2). In compliance.

3b(3). In compliance with the clarification that the criteria have been extended to include high energy (e.g., CVCS charging system) as well as moderate energy systems.

3b(4). In compliance.

3c. In compliance.

3d. In compliance.

b. The equipment or systems required to mitigate the effects of various types of breaks are listed in paragraph 3.6.1.2. The equipment layout and/or design features are such that high or moderate energy breaks will not adversely affect either train of any system required for shutdown or mitigate the consequences of the break. Therefore, the single failure analyses (refer to paragraph 6.2.1.3) do not require addition of direct high energy or moderate energy effects since these effects are precluded by design.

c. The response is given in amended paragraph 3.6.1.2.

d. The response is given in amended paragraph 3.6.1.2.

QUESTION 3A.20 (NRC Question 410.5) (3.6.1)

It is our position that the common compartment which houses the main steam lines and feedwater lines and the isolation valves for these lines (the main steam support structure) be designed to consider the environmental effects (pressure, temperature, humidity) and potential flooding consequences from an assumed crack of 1 square foot. The essential equipment located within the main steam support structure, including the atmospheric dump valves, main steam isolation valves, and feedwater isolation valves and their operators, and the essential auxiliary feedwater pumps and associated equipment should be capable of operating in the environment resulting from the above crack. Further, if this assumed crack could cause the structural failure of this compartment, then the failure should not jeopardize the safe shutdown of the plant.

We, therefore, request that you submit a subcompartment pressure analysis to confirm that the design of the main steam support structure conforms to our position as outlined above. The evaluation should include a verification that the methods used to calculate the pressure buildup in the main steam support structure for the postulated breaks are the same as those used for subcompartments inside the containment. Also, the allowance for structural design margins (pressure) should be the same. If different methods are used, justify that your method provides adequate design margins and identify the margins that are available. When you submit the results of

your evaluation, identify the computer codes used, and the assumptions used for mass and energy release rates. The peak pressures and temperatures resulting from the postulated break of a high energy pipe located in the main steam support structure is dependent on the mass and energy flows during the time of the break. Therefore, for each pipe break or crack analyzed, provide the total blowdown time and the mechanism used to terminate or limit the time of blowdown flow so that the environmental effects will not affect safe shutdown of the facility.

Also provide a similar analysis for other compartments outside containment in the vicinity of safety-related structures, systems, and components which house high energy lines such as CVCS charging, letdown, and steam generator blowdown.

RESPONSE: A pressure-temperature analysis of the main steam support structure (MSSS) was performed as discussed in amended paragraph 3.6.2.1.1.2. For the purpose of establishing design parameters (i.e., pressure, temperature) of the enclosing structure, a one square foot break of the main steam line was conservatively assumed. The results of the analysis indicate a peak temperature of 383F, a peak pressure of less than 2.1 psig, and a steady state pressure of less than 0.2 psig, which were conservatively selected for equipment qualification and structural design.

The pressure-temperature effects resulting from cracks in the main feedwater, steam generator blowdown, and steam

generator downcomer feed lines are bounded by the results from the main steam line break analysis.

A pressure-temperature analysis of the auxiliary building was performed utilizing the building's HVAC exhaust duct as an atmospheric vent path for the steam. The resulting transient environmental parameters from the postulated failure of the CVCS let down line and auxiliary steam line do not exceed the building allowable range for structural loading nor render safe shutdown equipment unqualified from the Equipment Qualification perspective.

An auxiliary steam line HELB will initiate neither a reactor trip nor a turbine trip. Therefore, a site Loss of Offsite Power (LOOP) is not postulated to occur concurrent with the HELB, and the building's HVAC exhaust duct can provide a passive atmospheric vent path for the steam to exit the building.

Should a loss of instrument air (IA) or loss of the non class 1E control power occur concurrent with a HELB, the pneumatic dampers in the exhaust duct will fail closed, blocking the atmospheric vent path. This loss of IA or the non class 1E control power will also result in the two redundant air operated auxiliary steam isolation valves failing closed position, and thereby isolating the auxiliary steam system, which results in an atmosphere that is not as harsh as an unlimited HELB.

Blowdown of the CVCS letdown line is terminated by operator action within 10 minutes of the initiation of three alarms in the control room:

- Regenerative heat exchanger high exit temperature
- Letdown line low pressure
- Low flow in the process radiation monitor loop.

Also see Question 3A.19 (NRC Question 410.4).

APPENDIX 3A

ATTACHMENT 3A1

VALIDITY OF THE COMPONENT FACTOR METHOD

This attachment presents a demonstration of the adequacy of the component factor method expressed by equation 1 when compared to the square-root-of-the-sum-of-the-squares (SRSS) method expressed by equation 2.

$$R' = 1.0\ R_i + 0.4\ R_j + 0.4\ R_k \quad (1)$$

$$R = \left\{R_i^2 + R_j^2 + R_k^2\right\}^{1/2} \quad (2)$$

To demonstrate this, first consider a combination response, R' defined as follows:

$$R' = R_i + 0.414R_j + 0.318R_K \quad (3)$$

in which

$$R_i \geq R_j \geq R_k \geq 0 \quad (4)$$

Let

$$R_j = \overline{R}_j + R_k \ \left(\overline{R}_j = 0 \text{ if } R_j = R_k\right) \quad (5)$$

$$R_i = \overline{R}_i + R_j = \overline{R}_i + \overline{R}_j + R_k \ \left(\overline{R}_i = 0 \text{ if } R_i = R_j\right)$$

Substituting these values into equation 2, the SRSS method gives:

$$R = \left\{\left(\overline{R}_i + \overline{R}_j + R_k\right)^2 + \left(\overline{R}_j + R_k\right)^2 + R_k^2\right\}^{1/2}$$

$$= \left\{3R_k^2 + 2\overline{R}_j^2 + \overline{R}_i^2 + 2\overline{R}_i\left(\overline{R}_j + R_k\right) + 4\overline{R}_j\ R_k\right\}^{1/2} \quad (6)$$

while substituting these values into equation 3, the component factor method gives:

$$R' = \left(\bar{R}_i + \bar{R}_j + R_k\right) + 0.414\left(\bar{R}_j + R_k\right) + 0.318R_k$$

$$= 1.732R_k + 1.414\bar{R}_j + \bar{R}_i = \left\{\left[1.732R_k + 1.414\bar{R}_j + R_i\right]^2\right\}^{1/2}$$

Therefore,

$$R' = \left\{3R_k^2 + 2\bar{R}_j^2 + \bar{R}_i^2 + 2\bar{R}_i\left(1.414\bar{R}_j + 1.732R_k\right) + 4.9\bar{R}_jR_k\right\}^{1/2} \qquad (7)$$

Comparing equations 6 and 7, it is obvious that the combined response calculated according to equation 3 is always more conservative than the combined response by the SRSS method given by equation 2. In the special case that $R_i + R_j + R_k$, they become identical to each other, i.e., $R + R' + \sqrt{3R_k}$. For convenience of engineering applications, equation 3 can be simplified by replacing the factors 0.414 and 0.318 by a common factor of 0.4. This reduces equation 3 to equation 1. By inspection, the maximum probable error of equation 1 with respect to the SRSS method is less than 1%. This maximum error occurs when $R_k = 0$ and $R_i = R_j$. In this special case, the SRSS method gives $R = 1.4R_i$ and equation 1 gives $R = 1.4R_i$.

APPENDIX 3B
COMPUTER PROGRAMS USED IN STRUCTURAL ANALYSES

3B.1 GENERAL

A number of computer programs, most of which use the finite-element numerical approach, are used in the structural analyses of the containment and other Seismic Category I structures. Each of these is described fully in sections 3B.2 through 3B.11.

There are many advantages to the finite-element method when compared to other numerical approaches. This method is completely general with respect to geometry and material properties. In addition, complex bodies composed of many different materials are easily represented. Therefore, in the analysis of the containment, concrete and foundation materials can be realistically analyzed. Also, arbitrary thermal, mechanical, and gravity loading can be analyzed.

The finite-element method assumes a compatible or semicompatible displacement field for a typical cross-sectional area (element equals cross-section of ring). The number of degrees of freedom determines the number of unknown generalized displacements of each element-nodal point, and consequently the number of generalized forces through the stiffness equation. Accuracy of results depends upon:

- Shape of element
- Assumed displacement field (linear, quadratic, or higher order)
- Number of nodal points per element
- Size of the elements

- Total number of elements and nodal points (with rounded-off computer errors in the solution of simultaneous linear equations)

Following is a listing of the computer programs which were used in the design of Palo Verde Nuclear Generating Station (PVNGS) and the section references where program descriptions may be found:

Computer Program	Section Reference
Axisymmetric Shell and Solid Computer Program (ASHSD) CE 803	3B.2
Structural Analysis Program (SAP) CE 800	3B.3
Description of Verification Problems (OPTCON MODULE) CE 201	3B.4
Dynamic Analysis Computer Program (ICES-DYNAL)	3B.5
Symbolic Matrix Interpretive System (SUPER SMIS) CE 804	3B.6
Spectra Computer Program (SPECTRA) CE 802	3B.7
LUCON Computer Program (LUCON) CE 970	3B.8
CECAP Computer Program (CECAP) CE 987	3B.9
FOSIN Computer Program (FOSIN) CE 299	3B.10
STICK Computer Program (STICK)	3B.11
Bechtel CE 800, Bechtel Structural Analysis Program (BSAP)	3B.12
Finite-Element Computer Program (FINEL)	3B.13

3B.1.1 OTHER COMPUTER PROGRAMS USED IN STRUCTURAL ANALYSES

In the course of generating structural design calculations, several programs were used to assist design efforts. These programs were limited in scope and were developed solely to assist the designer in making lengthy, repetitious calculations, thereby saving design efforts. The programs were validated by generating example problems or performing manual design checks. These validations were incorporated into the project design calculation books. These programs are not itemized here due to their simplicity and nature of use.

3B.2 AXISYMMETRIC SHELL AND SOLID COMPUTER PROGRAM (ASHSD) CE 803

The ASHSD program is capable of both static and dynamic elastic analysis of structural systems idealized by either axisymmetric shell or axisymmetric solid finite-elements or by a combination thereof.

The ASHSD code is also capable of handling both axisymmetric and asymmetric loadings.

This program is a refinement of the original ASHSD code by S. Ghosh, developed at the University of California at Berkeley under the direction of Dr. E. L. Wilson and published for the National Science Foundation Research Project GK4395. The present program is modified by Bechtel Power Corporation for the special purpose of static and dynamic analysis of nuclear containment structures. The modified program has the following features:

A. The original shell element used by the code is entirely replaced with a new shell finite-element that uses an interaction stiffness allowing analysis of layered shells. A complete discussion of the theory is given in Theory of Anisotropic Shells by S. A. Ambartsumyan.[1]

B. Since shell layers may be bonded or unbonded from each other, it is possible to describe concrete shells in their actual geometric form. For example, it is possible to describe liner plate, concrete, reinforcing steel, and post-tensioning steel in their real spatial locations.

C. Post-tension forces may be applied to the shell by subjecting only the unbonded post-tensioning elements to a pseudo-thermal loading.

D. Isotropic and orthotropic elastic constants are possible for both shell and solid elements. For example, the orthotropic material properties may be used to describe the different stiffnesses of reinforcing steel in the hoop and meridional directions.

E. Nonuniform axisymmetric or asymmetric thermal gradients through the wall thickness may be imposed.

F. Eigenvectors and eigenvalues may be computed by the program.

G. Three dynamic response routines are available in the program. They are:

   1. Arbitrary dynamic loading or earthquake, base excitation using an uncoupled (modal) technique

   2. Arbitrary dynamic loading or earthquake, base excitation using a coupled (direct integration) technique

   3. Response spectrum nodal analysis for absolute and square-root-of-the-sum-of-the-squares displacements and element stresses

The ASHSD computer model consists of containment, internal structure of axisymmetric shell, and a soil grid of

axisymmetric solid under basemat. The reactor cavity is modeled as an axisymmetric cylinder. The tendon cavity also may be included in the model. Interior structures have been idealized as an asymmetric shell and plate that are composed of primary shield, secondary shield, refueling canal, and operating floor. The liner plate also may be modeled as a finite-element in the inside face of concrete. The soil grid is extended sufficiently below the basemat and beyond the containment wall to enable ASHSD model to take into account the effects of soil interaction in seismic analysis and eliminate the effect of boundary conditions in all loading cases.

3B.2.1 ANALYSIS OF THE CONTAINMENT STRUCTURE FOR NONAXISYMMETRIC LOADS

3B.2.1.1 Nonaxisymmetric Loads

The nonaxisymmetric loadings include the earthquake forces, forces due to rupture of any pipe, forces due to thermal expansion of pipes in operating or accident conditions, wind loadings, and such other loadings that are not assumed to be symmetric with respect to the vertical axis of the containment structure.

3B.2.1.2 Analysis

The structure is idealized as an assemblage of elastic finite-element axisymmetric solids or thin shells. The solid of revolution is simulated as an assemblage of triangular or quadrilateral constant strain toroids interconnected at nodal

points, and the axisymmetric shell is modeled as a series of frustums of cones or cylinders. The structure can be idealized even as a combination of both types of elements. The only restriction is that the resultant model has to be axisymmetric.

The ASHSD computer program uses an extended Ritz technique of seeking a stationary value of an energy integral. Hamilton's variational principle is used to derive the equations of motion such as Lagrange's equations involving the total kinetic and potential energies of the system. If the program is used for only the static analysis, the kinetic energy being absent, the problem is governed by the principle of minimum potential energy.

Any arbitrary loading is approximated by the cosine terms of a Fourier series with a finite number of terms. For each Fourier component, the stiffness and mass matrices and the corresponding load vectors are formed. These are consistent with the assumed sinusoidal displacement field. After solving for the response of all the Fourier terms, their contributions are summed up to obtain the total response.

3B.2.1.3 Program Results

Typical program outputs from the ASHSD code are:

- Complete printout of all input data
- Complete displacements of each nodal point
- Shell element stresses and member forces
- Solid element stresses and strains

3B.2.2 EXTENT OF APPLICATION OF ASHSD PROGRAM

The ASHSD program is used in performing the preliminary static analyses of the containment structure for various loads. The results of these analyses are employed in arriving at the design section parameters for the cracked section analyses performed using the FINEL program.

3B.2.3 APPLICABILITY AND VALIDITY OF ASHSD PROGRAM

Six test problems, outlined in subsection 3B.2.4, demonstrate applicability and validity of the ASHSD program. Results of the problems for various loadings demonstrate that ASHSD results are essentially identical to the results obtained by hand calculations or those obtained by the closed-form analytical results available in technical literature.

3B.2.4 ASHSD VERIFICATION (TEST PROBLEMS)

3B.2.4.1 ASHSD Example 1, Closed Cylinder Under Internal Pressure

This test example demonstrates the membrane state of stress of a closed cylinder subjected to a uniformly distributed internal pressure. Because of symmetry, a finite-element idealization of one-half of the cylinder and the appropriate boundary conditions is used. The numerical data required for the ASHSD program input also are described. Refer to figure 3B.2-1.

For the purpose of illustrating the layered shell feature of the ASHSD program, a second test case is undertaken. The thickness of the closed cylinder used in the above example is divided into three layers as shown in figure 3B.2-2.

The longitudinal and circumferential forces for all node points of the two ASHSD program runs are listed in table 3B.2-1. The theoretical values for the membrane stress resultants are calculated to be PR/2 (=27,000 pounds per inch) and PR (=54,000 pounds per inch), respectively. As noted in table 3B.2-1, the results from both analyses compare with the theoretical values.

3B.2.4.2 ASHSD Example 2, Cylindrical Shell Under Internal Pressure

This test example illustrates the use of arbitrary static loading conditions. A sketch of the cylinder and the applied pressure is shown in figure 3B.2-3. Since there is a plane of symmetry, only one-half of the cylinder need be considered. The finite-element model, boundary conditions, and the relevant input data are described in figure 3B.2-4.

Figure 3B.2-5 shows a comparison of ASHSD radial displacements and analytically obtained displacements found in Theory of Plates and Shells.[2]

A comparison of ASHSD longitudinal moments and those obtained from Theory of Plates and Shells[2] is shown in figure 3B.2-6.

Both the radial displacements and the longitudinal moments check with analytical solutions obtained from Theory of Plates and Shells.[2]

3B.2.4.3 ASHSD Example 3, Spherical Dome, Dead Load Analysis

This test example demonstrates the dead load analysis feature of the ASHSD program. It considers a spherical dome of constant thickness under its own weight, as shown in figure 3B.2-7. The axisymmetric finite-element model and pertinent shell data are described in figure 3B.2-8.

The exact analytical solutions obtained from Applied Elasticity(3) for longitudinal and circumferential forces are compared to the ASHSD finite-element results in figures 3B.2-9 and 3B.2-10, respectively.

With the exception of forces near the shell boundary, all forces away from the boundary have excellent agreement between the two solutions.

16[a]	27,111.0	55,724.0	27,111.0	55,724.0

a. Results for node points 12 through 16 are influenced by the boundary conditions at node point 16.

3B.2.4.4 ASHSD Example 4, Cylindrical Shell Subjected to an Internal Pressure and a Uniform Temperature Rise

This test example demonstrates the use of arbitrary static load and thermal load conditions. A short circular cylindrical shell, clamped at both ends, is subjected to an internal pressure and a uniform temperature rise, as shown in figure 3B.2-11. Because of symmetry, one-half of the cylinder is used in this finite-element model, which is shown in figure 3B.2-12. For the purpose of inputting the thermal coefficient of expansion of this isotropic shell, it is required to identify the shell material as orthotropic.

A comparison of ASHSD longitudinal moments and the theoretical solutions reported in Thin Elastic Shells,(4) is displayed in figure 3B.2-13.

The finite-element model has approximately the same complexities as the examples demonstrating membrane stresses and displacements. Inasmuch as the moment involves higher-order effects, better correlation between the finite-element result and the theoretical solution is accomplished using a larger number of elements.

3B.2.4.5 ASHSD Example 5, Asymmetric Bending of Cylindrical Shell

This test example illustrates the use of higher harmonics for asymmetric loading cases. The cylindrical shell analyzed is a short, wide cylinder, as shown in figure 3B.2-14. The finite-element idealization of the cylinder and other pertinent

data are illustrated in figure 3B.2-15. At each end of the cylinder, moments of the form M = Mo cos nθ were input for harmonics n = 0, 2, 5, 20.

Figures 3B.2-16 through 3B.2-19 show the theoretical results per Analysis of Unsymmetric Bending of Shells(5) and ASHSD results for element longitudinal bending moments and radial displacements for harmonic number n = 0, 2, 5, and 20, respectively.

As noted in figures 3B.2-16 through 3B.2-19, the results obtained from the ASHSD program are in good agreement with that reported in Analysis of Unsymmetric Bending of Shells.(5)

3B.2.4.6 ASHSD Example 6, Isotropic Disk, Axisymmetric Solids

This test example illustrates the use of the ASHSD solid elements to evaluate the stress distribution in axisymmetric structures. The structural problem consists of a 2-inch-thick isotropic disk with a 10-inch inner radius and a 20-inch outer radius supported at the outer top edge. The finite-element model and the applied load are shown in figure 3B.2-20. The disk is divided into 10 quadrilateral solid elements having 22 node points.

The radial and axial displacements for all node points, obtained from the ASHSD computer run and Finite-Element Stress Analysis of Axisymmetric Solids with Orthotropic, Temperature-Dependent Material Properties,(6) are tabulated in table 3B.2 2. The radial, axial, and tangential stresses for all elements obtained from these same sources are tabulated in table 3B.2-3.

Table 3B.2-2

3B.3 STRUCTURAL ANALYSIS PROGRAM (SAP) CE 800

The SAP program is capable of both static and dynamic analysis of large elastic, three-dimensional structural systems.

The SAP code is used primarily in the analysis of the equipment hatch penetration areas, personnel lock penetration areas, and containment basemat. It also is used in much of the analysis of the internal reactor building.

The program has the following elements available, which are used in the containment analysis:

- Three-dimensional truss (axial) elements
- Three-dimensional beam (bending) elements
- Curved beam elements
- Quadrilateral plate (membrane, plate, or shell) elements
- Triangular plate (membrane, plate, or shell) elements
- Three-dimensional, eight-point brick solid (cube) elements
- Plane strain elements
- Boundary elements
- Sixteen-node-thick shell elements
- Axisymmetric ring elements

Systems composed of a large number of joints and members may be analyzed with the SAP program. The capacity of the program depends mainly on the total number of joints in the system. There is practically no restriction on the number of elements,

number of load cases, or the bandwidth of the equations to be solved.

3B.3.1 ANALYSIS OF EQUIPMENT HATCH AND PERSONNEL LOCKS BY THE SAP PROGRAM

All structural analysis for axisymmetric and nonaxisymmetric loadings is first carried out with either the FINEL or ASHSD codes.

An idealized finite-element model then is prepared for the region of the containment shell near the opening being analyzed.

The element mesh chosen considers the expected stress gradients at and near the shell opening. Enough of the region around the opening is included in the model to adequately eliminate the effect of the opening at the models boundaries.

The stress gradients considered in the preparation of the model are those obtained from the analytical solutions obtained from reference to State of Stress in a Circular Cylindrical Shell with a Circular Hole(1) and Reinforcement of a Small Circular Hole in a Plane Sheet Under Tension.(2)

A typical SAP penetration model, which is used for analysis, may have the following features:

A. Single layer (quadrilateral or triangular shell elements are used in the low stress gradient) outer regions of the model.

B. Near the opening being examined, the shell elements branch into a minimum of three layers of solid elements.

C. In the highly stressed regions, up to five layers of solid elements or a single layer thick shell element are used.

D. The element mesh describes the shell curvature and the thickening near the opening.

E. A mesh of truss elements is used to simulate the uneven post-tensioning around the opening. The mesh is geometrically located at the actual post-tensioning locations. The post-tensioning forces are induced in the truss elements by inducing pseudo-thermal loadings.

F. The model has loads applied to its surfaces and boundaries. The boundary conditions consider both specified displacement and force loads, which are obtained from the axisymmetric and nonaxisymmetric analyses.

3B.3.2 EXTENT OF APPLICATION OF SAP PROGRAM

The SAP program is used in performing the analysis of equipment hatch penetration areas, personnel lock penetration areas, and containment basemat. Details of the SAP methodology for these analyses are covered in Section 6.4 of BC-TOP-5-A. As an

alternative to ICES-STRUDL-II, the SAP program is used to analyze the containment internal structures.

3B.3.3 APPLICABILITY AND VALIDITY OF SAP PROGRAM

Applicability and validity of the SAP program are demonstrated in the four test problems outlined in subsection 3B.3.4. In each of the test problems, solutions are obtained by using the SAP program and some other analytical or computer program technique; then the results are compared. As will be noted, in all cases the solutions compare favorably and are essentially identical. The various analytical or computer program techniques used in the comparisons are extensively referenced within the test problems; they are collectively listed in the references for this appendix.

3B.3.4 SAP VERIFICATION (TEST PROBLEMS)

3B.3.4.1 SAP Example 1, Shell Element

This problem demonstrates the ability of the SAP program to give solutions to plate bending problems that are essentially identical to the results obtained from classical analytical techniques or independent computer programs. Details of the independent analysis are contained in Finite-Element Bending Analysis for Plates.(3)

The problem is solved once using the SAP triangular shell elements, and again using the SAP quadrilateral shell elements. The plate, which has a combination of fixed, free, and simple supported edges, is subjected to a uniform normal load of

1.0 pounds per square inch. Details of the problems are as follows:

A. Property Data

E = 30.0 x 10-6 pounds per square inch

υ = 0.3

B. Geometry

The geometry of the plate is shown in figure 3B.3-1. The plate is 0.01 inch thick.

C. Boundary Conditions

As shown in figure 3B.3-1, two edges of the plate are simply supported at X = 0.0 and x = 1.6. The edge at Y = 0 is fixed, while the edge at y = 0.8 is free. Because of the symmetry of the loading, structure, and support conditions, only half of the plate is modeled with appropriate boundary conditions imposed along the plane of symmetry.

D. Results

The results obtained from the SAP analysis are compared with the classical finite-element solution in figures 3B.3-2 through 3B.3-4. The results obtained using the triangular-element mesh are essentially identical to those obtained using the quadrilateral-element mesh. The sign convention for the above figures are shown in figure 3B.3-5.

3B.3.4.2 SAP Example 2, Static Analysis of Shell Structures

This problem demonstrates the agreement of results obtained using SAP shell elements and those obtained using classical analytical techniques and computer programs found in Pressure Vessel and Piping 1972 Computer Programs Verification (ASKA),[4] Theory of Plates and Shells,[5] Analysis of Thin Shells by a Finite-Element Procedure,[6] and a Mixed Finite-Element Method for Thin Shell Analysis.[7]

A spherical shell with clamped edges is subjected to a uniform external pressure. Due to the symmetry of the structure and the applied loading, only a segment of the shell is modeled, with appropriate boundary conditions applied at the meridional planes of symmetry. Details of the problems are as follows:

A. Property Data

E = 1.0 x 106 pounds per square inch

υ = 0.17

B. Geometry

The clamped spherical shell geometry is shown in figure 3B.3-6.

C. Loading Data

Uniform external load is 1.0 pounds per square inch, acting downward.

D. Results

The displacements, forces, and bending moments obtained from the SAP program, classical analytical techniques, and other referenced computer programs are plotted together for comparison in figures 3B.3-7 through 3B.3 10. The results are in good agreement.

3B.3.4.3 SAP Example 3, Static Analysis of Shell Structures

To demonstrate the validity of the static analysis capability of the SAP program for shell structures, a hyperboloid cooling tower is modeled as an assemblage of thin shell elements and analyzed to determine the effects of wind loading. The results thus obtained are compared to the solutions obtained using ASKA program from Pressure Vessel and Piping 1972 Computer Program Verification,(4) and The Analysis of Cooling Towers by the Matrix Finite-Element Method.[8]

The cooling tower is modeled using 240 thin shell elements and 143 nodal points. Since there is a vertical plane of symmetry for both the structure and the applied load, only half of the tower is modeled by imposing appropriate boundary conditions at the plane of symmetry. The base of the tower is clamped. Details of the problem are as follows:

A. Property Data

$E = 4.32 \times 108$ pounds per square feet

$\upsilon = 0.15$

B. Geometry

The geometry of the cooling tower is shown in figure 3B.3-11.

C. Loading Data

The cooling tower is subjected to the wind pressure distribution in figure 3B.3-12.

E. Results

The displacements at the top of the cooling tower obtained from the SAP program, classical analytical techniques, and other referenced computer programs are plotted together in figure 3B.3-13. The results are in good agreement.

3B.3.4.4 SAP Example 4, Three-Dimensional Solid Element

This problem demonstrates the applicability and validity of the SAP solid element for modeling and analyzing three-dimensional structures. The problem involves determining the magnitude of stress concentrations in the vicinity of a circular penetration through a pressurized cylinder. The results of the problem are compared to the theoretical solution provided in State of Stress in a Circular Cylindrical Shell with a Circular Hole.(1)

The three-dimensional, finite-element model used for this example is provided in figure 3B.3-14. The sign convention for resultant forces and moments is provided in figure 3B.3-15. The model consists of 20 elements and 60 nodal points. Details of the problem are as follows:

STRUCTURAL ANALYSIS

PROGRAM (SAP) CE 800

A. Property Data

E = 4.7 x 106 pounds per square inch

υ = 0.26

B. Geometry

1. Cylinder inside radius = 62 feet

2. Cylinder Thickness = 3.5 feet

3. Penetration radius = 5.17 feet

D. Loading Data

The closed-end cylinder is subjected to an internal pressure of 60 pounds per square inch. The shear force transferred from the penetration cover to the cylinder is included in the analysis.

E. Boundary Conditions

1. Symmetry

Because of the symmetry of the structure and the applied load, only one quadrant of the penetration is modeled by applying appropriate symmetry boundary conditions along two perpendicular planar boundaries.

2. Compatibility

The stress and displacement conditions at the circular boundary, which is sufficiently remote from the influence of the penetration, were required to be compatible with analytically

obtained values for a closed, thick-walled cylinder.

F. Results

The resultant forces and moments obtained from the SAP analysis are compared with the theoretical results in figures 3B.3-16 through 3B.3-19. The results are in good agreement.

3B.4 DESCRIPTION OF VERIFICATION PROBLEMS (OPTCON MODULE) CE 201

This section presents a description of verification for all test problems. Each problem is described with a sketch showing the OPTCON model, loading, and comparison of pertinent results.

3B.4.1 OPTCON MODULE VERIFICATION (TEST PROBLEMS)

3B.4.1.1 OPTCON Module Example 1 - CE201VER0P1

A section was designed for primary loads using the ASME service load criteria (figure 3B.4-1). The results compared closely with hand calculations.

3B.4.1.2 OPTCON Module Example 2 - CE201VER0P2

A section was designed for primary loads using the ASME factored load criteria (figure 3B.4-2). The results compared closely with hand calculations.

3B.4.1.3 OPTCON Module Example 3 - CE201VER0P3

A section was designed for primary loads using ACI 318-71 ultimate strength criteria (figure 3B.4-3). The results compared closely with hand calculations.

3B.4.1.4 OPTCON Module Example 4 - CE201VER0P4

A section was designed for primary plus secondary thermal loads using the ASME service load criteria (figure 3B.4-4). The results compared closely with hand calculations.

3B.4.1.5 OPTCON Module Example 5 - CE201VER0P5

A section was designed for primary plus secondary thermal loads using the ASME factored load criteria (figure 3B.4-5). The results compared closely with hand calculations.

3B.4.1.6 OPTCON Module Example 6 - CE201VER0P6

A section with primary plus secondary thermal loads was analyzed using the ASME service load criteria (figure 3B.4-6). The results compared closely with hand calculations.

3B.4.1.7 OPTCON Module Example 7 - CE201VER0P7

A fully cracked section with reinforcing yielding under primary plus secondary thermal loads was analyzed using the ASME factored load criteria (figure 3B.4-7). The results compared closely with hand calculations.

3B.4.1.8 OPTCON Module Example 8 - CE201VER0P8

A partially cracked section with reinforcing yielding under primary plus secondary thermal loads was analyzed using the ASME factored load criteria (figure 3B.4-8). The results compared closely with hand calculations.

3B.4.1.9 OPTCON Module Example 9 - CE201VER0P9

A section was analyzed to test the input flags, ITEMP and JTEMP, which define the type of secondary thermal loading (figure 3B.4-9). The results agreed with hand calculations,

and the secondary thermal moment input flags were shown to be functional.

3B.4.1.10 OPTCON Module Example 10 - CE201VER0P10

A section was analyzed to test the input flags on the OPTIONS card; NOPTN(1), NOPTN(2) and NOPTN(3). The ASME service load criteria was used for primary plus secondary thermal loading (figure 3B.4-10). The primary loading included tangential shear (membrane shear). The results agreed with hand calculations, and the OPTIONS input flags were shown to be functional.

3B.4.1.11 OPTCON Module Example 11 - CE201VER0P11

CE201VER0P6 (load case c) was reanalyzed using metric units, scale factors, and maximum percentages of reinforcing (figure 3B.4-11). The results compared closely with hand calculations. The conversion of units, scale factors, and maximum percentages was shown to be functional.

3B.4.1.12 OPTCON Module Example 12 - CE201VER0P12

A section with a liner plate was analyzed for primary loading using the ASME factored load criteria. The section was analyzed with and without liner plate temperature and finally without liner plate using the OFF LINER card (figure 3B.4-12). The results compared closely with hand calculations and the OFF LINER card was shown to be functional.

3B.4.1.13 OPTCON Module Example 13 - CE201VER0P13

CE201VER0P12 (load cases 1 and 2) was reanalyzed with an additional moment applied to the section to simulate the zero change in curvature conditions that would exist in the hoop direction of a containment shell (figure 3B.4-13). The results agreed closely with hand calculations.

3B.4.1.14 OPTCON Module Example 14 - CE201VER0P14

A section with a liner plate was analyzed with primary plus secondary thermal gradient loading using the ASME factored load criteria. Three liner plate conditions were investigated; liner on without temperature, liner on with temperature, and finally, liner off (figure 3B.4-14). The results agreed closely with the results determined from hand calculations.

3B.4.1.15 OPTCON Module Example 15 - CE201VER0P15

CE201VER0P14 (load cases 1 and 2) was reanalyzed with an additional moment applied to the section to simulate the zero change in curvature condition that would exist in the hoop direction of a containment shell (figure 3B.4-15). The results agreed closely with hand calculations.

3B.4.1.16 OPTCON Module Example 16 - CE201VER0P16

CE201VER0P14 was redesigned with the inclusion of a hot liner plate (figure 3B.4-16). The section was shown to be adequate with the liner plate and liner plate temperature. The stress results compared closely with hand calculations.

3B.4.1.17 OPTCON Module Example 17 - CE201VER0P17

CE201VER0P5 was redesigned with the inclusion of a hot liner plate (figure 3B.4-17). The section was shown to be adequate with the hot liner plate. The stress results compared closely with hand calculations.

3B.4.1.18 OPTCON Module Example 18 - CE201VER0P18

CE201VER0P2 was rerun to test the input flags, REF1 and RPEF1, which set the maximum allowable percentages of reinforcing and allow termination of the optimization process (figure 3B.4-18). The results compared closely with hand calculations and the input flags were shown to be functional.

3B.4.1.19 OPTCON Module Example 19 - CE201VER0P19

CE201VER0P1 was rerun to test the SET OUTPUT flag equal to 0 and 2 (figure 3B.4-19). For the flag set to 0, only the optimum reinforcing and thermal moment iteration should be printed. For the flag set to 2, the results are the same as for 0 but with the iteration diagram printed and plotted. The results for 0 were the same as those in CE201VER0P1 (i.e., all information was printed). The results for 2 were also the same as those in CE201VER0P1 except that no iteration diagram was plotted.

3B.4.1.20 OPTCON Module Example 20 - CE201VER0P20

CE201VER0P1 and CE201VER0P2 were rerun for certain load combinations using the SUPPRESS option in OPTCON. Two designs

were made using both the ASME service and ASME factored load criteria. The first design suppressed the ASME factored, and the second suppressed the ASME service criteria (figure 3B.4 20). The results compared exactly with those of 0P1 and 0P2 and the suppress option flags, NOUSD and NOWSD, were shown to be functional.

3B.4.1.21 OPTCON Module Example 21 - CE201VER0P21

CE201VER0P6 (load cases 1 and 2) was rerun with thermal parameter modifications and using the OFF THERMAL card (figure 3B.4-21). The thermal parameters modified were NPARAM, which defines the maximum number of steps in the thermal moment calculations, and AKKK, which defines the step size for iteration for thermal moments. The results compared closely with hand calculations except for the stresses after thermal moment relaxation. The final thermal moment was extrapolated correctly from just five cycles, and the design section was shown to be adequate. The stresses, however, which are based on the CURV value at five cycles, are incorrect. This discrepancy was identified as item AIF08. The thermal parameters NPARAM and AKKK and the OFF THERMAL card were shown to be functional.

3B.4.1.22 OPTCON Module Example 22 - CE201VER0P22

A section was analyzed for secondary thermal gradient loading using the ASME service load criteria. The effect of tension reinforcing on the relaxed thermal moment was investigated

(figure 3B.4-22). The results compared closely to hand calculations. This test case illustrates how the final or cracked thermal moment can be greater than the uncracked thermal moment.

3B.4.1.23 OPTCON Module Example 23 - CE201VER0P23

A section was analyzed with load input from a BSAP[a] Tape 27 and cards. Primary and secondary thermal loading were applied to the section using the ASME service load criteria (figure 3B.4-23). The results compared closely with hand calculations.

---

a. BSAP-POST (CE 201) is a general-purpose post-processor program for the BSAP (CE 800) finite-element analysis program. BSAP-POST can take the output from BSAP and display this data (graphically and/or on a line printer) or perform additional calculations. In addition, some of the capabilities of BSAP-POST can be used independently. For example, the concrete design module, OPTCON, can use design loads obtained from BSAP output (Tape 27) or from punched cards.

BSAP-POST consists of a number of modules that can be used independently or sequentially to display or modify the contents of a data base under the control of an executive supervisor program. The data base consists of the contents of a file (TAPE 27) created by a BSAP analysis problem. The executive supervisor ensures that each module in BSAP-POST is compatible with every other module and initiates the execution of each module when required by input data supplied by the user.

3B.5 DYNAMIC ANALYSIS COMPUTER PROGRAM (ICES-DYNAL)

The DYNAL,(1) another subsystem of ICES, is used for the dynamic analysis of Seismic Category I structures other than the containment. It analyzes the structural dynamics of the broad class of structures represented as assemblages of triangular elements, curved or straight prismatic beams and pipes, and springs. Present analysis capability consists of:

A. Computing system stiffness and mass matrices

B. Computing the structural modes (eigenvectors) and frequencies (eigenvalues)

C. Computing the structural response to:

   1. Excitation represented as a shock spectrum (used in many cases to represent earthquake and blast shocks)

   2. Harmonic (sinusoidal) forcing functions

   3. Time history (transient) forcing functions

The DYNAL uses a problem-oriented language very similar to that used in STRUDL. This is a very convenient language, and its use allows one who is familiar with STRUDL to use DYNAL with a minimum of effort.

The structural dynamic analyses available are based on the modal superposition method, which basically consists of reducing a set of second-order linear differential equations to their simplest form and solving the resulting equations. This approach is attractive because the reduced set of equations is uncoupled, and only a relatively small percentage of the total

number of equations is necessary to adequately represent the structural response.

Structural dynamic analyses by the modal superposition method invariably require three basic steps. These are:

A. Generation of mass and stiffness (or flexibility) matrices to represent the distributed mass and stiffness of the actual structure

B. Solution of the eigenvalue-eigenvector problem

C. Solution of a reduced set of uncoupled equations for response to a specified form of excitation

Some form of damping usually is included in the reduced set of equations, but sometimes is neglected depending on its magnitude and the form of excitation.

The generation of stiffness matrices follows procedures similar in many aspects to that used for STRUDL. A consistent mass matrix, as discussed by Archer(2), also may be generated. The terminology "consistent mass matrix" is used to indicate that mass matrix formulation uses deformation shapes that are consistent with the stiffness formulation. This approach provides a better representation of the kinetic energy than does the more conventional "lumping" technique, which consists of lumping the continuous mass distribution at discrete joints.

A technique called "kinematic condensation"(3) is available for reducing the size of structural mass and stiffness matrices before computing the normal modes and frequencies. The

condensation is such that the lower frequency modes of vibration are preserved.

The structural modes and frequencies are computed using any of three available methods, all of which are discussed by Wilkinson.[4] The recommended method uses Householder's transformation to tridiagonalize symmetric matrices, Ortega's bisection techniques for eigenvalues, and Weilandt inverse iteration for eigenvectors (also attributed to Wilkinson).

The other two available methods are Jacobi iteration and Francis' QR algorithm.

The response analysis computations provide joint displacements, velocities and accelerations, and member forces and moments.

The shock spectrum analysis is used in many cases for earthquake structural response. It requires, as input, a table expressing the maximum response of simple oscillators as a function of their natural frequency.

The harmonic analysis obtains the structural response to joint forces or base (support) excitations that can be expressed as cosine waves with arbitrary phasing.

The time-history (transient) analysis computes the response to joint loads or base excitations represented as tables of magnitude vs. time.

The DYNAL also may be used for shell vibration analysis. Provision has been made to read an output tape from the SABOR shell analysis program. A kinematic condensation and/or modal analysis may then be performed.

A sophisticated plotting capability is available for plotting planar and three-dimensional structural views and mode shapes.

3B.5.1 EXTENT OF APPLICATION OF ICES-DYNAL

The ICES-DYNAL program is one of the programs used in performing lumped mass dynamic analyses of Seismic Category I structures.

3B.5.2 APPLICABILITY AND VALIDITY OF ICES-DYNAL

The ICES-DYNAL program is in the public domain and has been in use since 1970. For this reason, no verification test problems are provided. However, following is a listing of the specific versions of ICES-DYNAL used:

A. McDonnell Douglas Release 3.2, dated February 5, 1973.

B. McDonnell Douglas Executive System Release 2.3, dated February 5, 1973.

The IBM 370-165 computer and applicable system programs are used in conjunction with the above programs to perform the lumped mass dynamic analyses covered herein.

3B.6 SYMBOLIC MATRIX INTERPRETIVE SYSTEM (SUPER SMIS) CE 804

The SUPER SMIS is a general-purpose program that is used to solve practically any problem in which matrix analysis is applicable. A common application of the SUPER SMIS program is the solution of static and dynamic structural problems.

This program is a refinement of the original Symbolic Matrix Interpretive System (SMIS) program developed at the University of California at Berkeley in 1963. The present program handles about 60 operations, including:

A. General matrix manipulations such as matrix addition, multiplication, and inversion

B. General tape and card-handling manipulations (including the savings of results on magnetic tapes and card-punching capability)

C. General element stiffness routines for plate or three-dimensional beam and truss elements and for a constant-strain, triangular-plate finite-element

D. Element stiffness routine for the three-dimensional beam includes axial, torsional, bending, and shearing stiffness and computation of a consistent element mass matrix

E. Eigenvalue and eigenvector capability

F. Element stress routines for finding the forces for each of the element types

G. Acceptability of matrices generated by other programs as input to the SUPER SMIS program

H. Uncoupled (normal mode) time-history response analysis of dynamic systems

I. Coupled time-history response analysis of dynamic systems

J. Sorting of results from both uncoupled and coupled analyses into forms desired for further analyses

K. Steady-state response analysis of uncoupled systems

The coupled time-history response analyses uses a Newmark-Beta direct-integration technique, which allows the solution of coupled or uncoupled systems of equations.(1) This, for example, allows the analysis of systems using any arbitrary damping matrix. It also may be used in the analysis of systems having different excitations at different support points. The system may be treated as either having displacement boundary conditions or as a free-free system with base displacement time-history excitations. The main feature of this program is its versatility, allowing almost any type of modification to be made to a matrix. This proves to be a distinct requirement where damping matrices or dynamic matrices are being formed for arbitrary structures.

3B.6.1 EXTENT OF APPLICATION OF SUPER SMIS

The SUPER SMIS program is one of the programs used in performing lumped mass dynamic analyses of Seismic Category I structures.

3B.6.2 APPLICABILITY AND VALIDITY OF SUPER SMIS

Applicability and validity of the SUPER SMIS program are demonstrated in the three test problems outlined in subsection 3B.6.3. In each test problem, the solutions are obtained by using SUPER SMIS and ICES-DYNAL programs, and then comparing the results.

3B.6.3 SUPER SMIS VERIFICATION (TEST PROBLEMS)

3B.6.3.1 SUPER SMIS Example 1, Lumped Mass Response Spectrum Analysis

This problem demonstrates the agreement of results obtained using SUPER SMIS and ICES-DYNAL for the lumped mass response spectrum analysis.

The lumped mass model used in the demonstration is illustrated in figure 3B.6-1. Each nodal point has two degrees of freedom: horizontal and rotational.

A. Problem Parameters

   1. Elastic modulus (E = 617,000 ksf)

   2. Poisson's ratio (υ = 0.167)

   3. The spectra acceleration input is taken from typical design spectra for 2% damping.

B. Results

   The natural frequency and displacement results obtained from the SUPER SMIS and ICES-DYNAL programs are summarized in tables 3B.6-1 and 3B.6-2.

3B.6.3.2 SUPER SMIS Example 2, Lumped-Mass Time-History Analysis

This problem demonstrates the agreement of results obtained using SUPER SMIS and ICES-DYNAL for the lumped-mass time-history analysis:

A. Problem Parameters

1. Elastic modulus (E = 617,000 ksf)

2. Poisson's ratio (υ = 0.167)

B Results

The solution using SUPER SMIS indicates a maximum absolute acceleration of 4.451 ft/s^2 at time 0.28 second; ICES-DYNAL indicates 4.444 ft/s^2 at time 0.28 second.

3. The spectra acceleration input is taken from typical design spectra for 2% damping.

3B.6.3.3 SUPER SMIS Example 3, Eigenvalue Analysis of Space Frames

This problem demonstrates the ability of SUPER SMIS in handling tridimensional elements using consistent mass. The natural frequencies are calculated using SUPER SMIS and ICES-DYNAL.

The eigenvalue analysis model used in the demonstration is illustrated in figure 3B.6-2. Each nodal point is assumed to have six degrees of freedom:

A. Problem Parameters

1. Elastic modulus (E = 617,000 ksf)
2. Poisson's ratio ($\nu = 0.167$)
3. Cross sectional area of elements ($A = 4.0\ ft^2$)
4. Shear area of elements ($A_y = A_z = 4.0\ ft^2$)
5. Moment of inertia ($I_y = I_z = 1.3\ ft^4$)
6. Mass density ($0.0045684\ ks^2/ft^4$)

B. Results

The natural frequency results obtained from SUPER SMIS and ICES-DYNAL programs are summarized in table 3B.6-3.

3B.7 SPECTRA COMPUTER PROGRAM (SPECTRA) CE 802

The SPECTRA program is a special-purpose program that is used to compute response spectra from a time-history accelerogram.

The SPECTRA program defined and used in the examples provided herein is a refinement of the original code developed at the California Institute of Technology.(1)(2) This modified program has the following additional features:

A. Cal-Comp plotting of accelerograms

B. The SC-4020 optical plots of computed response spectra. These plots are available for displacement, velocity, and acceleration spectra

The main feature of SPECTRA is its use of the closed-form recur-rence algorithm for a ramp function. This allows the exact solution of equations with the exception of machine roundoff.

3B.7.1 EXTENT OF APPLICATION OF SPECTRA

The SPECTRA program is used for Seismic Category I structures to generate floor response spectra, computed from time-history motions at various floor or other locations.

3B.7.2 APPLICABILITY AND VALIDITY OF SPECTRA

Applicability and validity of the SPECTRA program are demonstrated in the two test problems outlined in subsection 3B.7.3. In each test problem, the solutions are obtained by using SPECTRA and various analytical techniques,

and then comparing the results. In both examples the comparison of results are in good agreement.

3B.7.3 SPECTRA VERIFICATION

The two test problems described in the following paragraphs pro-vide comparisons of response spectra computed using the SPECTRA program and a classic analytical technique.

The SPECTRA program computes response spectra values from a time-history accelerogram digitized at equal time intervals using numerical analysis of closed-form recurrence equations.

In the first test problem, response spectra applicable to an undamped system are determined when subjected to a symmetrical triangular pulse load. In this example, the pulse duration is 5 seconds and various natural frequencies are used.

In the second test problem, response spectra applicable to an undamped system are determined when subjected to a sinusoidal force. As in the first example, various natural frequencies also are used in this example.

A typical undamped system is illustrated in figure 3B.7-1.

3B.7.3.1 Test Problem 1, Symmetrical Triangular Pulse

In this test problem the equation for the triangular pulse, taken from Engineering Vibrations(3) is:

$$DLF = \frac{x_m}{X_{st}} = \frac{2}{t_d}\left(t - \frac{\sin \omega t}{\omega}\right) \qquad ,0 \le t = 1/2\ t_d$$

$$DLF = \frac{2}{t_d}\left\{t_d - t + \frac{1}{\omega}\left[2 \sin \omega \left(t - \frac{t_d}{2}\right) - \sin \omega t\right]\right\},\ 1/2\ t_d \le t \le t_d$$

$$DLF = \frac{2}{\omega t_d}\left[2 \sin \omega \left(t - \frac{t_d}{2}\right) - \sin \omega t - \sin \omega \left(t - t_d\right)\right],\ t_d \le t$$

The analytical response spectra from the foregoing are plotted in figure 3B.7-2. This represents the maximum response, as a

SPECTRA COMPUTER PROGRAM

function of td/T where T is the natural period. The SPECTRA response spectra, tabulated in table 3B.7-1, also are shown in figure 3B.7-2.

In this test problem, static deflection is computed using equation of motion for a free vibration state:

Where: $MX + KX = 0$

$$X + (K/M)X = 0 \qquad (\text{Let } \omega = K/M)$$

Then, the solution is:

$$X = A \sin \omega t + B \sin \omega t$$

For: $X_o = 0$ at time $t = 0$

$$X = A \sin \omega t$$

$$X = A\omega \cos \omega t$$

$$X = -A\omega^2 \sin \omega t$$

Thus, X and X are related by the relationship:

$$X = -\frac{1}{\omega^2} X$$

Therefore, for maximum static deflection

$$X = -\frac{1}{\omega^2}$$

Since maximum dynamic displacement and input acceleration are present, the input acceleration is converted to static deflection by the relationship:

$$X = \frac{-1}{\omega^2} X$$

Thus, the DLF is computed from:

$$DLF = \frac{X_{dyn}}{\frac{1}{\omega^2} X}$$

$$DLF = \omega^2 \left(\frac{X_{dyn}}{X} \right)$$

For maximum static response:

$$DLF = \omega^2 \ X_{dyn}$$

Plotting t_d/T versus $(DLF)_{max}$ as:

$$\omega = \frac{2\pi}{T}$$

$$\boxed{(DLF)_{max} = \left(\frac{2\pi}{T} \right)^2 \left(X_{dyn} \right)_{max}}$$

3B.7.3.2 Test Problem 2, Symmetrical Sinusoidal Pulse

In this test problem the equation for the sinusoidal pulse, taken from Introduction to Structural Dynamics,(4) is:

$$MX + Kx = F_1 \sin \Omega t$$

SPECTRA COMPUTER PROGRAM

(SPECTRA) CE 802

The general solution is:

$$x = \frac{F_1}{M}\left(\frac{\sin \Omega t}{\omega^2 - \Omega^2} - \frac{\Omega}{\omega}\frac{\sin \omega t}{\omega^2 - \Omega^2}\right)$$

or:

$$DLF_{max} = \frac{1}{\left(1 - \Omega^2/\omega^2\right)}\left[\sin \Omega t - \frac{\Omega}{\omega} \sin \omega t\right]$$

The analytical response spectra derived from the foregoing are in two parts: transient (free part), and steady-state (forced part). The upper bound of free and forced parts combined, as well as forced parts only, are plotted in figure 3B.7-3. The SPECTRA response spectra, tabulated in table 3B.7-2, also are shown in figure 3B.7-3.

Table 3B.7-2

3B.8 LUCON COMPUTER PROGRAM (LUCON) CE 970

This section describes the theoretical basis, verification and usage of a computer program developed to evaluate the impedance functions for a rigid circular foundation placed on a layered viscoelastic medium.

Given the characteristics of the site and the geometry of the foundation, the program computes the vertical, rocking, and horizontal impedance functions, and its reciprocals, the compliance functions, for any given set of frequencies. The foundation medium may be layered or may be a uniform elastic half-space. Two types of material damping in the soil may be considered; namely, constant hysteretic type damping and Voigt type damping. The type of damping must be the same for all layers, but the values of the damping constants may differ from layer to layer.

3B.8.1 THEORETICAL BASIS

A key step in the evaluation of the soil-structure interaction effects on the earthquake response of a structure is the computation of the force displacement relationship for the foundation. Several such relationships, expressed in terms of impedance or compliance functions, are available at the present time.(1) However, most of these studies are restricted to a model of soil corresponding to a nondissipative, purely elastic medium. In these studies, no material or internal damping is considered, and, consequently, the only source of energy dissipation corresponds to the geometric attenuation, also called radiation damping.

LUCON COMPUTER PROGRAM

(LUCON) CE 970

The object of this study is to incorporate the effects of material damping in the analysis of the harmonic response of a rigid circular foundation placed on a layered medium. The need for incorporating the material damping in the solution of this problem arises from the important effects that internal damping has, particularly when large strains are involved or when the medium representing the soil is layered. In this study, two types of material damping are considered: viscous Voigt type damping and hysteretic type damping. Three types of harmonic excitations are investigated: vertical force, rocking moment, and horizontal force. In all cases, relaxed conditions on the contact between the circular foundation and the supporting medium are assumed.

In a previous study, Veletsos and Verbic[2] considered the harmonic response of a circular foundation placed on a visco-elastic half-space. The method of solution employed in rocking moment is approximate and does not lend itself to the analysis of layered media for which the impedance functions present strong fluctuations as a function of frequency. The studies reported in references 3, 4, and 5, although more general in regards to the incorporation of material damping, are based on an assumed stress distribution on the contact between the foundation and the soil.

The method of solution employed herein follows, except for consideration of the material damping, the procedure used by the author[6] to solve the problem for a nondissipative layered medium.

3B.8.2 PROBLEM DESCRIPTION

3B.8.2.1 Statement of the Problem

In what follows, a study is made of the forced harmonic vibrations of a rigid circular footing of radius a placed on the surface of a layered viscoelastic medium. The layered medium consists of N-1 parallel layers resting on a viscoelastic half-space. Both the layers and the elastic half-space are assumed to be homogeneous and isotropic with densities ρ_i, shear moduli G_i, and Poisson's ratios σ_i (i = 1, 2,....N), respectively. In addition, depending on the type of internal friction considered, the relative viscosity coefficient $(G_i^{'} / G_i)$ (for Voigt type dissipation), or, the hysteretic damping coefficient $x_i = wG'_i/2G_i$ (for hysteretic type dissipation) are assumed to be known for each one of the media forming the soil deposit. The geometry of the model and the coordinate systems used are shown in figure 3B.8-1.

A welded type of contact is assumed to exist between adjacent layers. Thus, the stresses and displacements are continuous across each interface. The contact between the foundation and the surface of the top layer is assumed to be relaxed, i.e., the contact is frictionless for vertical and rocking vibrations and pressureless for horizontal vibrations.

The boundary conditions on z = 0 expressed in terms of displacement and stress components in cylindrical coordinates are the following:

A. Vertical Vibrations

$$u_z(r, \theta, 0) = D_V e^{i\omega t} \qquad 0 \leq r \leq a \tag{1.a}$$

$$\sigma_{zz}(r, \theta, 0) = 0 \qquad r > a \tag{1.b}$$

$$\sigma_{zr}(r, \theta, 0) = \sigma_{z\theta}(r, \theta, 0) = 0 \qquad 0 < r < \infty \tag{2}$$

B. Rocking Vibrations

$$u_z(r, \theta, 0) = \alpha r \cos \theta \, e^{i\omega t} \qquad 0 \leq r \leq a \tag{3.a}$$

$$\sigma_{zz}(r, \theta, 0) = 0 \qquad r > a \tag{3.b}$$

$$\sigma_{zr}(r, \theta, 0) = \sigma_{z\theta}(r, \theta, 0) = 0 \qquad 0 < r < \text{¥} \tag{4}$$

C. Horizontal Vibrations

$$\left.\begin{aligned} u_r(r, \theta, 0) &= \Delta_H \cos \theta e^{i\omega t} \\ u_\theta(r, \theta, 0) &= -\Delta_H \sin \theta e^{i\omega t} \end{aligned}\right\} \qquad 0 \leq r \leq a \tag{5}$$

$$\sigma_{zr}(r, \theta, 0) = \sigma_{z\theta}(r, \theta, 0) = 0 \qquad r > a \tag{6}$$

$$\sigma_{zz}(r, \theta, 0) = 0 \qquad 0 < r < \infty \tag{7}$$

In the equations above, Δ_V is the amplitude of the vertical displacement of the center of the rigid foundation, α is the amplitude of the rocking angle about the y-axis ($\theta = \pi/2$), Δ_H is the amplitude of the horizontal displacement of the foundation in the direction of the x-axis ($\theta = 0$), and ω is the frequency of the steady-state vibrations.

The continuity conditions at the interface z = Hi are:

$$u_r^{i}(r, \theta, H_i) = u_r^{i+1}(r, \theta, H_i) \quad (8.a)$$

$$u_\theta^{i}(r, \theta, H_i) = u_\theta^{i+1}(r, \theta, H_i) \quad (8.b)$$

$$u_z^{i}(r, \theta, H_i) = u_z^{i+1}(r, \theta, H_i), \ (i = 2, \ldots N) \quad (8.c)$$

$$\sigma_{zr}^{i}(r, \theta, H_i) = \sigma_{zr}^{i}(r, \theta, H_i) \quad (9.a)$$

$$\sigma z_\theta^{i}(r, \theta, H_i) = \sigma_{z\theta}^{i}(r, \theta, H_i) \quad (9.b)$$

$$\sigma_{zz}^{i}(r, \theta, H_i) = \sigma_{zz}^{i}(r, \theta, H_i), \ (i = 1, 2, \ldots N) \quad (9.c)$$

where, the superscript i indicates the i^{th} layer. In addition, the displacement and stress components in the underlying half-space must tend to zero as $(r^2 + z^2)$ tends to infinity.

3B.8.2.2 Types of Energy Dissipation

In this study, two types of energy dissipation are considered; namely, the Voigt viscous model and the hysteretic model.

The stress-strain relationships for harmonic vibrations of a solid with Voigt type damping are of the form[7]

$$\sigma_{zz} = (\lambda + i\omega\lambda')\,H + 2(\mu + i\omega\mu')\,\varepsilon_{zz} \quad (10.a)$$

$$\sigma_{zx} = 2(\mu + i\omega\mu')\,\varepsilon_{xz} \quad (10.b)$$

where:

$$H = \varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz} \quad (10.c)$$

In equations 10.a and 10.b, ω is the frequency of the excitation; λ and μ are Lame's constants, and, λ', μ' are the viscosities. It is clear from equations 10.a and 10.b that the viscoelastic problem may be solved if the solution for the corresponding purely elastic problem is known by substituting in the elastic solution λ and μ by the complex moduli:

$$\lambda * = \lambda(1 + i\omega\lambda' / \lambda) \tag{11.a}$$

$$\lambda * = \mu(1 + i\omega\mu' / \mu) \tag{11.b}$$

In order to simplify the problem it is assumed that:

$$\frac{\lambda'}{\lambda} = \frac{\mu'}{\mu} \tag{12}$$

In this case the remaining complex constants are given by:

$$E* = \frac{(3\lambda * + 2\mu *) \mu *}{\lambda * + \mu *} = E(1 + i\omega\mu' / \mu) \tag{13.a}$$

$$k* = \lambda * + \frac{2}{3} \mu * = k(1 + i\omega\mu' / \mu) \tag{13.b}$$

$$\sigma * = \frac{\lambda *}{2(\lambda * + \mu *)} = \sigma \tag{13.c}$$

where E, k, and σ are the Young's modulus, the bulk modulus, and Poisson's ratio, respectively. The assumption given by equation 12 has the advantage that the Poisson's ratio for the viscoelastic medium is real and equal to the Poisson's ratio of the corresponding elastic medium. One disadvantage, however, is the fact that the bulk modulus is complex and

consequently there are losses associated with changes of volume.

Equation 10.b indicates that for shear deformations the stress-strain relationship could be described by an ellipse. The energy loss per cycle is given by the area of the ellipse and the corresponding 'specific loss' is:

$$\frac{\Delta W}{W} = 2\pi \frac{\omega\mu'}{\mu} \qquad (14)$$

Where W is the elastic energy stored when the strain is a maximum, equation 14 indicates that for a Voigt solid the 'specific loss', or the energy loss per cycle, is proportional to the frequency of the excitation. The elliptical stress-strain loop in this case is a direct result of the viscosity of the medium.

Laboratory tests on soils indicate that the 'specific loss' $\Delta W/W$ is independent of the frequency of the excitation and that the stress-strain loop is not an ellipse[8-12]. It appears then that the mechanism of energy loss in soils is not of the viscous type but rather is a direct result of the inelastic behavior of soils. In spite of this inelastic behavior, an approximate approach is to assume that the soil may be treated in a similar way as a viscoelastic medium, except that in this case the complex shear modulus μ^* and the 'specific loss' are taken to be equal to:

$$\mu^* = \mu(1 + 2i\xi) \tag{15}$$

$$\frac{\Delta W}{W} = 4\pi\xi \tag{16}$$

Where ξ is a damping constant independent of frequency. This model of internal damping is also called constant hysteretic type damping. The damping constant ξ is analogous to the percentage of critical damping under resonant conditions, or during free vibrations[9]. The hysteretic damping constant ξ is strain dependent: values for low strain may be less than 0.02, while for high strains ξ may reach values of 0.15 or 0.20.

In what follows, the shear modulus μ is designated by G, and the shear viscosity μ' is designated by G'.

3B.8.2.3 Integral Representation

A solution of the equations of motion in cylindrical coordinates satisfying the conditions at the interface between layers, as well as the conditions at infinity, may be obtained by application of the correspondence principle to a representation derived by Sezawa and reported in references 13 and 14.

The displacement and stress components of interest on z = 0 are given by:

$$u_r(r, \theta, 0) = a\, u_r^*(r') \cos(n\theta)$$

$$u_\theta(r, \theta, 0) = a\, u^*_\theta(r') \sin(n\theta) \qquad (17)$$

$$u_z(r, \theta, 0) = a\, u^*_z(r') \cos(n\theta)$$

$$\sigma_{zr}(r, \theta, 0) = G_1 \sigma^*_{zr}(r') \cos(n\theta)$$

$$\sigma_{z\theta}(r, \theta, 0) = G_1 \sigma'_{z\theta}(r') \sin(n\theta) \qquad (18)$$

$$\sigma_{zz}(r, \theta, 0) = G_1 \sigma^*_{zz}(r') \cos(n\theta)$$

where n = 0 for vertical vibrations, n = 1 for rocking and horizontal vibrations, r' = r/a, and

$$u^*_r(r') \pm u^*_\theta(r') = \mp 2 \int_o^\infty \{k[\Delta_{11}(k)C_1(k) + \Delta_{12}(k)C_2(k)]/\Delta_R \mp \Delta_{33}C_3(k)/\Delta_L\} J_{n\pm1}(a_o kr')dk \qquad (19)$$

$$u^*_z(r') = 2\int_o^\infty k\{[\Delta_{21}(k)C_1(k) + \Delta_{22}(k)C_2(k)]/\Delta_R\} J_n(a_o kr')dk \qquad (20)$$

$$\sigma^*_{zr}(r') \pm \sigma^*_{z\theta}(r') = \pm 2a_o \int_o^\infty [kC_1(k) \mp C_3(k)]J_{n+1}(a_o kr')dk \qquad (21)$$

$$\sigma^*_{zz}(r') = 2a_o \int_o^\infty kC_2(k)J_n(a_o kr')dk \qquad (22)$$

In equations 19 through 22, $a_o = \omega a/\beta_1$ is a dimensionless frequency defined in terms of the shear wave velocity β_1 of the top layer. The functions Δ_{ij} (i, j = 1,2), Δ_R, Δ_{33}, and Δ_L

appearing in equations 19 through 22 depend on the properties of the soil column, and are given in subsection 3B.8.5. The functions $C_1(k)$, $C_2(k)$, and $C_3(k)$ are to be determined by the boundary conditions on z = 0. For vertical and rocking vibrations, equations 2 and 4, together with equation 21, imply that:

$$C_1(k) = C_3(k) = 0. \tag{23}$$

Similarly, for horizontal vibrations, equations 7 and 22 imply that:

$$C_2(k) = 0. \tag{24}$$

Before imposing the remaining boundary conditions, it is convenient to introduce the following substitutions:(6)(13)

A. Vertical Vibrations

$$C_2(k) = -\left[\frac{\Delta_v k_1^2}{\pi a(1-\sigma_1)} a_o\right] \int_o^1 \phi_V(t) \cos(a_o kt)\, dt \tag{25}$$

B. Rocking Vibrations

$$C_2(k) = -\left[\frac{2\alpha\ \kappa_1^2}{\pi(1-\alpha_1)} a_o\right] \int_o^1 \phi_R(t) \sin\ (a_o kt) dt \tag{26}$$

C. Horizontal Vibrations

$$C_1(k) = \left[\frac{2\Delta H\ \kappa 1^2}{\pi a(2-\sigma_1)} a_o\right] \int_o^1 \Big\{\phi_1(t) \cos(a_o kt)$$

$$- \phi_2(t) [\cos(a_o kt) - \sin(a_o kt)/a_o kt]\Big\} dt \tag{27}$$

$$C_3(k) = -\left[\frac{2\Delta H\ \kappa 1^2}{\pi a(2-\sigma_1)} a_o k\right] \int_o^1 \Big\{-\phi_1(t) \cos(a_o kt)$$

$$-(1-\sigma_1)\ \phi_2(t)\ [\cos(a_o kt) - \sin(a_o kt)/a_o kt]\Big\}dt \qquad (28)$$

where $\phi_V(t)$, $\phi_R(t)$, and $\phi_1(t)$, $\phi_2(t)$ are functions to be determined by equations 1, 3, and 5, respectively. Also, $\kappa_1^{\,2} = (1 + i\omega G_1'/G_1)^{-1}$ for Voigt type damping, and $\kappa_1^{\,2} = (1 + 2i\xi_1)^{-1}$ for hysteretic type damping. The substitutions indicated above satisfy directly the stress boundary conditions prescribed in equations 1, 3, and 6.

3B.8.3 INTEGRAL EQUATIONS AND IMPEDANCE FUNCTIONS

Substitution from equations 25 through 28, together with equations 23 and 24, into equations 17, 19, and 20, and imposition of the remaining displacement boundary conditions leads to the following integral equations for the unknown functions $\phi_V(t)$, $\phi_R(t)$, $\phi_1(t)$, and $\phi_2(t)$:

A. Vertical Vibrations

$$\phi_V(t) + \int_o^1 K(t, t')\ \phi_V(t')dt' = 1 \qquad (0\ £\ t\ £\ 1) \qquad (29)$$

where:

$$K(t, t') = L_1(|t - t'|) + L_1(t + t') \qquad (30)$$

$$L_1(t) = -\frac{a_o}{\pi}\int_o^\infty \left[\frac{k\Delta_{22}}{(1-\sigma_1)\ \Delta_R \kappa_1^{\,2}} + 1\right]\cos(a_o kt)dk \qquad (31)$$

B. Rocking Vibrations

$$\phi_R(t) + \int_o^1 K(t,t')\phi_R(t')dt' = t \qquad (0 \le t \le 1) \qquad (32)$$

where:

$$K(t, t') = L_1(|t-t'|) - L_1(t+t'). \qquad (33)$$

The function $L_1(t)$ in equation 33 is defined by equation 31.

C. Horizontal Vibrations

$$\phi_1(t) + \int_o^1 [K_{11}(t,t')\phi_1(t')$$

$$+ K_{12}(t,t')\phi_2(t')]dt' = 0 \qquad (0 \le t \le 1) \qquad (34)$$

$$(1 - \sigma_1)\phi_2(t) + \int_o^1 [K_{21}(t,t')\phi_1(t')$$

$$+ K_{22}(t,t')\phi_2(t')]dt' = 0 \qquad (0 \le t \le 1) \qquad (35)$$

where:

$$K_{11}(t,t') = \frac{2a_o}{\pi}\left(\frac{1}{2-\sigma_1}\right)\int_o^\infty [(1-\sigma_1)H_1(k)$$

$$+ H_2(k)]\cos(a_o kt)\cos(a_o kt')dk \qquad (36)$$

$$K_{12}(t,t') = -\frac{2a_o}{\pi}\left(\frac{1-\sigma_1}{2-\sigma_1}\right)\int_o^\infty [H_1(k)$$

$$- H_2(k)]\cos(a_o kt)\left[\cos(a_o kt')\right.$$

$$\left. - \frac{\sin(a_o kt')}{a_o kt'}\right]dk \qquad (37)$$

$$K_{21}(t, t') = -\frac{2a_o}{\pi}\left(\frac{1 - \sigma_1}{2 - \sigma_1}\right)\int_0^{\infty} [H_1(k) - H_2(k)]\left[\cos(a_o kt) - \frac{\sin(a_o kt)}{a_o kt}\right]\cos(a_o kt')dk \tag{38}$$

$$K_{22}(t, t') = \frac{2a_o}{\pi}\left(\frac{1 - \sigma_1}{2 - \sigma_1}\right)\int_0^{\infty} [H_1(k) + (1 - \sigma_1)H_2(k)]\left[\cos(a_o kt) - \frac{\sin(a_o kt)}{a_o kt}\right]\left[\cos(a_o kt') - \frac{\sin(a_o kt')}{a_o kt'}\right]dk \tag{39}$$

and,

$$H_1(k) = \frac{k}{\kappa_1^2(1-\sigma_1)}\frac{\Delta_{11}}{\Delta_R} - 1 \tag{40}$$

$$H_2(k) = \frac{k\Delta_{33}}{\kappa_1^2\Delta_L} - 1. \tag{41}$$

The integral equations 29, 32, 34, and 35 are of the Fredholm type and have a form suitable for numerical solution. Once these integral equations have been solved, the entire displacement and stress field may be evaluated by substitution from equations 25 through 28 into equations 19 through 22. In particular, the total vertical load V, the rocking moment about the y-axis M, and the total horizontal load in the x-direction H may be found to be given by:

$$V = \frac{4G_1 a\Delta_V e^{i\omega t}}{(1 - \sigma_1)\kappa_1^2} \int_o^1 \phi_V(t)dt \quad (42)$$

$$M = \frac{8G_1 a^3 \alpha e^{i\omega t}}{(1 - \sigma_1)\kappa_1^2} \int_o^1 t\Phi_R dt \quad (43)$$

$$H = \frac{8G_1 a\Delta_h e^{i\omega t}}{(2 - \sigma_1)\kappa_1^2} \int_o^1 \Phi_1(t)dt \quad (44)$$

Equations 42, 43, and 44 constitute the force-displacement relationship for the circular foundation. It should be mentioned that in deriving these equations the terms coupling the horizontal and rocking vibrations have been neglected.

It is convenient to write equations 42 through 44 in the following form:

$$V = \frac{4G_1 a}{1 - \sigma_1} \left[k_{VV}(a_o) + ia_o c_{VV}(a_o)\right]\Delta_v e^{i\omega t} \quad (45)$$

$$M = \frac{8G_1 a^3}{3(1 - \sigma_1)} \left[k_{MM}(a_o) + ia_o c_{MM}(a_o)\right]\alpha e^{i\omega t} \quad (46)$$

$$H = \frac{2G_1 a}{2 - \sigma_1} \left[k_{HH}(a_o) + ia_o c_{HH}(a_o)\right]\Delta_H e^{i\omega t} \quad (47)$$

where:

$$k_{VV}(a_o) = \int_o^1 \mathrm{Re}\left[\phi_v(t) / \kappa_1^2\right] dt,$$

$$c_{VV}(a_o) = -\frac{1}{a_o} \int_o^1 \mathrm{Im}\left[\phi_v(t) / \kappa_1^2\right] dt \quad (48)$$

$$k_{MM}(a_o) = 3\int_o^1 \mathrm{Re}\left[t\phi_R(t) / k_1^2\right] dt,$$
$$c_{MM}(a_o) = \frac{3}{a_o}\int_o^1 \mathrm{Im}\left[t\phi_R(t) / k_1^2\right] dt, \qquad (49)$$

$$k_{HH}(a_o = \int_o^1 \mathrm{Re}\,[\phi_1(t)/\kappa_1^2]\,dt,$$

$$c_{HH}(a_o = \frac{1}{a_o}\int_o^1 \mathrm{Im}\,[\phi_1(t)/\kappa_1^2]\,dt \qquad (50)$$

The terms inside the square brackets in equations 45, 46, and 47 are the normalized impedance functions for vertical, rocking, and horizontal vibrations; the factors outside the parenthesis correspond to the static values ($a_o = 0$) of the impedance functions for an elastic half-space having the properties of the top layer. The functions $k_{VV}(a_o)$, $k_{MM}(a_o)$, and $k_{HH}(a_o)$, corresponding to the real part of the impedance functions, will be called here stiffness coefficients, while the functions $c_{VV}(a_o)$, $c_{MM}(a_o)$, and $c_{HH}(a_o)$, proportional to the imaginary part of the impedance functions, will be designated here as damping coefficients. Both the stiffness and damping coefficients are functions not only of the dimensionless frequency a_o but also depend on the properties of the different media forming the soil column.

In solving the problem of the horizontal vibrations, a further approximation has been introduced by assuming that $\phi_2(t)$ is

sufficiently small so that the integral equations 34 and 35 may be reduced to:

$$\tilde{\phi}_1(t) + \int_o^1 K_{11}(t, t')\,\tilde{\phi}_1(t')\,dt' = 1 \quad (0 \leq t \leq 1) \qquad (51)$$

where the kernel $K_{11}(t, t')$ is given by equation 36. The basis for this approximation is that for the case of a uniform half-space, the function $\phi_2(t)$ is much smaller than $\phi_1(t)$, in particular, for the static case $\phi_2(t) = 0$. The above approximation is equivalent to the requirement that $\sigma_{zy} = 0$ under the foundation and thus corresponds to a further relaxation of the boundary conditions.

3B.8.4 NUMERICAL SOLUTION

The numerical procedure used to solve the integral equations 29, 32, and 51, consists in reducing these equations to a system of algebraic equations that are solved by standard methods. A key step in this procedure is the evaluation of the kernels K(t, t') given by equations 30, 33, and 36. In the case of a medium with no internal friction, the functions Δ_R and Δ_L have zeroes for real values of k and consequently the integrads in equations 31 and 36 are singular at these points. This situation complicates the numerical evaluation of the kernels. However, if there is internal friction, then the zeroes of Δ_R and Δ_L are complex and consequently the numerical evaluation of the kernels is simplified. The kernels are

evaluated numerically by use of Filon's method of integration up to a sufficiently large value of k; the rest is evaluated analytically by using the asymptotic forms of the integrads for large k.

3B.8.5 APPLICABLE EQUATIONS

The functions $\Delta_{ij}(k)$ (i, j = 1, 2) and Δ_R (k) entering in equations 19 and 20 are defined by:

$$\begin{bmatrix} \Delta_{11}(k) & \Delta_{12}(k) \\ \\ \Delta_{21}(k) & \Delta_{21}(k) \end{bmatrix} = (T^*_{11}A + T^*_{12}B)\ \mathrm{adj}(T^*_{21}A + T^*_{22}B) \tag{52}$$

and,

$$\Delta_R = \det\left(T^*_{21}A + T^*_{22}B\right) \tag{53}$$

where the matrices [A] and [B] are given by:

$$[A] = \begin{bmatrix} -k & \nu'_N \\ \\ \nu_N & -k \end{bmatrix} \tag{54}$$

$$[B] = \frac{G^*_N}{G_1}\begin{bmatrix} -2\nu_N k & \left(2k^2 - k_N^2\right) \\ \\ -\left(2k^2 - k_N^2\right) & 2\nu'_N k \end{bmatrix} \tag{55}$$

and, T^*_{ij} (i,j = 1, 2) are the submatrices of the total transfer matrix T* associated with the set of layers overlaying the base half-space. The total transfer matrix T*

$$\left[T^*\right] = \left[\begin{array}{c|c} T^*_{11} & T^*_{12} \\ \hline T^*_{21} & T^*_{22} \end{array}\right] \quad (56)$$

may be obtained in terms of the transfer matrices for each layer T_j (j = 1, N-1) by means of the following product:

$$[T^*] = [T_1][T_2]....[T_j]....[T_{N-1}] \quad (57)$$

The transfer matrix for the j^{th} layer is in turn given by:

$$\left[T_j\right] = \left[\begin{array}{c|c} T_{11}{}^j & T_{12}{}^j \\ \hline T_{21}{}^j & T_{22}{}^j \end{array}\right] \quad (58)$$

$$T^j_{11} = -\frac{1}{\kappa^2_j}\begin{bmatrix} -2k^2CH_j + (2k^2 - \kappa_j{}^2)\,CHP_j & -k(2k^2 - \kappa_j{}^2)\,SH_j + 2k\upsilon_j'^2SHP_j \\ 2k\upsilon_j{}^2SH_j - k(2k^2 - \kappa_j{}^2)\,SHP_j & (2k^2 - \kappa_j{}^2)\,CH_j - 2k^2CHP_j \end{bmatrix}$$

$$T^j_{12} = -\left(\frac{\rho_1}{\rho_j}\right)\begin{bmatrix} -k^2SH_j + \upsilon_j'^2\;SHP_j & k(CH_j - CHP_j) \\ k(CH_j - CHP_j) & -\upsilon_h{}^2SH_j + k^2SHP_j \end{bmatrix}$$

$$T^j_{21} = -\frac{1}{\kappa_j{}^4}\left(\frac{\rho_1}{\rho_j}\right)\begin{bmatrix} -4\upsilon_j{}^2k^2SH_j + (2k^2 - \kappa_j{}^2)^2\,SHP_j & -2k\,(2k^2 - \kappa_j{}^2)\,(CH_j - CHP_j) \\ -2k\,(2k^2 - \kappa_j{}^2)\,(CH_j - CHP_j) & -(2k^2 - \kappa_j{}^2)^2\,SH_j + 4\upsilon_j'^2k^2SHP_j \end{bmatrix} \quad (59)$$

$$T^j_{22} = -\frac{1}{\kappa_j{}^2}\begin{bmatrix} -2k^2CH_j + (2k^2 - \kappa_j{}^2)\,CHP_j & 2k\upsilon_j{}^2SH_j - k\,(2k^2 - \kappa_j{}^2)\,SHP_j \\ -k\,(2k^2 - \kappa_j{}^2)\,SH_j + 2\upsilon_j'^2k\;SHP_j & (2k^2 - \kappa_j{}^2)\,CH_j - 2k^2CHP_j \end{bmatrix}$$

The different terms entering in equations 54 to 59 are defined by:

$$\nu_j = (k^2 - \gamma_j^2 \kappa_j^2)^{1/2} \qquad \nu_j' = (k^2 - \kappa_h^2)^{1/2}$$

$$\gamma_j^2 = (1 - 2\sigma_j) / 2(1 - \sigma_j) \qquad k_j^2 = G_1 \rho_j / G_j^* \rho_1$$

$$G_j{*} = G_j(1 + i\omega G_j' / G_j),\ \text{or,} \qquad G_j{*} = G_j(1 + 2i\xi_j) \qquad (60)$$

$$SH_j = \sinh(a_o \nu_j \lambda_j)/\nu_j \qquad SHP_j = \sinh(a_o \nu_j' \lambda_j)/\upsilon_j'$$

$$CH_j = \cosh(a_o \nu_j \lambda_j) \qquad CHP_j = \cosh(a_o \nu_j' \lambda_j)$$

$$\lambda_j - h_j/a$$

$$a_o = \omega a/\beta_1$$

where σ_j, ρ_j, G_j, G'_j/G_j, and h_j are, respectively, the Poisson's ratio density, shear modulus, relative viscosity, and thickness of the j^{th} layer. In the last two equations of equation 60, a is the radius of the circular foundation, ω is the frequency of the steady-state vibrations and β_1 is the shear wave velocity of the top layer. The first form of G_j^* corresponds to the Voigt type damping, while the second corresponds to the hysteretic type damping, x_j being the hysteretic damping constant for the j^{th} layer.

The functions Δ_{33} (k) and Δ_L (k) entering in equation 19 are defined by

$$\Delta_{33}(k) = L_{11}^* + L_{12}^* \ \upsilon'_N G_N^*/G_1 \qquad (61)$$

$$\Delta_L(k) = L_{21}^* + L_{22}^* \ \upsilon'_N G_N^*/G_1 \qquad (62)$$

where L^*_{ij} (i, j = 1,2) are the elements of the transfer matrix L*. The transfer matrix L*

$$\left[L^*\right] = \begin{bmatrix} L^*_{11} & L^*_{12} \\ L^*_{21} & L^*_{22} \end{bmatrix} \tag{63}$$

is defined in terms of the transfer matrices for each layer by:

$$[L^*] = [L_1] \cdot [L_2]. \ . \ . \ .[L_j]. \ . \ [L_{N-1}] \tag{64}$$

in which,

$$\left[L_j\right] = \begin{bmatrix} CHP_j & \left(G_1 / G *_j\right) SHP_j \\ \left(G^*_j / G_1\right) \nu'^{\,2}_j \; SHP_j & CHP_j \end{bmatrix} \tag{65}$$

3B.8.6 VERIFICATION OF THE METHOD AND COMPUTER PROGRAM

3B.8.6.1 Introduction

The objective of this part is to test, by means of several comparisons, the adequacy of the method of solution described in subsections 3B.8.1 through 3B.8.5, and also, to verify the accuracy of the computer program developed to carry on the numerical computations.

One of the problems that appears in trying to reach this objective is the lack of "exact" solutions for the problem of forced vibrations of rigid foundations on viscoelastic layered media. There are, however, some approximate results that may be used as a basis of comparison [Veletsos and Verbic[(2)]].

Also, by considering the case of low damping values it is possible to compare results with the purely elastic case.

3B.8.6.2 Circular Foundation on a Viscoelastic Half-Space

A first test of the method of solution and associated computer program is provided by considering the harmonic response of a rigid circular foundation on a uniform viscoelastic half-space. Although this is the first time that an "exact" solution for the problem could be obtained, approximate results that can be used as a basis of comparison have been obtained by Veletsos and Verbic[2]. The approximate method used by Veletsos and Verbic is based on establishing analytical approximations to the numerically obtained solutions for the elastic problem and in extending these approximations to the viscoelastic case by use of the correspondence principle.

The vertical, rocking, and horizontal impedance functions for a rigid circular foundation on a uniform viscoelastic half-space with a Poisson's ratio of 1/3 were obtained by means of the computer program described here and the results compared with those obtained by Veletsos and Verbic. The comparisons are shown in figures 3B.8-2 through 3B.8-7. The continuous or segmented lines correspond to the results obtained by Veletsos and Verbic. The results obtained here are indicated in the figures by crosses, triangles, and circles, and are also listed in section 3B.8.6. The comparisons were made for the following six cases:

Case	Type of Damping	Damping Constant
1.a	Hysteretic	x = 0.05
2.a	Hysteretic	x = 0.15
3.a	Hysteretic	x = 0.25
1.b	Voigt	G'/G = 0.1 a/b
2.b	Voigt	G'/G = 0.3 a/b
3.b	Voigt	G'/G = 0.5 a/b

It may be seen in figures 3B.8-2 to 3B.8-7 that the results obtained here follow the same trend as those obtained by Veletsos and Verbic(2). However, some differences may be observed. These differences are in part a result of the approximate method used by the authors just mentioned. Some differences at high frequencies, i.e., for values of ao ~ 10., may be due to lack of accuracy of the computer program for these high frequencies.

3B.8.6.3 Viscoelastic Half-Space Represented by Several Layers with Equal Properties

Having verified the accuracy of the program for a uniform viscoelastic half-space, the next step is to verify that the program leads to the same results when the uniform half-space is represented by means of several layers all having the same viscoelastic properties. Six cases labeled 4.a, 4.b, 5.a, 5.b, 6.a, and 6.b, were considered. The cases indicated by the

letter a correspond to hysteretic type damping (ξ=0.05), the case designated by the letter b correspond to Voigt type damping (G'/G=0.10 a/β_1). In all cases a Poisson's ratio of 1/3 was used. The geometric properties for each case are given in the following:

Case	Geometry
4.a and 4.b	Three layers and underlying half-space $h_i = a$ (i = 1,3)
5.a and 5.b	Four layers and underlying half-space $h_1 = 0.25a$ $h_2 = 0.50a$ $h_3 = 0.75a$ $h_4 = 1.50a$
6.a and 6.b	Nine layers and underlying half-space $h_i = a$ (i = 1,9)

The results for cases 4.a, 4.b, 5.a, and 5.b match those for the viscoelastic half-space up to five significant figures (compare with cases 1.a and 1.b of the previous section). The results for case 6.b also coincide to the fifth significant figure with those for the viscoelastic half-space. The results for case 6.a are exact up to a value of a_o = 4.0; for higher frequencies the results are in error. These errors result from the combination of large number of layers (9), low damping value (χ = 0.05), and relatively high frequencies

($a_o \geq 5.0$). The important effect of damping in controlling the accuracy for high frequencies when several layers are involved is illustrated by the fact that the results for the Voigt model with the same number of layers (case 6.b) are exact. For a Voigt model damping increases with frequency and, consequently, more accurate results are obtained.

3B.8.6.4 Comparison with an Elastic Half-Space

One other test of the accuracy of the computer program is based on comparing the results obtained for a viscoelastic half-space with a low damping value with those for a purely elastic half-space. Shah[15], Veletsos and Wei,[16] and Luco and Westmann[13] have evaluated numerically the impedance or compliance functions for a rigid disc foundation on a purely elastic half-space. Comparisons with the values obtained by these authors allow the evaluation of the accuracy of the program under study for low values of the damping constant. Two cases with the following characteristics were considered:

Case	Geometry	Damping
7.a	half-space	hysteretic χ = 0.005
7.b	half-space	Voigt G'/G = 0.01 a/β

The results for these cases are shown in figures 3B.8-8, 3B.8-9, and 3B.8-10. The comparisons shown in these figures indicate a good accuracy in the evaluation of the imaginary parts of the impedance functions. The results for the real part of the impedance functions compare well for values of a_o up

to 4 or 5. For larger values of a_o some differences may be observed. These differences result in part from the effects of the damping, but they also reflect the numerical difficulties of evaluating the values of $k_{MM}(a_o)$, $k_{HH}(a_o)$, and $k_{VV}(a_o)$ for high frequencies for both the elastic and viscoelastic case.

3B.8.6.5 Comparison with an Elastic Two-Layered Medium

A computer program to evaluate the impedance functions for a rigid circular foundation placed on an elastic layer overlaying an elastic half-space is available(6). It is then possible to compare the results for a viscoelastic two-layered medium with low damping values with those for a purely elastic two-layered medium. This comparison was made for the four cases described below:

Case	Geometry	Elastic Properties
8	h = 0.5a	$\beta_1/\beta_2 = 0.8$, $\rho_1/\rho_2 = 0.85$, $\sigma_1 = \sigma_2 = 0.25$
9	h = 3a	$\beta_1/\beta_2 = 0.8$, $\rho_1/\rho_2 = 0.85$, $\sigma_1 = \sigma_2 = 0.25$
10	h = 0.5a	$\beta_1/\beta_2 = 0.2$, $\rho_1/\rho_2 = 0.85$, $\sigma_1 = 0.35$, $\sigma_2 = 0.25$
11	h = 5a	$\beta_1/\beta_2 = 0.2$, $\rho_1/\rho_2 = 0.85$, $\sigma_1 = 0.35$, $\sigma_2 = 0.25$

In all cases the viscoelastic medium was assumed to have constant hysteretic type damping. A value of $\chi = 0.05$ was used. The comparisons for cases 8 and 9 are shown in figures 3B.8-11, 3B.8-12, and 3B.8-13. It may be seen that for low frequencies the stiffness coefficients for the viscoelastic case tend to match those of the elastic case.

Similarly, for high frequencies the damping coefficients for the viscoelastic case tend to match those for the elastic case.

The comparisons for cases 10 and 11 are shown in figures 3B.8-14, 3B.8-15, and 3B.8-16. Again, the comparisons indicate the correct behavior at low and high frequencies. For values of $a_o \leq 0.2$, the stiffness coefficients for the viscoelastic case for a thin layer ($h/a = 0.5$) tend to be lower than those for the elastic case. This behavior has been corrected in the final version of the computer program.

3B.8.6.6 Conclusions

The comparisons made indicate that the computer program described here leads to results that are consistent with what is known about the response of rigid foundations on a layered viscoelastic medium. As a result of these comparisons, some limitations on the use of the program are described below:

A. In the first place the combination of very thin layers ($h/a < 0.25$) and low frequencies ($a_o < 0.2$) may lead to slightly lower values of the stiffness coefficients for these frequencies.

B. There is a loss in accuracy for a combination of high frequencies, several layers, and low damping constants.

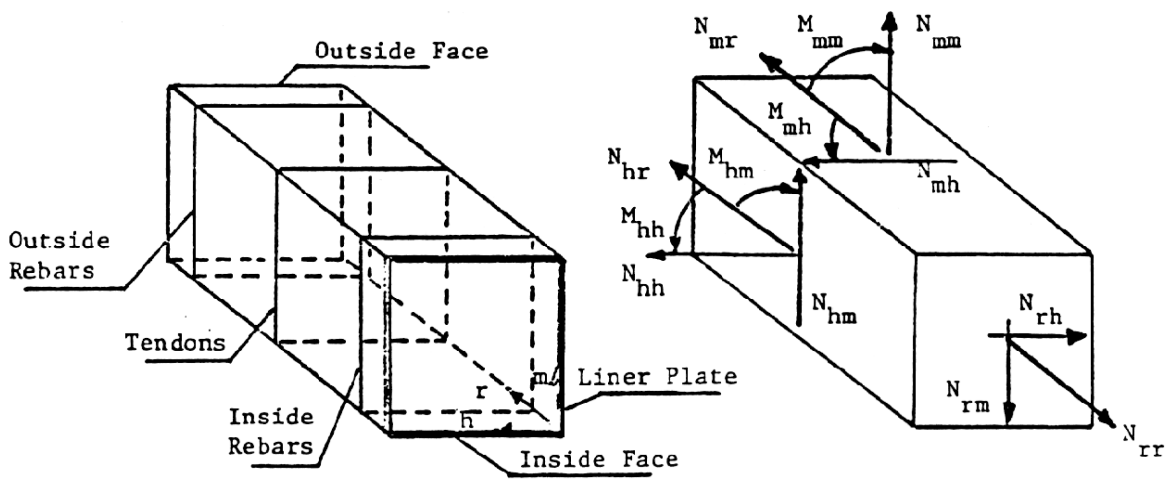
3B.9 CECAP COMPUTER PROGRAM (CECAP) CE 987

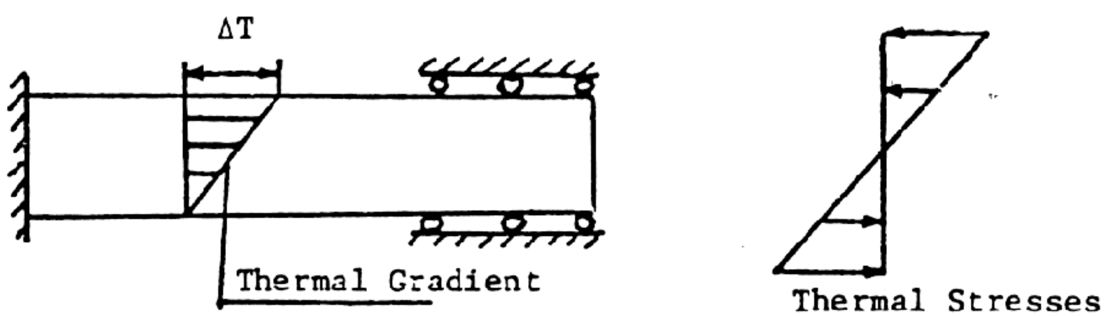
CECAP computes stresses in a concrete element under thermal and/or nonthermal (real) loads, considering effects of concrete cracking. The element represents a section of a concrete shell or slab, and may include two layers of reinforcing, transverse reinforcing, prestressing tendons, and a liner plate. The program has been developed primarily for analysis of nuclear plant containments, but may also be used for analysis of basemats, fuel pools, or other structures, providing program assumptions are valid. The configuration of the element and applied force/moment loadings are as follows:



Nonthermal force/moment loads on the element must be determined in a separate analysis of the structure containing the element, and input to the program. Thermal loads may be determined and input in similar fashion, or alternatively input as linear temperature gradients through the thickness.

CECAP assumes linear stress-strain relationships for steel and concrete in compression. Concrete is assumed to have no

tensile strength. The solution is an iterative process, whereby tensile stresses found initially in concrete are relieved (by cracking) and redistributed in the element. Equilibrium of nonthermal loads is preserved. For thermal effects, the element is assumed free to expand inplane, but fixed against rotation as shown:



The capability for expansion and cracking generally results in a reduction in thermal stresses from the initial condition.

The program will output stresses and strains at selected locations in the concrete, reinforcement, tendons, and liner plate; and resultant forces and moments for the composite concrete element.

3B.9.1 ANALYSIS OF SAMPLE PROBLEM WITH CECAP

3B.9.1.1 Introduction

The analysis of a reinforced concrete beam subjected to a linear thermal gradient was performed to test the redistribution of thermal stresses due to the relieving effect

of concrete cracking. The results were compared with hand calculations.

3B.9.1.2 Problem Description

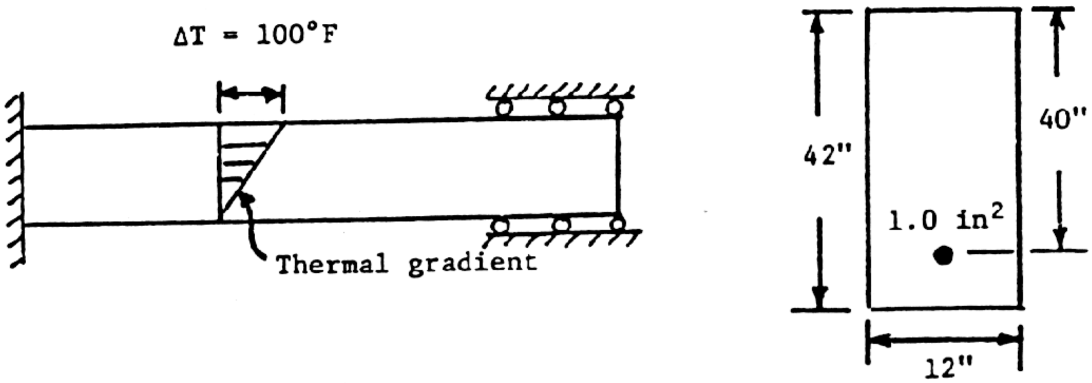
Sample A.1 shows the reinforced concrete beam and the corresponding CECAP concrete element used in the analysis. Boundary conditions, geometry, and applied loads are illustrated.

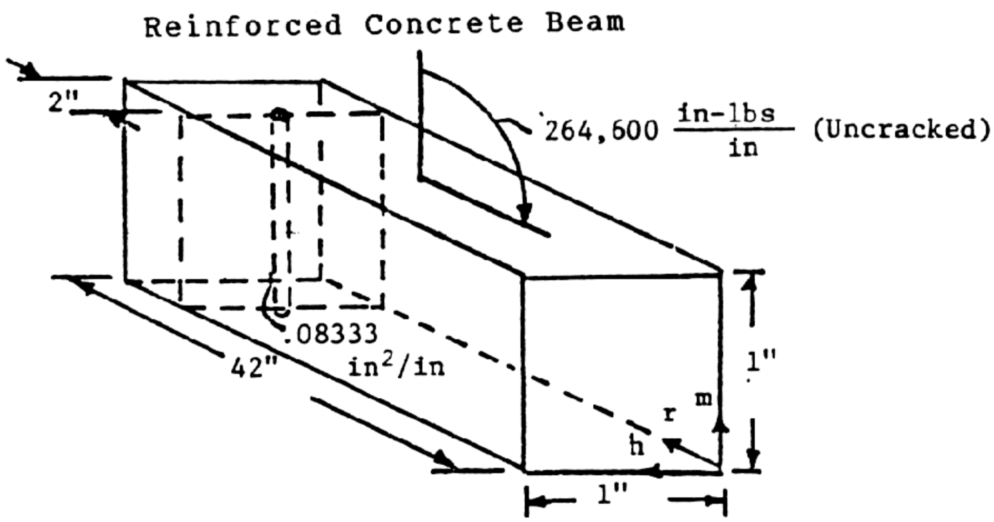
3B.9.1.3 Problem Parameters

Concrete modulus of elasticity	$E_c = 3 \times 10^6$ psi
Rebar modulus of elasticity	$E_s = 30 \times 10^6$ psi
Concrete Poisson's ratio	$\upsilon_c = 0.22$
Concrete coefficient of thermal expansion	$\alpha_c = 6 \times 10^{-6}$ in/in/°F
Temperature difference	$\Delta T = 100F$
Rebar coefficient of thermal expansion	$\alpha_R = \alpha_c$

CECAP COMPUTER PROGRAM (CECAP)

CE 987





CECAP Concrete Element Model

Sample A.1 Reinforced Concrete Beam and

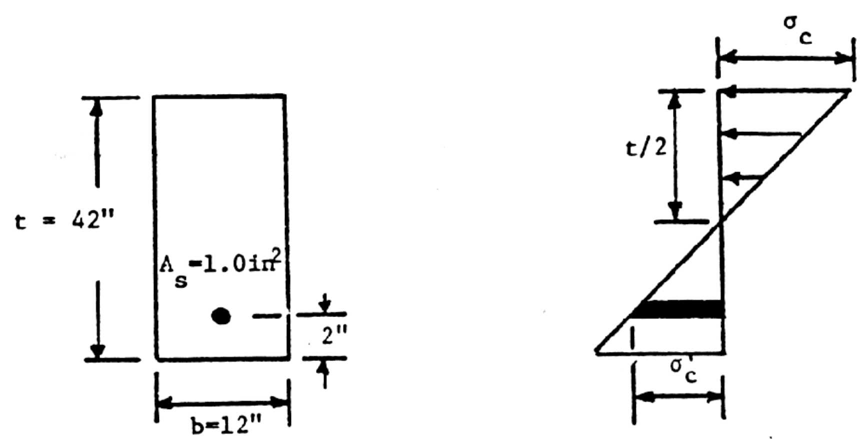
CECAP Concrete Element Model

3B.9.1.4 Hand Calculations

The following illustrates how thermal loads are treated in a cracked section analysis of a reinforced concrete beam. The main assumptions pertaining to thermal boundary conditions are:

- The beam is allowed to expand freely axially.
- There is no rotation of the initial thermal stress slope.

The beam cross-section and initial thermal stress distribution are:



where, for ΔT = 100F, the equivalent thermal moment, concrete, and rebar stresses are:

$$M = \Delta T \alpha_c E_c bt^2/12 = (100)(6 \times 10^{-6})(3 \times 10^{6})(12)(42)^2/12$$

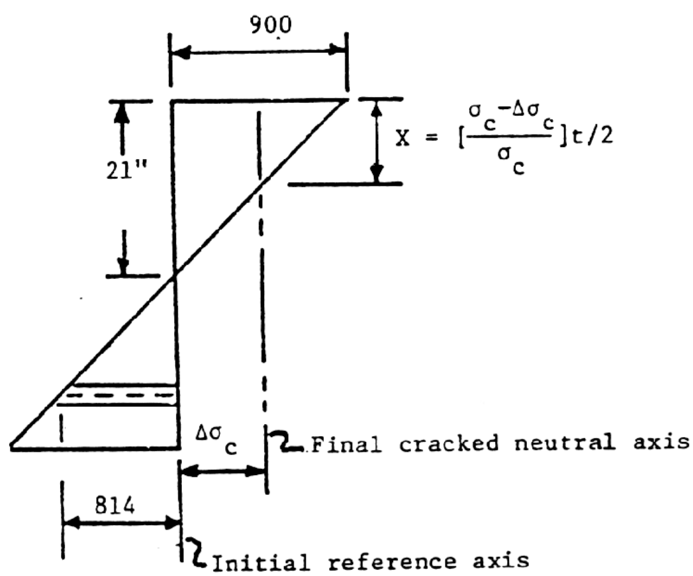
$$= 3,175,000 \text{ in-lbs}$$

$$\sigma_c = \Delta T \alpha_c E_c/2 = (100)(6 \times 10^{-6})(3 \times 10^{6})/2$$

= 900 psi (compression)

$$\sigma_c' = \frac{(t/2 - 2)}{t/2}\sigma = \frac{(21 - 2)}{21} 900 = 814 \text{ psi (tension)}$$

The stress diagram used for the cracked section analysis with thermal loading is as follows. The assumptions of free movement axially and constant thermal stress slope are maintained by a lateral translation of the initial reference axis to a final cracked position.



From Force Equilibrium:

$$F_{rebar} + F_{concrete} = 0$$

$$\underbrace{1.0(814 + \Delta\sigma_c)10}_{F_{rebar}} - \underbrace{900\left(\frac{42}{2}\right)\left(\frac{12}{2}\right) + \frac{\Delta\sigma_c(12)}{2}\left[21 + \left(\frac{900 - \Delta\sigma_c}{900}\right)21\right]}_{F_{concrete}}$$

$$= 0$$

Solving for $\Delta\sigma_c$

$$\Delta\sigma_c = 582 \text{ psi}$$

Rebar and concrete stresses are:

$$f_s = (814 + 582)10 = 13,970 \text{ psi (tension)}$$

$$f_c = 900 - 582 = 318 \text{ psi (compression)}$$

Locations of cracked neutral axis is:

$$kd = x = \left(\frac{900 - 582}{900}\right) 21 = 7.42 \text{ in.}$$

Self-relieved thermal moment is:

$$M_T = \frac{f_s A_s \left(d - \frac{x}{3}\right)}{12} = \frac{13970\,(1)\,(40 - 2.47)}{12} = 43{,}690\,\frac{\text{in} - \text{lb}}{\text{in}}$$

3B.9.1.5 Comparison of Results

The rebar and concrete stresses, self-relieved thermal moment, and neutral axis location obtained from the CECAP program are compared with the hand calculations in table 3B.9-1. It can be seen that the CECAP results compare favorably with the hand calculations.

3B.9.1.6 Conclusions

The difference in the stress results are largely due to the accuracy limit defined for the force iterations. Smaller errors would result with smaller accuracy limits, but the

trade-off would be with longer run times. The CECAP program is verified for this type of thermal loading.

Table 3B.9-1

CECAP AND HAND CALCULATION COMPARISON - THERMAL GRADIENT

	CECAP	Hand Calculations	Percent Error
f_s	13,150 psi	13,790 psi	5.9
f_c	-331 psi	-318 psi	4.1
k_d	7.55 in.	7.42 in.	1.8
M_T	43,760 in-lb/in	43,690 in-lb/in	0.2

3B.9.2 DESCRIPTION OF VERIFICATION PROBLEMS (CECAP) - CE 987

Eleven example problems were analyzed by the CECAP program and compared to hand-calculated solutions. The problems were chosen to verify the program for various combinations of thermal and nonthermal (real) loads. A list of verification problems with short descriptions follows. More detailed descriptions of the problems and their hand calculated solutions can be found in the appendices.

CECAP COMPUTER PROGRAM (CECAP)

CE 987

CECAPVER Number	Description
1	Thermal moment
2	Thermal moment and real axial load
3	Real moment
4	Real moment and real axial load
5	Thermal moment, real moment and real axial load
6	Uniaxial tension
7	Biaxial tension
8	Biaxial tension with shear
9	Uniaxial tension with liner
10	Thermal moment with liner
11	Thermal moment with tension and compression reinforcement

3B.9.2.1 Summary of Verification

The results of the CECAP analyses of the 11 verification problems and comparisons with hand-calculated solutions are summarized in figures 3B.9-1 through 3B.9-11. Each figure shows the verification problem, corresponding CECAP element model, and comparison of pertinent results. The comparisons show that the CECAP results for rebar and concrete stresses, self-relieved thermal moments, and neutral axes locations are in good agreement with hand-calculated values for all test cases. Detailed descriptions of hand-calculated solutions and

computer output results can be found in the appendices. Note that some of the stress results may be above accepted code limits for concrete or steel. CECAP is a linear program and the magnitude of the loads were chosen for illustration purposes only.

3B.10 FOSIN COMPUTER PROGRAM (FOSIN) CE 299

The FOSIN program performs a dynamic analysis on a structure foundation system by a modal analysis technique. Input consists of the structure definition in the form of mass, stiffness, and damping matrices, foundation geometry, soil impedances, and the free field time-history input motion. The program calculates modal frequencies, mode shapes, a measure of the ratio of critical damping in each mode, and the time-history record for each degree of freedom.

3B.10.1 DESCRIPTION OF VERIFICATION

Three test problems were considered in the verification of the FOSIN program.

A. Comparison with results published by Jacobo Bielak in his doctoral thesis "Earthquake Response of Building Foundation Systems," California Institute of Technology, 1971.

   Operations utilized in case 1:

   1. Input impedance table
   2. Default impedance table
   3. Determination of the frequencies and damping values
   4. Time-history analysis
   5. Base line correction of time history
   6. Unequally spaced time history

B. Comparison of the dynamic analysis of a structure; first, as a fixed-base, three-degree of freedom model, and second, as a two-degree of freedom model with frequency dependent impedances modeling the dynamic properties of the lower portion of the structure.

   Operations utilized in case 2:

   1. Input impedance table

   2. Determination of the frequencies and damping values

   3. Time-history analysis

   4. Equally digitized time-history

C. A repeat of problem 2 for a 10-degree of freedom structural model. The same operations will be utilized.

3B.10.2 SUMMARY OF THE VERIFICATION

The results of the three problems tested here show that the FOSIN program is giving very reasonable answers. Please refer to the appendices for the actual numerical comparisons for each of the three problems.

3B.10.3 FOSIN VERIFICATION (TEST PROBLEMS)

3B.10.3.1 FOSIN Example 1, Bielak Soil Structure Interaction

The following problem presents a comparison of results obtained by use of the FOSIN computer program and those published by Bielak[(1)] for a simple structure founded upon uniform soil deposits with different shear wave velocities. Bielak used the LaPlace transform method to solve the equations of motion of the dynamic system while the method employed by the FOSIN computer code is based on uncoupling the equations of motion by Foss's method.[(2)]

A. Problem Description

The superstructure is represented by a two-node model with a single horizontal degree of freedom per node. Rotation of the nodes is restrained; thereby, allowing the structure to deform only in shear between nodes. Figure 3B.10-1 shows a sketch of the model as proposed by Bielak along with the soil and structural properties. This same data was input into the FOSIN program and the resulting undamped system frequencies and modal damping values were then calculated.

The compliances, C, used by Bielak in reference 1 are listed in table 3B.10-1. These compliances must first be inverted to their corresponding impedance values, K, before they can be input into the FOSIN program. The relationship between the compliances and impedances may be expressed by the equation:

$$K = 1/C$$

where:

$$K = k_1 + ik_2$$

$$C = c_1 + ic_2$$

$$K = \frac{1}{C_1 + ic_2} \quad \frac{c_1 - ic_2}{c_1^2 + c_2^2} = \frac{c_1}{c_1^2 + c_2^2} - \frac{ic_2}{c_1^2 + c_2^2}$$

therefore:

$$k_1 = \frac{c_1}{c_1^2 + c_2^2} \text{ and } k_2 = \frac{-c_2}{c_1^2 + c_2^2}$$

The results of this data transformation are also listed in table 3B.10-1.

* From Reference 1

** The impedance, K is calculated from the compliance, C, as follows:

$K = K_1 + iK_2$

$C = C_1 + iC_2$

$$K = \frac{1}{C} = \frac{1}{C_1 + iC_2} = \frac{C_1 - iC_2}{(C_1)2 + (C_2)2}$$

In addition to running the cases as performed by Bielak with the uncoupled impedances, the FOSIN program was used to solve the problems by generating a set of soil impedance values by using the default impedance table contained in the program; the other parameters of the Bielak problem remained the same. The default impedance table was derived by inverting the complete coupled compliances developed by J. E. Luco for an elastic half-space.(3) It should be noted that Bielak also used the compliances developed by Luco but neglected the coupling terms which he considered insignificant.

The results of the FOSIN analysis, first using the default impedance table and then using Bielak's impedance data, will be compared to the original work of Bielak.

A comparison of the response of the system due to a "free field" acceleration was also made. The time-history acceleration record used was the N33E component of the earthquake motion recorded at the SONGS Unit 1 Power Plant, San Onofre, California on April 8, 1968. This time-history, as obtained from Caltech, was the uncorrected record; therefore, it was base line corrected internally as a portion of the computer run. The analytical model used was again that of figure 3B.10-1 with the shear wave velocity of the foundation medium taken as 1500 feet per second.

B. Problem Parameters

Symbol	Description
m_i	lumped mass parameter, kip-s^2/ft
k_i	stiffness of idealized stick between masses, kip/ft
I_t	mass moment of inertia about the base of the model, kip-s^2-ft
ρ	mass density of soil, k-s^2/ft^4
σ	Poisson's ratio
V_s	shear wave velocity, ft/s
r	radius of foundation, ft
h_i	height of mass m_i above base, ft
K_i	impedance of soil, kip/ft
C_i	compliances of soil, ft/kip
$\varnothing$	rotation at base of model, rad
v_i	horizontal displacement of mass m_i
ω	frequency of vibration, rad/s
β	% critical damping

C. Results

The computed frequencies and damping values of the two problems (one using the Bielak impedance data, and the

other using the coupled impedances from the FOSIN default table) are shown compared to the results given by Bielak in table 3B.10-2. The response of the model to the "free field" acceleration (N33E component of the SONGS 1 Power Plant) is shown in figure 3B.10-2. This may be compared to the results obtained by Bielak that are shown in figure 3B.10-3. In both figures, the horizontal displacement time-history is shown for the base and the two masses representing the super-structure. Also shown is the horizontal displacement of mass m_1 due to the rotation of the structure about m_0.

D. Solution of the Bielak Model for Fixed Base Free Vibration Conditions

$$[M]\ \{\ddot{x}\} + [K]\ \{x\} = 0$$

let:

$$\{x\} = \{A\}\ e^{i\omega t}$$

now substituting this into the equation above yields:

$$-\omega^2\ [M]\ \{A\}\ e^{i\omega t} + [K]\ \{A\}\ e^{i\omega t} = 0$$

$$\left[[K] - \omega^2\ [M]\right] \{A\}\ e^{i\omega t} = 0$$

$$[M]^{-1}\ [K] - \omega^2\ [I] = 0$$

where:

[I] = identity matrix

$$[M] = m\begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} => [M]^{-1} = \frac{1}{m}\begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}$$

* Convergence limit of 0.1% on system frequency not satisfied after five iterations, fifth iteration used.

** B Results tabulated in reference 2, page 123

F-UCI Results obtained using the FOSIN program with the uncoupled impedance functions used by Bielak.

F-D Results obtained using the FOSIN program with the default coupled impedance functions.

$$[K] = \frac{k}{4}\begin{bmatrix} 3 & -3 \\ -3 & 7 \end{bmatrix}$$

$$\therefore \; [M]^{-1} \; [K] - \omega^2 \; [I] =$$

$$\begin{bmatrix} (3/2 \text{ k/m} - \omega^2) & (-3/2 \text{ k/m}) \\ (-3/4 \text{ k/m}) & (7/4 \text{ k/m} - \omega^2) \end{bmatrix} = 0$$

the determination of the above matrix yields the characteristic equation

$$\lambda^2 - \left(\frac{13k}{4m}\right)\lambda + 3/2\,(k/m)^2 = 0$$

where

$$\lambda = \omega^2$$

solving for λ yields:

$$\lambda = .56 \text{ k/m}, \; 2.69 \text{ k/m}$$

where:

$$k/m = \frac{5.394 \bullet 10^5}{.475 \bullet 10^3} = 1135.58 \text{ rad / s}^2$$

therefore,

$$\lambda_1 = 632.52 \text{ rad/s}^2 \text{ and } \omega_1 = 25.15 \text{ rad/s} = 4.00 \text{ Hz}$$

$$\lambda_2 = 3058.12 \text{ rad/s}^2 \text{ and } \omega_2 = 55.30 \text{ rad/s} = 8.80 \text{ Hz}$$

As the shear wave velocity of the soil is increased to that of a rigid material, the system frequencies should approach the fixed-base values calculated above.

E. Comparison of Results

The calculated system frequencies and modal damping values are tabulated in table 3B.10-2. The maximum percent difference between Bielak's results for the first three system frequencies, and the results of the FOSIN analysis using the uncoupled impedances, is 0.1% which corresponds well with the convergence limit of 0.001 that was specified in the FOSIN input. The frequencies calculated for the fourth mode differed by a maximum of 0.4%.

A comparison of damping values from the two sources also showed good agreement. The first mode damping values differed by a maximum of one hundredth of a percent of critical. The damping values agreed to within 1% for modes two and three, with mode four showing a maximum difference of 1.6%.

The results of the forced vibration analysis are compared on the basis of the computer response displacement time-histories. A better comparison would have been to compare the resulting response spectra for each node; however, this information from the Bielak solution is not available. The displacement time-histories obtained by Bielak are shown in figure 3B.10-3 and the corresponding results from the FOSIN program are given in figure 3B.10-2.

F. Conclusions

The FOSIN program determines the natural frequencies and modal damping characteristics by solving for an individual mode in a system where the soil parameters are compatible with that particular modal frequency. The comparison of frequencies and modal damping values obtained by use of the FOSIN program with those calculated by Bielak verify that the program is adequately representing the frequency dependence of the half-space dynamic properties.

The time-history displacement records shown in figures 3B.10-3 and 3B.10-2 do not provide sufficient detail to verify the FOSIN program for forced vibration analysis. However, the comparison of the records does tend to show a good correspondence.

G. Computer Runs

1. FOSIN frequency analysis of the Bielak model for Vs values between 800 feet per second and 1500 feet per second using the Bielak impedance table

2. FOSIN frequency analysis of the Bielak model for Vs values between 800 feet per second and 1500 feet per second using the default impedance table derived from the Luco compliances

3. FOSIN time-history analysis of the Bielak model for Vs = 1500 feet per second and using the San Onofre earthquake of 1968

3B.10.3.2 FOSIN Example 2, Comparison of a Three-Mass, Fixed Base System with an Equivalent Two-Mass Interaction System

This problem will test the FOSIN program by comparing an exact solution of a three-mass system using modal synthesis with the approximate FOSIN analysis of the system after it has been converted to a two-mass system resting on a frequency-dependent impedance foundation. The impedance foundation will be representing the remaining lower portion of the structure. See figures 3B.10-4 and 3B.10-5.

The following calculations will be performed in the process of exercising this problem.

A. Theoretical verification of the equivalence of the response for the top masses of the three-mass fixed base system and the two-mass interaction system. See paragraph 3B.10.3.2.3.

B. A hand calculation of the fixed-base, three-mass system to include:

   1. System frequencies

   2. Mode shapes

   3. Damping ratios

4. Damped frequencies of vibration

5. Modal mass

6. Participation factors

See paragraph 3B.10.3.2.4.

C. The SUPER SMIS program will be used to calculate the frequencies and eigenvectors and will also perform a time-history analysis of the three mass model.

See program "A".

D. A SUPER SMIS analysis of subsystem "A" to generate the modified base motion to be used with subsystem "B" by FOSIN.

See program "B".

E. An evaluation of the substructure impedances to be used by FOSIN to represent subsystem "A".

See paragraph 3B.10.3.2.5, program "D", table 3B.10-3.

F. A FOSIN analysis of the interaction system using sub-system "B", the modified base motion and the impedance table calculated above. The following quantities will be found:

1. The first two system frequencies of the complete three mass system

2. A measure of the damped system frequencies

3. Eigenvectors for the first two modes

4. Time-history analysis for masses m_1 and m_2.

See program "E".

3B.10.3.2.1 Problem Description

Consider a simple three-mass system having only three translational DOFF in the vertical direction which is subjected to a support motion input at its base. This basic system will

$m_2' = 10$ K-sec ^{2}/ft $c_2 = 2000$ K-sec /ft $k_2 = 100000$ K/ft

$m_3 = 200$ $c_3 = 2000$ $k_3 = 100000$

Note: The value of R,G and p were chosen so that Ao = ω

Be modeled by two different techniques. In the first case, the complete three-DOF system will be subjected to the base acceleration input z(t) as shown in figure 3B.10-4. The response of the system in this case can be calculated exactly using mode superposition procedure and the standard time-history analysis.

In the second case, the three-DOF system is treated as an interaction system formed by coupling two subsystems, designated as subsystems "A" and "B". These subsystems will be obtained by dividing the three-DOF system into two parts by separating the middle mass into two arbitrary segments, as shown in figure 3B.10-5. Subsystem "A" may be considered to represent a two-DOF foundation model from which the foundation impedances $k^*(\omega) + i\omega c^*(\omega)$ and the modified "free-field" motion z(t) can be determined. Subsystem "B" may be considered as a single DOF structural model with a base mass supported on subsystem "A". The interaction system is thus obtained by coupling subsystem "B" with the foundation impedance that can be derived from subsystem "A". The response of this interaction system subjected to the free-field motion z(t) can then be evaluated.

Theoretically, the response of the three-DOF system as evaluated by both approaches should be identical with each other for the top and the middle masses. This is proven in paragraph 3B.10.3.2.3.

3B.10.3.2.2 Problem Parameters

The analysis was carried out using the following values for the three-DOF system:

	Mass ($k\text{-}s^2/ft$)	Damping (k-s/ft)	Stiffness (k/ft)
1	100	200	10,000
2	200	2,000	100,000
3	200	2,000	100,000

See figure 3B.10-4.

As can be seen, the damping values c_1, c_2, and c_3 were so chosen that the damping matrix of the three-DOF system is proportional to the stiffness matrix. This enables the modal superposition method to be used for an exact time-history solution; it also allows the division of the model without distorting the damping characteristics.

The interaction system in the second case was obtained by arbitrarily splitting the middle mass m_2 into two parts, m_2' (10 $k\text{-}s^2/ft$) and m_2'' (190 $k\text{-}s^2/ft$), for subsystems "A" and "B", respectively. See figure 3B.10-5.

The input acceleration time-history $\ddot{z}(t)$ is shown in figure 3B.10-6. It is the Bechtel Synthetic time-history (H1) with 4800 points sampled at every 0.005 second. The modified

"free-field" motion $\ddot{z}(t)$ calculated from $\ddot{z}(t)$ is shown in figure 3B.10-7. The impedance functions $k^*(\omega)$ and $c^*(\omega)$ of the lower structure that were computed from subsystem "A" are shown in figure 3B.10-8. See paragraphs 3B.10.3.2.3 and 3B.10.3.2.5.

3B.10.3.2.3 The Interaction Analysis of a Three-DOF System (Taken from the Theoretical Manual for the Computer Program FASS, CE933, by W. S. Tseng)[4]

3B.10.3.2.3.1 Introduction. In this paragraph (3B.10.3.2), it will be shown that under the base input motion z(t), the response of the three-DOF system as a whole (figure 3B.10-4), is identical to that of an interaction system derived from splitting the three-DOF system into two subsystems, "A" and "B", as shown in figure 3B.10-5. The middle mass, m2, can be divided into and in any proportion for subsystems "A" and "B", respectively. Subsystem "A" may be considered as a two DOF foundation model from which the foundation impedances

and the response motion (t), resulting from the input motion (t) prescribed at the base, can be obtained. Subsystem "B" represents a single DOF structural system with a base mass supported on subsystem "A". By coupling the foundation impedances derived from subsystem "A" with the structural model represented by subsystem "B", an equivalent interaction system is formed and its response under the "free-field" input (t) can be calculated.

To show the equivalence of the two systems, it suffices to consider only their frequency responses.

FOSIN COMPUTER PROGRAM (FOSIN)

CE 299

A. Response of the three-DOF System as a Whole

The equation of motion can be separated into two parts for subsystem "A" and subsystem "B". The equations of motion for subsystem "A" subjected to the input motion $\ddot{z}(t)$ at its base can be written as:

$$\begin{bmatrix} m_1 & & \\ & m_2 & \\ & & m_3 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} + \begin{bmatrix} c_1 & -c_1 & \\ -c_1 & c_1 + c_2 & -c_2 \\ & -c_2 & c_2 + c_3 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix}$$

$$+ \begin{bmatrix} k_1 & -k_1 & \\ -k_1 & k_1+k_2 & -k_2 \\ & -k_2 & k_2+k_3 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = - \begin{Bmatrix} m_1 \\ m_2 \\ m_3 \end{Bmatrix} \ddot{z}(t) \tag{1}$$

where x_i, i=1, 2, 3 is the displacement of mass point i relative to the input motion z(t). The total displacement u_i, i=1, 2, 3 is determined by the relation:

$$\begin{Bmatrix} u_1 \\ u_2 \\ u_3 \end{Bmatrix} = \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} + \begin{Bmatrix} 1 \\ 1 \\ 1 \end{Bmatrix} z(t) \tag{2}$$

The frequency response of the system can be obtained by considering the input motion $\ddot{z}(t)$ to be the linear combination of harmonic motions $e^{i\omega t}$ at each frequency, ω, i.e.,

$$\ddot{z}(t) = Z(\omega)e^{i\omega t} \qquad (3)$$

Let:

$$\begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = \begin{Bmatrix} X_1 \\ X_2 \\ X_3 \end{Bmatrix} e^{i\omega t}; \quad \begin{Bmatrix} u_1 \\ u_2 \\ u_3 \end{Bmatrix} = \begin{Bmatrix} U_1 \\ U_2 \\ U_3 \end{Bmatrix} e^{i\omega t}$$

$$\begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \\ \ddot{x}_3 \end{Bmatrix} = \begin{Bmatrix} \ddot{X}_1 \\ \ddot{X}_2 \\ \ddot{X}_3 \end{Bmatrix} e^{i\omega t}; \quad \begin{Bmatrix} \ddot{u}_1 \\ \ddot{u}_2 \\ \ddot{u}_3 \end{Bmatrix} = \begin{Bmatrix} \ddot{U}_1 \\ \ddot{U}_2 \\ \ddot{U}_3 \end{Bmatrix} e^{i\omega t} \qquad (4)$$

and let:

$$\begin{aligned} s_1 &\circ\ k_1 + i\omega c_1 \\ s_2 &\circ\ k_2 + i\omega c_2 \qquad (5) \\ s_3 &\circ\ k_3 + i\omega c_3 \end{aligned}$$

The equations of motion in frequency domain become:

$$\begin{bmatrix} (s_1 - \omega^2 m_1) & -s_1 & \\ -s_1 & (s_1 + s_1 - \omega^2 m_2) & -s_2 \\ & -s_2 & (s_2 + s_3 - \omega^2 m_3) \end{bmatrix} \begin{Bmatrix} X_1 \\ X_2 \\ X_3 \end{Bmatrix}$$

$$= -\begin{Bmatrix} m_1 \\ m_2 \\ m_3 \end{Bmatrix} Z \qquad (6)$$

Solving equation 6 gives the frequency responses X_1, X_2 in the following form:

$$X_1 = \frac{-(M_1 + m_1)}{s_1 - (K_1 + \omega^2 m_1)} Z$$
$$X_2 = \frac{-\left[K_1 m_1 + M_1 (s_1 - \omega^2 m_1)\right]}{s_1(s_1 - K_1 - \omega^2 m_1)} Z \qquad (7)$$

where:

$$K_1 = \frac{s_1^2}{s_1 + s_2 - (K_2 + \omega^2 m_2)} \qquad (8)$$

$$M_1 = \frac{s_1(M_2 + m_2)}{s_1 + s_2 - (K_1 + \omega^2 m_2)}$$

and

$$K_2 = \frac{s_2^2}{s_2 + s_3 - \omega^2 m_3} \qquad (9)$$

$$M_2 = \frac{s_2 m_3}{s_2 + s_3 - \omega^2 m_3}$$

By equations 2, 4, and 7, the absolute acceleration responses $\ddot{U}_1$ and $\ddot{U}_2$ in the frequency domain can be expressed as:

$$\ddot{U}_1 = \ddot{X}_1 + Z = \frac{s_1 - K_1 + \omega^2 M_1}{s_1 - (K_1 + \omega^2 m_1)} Z \qquad (10)$$

$$\ddot{U}_2 = \ddot{X}_2 + Z =$$

$$\frac{s_1(s_1 - K_1 - \omega^2 m_1 + \omega^2 M_1) + \omega^2 m_1 (K_1 - \omega^2 M_1)}{s_1(s_1 - K_1 - \omega^2 m_1)} Z$$

B. Response of the Interaction System

The equations of motion 1 can be separated into two parts for subsystem "A" and subsystem "B". The equations of motion for subsystem "A" subjected to the input motion $\ddot{z}(t)$ at its base can be written as:

$$\begin{bmatrix} m_2' & \\ & m_3 \end{bmatrix} \begin{Bmatrix} \ddot{x}_2 \\ \ddot{x}_3 \end{Bmatrix} + \begin{bmatrix} c_2 & -c_2 \\ -c_2 & c_2+c_3 \end{bmatrix} \begin{Bmatrix} \dot{x}_2 \\ \dot{x}_3 \end{Bmatrix} \tag{11}$$

$$+ \begin{bmatrix} k_2 & -k_2 \\ -k_2 & k_2+k_3 \end{bmatrix} \begin{Bmatrix} x_2 \\ x_3 \end{Bmatrix} = -\begin{Bmatrix} m_2' \\ m_3 \end{Bmatrix} \ddot{z}(t) + \begin{Bmatrix} f_2(t) \\ 0 \end{Bmatrix}$$

where $f_2(t)$ is the interaction force acting on m_2' from subsystem "B". Using the notations introduced previously, equation 11 in the frequency domain becomes:

$$\begin{bmatrix} s_2-\omega^2 m_2' & -s_2 \\ -s_2 & s_2+s_3-\omega^2 m_3) \end{bmatrix} \begin{Bmatrix} X_2 \\ X_3 \end{Bmatrix} = -\begin{Bmatrix} m_2' \\ m_3 \end{Bmatrix} Z$$

$$+ \begin{Bmatrix} F_2(\omega) \\ 0 \end{Bmatrix} \tag{12}$$

where $F_2(\omega)$ is the harmonic component of $f_2(t)$ at frequency ω; i.e., $f_2(t) = F_2(\omega)\ e^{i\omega t}$.

By reduction of equation 12, the following expression is obtained:

$$F_2(\omega) = (s_2 - K_2 - \omega^2 m_2') X_2 + (M_2 + m_2') Z \qquad (13)$$

By definition, the impedance $K_2^*(\omega)$ of subsystem "A" can be obtained from equation 13 by putting Z = 0, i.e.,

$$F_2(\omega) = K_2^* (\omega) X_2$$

where: (14)

$$K_2^*(\omega) = s_2 - K_2 - \omega^2 m_2' = k_2^*(\omega) + i\omega c_2^*(\omega)$$

Again, by definition, the free-field motion $\ddot{z}(t)$ of subsystem "A" is the absolute acceleration response of mass m_2' when $f_2(t) = 0$. Thus putting $F_2(\omega) = 0$ in equation 13 gives:

$$X_2 = \frac{-(M_2 + m_2')}{s_2 - k_2 - \omega^2 m_2'} Z \qquad (15)$$

Let $\ddot{z}(t) = \overline{Z} e^{i\omega t}$, hence;

$$\overline{Z} = \omega^2 X_2 + Z = \frac{s_2 - k_2 + \omega^2 M_2}{s_2 - k_2 - \omega^2 m_2'} Z \qquad (16)$$

$\overline{Z}$ is the "free-field" motion in the frequency domain.

The equations of motion for the interaction system formed by coupling the impedance $K_2^*(\omega)$ with subsystem "A" subjected to the "free-field" motion $\ddot{z}(t)$ are:

$$\begin{bmatrix} m_1 & \\ & m_2'' \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} c_1 & -c_1 \\ -c_1 & c_1 + c_2^*(\omega) \end{bmatrix} \begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix}$$

$$+\begin{bmatrix} k_1 & -k_1 \\ -k_1 & k_1 + k_2^{*}(\omega) \end{bmatrix} \begin{Bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{Bmatrix} = - \begin{Bmatrix} m_1 \\ m_2'' \end{Bmatrix} \ddot{\bar{z}}\,(t) \qquad (17)$$

where $\bar{x}_1$ and $\bar{x}_2$ are the displacements of m_1 and m_2'', respectively, relative to the free-field input motion $\ddot{\bar{z}}\,(t)$, and where $m_2'' = m_2 - m_2'$. The absolute displacements $\bar{u}_1$ and $\bar{u}_2$ of m_1 and m_2'' can be determined by:

$$\bar{u}_1 = \bar{x}_1 + \bar{z}(t) \qquad (18)$$

$$\bar{u}_2 = \bar{x}_2 + \bar{z}(t)$$

Let:

$$\begin{Bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{Bmatrix} = \begin{Bmatrix} \bar{X}_1 \\ \bar{X}_2 \end{Bmatrix} e^{i\omega t} \qquad (19)$$

Thus equation 17 in the frequency domain becomes:

$$\begin{bmatrix} s_1 - \omega^2 m_1 & -s_1 \\ -s_1 & s_1 + k_2^{*}(\omega) \end{bmatrix} \begin{Bmatrix} \bar{X}_1 \\ \bar{X}_2 \end{Bmatrix} = \bar{Z} \begin{Bmatrix} m_1 \\ m_2'' \end{Bmatrix} \qquad (20)$$

Solving equation 20 for $\bar{X}_1$ and $\bar{X}_2$, and noting equation 14 gives:

$$\bar{X}_1 = \frac{-(m_1 + M_1'')}{s_1 - k_1 - \omega^2 m_1} \bar{Z} \qquad (21)$$

$$\overline{X}_2 = \frac{\omega^2(k_1 m_1 + s_1 M_1'' - \omega^2 m_1 M_1''}{s_1(s_1 - k_1 - \omega^2 m_1)} \overline{Z}$$

where:

$$M_1'' = \frac{s_1 m_2''}{s_1 + s_2 - k_2 - \omega^2 m_2} \tag{22}$$

Let:

$$\left\{\begin{matrix} \ddot{u}_1 \\ \\ \ddot{u}_2 \end{matrix}\right\} \left\{\begin{matrix} \ddot{\overline{U}}_1 \\ \\ \ddot{\overline{U}}_2 \end{matrix}\right\} e^{i\omega t}, \left\{\begin{matrix} \ddot{x}_1 \\ \\ \ddot{x}_2 \end{matrix}\right\} \left\{\begin{matrix} \ddot{\overline{X}}_1 \\ \\ \ddot{\overline{X}}_2 \end{matrix}\right\} e^{i\omega t} \tag{23}$$

Hence:

$$\begin{aligned} \ddot{\overline{U}}_1 &= \ddot{\overline{X}}_1 + \overline{Z} = \frac{s_1 - K_1 + \omega^2 m_1''}{s_1 - K_1 - \omega^2 m_1} \overline{Z} \\ \ddot{\overline{U}}_2 &= \ddot{\overline{X}}_2 + \overline{Z} = \left[\frac{\omega^2(K_1 m_1 + s_1 M_1'' - \omega^2 m_1 M_1''}{s_1(s_1 - K_1 - \omega^2 m_1)} + 1\right] \overline{Z} \end{aligned} \tag{24}$$

which, after substituting the expressions for M_1'' and $\overline{Z}$ from equations 16 and 22, become:

$$\begin{aligned} \ddot{\overline{U}} &= \frac{s_1 - K_1 - \omega^2 M_1}{s_1 - K_1 - \omega^2 m_1} Z \\ \ddot{\overline{U}}_2 &= \frac{(s_1 - \omega^2 m_1)\,(s_2 - K_2 + \omega^2 M_2)}{(s_1 - K_1 - m_1\omega_1^2)\,(s_1 + s_2 - K_2 - \omega^2 m_2)} Z \end{aligned} \tag{25}$$

By comparing $\ddot{U}_1$ and $\ddot{U}_2$ in equation 10 with $\ddot{\overline{U}}_1$ and $\ddot{\overline{U}}_2$ in equation 25, it is easily seen that:

$$\ddot{U}_1 = \dddot{U}_1$$
$$\ddot{U}_2 = \dddot{U}_2 \qquad (26)$$

Thereby, the objective of this section has been proved.

3B.10.3.2.4 Solution of the Three Degrees of Freedom, Fixed Base Model

The dynamic equation of motion is:

$$|m|\{\ddot{x}\} + |c|\{\dot{x}\} + |k|\{x\} = -\{m\}\ddot{z}(t)$$

where:

$$|m| = \begin{vmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & m_3 \end{vmatrix} = \begin{vmatrix} 100 & 0 & 0 \\ 0 & 200 & 0 \\ 0 & 0 & 200 \end{vmatrix} \frac{kip - s^2}{ft}$$

$$|m|^{-1} = \frac{1}{200}\begin{vmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{vmatrix} \frac{ft}{kip - s^2}$$

$$|k| = \begin{vmatrix} k_1 & -k_1 & 0 \\ -k_1 & (k_1+k_2) & -k_2 \\ 0 & -k_2 & (k_2+k_3) \end{vmatrix} = 10^4 \begin{vmatrix} 1 & -1 & 0 \\ -1 & 11 & -10 \\ 0 & -10 & 20 \end{vmatrix} \frac{kip}{ft}$$

$$|c| = \begin{vmatrix} c_1 & -c_1 & 0 \\ -c_1 & (c_1+c_2) & -c_2 \\ 0 & -c_2 & (c_2+c_3) \end{vmatrix} = 10^2 \begin{vmatrix} 2 & -2 & 0 \\ -2 & 22 & -20 \\ 0 & -20 & 40 \end{vmatrix} \frac{kip - s}{ft}$$

$$\{m\} = \begin{Bmatrix} 100 \\ 200 \\ 200 \end{Bmatrix} \qquad \{x\} = \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix}$$

For the free vibration response [c] = 0, $\ddot{z}(t) = 0$

$$[m]^{-1}\,[m]\,\{\ddot{x}\} + [m]^{-1}\,[k]\,\{x\} = 0$$

$$[I]\,\{\ddot{x}\} + [m]^{-1}\,[k]\,\{x\} = 0$$

Let $\{x\} = \{A\}e^{i\omega t}$ then:

$$-\omega^2[I]\{A\}e^{i\omega t} + [m]^{-1}[k]\{A\}e^{i\omega t} = 0$$

$$\left[[m]^{-1}\,[k] - \omega^2\,[I]\right]\{A\}e^{i\omega t} = 0$$

$$[m]^{-1}\,[k]\,-\omega^2\,[I] = 0 \text{ for } \{A\}e^{i\omega t} \neq 0$$

To solve the above equation for our particular problem, first find $[m]^{-1}$ [k]. After making the appropriate matrix operations, the result is:

$$[m]^{-1}\,[k] = 50 \begin{vmatrix} 2 & -2 & 0 \\ -1 & 11 & -10 \\ 0 & -10 & 20 \end{vmatrix}$$

Let $\lambda = \dfrac{\omega^2}{50} => \omega = \sqrt{50\lambda}$

Then:

$$50\begin{vmatrix} 2-\lambda & -2 & 0 \\ -1 & 11-\lambda & -10 \\ 0 & -10 & 20-\lambda \end{vmatrix} = [m]^{-1}\ [k] - \omega^2\ [I] = 0$$

The characteristic equation to be solved for the eigenvalues is:

$$\lambda^3 - 33\lambda^2 + 180\lambda - 200 = 0$$

The solutions for λ are:

$$\lambda_1 = 1.5100 \qquad \omega_1 = 8.68909 \text{ rad/s}$$

$$\lambda_2 = 5.0000 \quad \Rightarrow \quad \omega_2 = 15.81139$$

$$\lambda_3 = 26.4900 \qquad \omega_3 = 36.39368$$

To find the mode shapes let:

$$[m]^{-1}\ [k]\ -\omega^2\ [I] = [E] = 0$$

Now partition [E] in the following form:

$$[E] = \left|\begin{array}{c:c} E_{11}' & E_{10} \\ (1x1) & (1x2) \\ \hdashline E_{01} & E_{00} \\ 2x1 & 2x2 \end{array}\right| = 0$$

To find the mode shapes let the first unknown be 1:

$$\begin{vmatrix} E_{11} & E_{10} \\ E_{01} & E_{00} \end{vmatrix} \begin{Bmatrix} 1 \\ V_{on} \end{Bmatrix} = 0$$

Solving the second equation for $\{V_{on}\}$ yields:

$$\{V_{on}\} = -[E_{00}]^{-1} \{E_{01}\}$$

This equation will yield the eigenvectors.

For $\lambda = 1.51$:

$$[E_{00}] = \begin{bmatrix} (11-1.51) & -10 \\ -10 & (20-1.51) \end{bmatrix} = \begin{bmatrix} 9.49 & -10 \\ -10 & 18.49 \end{bmatrix}$$

$$[E_{00}]^{-1} = \frac{1}{75.47} \begin{vmatrix} 18.49 & 10 \\ 10 & 9.49 \end{vmatrix}$$

and $\{E_{01}\} = \begin{Bmatrix} -1 \\ 0 \end{Bmatrix}$

$\{V_{01}\}$ may now be found

$$\{V_{01}\} = \frac{-1}{75.49} \begin{vmatrix} 18.49 & 10.00 \\ 10.00 & 9.49 \end{vmatrix} \begin{Bmatrix} -1 \\ 0 \end{Bmatrix} = \begin{Bmatrix} 0.2450 \\ 0.1325 \end{Bmatrix}$$

The complete eigenvector may be written as:

$$\{V_1\} = \begin{Bmatrix} 1.0000 \\ 0.2450 \\ 0.1325 \end{Bmatrix}$$

In a similar manner $\{V_2\}$ and $\{V_3\}$ may be found. The results are:

$$\{V_2\} = \begin{Bmatrix} 1.0000 \\ -1.5000 \\ -1.0000 \end{Bmatrix} \qquad \{V_3\} = \begin{Bmatrix} 1.0000 \\ -12.2430 \\ 18.8644 \end{Bmatrix}$$

The matrix of mode shapes [V] is then:

$$[V] = \begin{vmatrix} 1.0000 & 1.0000 & 1.0000 \\ 0.2450 & -1.5000 & -12.2430 \\ 0.1325 & -1.0000 & 18.8644 \end{vmatrix}$$

To orthonormalize the matrix of eigenvectors, first find:

$$(M_n)^{1/2} = \left[\sum_{i-1}^{3} V_{in}^{\ 2}\ m_1\right]^{1/2}$$

Substituting the values yields:

$$(M_1)^{1/2} = \left[(1)^2(100) + (.2450)^2(200) + (.1325)^2(200)\right]^{1/2}$$

$$= 10.7480\ \text{Kips}^2/\text{ft}$$

$$(M_2)^{1/2} = \left[(1)^2(100) + (-1.5)^2(200) + (-1)^2(200)\right]^{1/2}$$

$$= 27.3861$$

$$(M_3)^{1/2} = \left[(1)^2(100) + (-12.2430)^2(200) + (18.8644)^2(200)\right]^{1/2}$$

$$= 318.2001$$

The orthonormalized mode shape matrix [ϕ] may now be found by using the relationship $\{\phi_n\} = \dfrac{1}{M_n^{1/2}}\{V_n\}$

This relationship yields the following matrix of mode shapes stored in columns:

$$[\phi] = \begin{vmatrix} 0.093041 & -0.036515 & 0.003143 \\ 0.022795 & -0.054772 & -0.038476 \\ 0.012328 & -0.036515 & 0.059285 \end{vmatrix}$$

Now by introducing the relationship $\lceil C \rfloor = [\phi]^T [c] [\phi]$ and making the indicated matrix multiplications the diagonal modal damping matrix is formed. The result is:

$$\lceil C \rfloor = \begin{vmatrix} 1.51 & 0.00 & 0.00 \\ 0.00 & 5.00 & 0.00 \\ 0.00 & 0.00 & 26.49 \end{vmatrix}$$

Note that this result could have also been obtained in a much simpler manner by making use of the knowledge that the [k] and [c] matrix are proportional.

$$\lceil C \rfloor = [\phi]^T \alpha [k] [\phi] \qquad \text{where } [c] = \alpha [k] \qquad \alpha = 1/50$$

$$= \alpha [\phi]^T [k] [\phi]$$

$$= \alpha [K] \qquad \text{where } [K] = [\phi]^T [k][\phi]$$

$$= a \lceil w^2 \rfloor [M] \qquad \text{where } [M] = [I]$$

$$[K] = \lceil \omega^2 \rfloor [M]$$

$$\lceil c \rfloor = \alpha \lceil \omega^2 \rfloor = \begin{vmatrix} 75.50/50 & 0 & 0 \\ 0 & 250/50 & 0 \\ 0 & 0 & 1324.5/50 \end{vmatrix}$$

Now that the modal damping matrix has been obtained, the damping ratio β for each mode may be found in the following manner:

$$C_n = 2\beta_n \omega_n M_n$$

Recall that $[M] = [\phi]^T [m] [\phi] = [I]$. This is due to the orthonormalization of $[\phi]$, so $M_n = 1$. Then solving for β_n yields:

$$\beta_n = \frac{C_n}{2\omega_n} = \frac{\alpha\omega_n 2}{2\omega_n} = \frac{\omega_n}{100}$$

$\beta_1 = 0.086891$ (fraction of critical)

$\beta_2 = 0.158114$

$\beta_3 = 0.363937$

An estimate of the damped frequency of vibration may be found by the approximate relationship.

$$\omega_n^D = \omega_n \sqrt{1 - \beta_n^2}$$

$$\omega_1^D = 8.68909 \sqrt{1 - (0.0868909)^2} = 8.65623 \text{ rad/s}$$

Similarly:

$$\omega_2^D = 15.61250 \text{ rad/s}$$

$$\omega_3^D = 33.89793 \text{ rad/s}$$

To complete this analysis, the modal participation factors and the modal masses will be calculated. Recall that the participation factors may be obtained by the relationship:

$$L_n \equiv \phi_n^T [m] \{1\}$$

By making the appropriate substitution for n=1

$$L_1 = \begin{Bmatrix} 0.093041 \\ 0.022795 \\ 0.012328 \end{Bmatrix}^T \begin{bmatrix} 100 & 0 & 0 \\ 0 & 200 & 0 \\ 0 & 0 & 200 \end{bmatrix} \begin{Bmatrix} 1 \\ 1 \\ 1 \end{Bmatrix}$$

$$= 9.3041 + 4.559 + 2.4656$$

$$L_1 = 16.3287$$

Similarly:

$$L_2 = -14.6059$$

$$L_3 = 4.4761$$

Now the modal masses may be found by:

$$\Omega n = L_n^2$$

so:

$$\Omega_1 = 266.63$$

$$\Omega_2 = 213.33$$

$$\Omega_3 = 20.04$$

Note that $\sum_{i=1}^{n} \Omega_n = 500$ and is equal to the total mass of the system as would be expected.

3B.10.3.2.5 The Impedance Function of Substructure "A"

The equation of motion is:

$$\begin{bmatrix} m'_2 & 0 \\ 0 & m_3 \end{bmatrix} \begin{Bmatrix} \ddot{x}_2 \\ \ddot{x}_3 \end{Bmatrix} + \begin{bmatrix} c_2 & -c_2 \\ -c_2 & c_2 - c_3 \end{bmatrix} \begin{Bmatrix} \dot{x}_2 \\ \dot{x}_3 \end{Bmatrix} + \begin{bmatrix} k_2 & -k_2 \\ -k_2 & k_2 + k_3 \end{bmatrix} \begin{Bmatrix} x_2 \\ x_3 \end{Bmatrix} = \begin{Bmatrix} e^{i\omega t} \\ 0 \end{Bmatrix}$$

let $x_2 = Ae^{i\omega t}$ and $x_3 = Be^{i\omega t}$

then $\dot{x}_2 = i\omega Ae^{i\omega t}$ $\dot{x}_3 = i\omega Be^{i\omega t}$

x defines the motion relative to the base

$\ddot{x}_2 = -\omega^2 Ae^{i\omega t}$ $\ddot{x}_3 = -\omega^2 Be^{i\omega t}$

Where “A” and “B” are complex constants. By substituting the above quantities into the equation of motion and simplifying yields :

$$\left[-\omega^2 \begin{bmatrix} m'_2 & 0 \\ 0 & m_3 \end{bmatrix} + i\omega \begin{bmatrix} c_2 & -c_2 \\ -c_2 & c_2 + c_3 \end{bmatrix} + \begin{bmatrix} k_2 & -k_2 \\ -k_2 & k_2 + k_3 \end{bmatrix} \right] \begin{Bmatrix} A \\ B \end{Bmatrix} = \begin{Bmatrix} 1 \\ 0 \end{Bmatrix}$$

Combining terms yields:

$$\begin{bmatrix} (-\omega^2 m'_2 + i\omega c_2 + k_2) & (-i\omega c_2 - k_2) \\ (i\omega c_2 - k_2) & (-\omega^2 m_3 + i\omega\ (c_2 + c_3) + k_2 + k_3) \end{bmatrix} \begin{Bmatrix} A \\ B \end{Bmatrix} = \begin{Bmatrix} 1 \\ 0 \end{Bmatrix}$$

$$\text{let } [D] = \begin{bmatrix} (-\omega^2 m'_2 + i\omega c_2 + k_2) & (-i\omega c_2 - k_2) \\ (-i\omega c_2 - k_2) & (-\omega^2 m_3 + i\omega(c_2 + c_3) + k_2 + k_3) \end{bmatrix}$$

The determinent of [D] is

$$\left| D \right| = (-\omega^2 m'_2 + k_2 + i\omega c_2)\ (-\omega^2 m_3 + k_2 + k_3 + i\omega(c_2 + c_3)$$

$$- (k_2 + i\omega c_2)^2 = (-\omega^2 m'_2 + k_2)\ (-\omega^2 m_3 + k_2$$

$$+ k_3)\ -\omega^2 c_2(c_2 + c_3)\ - k_2^2 + \omega^2 c_2^2 + i\omega c_2(-\omega^2 m_3$$

$$+ k_2 + k_3) + i\omega(c_2 + c_3)(-\omega^2 m_2' + k_2) - 2i\omega c_2 k_2$$

$$= (k_2 - \omega^2 m_2')(k_2 + k_3 - \omega^2 m_3) - \omega^2 c_2(c_2 + c_3) - k_2^2 + \omega^2 c_2^2$$

$$+ i\omega(c_2(k_2 + k_3 - \omega^2 m_3) + (c_2 + c_3)(k_2 - \omega^2 m_2') - 2c_2 k_2)$$

let $\Delta_1 = k_2 + k_3 - \omega^2 m_3$

$\Delta_2 = \omega(c_2 + c_3)$

$\Delta_3 = \Delta_1(k_2 - \omega^2 m_2') - \Delta_2 \omega c_2 - k_2^2 + \omega^2 c_2^2$

$\Delta_4 = \Delta_1 \omega c_2 + \Delta_2(k_2 - \omega^2 m_2') - 2\, k_2 \omega c_2$

The determinant of [D] can now be written:

$$|D| = \Delta_3 + i\Delta_4$$

The inverse of [D] is then:

$$[D]^{-1} = \frac{\begin{vmatrix} (\Delta_1 + 1\Delta_2) & (k_2 + i\omega c_2) \\ (k_2 + i\omega c_2) & (k_2 - \omega^2 m_2 + i\omega c_2) \end{vmatrix}}{\Delta_3 + i\Delta_4}$$

The complex constant "A" may now be determined from:

$$\begin{Bmatrix} A \\ B \end{Bmatrix} = [D]^{-1} \begin{Bmatrix} 1 \\ 0 \end{Bmatrix}$$

$$A = \frac{\Delta_1 + i\Delta_2}{\Delta_3 + i\Delta_4}$$

Note that the complex constant "B" is identically zero.

Since “A” is a compliance term and we are interested in the impedances, the inverse relation of “A” must be found.

$$I = \frac{1}{A} = \frac{\Delta_3 + i\Delta_4}{\Delta_1 + i\Delta_2} = \frac{(\Delta_3 + i\Delta_4)(\Delta_1 - i\Delta_2)}{\Delta_1^2 + \Delta_2^2}$$

$$I = \frac{\Delta_1\Delta_3 + \Delta_2\Delta_4}{\Delta_1^2 + \Delta_2^2} + i\left(\frac{\Delta_1\Delta_4 + \Delta_2\Delta_3}{\Delta_2^2 + \Delta_2^2}\right)$$

$$I_{REAL} = \frac{\Delta_1\Delta_3 - \Delta_2\Delta_4}{\Delta_1{}^2 + \Delta_2{}^2} \text{ (equivalent spring)}$$

$$I_{IM} = \frac{\Delta_1\Delta_4 - \Delta_2\Delta_3}{\Delta_1{}^2 + \Delta_2{}^2} \text{ (equivalent spring)}$$

Now all the variables but ω are known for the above relations, so ω will be varied over the frequency range of interest and a table of impedances will then be generated for use with the FOSIN analysis. See computer programs “D” and “E”. For convenience the values used are listed in table 3B.10-3.

3B.10.3.2.6 Comparison of the Results

The FOSIN impedance approach and the theoretical solutions of the complete three-mass model yielded the following frequencies.

Frequency (rad/s)

Mode	Exact	FOSIN	Error %
1	8.6891	8.6911	.02
2	15.811	15.935	.78
3	36.394	---	

A comparison of the mode shapes, time-history responses, and response spectra analysis of m1 and m2 can be found in figures 3B.10-6, 3B.10-7, and 3B.10-9 through 3B.10-14. In general, the comparisons of the mode shapes and response spectra are very good. The results obtained by comparing the two runs for the shape of the first mode and the response of the first mass were found to be almost identical. As would be expected for this small model, the results begin to deteriorate for the response of the second mass.

The pseudo damping values that were obtained by the FOSIN analysis can be found on figure 3B.10-9. The difference in the first mode damping value was found to be only 4%; however, for the second mode the difference is about 40%. So it appears that for some models the correspondence between the actual and the pseudo damping computed by FOSIN may be considerably different. This may be due to our oversimplification of the problem, in that we are only looking at one of the terms associated with the dissipation of the energy in the system while we are neglecting the effect of the phasing inherent in the real and imaginary parts of the response. The important

point to make here is that the response of the model is the same.

3B.10.3.2.7 Conclusions

While the results found here are very good, considering the severity of the modeling constraints, it was decided to rerun the analysis using the same procedure on a larger model. The new fixed-base model will consist of 10 mass points and again the second mass up from the fixed-base will be the division point to form the two substructures. This will provide an eight-mass structural model to compare the interaction impedance solution of FOSIN to the full structure solution of SUPER SMIS.

3B.10.3.2.8 List of Computer Runs

Run "A": Run SUPER SMIS to analyze the complete three-mass system of figure 3B.10-4 that will be subjected to the Bechtel Synthetic Time-History H1 and obtain the time-histories of m1.

Run "B": Run SUPER SMIS to analyze subsystem "A" of figure 3B.10-5 that will be subjected to the Bechtel Synthetic Time-History H1 and obtain the absolute acceleration z(t) of for input into run "E".

Run "C": Run SPECTRA to obtain the response spectra of the input motion H1, the time-history response of m1 from run "A".

Run "D": Run IMPEDANCE to analyze the complex impedances and for use in run "E".

Run "E": Run FOSIN to analyze subsystem "B" using z(t) from run "B" and the substructure impedances from run "D". Obtain the time-history of m1.

Run "F": Run SPECTRA to obtain the response spectra of the time-history for m1 from run "E".

3B.10.3.3 FOSIN Example 3, Comparison of a 10-Mass Base with an Equivalent Eight-Mass Interaction System

This problem is an extension of the three-mass model used in paragraph 3B.10.3.2. It may be observed that the lower portion of the 10-mass model is identical to model "A" of the three-mass model previously used. By keeping the lower portions of both models identical to each other, there will be no need to recalculate the substructure impedance properties that must be input into FOSIN. This more extensive model should provide some insight into how accurately a more realistic model is handled by FOSIN.

For a more detailed analysis of a similar problem, please refer to the analysis of the three-mass model of paragraph 3B.10.3.2.

The following calculations will be performed in the process of exercising this problem:

A. A SUPER SMIS analysis of the complete 10-mass system subjected to a vertical excitation to produce:

- The system frequencies

- Mode shapes
- Modal damping ratios
- Time-history analysis

B. A FOSIN analysis of the interaction system using the substructure impedances and modified input motion z(t) to calculate all the items of listing A above.

C. A comparison of the response spectra for the time-histories generated for each mass by both the SUPER SMIS and FOSIN programs.

3B.10.3.3.1 Problem Description

Consider a 10-mass system, having only vertical translation degrees of freedom, which is subjected to a base excitation (t). (See figure 3B.10-13.) This system will be divided into two subsystems that will be designated as subsystem "A" and subsystem "B". (See figure 3B.10-14.) Subsystem "A" will be used to model the foundation. From subsystem "A" can be derived the impedance relationships of the foundation model as well as the modified base input motion (t). Since subsystem "A" for this problem is the same as that used in paragraph 3B.10.3.2, there will be no need to recalculate these quantities.

Subsystem "B" is an eight-degree of freedom model that will represent the structural portion of the model. This subsystem will be combined with the impedances of subsystem "A" and input into FOSIN. The results of the FOSIN time-history analysis

will be compared to the time-history analysis of the complete system performed by SUPER SMIS. The equivalence of the two approaches was proven in paragraph 3B.10.3.2. Although the proof was established for a three-mass system, it could be extended to cover any lumped mass system. Refer to paragraph 3B.10.3.2 for a more detailed accounting of the formulation of the three-mass problem.

3B.10.3.3.2 Problem Parameters

The analysis was carried out using the following values for the 10-mass system:

m_1 through m_8 = 100 K-s^2/ft

m_9 , m_{10} = 200 K-s^2/ft

k_1 through k_8 = 10^4 K/ft

k_9, k_{10} = 10^5 K/ft

c_1 through c_8 = 200 K-s/ft

c_9 , c_{10} = 2000 K-s/ft

See paragraph 3B.10.3.2.2 for the specification of the remainder of the parameters of the problem.

3B.10.3.3.3 Comparison of Results

The FOSIN impedance approach and the theoretical solution of the complete 10-mass model yielded the frequencies shown in table 3B.10-4.

As can be seen by table 3B.10-4, the maximum error found in the frequency determination was less than 2%. Also note that the error involved in calculating the first five frequencies was less than 1%.

The mode shapes have been recorded in table 3B.10-5 for comparison. The mode shapes have been normalized so that the responses shown for m1 are matched identically for both cases. It may be observed that the first three modes are identical for the first three significant figures. In general all nine modes agree very well. For convenience the mode shapes have been plotted in figure 3B.10-15.

A comparison of the response spectra of each node was also made. The results may be found in figures 3B.10-16 through 3B.10-23. Note that the only differences are in the high frequency end of the spectrum, and that they are generally very minor.

Of lesser importance, but of some interest, was the comparison of the damping ratios. The comparison of these values may be seen on figure 3B.10-15. The maximum difference was found to be 14% for mode 6.

3B.10.3.3.4 Conclusions

The results shown here for the 10-mass model compare very well. The approximations used by FOSIN give very good answers, especially for the first few frequencies and mode shapes. Since, for all practical purposes, the first few modes are responsible for the majority of the response of the typical

lumped-mass structural model, it can be expected that the FOSIN program will give reasonable and accurate results.

3B.11 STICK COMPUTER PROGRAM (STICK)

In order to evaluate the responses of structures, the effects of soil-structural interactions must be investigated. A computer program named FOSIN was developed for this purpose by LAPD of Bechtel Power Corporation. The program utilizes the FOSS method to solve the problem; the general theory upon which the program is based is explained briefly in the user's manual of FOSIN Version FO.0.

The output of FOSIN computer program consists of: relative accelerations, relative velocity, relative displacement, and/or absolute acceleration for each degree of freedom.

Relative implies relative to base, with the base considered to be fixed. While these outputs very readily provide the response spectra, they are nevertheless rather difficult to use in the design of structural members. Usual modal analysis techniques break down in the formation of soil structural interaction analysis, and SRSS criteria can no longer be applied. A post-processing computer program, STICK, was thus developed with the object of determining the critical condition on the basis of which structural members are to be designed.

In this report, the basic theory for the method of approach is explained and the procedures of solution presented. Application of the method is shown through a number of numerical examples dealing with rigid frame structural system.

STICK COMPUTER PROGRAM (STICK)

3B.11.1 BASIC THEORY AND METHOD OF APPROACH

Linear elastic analysis of structural systems is based upon two assumptions; namely, of small deformation and linear stress-strain relationship. The assumption of small deformation implies linear strain-deformation relationship. Therefore, in the case of horizontal excitation, the strains will increase linearly with horizontal displacements of floors. The assumption of linear stress-strain implies that the internal stresses (forces) of structural members increase proportionately with the increase of horizontal displacement of floors. Particularly, the internal stresses of members between any two adjacent floors will be maximum when the relative horizontal displacement between two floors becomes maximum.

FOSIN computer program will, as mentioned previously, generate the time-history of horizontal displacements of floors. Therefore, finding the critical conditions for members involves no more than establishing the instant at which absolute relative horizontal displacements between adjacent floors is maximum.

FOSIN computer program utilizes a lumped-mass model for analyzing the structural system. Thus, in the case of vertical excitation, the critical condition during whole time-history will be at an instant when relative vertical displacements between two adjacent floors is either maximum (for tension stress) or minimum (for compressive stresses).

3B.11.2 PROCEDURES OF ANALYSIS

It has been concluded that the critical conditions for a member will occur at a moment when the relative displacement between two adjacent floors becomes maximum during whole time history. Thus, in the case of member design between the $(i-1)^{th}$ and i^{th} floor due to horizontal excitation. The first step is to find out a time instant, say Ti, such that the absolute relative horizontal displacement between the $(i-1)^{th}$ and i^{th} floor becomes maximum at t = Ti.

If [Di] be a displacement vector for all floors at a time t = Ti, then the corresponding equivalent force {Fi}, acting at the floors is given by:

$$\{Fi\} = [k]\ \{Di\}$$

where [k] is the stiffness matrix.

Finally, by applying the force vector {Fi} to the actual structural system (as distinct from the lumped mass model), the internal forces in members between the $(i-1)^{th}$ and i^{th} floor can be analyzed. In general, n sets of force vectors may be obtained for an n-floor structure.

The procedure discussed so far may be summarized as follows (for a case of horizontal excitation):

A. Model the structural system as a lumped-mass system - assigning the mass point numbers in sequence starting from the base. Generate the equivalent stiffness matrix [k] of the fixed-base structure.

B. Generate the horizontal displacement time-histories of the floors using FOSIN computer program.

C. Generate displacement matrix [D] whose i^{th} column will be a displacement vector at t = Ti when the absolute relative displacement between $(i-1)^{th}$ and i^{th} floor is maximum.

D. Multiply the displacement matrix {D} by the stiffness matrix {k} and obtain the force matrix {F}. The i^{th} column of force matrix {Fi} will represent the force vector {Fi}. These are the equivalent force acting on the structural system at t = Ti.

E. Apply the force vector {Fi} one at a time to the structure and calculate the members' internal stresses. Use the highest values obtained as design stresses.

3B.11.3 NUMERICAL EXAMPLES AND DISCUSSIONS

To demonstrate the application of the method, rigid frame structures will be analyzed numerically. In the following examples, the structural systems are kept the same but girder moment of inertia is altered.

The structure is first modeled as a lumped mass system and the fixed-base equivalent stiffness matrix generated by CE 917 computer program. Kern County Earthquake (1952) is used for input in FOSIN computer program. STRUDL computer program is then used to calculate members' internal forces.

For convenience, the terms "predicted maximum" and "actual maxi-mum" will be used in the following discussions. The term "predicted maximum" implies the maximum value was obtained according to the criteria of maximum absolute relative displacement as discussed earlier. The term "actual maximum" implies the maximum values actually occurred during the earthquake excitation.

3B.11.4 STICK VERIFICATION (TEST PROBLEMS)

3B.11.4.1 STICK Example 1

Consider the rigid frame structure shown in figure 3B.11-1. The structure is then modeled as a lumped mass system as shown in figure 3B.11-2. Considering the horizontal degree of freedom only, the equivalent stiffness matrix for fixed-base system is:

(kip/ft)

The outputs of FOSIN computer program is stored on HI magnetic tape. By using the post-processing computer program, STICK, the displacement matrix [D] and the force matrix [F] are generated and tabulated in table 3B.11-1. The member forces calculated according to force matrix [F] are given in tables 3B.11-2 through 2B.11-4; the values appearing in the solid line boxes are the predicted maximum member forces. It is seen that, for most of the members, the predicted maximum bending moments and shearing forces are the maximum values stated in tables 3B.11-2 through 3B.11-4. The maximum bending moments and shearing forces for column between the first and second floor and for girders for the second and third floor are

not the predicted maximum. However, the discrepancies are less than 1%.

Members 6, 7, and 8, which are columns between first and second floor, for instance, have the maximum bending moments and shearing forces at t = 353 and the predicted maximum bending moments and shearing forces are at t = 354. The absolute relative displacement between the first and second floors is 2.355 x 10-4 feet at t = 354 and 2.344 x 10-4 feet at t = 353. The difference between these two values is less than 1%. This closeness, coupled with the effect of the interaction between the shear and flexural deformation, is in all probability the explanation for the discrepancies between the predicted and the actual maximum member forces.

In order to show whether the predicted maximum is the actual maximum for horizontal excitation, a portion of time-history between t = 401 and t = 450 has been studied. The predicted maximum member forces are tabulated in the last three columns of table 3B.11-5. On the other hand, member forces for the whole portion of time-history have been calculated, and the actual maximum shearing force and bending moments were then obtained. It is seen that, except for the column between the first and second floor (members 6, 7, and 8), the predicted maximum member forces come out to be the actual maximum. For members 6, 7, and 8, the predicted maximum occurred at t = 415 while the actual maximum occurred at t = 416, and the absolute relative displacement between floors at t = 416 is about 0.2% less than that at t = 415. Table 3B.11-6 summarizes the

predicted maximum and actual maximum for the time interval between t = 401 and t = 450.

In this example, the girders' flexural rigidity (EI/) is about 1.2 of the columns' flexural rigidity.

*Same as first two columns.

3B.11.4.2 STICK Example 2

In order to investigate the effects of girders' bending rigidities, moment of inertia of all girders is first reduced to one half of the original values. The equivalent stiffness matrix for lumped mass model is:

$$[k] = \begin{bmatrix} 5724.6 & -3674.2 & 59.03 & -21.0 \\ -3674.2 & 5567.3 & -2650.9 & 126.7 \\ 59.03 & -2650.9 & 2615.2 & -488.8 \\ -21.0 & 126.7 & -488.8 & 380.4 \end{bmatrix} \quad \text{(kip/ft)}$$

Since the effect of soil-structure interactions is not important in these studies, the same FOSIN outputs of the previous example may be used. The members' force corresponding to the force matrix given in table 3B.11-7 is tabulated in table 3B.11-8. The predicted maximum and actual maximum member forces are summarized in table 3B.11-9. Again, the only discrepancy occurs with respect to the column members between the first and second floor. Although an error of 35% occurs at joint 2 of member 6, this error is of no practical importance. Since the load at that joint is not a design load; this, by virtue of the fact that its magnitude is less than that occurring at joint 3 where attendant error is only 3.7%.

3B.11.4.3 STICK Example 3

The moment of inertia of the girders is again reduced to one-fifth of the actual values in the structure. The force matrix is tabulated in table 3B.11-10, and the corresponding member forces are given in table 3B.11-11. The predicted maximum and actual maximum member forces are summarized in table 3B.11-12. It is seen that, in the event of predicted

Note: *Denotes Actual Maximum is the Same as the Predicted Maximum

maximum being different from actual maximum, the bending moments at the ends of the member becomes maximum at different instances. The predicted maximum member force may practically be used as design forces.

3B.11.5 CONCLUSION

Since the axial member forces offer no major contribution to horizontal displacements of floors, the predicted maximum axial force of the members are, in general, far removed from the actual maximum. Fortunately, stress due to axial forces are generally not important and may, therefore, be neglected in the case of horizontal excitation.

The predicted maximum values for the shear force and bending moments emerge, in general, the actual maximum for most members. The results of the numerical examples indicate that the predicted maximum is at most 5% less than actual maximum.

In case of vertical excitation, design criteria for compressive and tension members are generally different. Thus, maximum relative vertical displacement and minimum relative vertical displacement between two adjacent mass points should be considered to obtain the maximum compression and maximum tension stress.

If the rotational degree of freedom is considered in analysis, the additional criteria of maximum relative rotation between two adjacent mass points should be included. The rotation degree of freedom, however, is generally not being considered in analysis since its effect is negligible.

3B.12 BECHTEL CE 800, BECHTEL STRUCTURAL ANALYSIS PROGRAM (BSAP)

A. Description

The program performs the static and dynamic analyses of linear, elastic, three-dimensional structures, using the finite-element method. The finite-element library contains truss and beam elements, plane and solid elements, plate and shell elements, axisymmetric (torus) elements, and special boundary (spring) elements.

Element stresses and displacements are solved for either applied loads or temperature distributions. Concentrated loads, pressures, or gravity loads may be applied. Temperature distributions are assigned as an appropriate uniform temperature change in each element. Prestressing may be simulated by using artificial temperature changes on rod elements.

Dynamic response routines are available for solving arbitrary dynamic loads or seismic excitations, using modal superposition. The program can also perform response spectrum and time-history analyses.

B. Validation

The solutions to test problems have been demonstrated to be essentially identical to the results obtained, using the following recognized public-domain computer programs:

BECHTEL STRUCTURAL ANALYSIS PROGRAM

(BSAP) CE 800

1. EASE - Elastic Analysis Corporation
2. STARDYNE - Mechanics Research Incorporated
3. ANSYS - Swanson Engineering Corporation
4. ICES/STRUDL - McDonnell-Douglas Automation
5. MSC/NASTRAN - MacNeil Schwendler Corporation

Agreement has also been established between BSAP program results and the results presented in the ASME Library of Benchmark Computer problems and solutions[4] and in recognized technical journals. Document traceability is available at Bechtel Power Corporation.

C. Extent of Application

The program was used to perform structural analysis for concrete structures.

BECHTEL STRUCTURAL ANALYSIS PROGRAM

(BSAP) CE 800

3B.13 FINITE-ELEMENT COMPUTER PROGRAM (FINEL)

3B.13.1 DESCRIPTION

FINEL is a two-dimensional, static, small displacement, bilinear-elastic, finite-element computer program. FINEL is an improved version of the original FINEL code developed under the direction of Dr. E. L. Wilson at the University of California at Berkeley in 1962 under a National Science Foundation grant G18986.

The primary purpose of this program is to perform plane or axisymmetric stress analysis of reinforced concrete structures. The program allows for concrete cracking and reinforcement yielding. This is done by a series of successive elastic iterations in which the stiffness matrix is modified to account for the nonlinear effect of cracking or yielding of each element. Loading includes concentrated, pressure, displacement (no inclined roller), thermal, inertial and, for axisymmetric problems, centrifugal forces.

In addition to analysis of reinforced concrete structures, FINEL can perform linear stress analysis on structures that can be modeled as plane stress, plane strain, or axisymmetric problems with axially symmetric material properties; i.e., isotropic in the plane (radial plane for axisymmetric problems), with the same or different properties normal to the plane.

FINEL has been used extensively to analyze reinforced concrete containment vessels.

Two types of material behavior are incorporated into FINEL:

A. Ductile

The stress-strain curve is bilinear in compression and bilinear in tension. This type of material behavior is used to model reinforcing steel and the liner plate material.

B. Brittle

The stress-strain curve is bilinear in compression and fractures (cracks) in tension. This type of material behavior is used to represent concrete and the foundation media.

3B.13.2 VALIDATION

Demonstration of the applicability and validity of the FINEL program is achieved through the comparison of the results obtained using the program with experimental and/or manually-calculated solutions.

Eight test problems, outlined in paragraphs 3B.13.2.1 through 3B.13.2.8, were used in this demonstration, the results of which show that the FINEL solutions are essentially identical to experimental and/or manually-calculated solutions.

3B.13.2.1 FINEL Example 1, Cracking Analysis of a Prestressed Concrete Reactor Vessel (PCRV)

The purpose of this test problem is to compare the results obtained from the FINEL program with the results obtained from both experimental and analytical investigation of the cracking

of a cylindrical PCRV subjected to internal pressurization. A pictorial representation of the PCRV under investigation is shown in figure 3B.13-1.

The finite-element idealization used in the FINEL analysis is shown in figure 3B.13-2. The zoning is obtained from the zoning used in reference 1 by subdividing each element into four elements. Since reference 1 used a quadratic element, while FINEL uses a linear element, the two zonings will have the same order of accuracy. Another difference between the analysis of reference 1 and the FINEL analysis is the assumed cracking criteria. Reference 1 used the following maximum strain criteria:

$$\varepsilon_{crack} = \frac{500\ \text{lb/in.}^2}{E} = 0.000116$$

(incorrectly reported as 0.00015 in reference 1).

The FINEL program used the following maximum stress criteria:

$$T_{crack} = 500\ \text{lb./in.}^2$$

Also, reference 1 reduced the shear stiffness to zero once an element cracked, while a shear stiffness reduction factor of 0.5 was used in the FINEL analysis.

The loading steps applied to the FINEL model of the PCRV are given in table 3B.13-1. Other parameters used are:

Young's Modulus = E = 4.3 x 10^6 pounds per square inch

Poisson's Ratio = ν = 1/3

Cracking Stress = T_{crack} = 500 pounds per square inch

The cracking patterns calculated by reference 1 (= 1/3) and the FINEL analysis are shown in figure 3B.13-3. Agreement is very good, taking into account the difference in the load-deformation curves, i.e., similar patterns, with the cracks from reference 1 growing more rapidly with increased load.

Load-deformation curves for a point on the PCRV from references 1 and 2 and the FINEL analysis are shown in figure 3B.13-4. The numerical results of reference 1 and the FINEL analysis as shown in figures accurately predict the load at which significant cracking begins.

However, after significant cracking occurs, both the results of reference 1 and the FINEL analysis underestimate the deformation. Therefore, it is apparent that after significant cracking has occurred, a more accurate stiffness formulation is needed to predict the deformations of a PCRV. The fact that the results of the FINEL analysis agree more closely with the results of reference 1 where = 0 than to reference 1 where = 1/3 is due to the different failure criteria assumed. Reference 1 used a maximum strain criteria and FINEL uses a maximum stress criteria.

The results of this investigation indicate that the FINEL program can accurately predict loads at which significant cracking is initiated in a PCRV. As the load is increased above the point where significant cracking occurs, the results

are only approximate. A more accurate stiffness formulation is needed to accurately predict the behavior of a PCRV after significant cracking has occurred.

Table 3B.13-1

LOADING STEPS FOR FINEL MODEL

(FINEL Example 1)

Step	Longitudinal Prestress (lbs)	Circumferential Prestress (lb/in.^{2})	Internal Pressure (lb/in.^{2})	No. of Iterations Required for Convergence
1	760,000	620	0	1
2	760,000	620	500	4
3	760,000	620	575	6
4	760,000	620	625	5
5	760,000	620	675	5
6	760,000	620	725	10

3B.13.2.2 FINEL Example 2, Analysis of a Simply Supported Beam

The purpose of this test problem is to compare the results obtained from the FINEL program with the results obtained from both experimental and analytical investigation of the cracking of a simply supported beam. A pictorial representation of the characteristics of the simply supported beam under investigation is shown in figure 3B.13-5.

The finite-element mesh used in reference 3 and in the FINEL analysis are shown in figure 3B.13-6. The FINEL analysis requires a finer mesh because it used linear displacement elements while reference 2 used quadratic displacement elements.

The material properties of the concrete and reinforcing steel, and the loading history used in the FINEL analysis are given in tables 3B.13-2 and 3B.13-3.

This problem solution was not continued beyond the yield point of the reinforcing steel due to an error in the FINEL program which has since been corrected.

The cracking patterns obtained from reference 3 and FINEL are shown in figure 3B.13-7. The load deflection curves from references 3 and 4 and the FINEL analysis are shown in figure 3B.13-8. The load deflection curve obtained from the FINEL analysis shows very good agreement with the experimental results. The cracked region grows faster in the FINEL analysis and more slowly in reference 3, since the FINEL and reference 3 load deflection curves show different gradients (stiffnesses).

T_{yield}	-4,820 lb/in.^{2}	± 44,900 lbs/in.^{2}
E_{yield}	0.	0.
T_{crack}	+546 lb/in.^{2}	-----
E_{crack}	1.0 lb/in. ^{2}	-----
Shear stiffness reduction factor for once cracked concrete	0.5	-----

3B.13.2.3 FINEL Example 3, Analysis of an End-Loaded Cantilever

The analysis of an end-loaded cantilever prismatic beam is performed to test the constant strain finite-elements. The results are compared to theory. The beam geometry and finite-element mesh are illustrated in figure 3B.13-9. The problem is treated by a plane stress analysis, and the mesh contains 119 nodes and 96 quadrilateral constant strain elements.

FINITE-ELEMENT COMPUTER

PROGRAM (FINEL)

The deflections and stress results from the FINEL program are compared with the hand calculations in tables 3B.13-4 and 3B.13-5. The theoretical linear strain variation across the

depth of the beam is represented by discrete constant strain "steps" due to these finite-elements. The differences in results are largely due to this feature of the constant strain elements.

3B.13.2.4 FINEL Example 4, Analysis of an Axially Constrained Hollow Cylinder with a Distributed Pressure Loading

The purpose of this test problem is to compare the response of an axially constrained hollow cylinder to internal pressure, determined using FINEL, with an analytical solution of the same problem. The finite-element model is illustrated in figure 3B.13-10. Nodal points are free to move only in the radial direction, modeling the conditions of axisymmetry and plane strain.

The closed-form solution is based upon Roark Formulas for Stress and Strain.(5) A summary comparison between the closed form and FINEL solutions is given in table 3B.13-6.

3B.13.2.5 FINEL Example 5, Analysis of an Axially Constrained Hollow Cylinder with a Linear Temperature Gradient

The purpose of this test problem is to compare the response of an axially constrained hollow cylinder to a radially varying temperature gradient, determined using FINEL, with a closed-form solution to the same problem. The finite-element model is illustrated in figure 3B.13-11. The conditions of axisymmetry and plane strain are imposed by using the axisymmetric quadrilateral element and restraining all nodes

against axial displacement. The temperature is illustrated in figure 3B.13-12.

The closed-form solution is based on Timoshenko, Elasticity(6) and Manson, Thermal Stress.(7) A summary comparison between the closed-form and FINEL solutions is given in table 3B.13-7.

3B.13.2.6 FINEL Example 6, Analysis of an Axially Constrained Hollow Cylinder with a Nonlinear Temperature Gradient

The purpose of this test problem is to compare the response of an axially restrained hollow cylinder to a radially varying temperature gradient, determined using FINEL, with a closed-form solution to the same problem. The finite-element model is illustrated in figure 3B.13-13. The conditions of axisymmetry and plane strain are imposed by using the axisymmetric quadrilateral element and restraining all nodes against axial displacement. The bilinear temperature gradient is illustrated in figure 3B.13-14.

The closed-form solution is based on Timoshenko, Elasticity[6] and Manson, Thermal Stress[7]. A summary comparison between the closed-form and FINEL solutions is given in table 3B.13-8.

3B.13.2.7 FINEL Example 7, Analysis of a Deep Elastic Panel

The purpose of this test problem is to compare the response of a deep elastic panel subjected to a uniformly distributed load determined using FINEL with a closed-form solution to the same problem. The finite-element model is illustrated in figure 3B.13-15.

Due to the symmetry of the actual problem, only half of the panel has been modeled. Appropriate boundary conditions are applied to the nodal points along the axis of symmetry.

Boundary conditions along axis X = 0

θ rotation = 0

X displacement = 0

The closed-form solution is based on Timoshenko, Elasticity.[8] The stress results from FINEL represent the centroidal value for each plate elements. Therefore, in order to obtain stress values at locations more suitable for comparison with the theoretical solution, a graphical extrapolation of the results obtained from the FINEL analysis is necessary to establish stress values at nodal points along the axis of symmetry. Figure 3B.13-16 illustrates the approach used to establish the stress levels at nodal points 1 and 61.

Table 3B.13-8

SUMMARY COMPARISON

(FINEL Example 6)

10	68.56	194.82	197.37	138.83	139.51	-0.56	-0.54

a. Based on formula given in Timoshenko, Elasticity[6] and Manson, Thermal Stress.[7]

The results from the FINEL solution for the stresses at the nodal points located at the top and bottom of the panel along the axis of symmetry were compared to those from the manually-calculated solution as shown in table 3B.13-9.

The magnitude of the error reflects the use of graphical extrapolation in conjunction with a relatively coarse mesh of constant strain elements.

This verification problem demonstrates the performance of the constant strain finite-elements to solve an elasticity problem where shear effects are significant. These results confirm the known limitations of this type of element.

Node 61	-52.0	-48.8
Node 1	146.0	126.8

3B.13.2.8 FINEL Example 8, Analysis of a Deep Elastic Panel (Finer Mesh Size)

The purpose of this test problem is to compare the response of a deep elastic panel subjected to a uniformly distributed load determined using FINEL with a closed-form solution to the same

problem. The problem is identical to the one presented in paragraph 3B.13.2.7 except that the mesh size of the finite model has been reduced. The actual mesh size of the finite-element model is shown in figure 3B.13-17.

The closed-form solution is based on Timoshenko, Elasticity.[8] For comparison purposes, the FINEL results at the nodal points located at the top and bottom of the panel along the axis of symmetry are extrapolated from the centroidal plate element results along the diagonal away from these nodal points using the following cubic polynomial curve fit algorithm.[9]

$$4 = (ao + x (a1 + x (a2 + a3x)))$$

The results from the FINEL solution for the stress at the points of interest were compared to those from the manually calculated solution as shown in table 3B.13-10.

This verification problem demonstrates the performance of the constant strain finite-elements to solve an elasticity problem where shear effects are significant. These results confirm the known limitations of this type of element.

1	137.925	126.8

3B.13.3 EXTENT OF APPLICATION

FINEL is used to perform the cracked-section analysis of the containment structure, based on an axisymmetric analysis. The program performs a design check of the structure for which all geometric and design parameters are known.

3B.14 TENDON COMPUTER PROGRAM CE 239

A. Description

The dome tendon computer program calculates forces and pressures on a hemispherical dome of a prestressed, three-buttress concrete containment building, resulting from prestress by two orthogonal groups of vertical dome tendons and one group of horizontal hoop tendons.

The program calculates pressures at elements in the radial direction, and forces at nodes in the circumferential (hoop or azimuth) and meridional directions. Nodal forces in the hoop and meridional directions are calculated at each node point.

The pressures and forces calculated by this program are intended for use as input to a finite-element computer program to determine the stress distribution in the dome.

B. Validation

Program verification and document traceability are available at Bechtel Western Power Corporation.

3B.15 COMDAM COMPUTER PROGRAM (COMDAM)

3B.15.1 DESCRIPTION

Nuclear power plant structures are usually made up of several substructures with different dynamic characteristics. Addition-ally, the superstructure and the foundation are coupled to form the total soil-structure interaction system. In order to evaluate the structure responses due to seismic excitation, the proper modeling of the damping characteristics for the total system must be adequately treated. In general, the structure damping is usually specified by a fraction of critical viscous damping for each mode of vibration, and the soil damping represented by dashpots. Because damping varies as to magnitude and type, the classical model analysis generally is not strictly applicable to such a highly complex system. Therefore, it will be desirable to obtain the approximate composite modal damping values for the component-structure-foundation interaction system.

3B.15.2 BASIC THEORY AND METHOD OF APPROACH

The formulation of a rigorous composite damping matrix for complex systems can be derived by first obtaining the damping submatrices of the substructures as free-free systems, and then assembling these submatrices into a global matrix that represents the damping characteristics of the total system.

Given the modal damping values of a fixed base substructure, the corresponding damping matrix $[C_{fb}]$ can be obtained by:

$$[C_{fb}] = [\phi^{-1}]^T \, [{}^{\prime}2\zeta iWi_{.}] \, [\phi^{-1}]$$

where the ζi are the modal damping values and Wi and $[\phi]$ are the eigenvalues and eigenvectors of the undamped fixed-base sub-structure obtained from the solution of the eigenvalue problem:

$$[K_{fb}]\ [\phi] - \{W^2\}\ [M_{fb}]\ [\phi] = 0$$

Once the fixed-base damping matrix is known, the free-free damping matrix [Cff] of the substructure can be obtained from the following transformation:

$$[C_{ff}] = [\alpha^{-1}]^T [C_{fb}]\ [\alpha^{-1}]$$

where $[\alpha] = \begin{bmatrix} I & O \\ T & I \end{bmatrix}$ is the transformation matrix and matrix [T] is defined by the displacements of the interior freedoms due to successive unit displacement of boundary points, all other boundary points being totally constrained.

After the free-free damping matrices of each substructure are formed, these submatrices are then assembled into the global damping matrix [C].

Finally, the composite modal damping values β for the total system are then calculated by assuming that normal modes exist in the classical sense which is equivalent to neglecting the off-diagonal terms in the total system damping matrix in generalized coordinates.

$$\beta_n = \frac{\{Q\}_n^T [C]\ \{Q\}_n}{ZW_n}$$

where W_n and $\{Q\}_n$ are the eigenvalue and eigenvector of the n-th mode of the undamped total system and $[Q]^T [M] [Q] = [I]$.

3B.15.3 PROGRAM VERIFICATION

Evaluation of the adequacy of composite modal damping values obtained by the method described above may be assessed by comparing the responses using normal mode solution with the corresponding responses from the rigorous solution obtained by solving the coupled equations of motion.

The formulation of the damping matrix and the calculation of composite modal damping have been implemented into the Bechtel Standard Computer Program DAMPSI (CE 251) which has been verified. Therefore, it will be only necessary to prove that the composite modal damping values obtained by the COMDAM program code are similar to those obtained from DAMPSI program.

The structural properties and sketch of the test problem are shown in table 3B.15-1 and figure 3B.15-1, respectively; the test problem is the same as the VM-A03 model of the DAMPSI program. System frequencies and comparison of the damping results are tabulated in table 3B.15-2, and the system mode shapes are graphed in figure 3B.15-2.

From a comparison of the results, it can be concluded that the COMDAM approach is appropriate and correct.

3B.16 ICES-STRUDL II COMPUTER PROGRAM CE 901

3B.16.1 DESCRIPTION

The STRUDL subsystem of ICES is designed as a structural information system, to assist the engineer throughout the design process. STRUDL is designed for application to a wide range of structural types including two and three dimensional structures consisting of truss and frame members. The program assumes, for the frame analysis, that the linear, slender, elastic members are subjected to small displacements. Member end conditions can be pinned or rigid. A wide variety of loading conditions and combinations can be considered.

For program limitations, see Appendix A in the Bechtel developed user's manual, and STRUDL news.

3B.16.2 VALIDATION

The solutions to test problems have been demonstrated to be essentially identical to the results obtained using the following recognized public-domain computer programs.

- SAP 1.9 program (Bechtel standard computer program)
- MSC/NASTRAN (MacNeil Schwendler Corporation)
- CE 800 BSAP (Bechtel standard computer program)
- CE 401 (Bechtel standard computer program; AISC computer program for steel beam and girder design)

Agreement has also been established between STRUDL program results and the results of benchmark computer problems and solutions using other independent programs available in

engineering journals. Document traceability is available at Bechtel Power Corporation.

3B.16.3 EXTENT OF APPLICATION

The program was used to perform structural analysis for pipe supports.

3B.17 SARGENT AND LUNDY PIPING ANALYSIS COMPUTER PROGRAMS

3B.17.1 INTEGRATED PIPING ANALYSIS SYSTEM COMPUTER PROGRAM (PIPSYS)

The program number for PIPSYS is 09.5.065-6.1.

3B.17.1.1 Description

PIPSYS analyzes piping systems of power plants for static and dynamic loadings, and computes the combined stresses. The following analyses are performed.

A. Static: Analysis of thermal, displacement, distributed, and concentrated weight loadings on piping systems.

B. Dynamic: Analysis of piping system response to seismic and fluid transient loads.

C. Stress Combination: Computation of the combined stresses in the piping components in accordance with the ASME Boiler and Pressure Vessel Code, Section III.(1)

The static, dynamic, and stress combination analyses can be performed independently or in sequence. Results of the static and dynamic analyses can be stored on magnetic tape for use at a later date to perform the stress combination analysis. The piping configuration can be plotted on a CalComp plotter.

The input consists of the piping system geometry, material properties, and static and dynamic loading. Various options exist to control the length of the output. The default option generally prints only the summary of input data and final results.

SARGENT AND LUNDY PIPING ANALYSIS

COMPUTER PROGRAM

PIPSYS was developed at Sargent and Lundy in 1972. It is currently maintained on a UNIVAC 1106 operating under EXEC-8.

3B.17.1.2 Validation

To demonstrate the validity of the PIPSYS program, the following three examples are presented.

To illustrate the validity of the static portion of PIPSYS, the problem shown in figure 3B.17-1 was analyzed and the results compared to those given in reference 2. Table 3B.17-1 shows the comparison of member end moments. As shown, the results from PIPSYS and reference 2 are in good agreement.

Table 3B.17-1

COMPARISON OF MOMENTS FOR SELECTED MEMBERS

	Moments From Reference 2 (kip-ft)	Moments From PIPSYS (kip-ft)
M_{AB}	106.0	102.8
M_{BA}	72.0	72.5
M_{BC}	133.0	131.8
M_{CB}	133.0	131.8
M_{CD}	-133.0	-131.8
M_{DC}	-133.0	-131.8
M_{DE}	133.0	131.8
M_{ED}	86.0	84.2
M_{BE}	-158.0	-156.6
M_{EB}	-158.0	-156.6
M_{FE}	106.0	102.8
M_{EF}	72.0	72.5

To illustrate the validity of the stress combination analysis portion of PIPSYS, the problem outlined in reference 3 was reanalyzed on the PIPSYS program. The layout of the piping system is shown in figure 3B.17-2. The stress analysis is performed at location 19. The summary of loads sets and descriptions are presented in table 3B.17-2. The results of the stress analysis are presented in tables 3B.17-3 and 3B.17-4. The notations and equation numbers correspond to the ASME Boiler and Pressure Vessel Code.(1)

It is observed that the PIPSYS results are very close to those presented in reference 3.

To illustrate the validity of the dynamic analysis portion of PIPSYS, a problem was analyzed and the results obtained from PIPSYS were compared with those from two public domain computer programs, DYNAL(4) AND NASTRAN.(5)(6)

Figure 3B.17-3 shows a schematic representation of the piping system analyzed. The system is modeled with simple beam elements with a total of 136 degrees-of-freedom. Figure 3B.17 4 shows the time-dependent blowdown forces at the relief valves' locations. Results of PIPSYS are compared with DYNAL and NASTRAN in table 3B.17-5 and figure 3B.17-5. The results from all three programs are quite close.

3B.17.2 INTEGRATED PIPING ANALYSIS SYSTEM FOR MICROCOMPUTERS (PIPSYS/PC)

The program number for PIPSYS/PC is 03.7.026-1.20 and the authors are J. A. Stirk, S. A. Keller, and N. A. Holmes.

3B.17.2.1 General Description

PIPSYS/PC consists of (1) an interactive graphics module for the generation, review, and modification of piping data, and (2) static and dynamic modules. PIPSYS/PC can be used as a stand-alone piping analysis system or as a graphic input or analysis interface to the mainframe PIPSYS programs (Sargent and Lundy program numbers 09.5.218-2.0 and 09.5.065-6.1).

Table 3B.17-5

20	103.03	107.7136	107.52304

3B.17.2.2 Validation

The analysis results of the PIPSYS/PC run programs were compared to the results produced by PIPSYS on the mainframe. All results were identical.

3B.17.3 NONLINEAR HEAT TRANSFER ANALYSIS OF AXISYMMETRIC SOLIDS (NOHEAT)

The program number for NOHEAT is 09.5.075 and the authors are I. Harhoomand and E. L. Wilson, University of California, Berkeley, California.

3B.17.3.1 Program Scope

The program uses the finite element method to calculate the temperature distribution in an axisymmetric solid that results from nonlinear heat transfer. The nonlinear effects of conduction, radiation, and convection can be included. A temperature history for each node point is presented. Internal generation has been provided for several of the most frequently used meshes. In addition, stresses resulting from linear thermal expansion are calculated for certain appropriate sections. Options have been added that calculate linearized thermal gradients and that plot the finite-element mesh.

3B.17.3.2 Validation

Two problems have been selected to validate this program. The first is taken from "ASME/Pressure Vessel and Piping/1972 Computer Program Verification" and is problem AER-1, "An Axisymmetrical Transient Thermal Analysis."

The second problem is a straight length of pipe subject to an internal temperature change of 432F in 0.5 second. This problem was solved using both NOHEAT and TSHOK (Sargent and Lundy program number 09.5.033) and the results were compared.

3B.17.4 HYDRAULIC TRANSIENT ANALYSIS (HYTRAN)

The program number for HYTRAN is 09.5.121 and the authors are C. H. Li and V. K. Verma.

3B.17.4.1 Program Scope

HYTRAN calculates pressures, velocities, and force transients in a liquid-filled piping network with up to 60 legs of 40 nodes or 200 legs of 15 nodes each. Transients may be initiated by valve closure, pump trip or startup, or by pressure changes at a piping terminal.

The pump characteristics may be described using two methods: polynomial input or trigonometric input. Sets of data are provided in HYTRAN for pump-specific speeds of 1800, 7600, and 13500 rpm. These data may be chosen and then modified to match available data, or the entire set of data may be input.

Output of force-time history can be plotted and/or saved on a data file for use as input to PIPSYS.

3B.17.4.2 Validation

The program was validated by comparison with the following problems:

A. Hydraulic Transients; V. L. Streeter and E. B. Wylie, 1967 (Problems 3.1, 3.4, and 3.6).

B. Waterhammer Analysis, John Parmakian, 1963 (Problem on pg. 83).

C. Transient Analysis of Offshore Loading Systems, V. L. Streeter and E. B. Wylie, Transactions of the ASME Journal of Engineering Industry, February 1975.

3B.17.5 LOCAL STRESSES IN SPHERICAL AND CYLINDRICAL SHELLS DUE TO EXTERNAL LOADINGS ON NOZZLES (LSS)

The program number for LSS is 09.5.117 and the author is A. J. Weiss.

3B.17.5.1 Program Scope

This program uses the Bijlaard method of stress analysis to calculate stresses due to external loading on nozzles described in the Welding Research Council Bulletin 107. All the empirical curves in Bulletin 107 were put into equation form, using the curve-fitting program POLYFIT (Sargent and Lundy program number 09.5.130-1.0).

3B.17.5.2 Validation

LSS was validated by manual calculation. All equations generated by POLYFIT were also checked by comparing the values generated by the equations with the original input data.

APPENDIX 3C

DESIGN OF STRUCTURES FOR TORNADO MISSILE IMPACT

CONTENTS

CONTENTS (Cont'd)

TABLES

FIGURES

APPENDIX 3C
DESIGN OF STRUCTURES FOR
TORNADO MISSILE IMPACT

3C.1 INTRODUCTION

3C.1.1 GENERAL

This appendix contains methods and procedures for analysis and design of steel and reinforced concrete structures and structural elements subject to tornado-generated missile impact effects. Structures subject to missile impact, postulated missiles, and other concurrent loading conditions are identified in section 3.5.

Missile impact effects are assessed in terms of local damage and structural response. Local damage (damage that occurs in the immediate vicinity of the impact area) is assessed in terms of perforation and spalling.

Evaluation of local effects is essential to ensure that protected items would not be damaged directly by a missile perforating a protective barrier, or by secondary missiles such as spall particles. Empirical formulae are used to assess local damage. This evaluation was made in accordance with BC-TOP-9-A.

Evaluation of structural response is essential to ensure that protected items are not damaged or functionally impaired by deformation or collapse of the impacted structure.

STRUCTURAL RESPONSE DUE TO

MISSILE IMPACT LOADING

Structural response is assessed in terms of deformation limits, strain energy capacity, structural integrity, and structural stability. Structural dynamic principles are used to predict structural response.

3C.1.2 PROCEDURES

The general procedures for analysis and design of structures or structural elements for missile impact effects include:

A. Defining the missile properties (such as type, material, deformation characteristics, geometry, mass, trajectory, strike orientation, and velocity).

B. Determining impact location, material strength, and thickness required to preclude local failure (such as perforation for steel targets and spalling for reinforced concrete targets).

C. Defining the structure and its properties, (such as geometry, section strength, deformation limits, strain energy absorption capacity, stability characteristics, and dynamic response characteristics).

D. Determining structural response considering other concurrent loading conditions

E. Checking adequacy of structural design (stability, integrity, deformation limits, etc.) to verify that local damage and structural response (maximum deformation) will not impair the function of safety-related items.

3C.2 STRUCTURAL RESPONSE DUE TO MISSILE IMPACT LOADING

3C.2.1 GENERAL

When a missile strikes a structure, large forces develop at the missile-structure interface, which decelerate the missile and accelerate the structure. The response of the structure depends on the dynamic properties of the structure and the time-dependent nature of the applied loading (interface force-time function). The force-time function is, in turn, dependent on the type of impact (elastic or plastic) and the nature and extent of local damage.

In an elastic impact, the missile and the structure deform elastically, remain in contact for a short period of time (duration of impact), and subsequently disengage due to the action of elastic interface restoring forces.

In a plastic impact, the missile or the structure (or both) may deform plastically or sustain permanent deformation or damage (local damage). Elastic restoring forces are small, and the missile and the structure tend to remain in contact after impact. Plastic impact is much more common in nuclear plant design than elastic impact (which is rarely encountered). For example, test data indicate that the impact from all postulated tornado-generated missiles can be characterized as a plastic collision.

If the interface forcing function can be defined or conservatively idealized (from empirical relationships or from theoretical considerations), the structure can be modeled

mathematically, and conventional analytical or numerical techniques can be used to predict structural response. If the interface forcing function cannot be defined, the same mathematical model of the structure can be used to determine structural response by application of conservation of momentum and energy balance techniques with due consideration for type of impact (elastic or plastic).

In either case (in lieu of a more rigorous analysis), a conservative estimate of structural response can be obtained by first determining the response of the impacted structural element and then applying its reaction forces to the supporting structure. The predicted structural response enables assessment of structural design adequacy in terms of strain energy capacity, deformation limits, stability, and structural integrity.

3C.2.2 MASS-SPRING MODEL

To facilitate determination of structural response due to missile impact loading, a dynamically similar lumped mass spring model of the structure can be utilized.

3C.2.2.1 Definition of Model

The structural element that is struck by the missile is modeled as a mass, $M_{(e)}$, backed by a spring that has a resistance-displacement function corresponding to that of the struck element with a concentrated load applied at the location of impact. For dynamic similarity and calculation convenience,

the model is defined so that the following conditions are satisfied:

A. The deflection, internal strain energy, and kinetic energy of the model must be the same as that of the structure.

B. The external work done on the model by the missile and by other concurrent loads must be equal to (or greater than) the external work done on the structure.

Other loads that may be present during structural response can be accounted for in the model by replacing these loads with equivalent concentrated loads (that will do the same amount of external work on the model as would be done on the structure during structural response), using procedures such as those contained in references 1, 2, and 3.

Following these procedures, the relative dynamic displacement of the model will be equal to that of the structure.

3C.2.2.2 Determination of Effective Mass

For distributed mass elements (such as slabs and beams), the effective mass, M_e, during impact varies with the deformed shape of the element during impact. In order for the whole element to be deformed during impact, the duration of impact, t_i, must exceed the stress wave travel time, t_c, between the impact location and the supports. If t_c is significantly less than t_i (which is most generally the case), the deflected shape

during impact can be approximated by the first mode shape which results in the following expression for M_e:

$$M_e = \frac{k}{\omega^2} \text{ or } M_e = k\left[\frac{T_n}{2\pi}\right]^2 \qquad (2\text{-}1)$$

where:

k = spring constant of model spring (same as for a concentrated load applied at the impact location), (load per unit displacement)

ω = calculated natural frequency of the element, rad/s

T_n = calculated natural period of the element, s

For relatively deep short-span elements, the element thickness or depth establishes a lower limit of coupled mass during impact which can exceed that determined from equation 2-1. For these cases, the effective mass should not be less than the following:

For slabs and plates:

$$M_e = \frac{Y}{g} T(D + T)^2 \qquad (2\text{-}2)$$

For beams:

$$M_e = M_b (D + 2T) \qquad (2\text{-}3)$$

where:

γ = weight per unit volume

M_b = mass per unit length of member

T = thickness or depth of member

D = maximum missile contact dimension or effective diameter

Very long span flexural members subjected to a very short duration impact may have insufficient time to approach a first mode deformed shape during impact, in which case effective mass is an undefined variable. An example of this would be the case where the stress wave travel time to the supports, t_c, exceeds the duration of the impact, t_i. In this case, design adequacy can generally be demonstrated by an analysis using an effective mass corresponding to a similar element with a shorter span.

3C.2.3 FORCE-TIME SOLUTION

A force-time solution can be used to determine the maximum displacement when the interface forcing function can be defined (see BC-TOP-9-A). This enables direct solution of the equation(s) of motion for the struck element.

$$F_{(t)} + F_o - R_{(x)} = M_e\ddot{X} \qquad t \leq t_i \qquad (2-4)$$

$$F_o - R_{(X)} = M_e\ddot{X} \qquad t > t_i \qquad (2-5)$$

$$F_o - R_{(x)} = (M_e + M_m)\ddot{X} \qquad t > t_i \qquad (2-6)$$

where:

$F_{(t)}$ = force-time function

F_o = equivalent force due to other concurrent loads

$R_{(x)}$ = available resisting spring force as a function of displacement, x

$\ddot{X}$ = acceleration of mass M_e

M_e = effective mass of the struck element

M_m = mass of the missile

T = time

T_i = duration of impact (pulse duration)

Equation 2-4 is used when the time to maximum response, t_m, is less than t_i. When t_m is greater than t_i and the missile remains disengaged from the struck element (such as in an elastic collision) subsequent to t_i, equations 2-4 and 2-5 are used. When t_m is greater than t_i and the missile and struck element remain in contact subsequent to t_i (plastic impact), equations 2-4 and 2-6 are used. It should be noted that in using these relationships, the forcing function, $F_{(t)}$ should be based on the change of missile velocity, V_c, during time t_i. A more conservative solution is obtained when the striking velocity, V_s, is used in lieu of V_c for defining $F_{(t)}$.

3C.2.4 RESPONSE CHART SOLUTION

Response charts such as figure 3C.2-1 from reference 1 (with modifications) can be used to determine structural response (in lieu of numerical integration of equations 2-4 through 2-6) in cases where the idealized forcing function, $F_{(t)}$, and resistance-displacement function, $R_{(x)}$, are compatible with the charts.

Structural response is determined by entering the charts with calculated values of C_T and C_R to determine the ductility ratio, μ. The dimensionless ratios are defined as follows:

$$C_R = \frac{R_y}{F} \qquad (2\text{-}7)$$

$$C_T = \frac{t_i}{T_n} \qquad (2\text{-}8)$$

$$\mu = \frac{x_m}{x_e} \qquad (2\text{-}9)$$

where:

C_R	=	resistance-to-force ratio
C_T	=	time ratio
μ	=	ductility ratio
R_Y	=	yield resistance
F	=	peak force
t_i	=	force duration
T_n	=	natural period
X_m	=	maximum displacement

X_e = yield displacement

When other loads are acting on the structural element during structural response, the ductility ratio þ and maximum displacement X_m can be determined by the following procedure:

A. Determine C_R using R_a in place of R_y

$$R_a = R_y - R_o \qquad (2\text{-}10)$$

where:

R_o = effective resistance required for other loads (see paragraph 3C.2.2.1 and figure 3C.2-2)

R_a = available resistance

B. Determine the partial ductility ratio μ' from figure C.2-1 or 3C.2-3

$$\mu' = \frac{X'_m}{X'_e} \qquad (2\text{-}11)$$

$$X'_m = X_m - X_o \qquad (2\text{-}12)$$

$$X'_e = X_e - X_o \qquad (2\text{-}13)$$

C. Determine the maximum displacement and combined ductility ratio

$$X_m = \mu'(X_e - X_o) + X_o \qquad (2\text{-}14)$$

$$\mu = \frac{\mu'(X_e - X_o) + X_o}{X_e} \qquad (2\text{-}15)$$

3C.2.5 ENERGY BALANCE SOLUTION

The energy balance method can be used to obtain an upper limit estimate of structural response. This method involves determining the displacement, X_m, at which the available strain energy of the system is equal to the kinetic energy of the system after impact, E_s. An upper limit estimate of E_s is obtained by assuming resisting spring forces, R_x, do not act during impact.

The impact can then be characterized as a collision of two solid bodies; a missile with velocity V_s and mass M_m striking a structural element of mass M_e which is initially at rest. The kinetic energy of the system after a plastic impact would, therefore, be:

$$E_s = \frac{M_m^2 V_s^2}{2(M_m + M_e)} \qquad (2\text{-}16)$$

The kinetic energy after an elastic impact (with the coefficient of restitution assumed to be unity) would be:

$$E_s = \frac{2M_m^2 M_e V_s^2}{(M_m + M_e)^2} \qquad M_m \le M_e \qquad (2\text{-}17)$$

$$E_s = \frac{M_m V_s^2}{2} \qquad M_m > M_e \qquad (2\text{-}18)$$

The maximum displacement, X_m, can then be determined as the displacement at which the available strain energy (see figure 3C.2-2) is equal to E_s.

For an elastic response:

$$X_m = X_o + \left[\frac{2\,E_s}{k}\right]^{1/2} \qquad X_m < X_e \qquad (2\text{-}19)$$

For an elasto-plastic response:

$$X_m = \frac{E_s}{k\,(X_e - X_o)} + \frac{X_e + X_o}{2} \qquad X_m > X_e \qquad (2\text{-}20)$$

$$\mu = \frac{E_s}{R_y(X_e - X_o)} + \frac{X_o}{2X_e} + \frac{1}{2} \qquad (2\text{-}21)$$

where:

X_o = displacement due to other loads

X_e = yield displacement

X_m = maximum combined displacement

R_y = yield resistance

k = elastic spring constant

μ = required ductility ratio

For nonlinear systems, X_m is the displacement that satisfies the following relationship:

$$E_s = \int_{X_o}^{x_m} R_{(x)} d_x - R_o(X_m - X_o) \qquad (2\text{-}22)$$

where:

$R_{(x)}$ = the resistance as a function of displacement

R_o = equivalent static resistance required for other loads

3C.2.6 STRUCTURAL ASSESSMENT

The predicted structural response enables assessment of design adequacy in terms of strain energy capacity, deformation limits, stability, and structural integrity.

For elements required to remain elastic, a check is made to ensure that the usable strength capacity of the element would not be exceeded at the calculated displacement.

For structures allowed to displace beyond yield (elasto-plastic response) a check is made to ensure that deformation limits would not be exceeded by comparing calculated displacements or required ductility ratios with allowable values (such as contained in section 3C.3).

For nonlinear elements, the strain energy utilized in resisting the impact loading, E_s, must be less than the available strain energy at failure, E_f.

$$E_f = \int_{X_o}^{X_f} R_{(x)}dx - R_o(X_f - X_o) \qquad R_o \le R_f \qquad (2\text{-}23)$$

where:

E_f = available strain energy at failure

X_f = displacement at failure

R_f = resistance at failure

When E_f can be well defined such as from test results, E_s should not be greater than $0.7E_f$. When E_f is analytically defined, E_s should not exceed $0.5E_f$.

3C.3 DESIGN GUIDELINES

This section contains criteria and design guidelines for determination of structural capacities, deformations, deformation limits, and dynamic properties of structural elements subject to missile impact.

3C.3.1 GENERAL

Resistance-displacement functions are defined utilizing conventional structural analysis techniques for determining elastic displacements. Methods such as limit design and yield line theory are utilized for determining limiting resistance values for ductile elements. Some typical values of effective yield displacement and maximum resistance for ductile flexural members are listed in tables 3C.3-1 and 3C.3-2 (similar expressions can be developed for other configurations and load cases).

Structures and structural elements are allowed to sustain inelastic deformations, providing the deformation and strain limits specified herein are not exceeded. These structures and structural elements must be designed and proportioned to ensure ductile behavior in the intended deformation mode. Failure leading to collapse in a less ductile failure mode must be precluded and structural stability must be maintained.

The maximum allowable resistance is determined using dynamic section strengths with appropriate capacity reduction factors.

3C.3.1.1 Dynamic Material Strengths

Dynamic material strengths are obtained by multiplying the static material strength values by dynamic increase factors (DIFs). DIF values for various materials are contained in table 3C.3-3

STRUCTURAL RESPONSE DUE TO

MISSILE IMPACT LOADING

Table 3C.3-1

RESISTANCE-YIELD DISPLACEMENT VALUES FOR BEAMS

DESCRIPTION	RESISTANCE	YIELD DISPLACEMENT
(1) CANTILEVER 	$R = \frac{M_u}{L}$	$X_e = \frac{RL^3}{3EI}$
(2) SIMPLY SUPPORTED 	$R = \frac{4M_u}{L}$	$X_e = \frac{RL^3}{48EI}$
(3) FIXED SUPPORTS 	$R = \frac{4(M_u^+ + M_u^-)}{L}$	$X_e = \frac{RL^3}{192EI}$
(4) MULTI-SPAN 	$R = \frac{4(M_u^+ + M_u^-)}{L}$	$X_e = \frac{0.011RL^3}{EI}$

WHERE M_u^+ = PLASTIC POSITIVE MOMENT CAPACITY
M_u^- = PLASTIC NEGATIVE MOMENT CAPACITY
I = MOMENT OF INERTIA (in^4)
FOR REINFORCED CONCRETE $I = I_e$

STRUCTURAL RESPONSE DUE TO

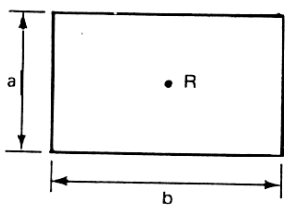
MISSILE IMPACT LOADING

Table 3C.3-2

RESISTANCE YIELD DISPLACEMENT VALUES

FOR SLABS AND PLATES[a]

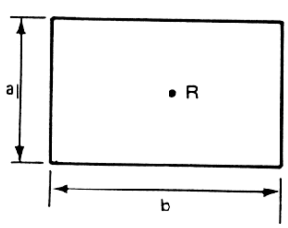
DESCRIPTION	RESISTANCE	YIELD DISPLACEMENT
(1) SIMPLY SUPPORTED ON ALL 4 SIDES WITH LOAD AT CENTER	$R = 2\pi M_u$	$X_e = \frac{\alpha R a^2}{12EI}(1-\nu^2)$



b / a	1.0	1.1	1.2	1.4	1.6	1.8	2.0	3.0	∞
α	.1390	.15.8	.1624	.1781	.1884	.1944	.1981	.2029	.2031

(2) FIXED SUPPORTS ON ALL 4 SIDES WITH LOAD AT CENTER

α = DISPLACEMENT COEFFICIENT
ν = POISSON'S RATIO
t = THICKNESS (in)
E = MODULUS OF ELASTICITY (lb/in^2)
I = MOMENT OF INERTIA PER UNIT WIDTH (in^4/in) FOR REINFORCED CONCRETE SECTION $I = I_e$
M_u^+ = PLASTIC POSITIVE MOMENT CAPACITY (in lb/in)
M_u^- = PLASTIC NEGATIVE MOMENT CAPACITY (in lb/in)



$R = 2\pi (M_u^+ + M_u^-)$ $\quad$ $X_e = \frac{\alpha R a^2}{12EI}(1-\nu^2)$

b/a	1.0	1.2	1.4	1.6	1.8	2.0	∞
α	.0671	.0776	.0830	.0854	.0864	.0866	.0671

a. From references 4 through 8. For plates, this neglects membrane action. Therefore a more detailed analysis utilizing membrane theory is acceptable.

STRUCTURAL RESPONSE DUE TO

MISSILE IMPACT LOADING

Table 3C.3-3

DYNAMIC INCREASE FACTOR[a]

Material and Stress Condition	DIF
Reinforced Or Prestressed Concrete	
Concrete:	
Compression	1.25
Diagonal tension and direct shear (punch out)	1.10
Reinforcing steel:	
Tension, compression and shear steel	
40 ksi yield strength steel	1.20
50 ksi yield strength steel	1.15
60 ksi yield strength steel	1.10
Structural Steel	
Flexural, shear, tension and compression for:	
$F_y \leq 40$ ksi yield strength steel	1.20
$F_y \leq 50$ ksi yield strength steel	1.10
$F_y \leq 60$ ksi yield strength steel	1.00
Shear 1.00	

a. Based on information contained in references 9 through 14.

$$f_{dyn} = (DIF) f_{stat} \qquad (3\text{-}1)$$

where:

f_{dyn} = allowable dynamic strength value

f_{stat} = specified static strength value

DIF = dynamic increase factor

3C.3.1.2 Allowable Deformations

Maximum allowable displacements are determined from the ductility ratios (ratio of maximum displacement to yield displacement) contained in table 3C.3-4 and the provisions of paragraph 3C.3.1.3 and subsections 3C.3.2 and 3C.3.3. As an alternative, the allowable displacement of reinforced concrete flexural members can be based on an upper limit for plastic hinge rotation which can be defined as follows:[9]

$$r_\theta = 0.0065\frac{d}{c} \leq 0.07 \qquad (3\text{-}2)$$

where:

r_θ = hinge rotation, radians

d = distance from compression face to centroid of tensile steel reinforcement, in.

c = distance from compression face to the neutral axis at ultimate strength, in.

A check should be made to ensure that the resulting deformation will not impair the function of essential safety-related equipment.

3C.3.1.3 Nonductile Elements and Components

The deformation of nonductile elements (those subject to abrupt or brittle type failure) must be limited to ensure that the strength capacity of these elements is not exceeded.

STRUCTURAL RESPONSE DUE TO

MISSILE IMPACT LOADING

Table 3C.3-4

DUCTILITY RATIOS

Member Type and Load Condition	Maximum Allowable value of μ
Reinforced Concrete	
Flexure:	
Beams and one-way slabs	$\frac{0.05}{p - p'} \leq 10$
Slabs with two-way reinforcing	$\frac{0.05}{p - p'} \leq 10^{(a)}$
Axial compression:	
Walls and columns[30]	1.3
Shear, concrete beams and slabs in region controlled by shear:	
Shear carried by concrete only	1.3
Shear carried by concrete and stirrups	1.6
Shear carried completely by stirrups	2.0
Shear carried by bent-up bars	3.0
Structural Steel	
Columns and beams with uniform moment[31]	$\mu \leq \frac{14x10^4}{F_y\left(\frac{KL}{r}\right)^2} + 1/2 \leq 10$
Beams with moment gradient	10
Shear	10
Axial tension and steel plates membrane tension[32]	$0.5\frac{e_u}{e_y}$

a. A ductility ratio of 22.8 was used in the cask drop analysis.

Notes:

1. Based on information contained in references 9, 12, and 14 through 25.

2. p and p' are the positive and negative reinforcing steel ratios.

3. See figure 3C.3-2 for allowable ductility ratios where there is a beam-column action.

4. KL/r is the member slenderness ratio. F_y is the yield stress (ksi).

5. e_u and e_y are the ultimate and yield strains. e_u Shall be taken as the ASTM specified minimum.

Structures may contain nonductile elements or components and still be allowed to deform inelastically (per paragraph 3C.3.1.2) provided that the strength capacity of the nonductile elements or components is at least 20% greater than the imposed loading from the structure in its fully developed ductile deformation mode.

3C.3.2 REINFORCED CONCRETE

The dynamic section strengths of reinforced concrete members are determined using strength design methods and dynamic material strengths. For reinforced concrete flexural members (with tension reinforcing only), the plastic resisting moment is:

$$M_{\mu} = \phi A_s f_{dy}\left(d - \frac{a}{2}\right) \qquad (3\text{-}3)$$

$$a = \frac{A_s f_y}{.85 f'_c b}$$

where:

ϕ = capacity reduction factor with a value of 0.9 for flexure

A_s = area of tension steel

a = depth of equivalent stress block

b = width of member

d = distance from compression face to centroid of tension steel

f_{dy} = dynamic yield strength of reinforcing steel (see paragraph 3C.3.1.1)

f'_c = concrete compressive strength, psi

f_y = yield strength of steel, psi

The moment capacity of members with compression reinforcing can be similarly obtained using procedures such as contained in reference 26.

The flexural stiffness of reinforced concrete members is determined using the effective moment of inertia, I_e (10), which is defined as follows:

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left[1 - \left(\frac{M_{cr}}{M_a}\right)^3\right] I_c \leq \frac{1}{2}\left(I_g + I_c\right) \qquad (3\text{-}4)$$

where:

M_{cr} = cracking moment = $1.25\sqrt{f'_c}\,bt^2$

M_a = maximum moment in member. For member deforming plastically, $M_a = M_u$

I_g = gross uncracked section moment of inertia

I_c = transformed moment of inertia of the cracked section = Fbd^3

F = coefficient for determining the transformed moment of inertia of the cracked section (see figure 3C.3-1)

To ensure ductile flexural deformations, reinforcing ratios must be within the following limits:

For members with tension reinforcing only:

$$\frac{1.4\sqrt{f'_c}}{f_y}\left(\frac{t}{d}\right)^2 \leq \frac{A_s}{bd} \leq 0.25\,\frac{f'_c}{f_y} \qquad (3\text{-}5)$$

For members with tension and compression reinforcing:

$$\frac{1.4\sqrt{f'_c}}{f_y}\left(\frac{t}{d}\right)^2 \leq \frac{A_s}{bd} \qquad (3\text{-}6)$$

$$\frac{A_s - A'_s}{bd} \leq 0.25\,\frac{f'_c}{f_y} \qquad (3\text{-}7)$$

where:

f'_c = compressive strength of concrete, psi

f_y = yield strength of reinforcing steel

b = width of member

t = total thickness of member

A'_s = area of compression steel

Reinforcing ratios must also satisfy other design requirements such as minimum temperature steel and reinforcing limits for seismic loading.

To ensure ductile deformation in flexure, the shear capacity, as determined by conventional procedures (9) using appropriate DIF for shear, should be at least 20% greater than that required to develop the ductile deformation mode. In cases where the thickness of one-way and two-way reinforced concrete elements is greater than (or equal to) the thickness for threshold of spalling, as determined by applicable empirical local damage formulae (see BC-TOP-9-A) or tests, further design provision for punching shear is not required. Likewise, for two-way elements where the shear intensity diminishes radially from the potential back face fracture plane, further shear failure will not occur outside the fracture plane, and further design provisions for reaction shear is not required.

Impact tests on reinforced concrete panels indicate that the extent of local damage is essentially independent of impact location and overall structural deformation appears to be slightly greater for a center impact (attributable to effects such as an increase in coupled mass and resistance as the impact is moved closer to a support). A center impact is, therefore, considered to be the critical impact location for structural response of two-way concrete elements.

The maximum resistance of reinforced concrete columns loaded in axial compression is:

$$P_u = \phi\left(0.85f'_{dc}A_g + f_{dy}A_{sl}\right) \quad (3\text{-}8)$$

where:

f_{dc} = dynamic compressive strength of the concrete

f_{dy} = dynamic yield strength of longitudinal reinforcing steel

A_g = gross cross-sectional area of the column

A_{sl} = area of longitudinal reinforcing steel

The capacity reduction factor, ϕ, and limiting reinforcing requirements shall be in accordance with reference 9.

The capacity of reinforced concrete members with combined axial and flexural loading can be determined from an interaction diagram based on dynamic material strengths and appropriate capacity reduction factors. The ductility ratio for dynamic axial compression loading shall not exceed that given in table 3C.3-4 for axial compression. The ductility ratio for the dynamic flexural loading is determined as follows.

A. When compression controls the design ($P > P_b$, as determined from the interaction diagram, see figure 3C.3-2 the allowable ductility ratio shall be 1.3.

B. When the compressive load P does not exceed $0.1f'_{dc}A_g$, the allowable ductility ratio shall be that listed in table 3C.3-4 for flexure.

C. When the compressive load P is greater than $0.1f'_{dc}A_g$, but less than that for balanced design, P_b, the ductility ratio shall vary linearly with P between the values specified in listings A and B.

A graphical representation of these provisions is illustrated in figure 3C.3-2.

3C.3.3 STRUCTURAL STEEL

The dynamic section strengths of structural steel members are determined using plastic design methods and dynamic material strengths.

The plastic resisting moment, M_u, of structural steel flexural members is determined as follows:

$$M_u = 0.9f_{dy}Z \quad (3\text{-}9)$$

where:

f_{dy} = dynamic yield strength of the steel (see paragraph 3C.3.1.1)

Z = plastic section modulus of the structural member

The maximum resistance of flexural members is determined by the moment or shear resistance, whichever is less. When shear controls the member, it is still capable of deforming in a ductile mode providing stability is maintained.

Riveted or bolted connections are considered nonductile components and must satisfy the provisions of paragraph 3C.3.1.3.

The maximum resistance of structural steel columns dynamically loaded in axial compression is:

$$P_u = 0.9 f_{dy} A \quad (3\text{-}10)$$

where:

A = cross-sectional area of the column

The capacities of steel members subjected to combined axial flexure can be determined using procedures such as contained in reference 27.

Structural steel members that are allowed to sustain inelastic deformations must satisfy the following provisions for stability:[a]

A. Width-Thickness Ratios:

Outstanding leg of compression flange or other element:

$$\frac{b}{t_b} < \frac{52}{\sqrt{F_y}} \quad (3\text{-}11)$$

Web of beams

$$\frac{d}{t} \leq \frac{257}{\sqrt{F_y}} \quad (3\text{-}12)$$

Web of columns

a. These values were obtained and/or derived from information contained in references 1, 2, 14, 27, and 28

$$\frac{d}{t} \leq \frac{190}{\sqrt{f_y}} \qquad (3\text{-}13)$$

Stiffened compression element

$$\frac{b_s}{t_b} \leq \frac{190}{\sqrt{f_y}} \qquad (3\text{-}14)$$

B. Slenderness Ratios

Columns and beams with uniform moment

$$\frac{KL}{r} \leq \left[\frac{1.4 \times 10^5}{(\mu - 1/2)F_y}\right]^{1/2} < \left[\frac{2.8 \times 10^5}{F_m}\right]^{1/2} \qquad (3\text{-}15)$$

Beams with moment gradients per Section 2.9 (pages 5-61) of reference 28 (AISC Manual).

where:

b = unsupported width of outstanding compression flange or other element, in.

b_s = width of stiffened compression element, in.

t_b = compression element thickness, in.

t = thickness of web, in.

d = depth of member, in.

F_y = steel yield stress, ksi

F_m = maximum stress in member (for $\mu > 1$, $F_m = F_y$, ksi

L = unsupported length of member, in.

r = radius of gyration, in.

μ = ductility ratio

K = effective length factor; for segments of laterally stayed members, K may be taken as 0.54 if adjacent segments are elastic and as 0.8 if adjacent segments are fully yielded

3C.3.4 NATURAL PERIOD OF VIBRATION FOR BEAMS AND SLABS

The structural elements subject to missile impact typically respond in their first (fundamental) mode of vibration and higher mode participation is usually negligible. Therefore, formulae and constants for determining the fundamental period of vibration are included for convenient reference.

3C.3.4.1 Beams and One-Way Slabs

Fundamental period of vibration (first mode) for beams and one-way slabs with uniformly distributed mass is:

$$T_n = \frac{2\pi}{C_n}\sqrt{\frac{ML^4}{EI}} \qquad (3\text{-}16)$$

where:

E = modulus of elasticity, psi

I = moment of inertia of beam cross-section; for reinforced concrete section, $I = I_e$, $in.^4$

L = length of beam or slab, in.

M = mass per unit length, $lb\text{-}s^2/in./in.$

C_n = coefficient (see table 3C.3-5)

3C.3.4.2 Two-Way Slabs

Fundamental period of vibration (first mode) for two-way slabs with uniform distributed mass is:

$$T_n = \frac{2\pi}{C_n}\sqrt{\frac{(1 - \nu^2)M' a^4}{EI}} \qquad (3\text{-}17)$$

where:

M' = mass per unit area, $lb\text{-}s^2/in./in.^2$

ν = Poisson's ratio; for concrete, ν varies between 0 and 0.2, and when unknown, may be taken as 0 with only a slight error

C_n = coefficient (see table 3C.3-6)

a = length of side of slab (see table 3C.3-6)

I = moment of inertia of slab per unit length ($in.^4/in.$); for reinforced concrete section, $I = I_e$

3C.3.5 LOAD CONVERSION FACTORS

The effect of other concurrent loads applied at locations on a member other than that of the impact load can be accounted for (in determining R_o) by replacing these loads with an equivalent concentrated load that will do the same amount of external work during structural response when applied at the location of

impact. For a concentrated load, F_a, applied at location a, which would displace through a distance X_a during response to a missile impact at location b, the equivalent load F_e at point b would be:

$$F_a X_a = F_e X_b$$

$$F_e = \frac{F_a X_a}{X_b} \tag{3-18}$$

$$F_e = K_L F_a$$

where:

F_e = equivalent load at location b

X_b = displacement at b due to load F_e

K_L = load conversion factor; for this example, numerically equal to X_a/X_b

For a distributed load over a length or area of a member, the load conversion factor is again determined by equating the work done by the distributed load on the member to the work done by the equivalent concentrated load applied at the impact location. Load conversion factors, K_L, for uniform loads on flexural members with midspan impact location are given in table 3C.3-7. Load conversion factors for other impact locations can be similarly obtained. The equivalent concentrated load at the impact location is then determined by multiplying the total force on the member associated with the uniform load by the load conversion factor, K_L.

APPENDIX 3F
TANGENTIAL AND RADIAL SHEAR

3F.1 GENERAL

Tangential shear stresses are evaluated in detail in this appendix. The critical loading combinations included in this appendix are listed below:

RLC No. 1: $D + F_i + P_t + T_t$

RLC No. 2: $D + F_i + T_t$

RLC No. 3: $D + F + P_v + T_o$

RLC No. 4: $D + F + E_o + T_o$

RLC No. 11: $D + F + E_{ss} + T_o$

RLC No. 15: $D + F + 1.5\ P_a + T_a$

RLC No. 18: $D + F + 1.25\ P_a + 1.25\ E_o + T_a$

RLC No. 24: $D + F + P_a + E_{ss} + T_a$

3F.2 TANGENTIAL SHEAR

There are no criteria in the code for tangential shear in pre-stressed concrete containments. The tangential shear is evaluated in the following paragraphs using Bechtel's criteria.

A. Containment Sections and Governing Loading Combinations

The only loading that induces significant tangential shear (in-plane shear) in the structure is seismic loading. Also, tangential shear may be significant only in the shell. Furthermore, the effect of

tangential shear is more significant when it occurs simultaneously with the internal pressure (postulated LOCA) because the shear capacity of a section decreases with reduced membrane compression, and internal pressure tends to reduce membrane compression due to pre-stressing and dead load. For these reasons, it will be sufficient to consider only three reference loading combinations. These combinations are: RLC Nos. 11, 18, and 24.

B. Section Resultants

Horizontal and vertical membrane forces (N_h and N_v) due to all loads other than earthquake are obtained from the FINEL analysis and are shown in table 3F-1.

Horizontal and vertical membrane forces (N_{he} and N_{ve}) and tangential shear (V_u) due to earthquake loads are also shown in table 3F-1.

C. Maximum Applied Shear

Maximum applied tangential shear must not exceed $v_u \leq 8.5bt\sqrt{f_c'} \cong 379$ k/ft. In the above equation b = width (12 inches) t = thickness (48 inches), and f_c' = concrete strength (6000 psi). This limit is based on the ACI 318-77 Code.

Table 3F-1 shows that the maximum tangential shear is far less than the maximum allowable for each section.

D. Shear Carried by Concrete

If the section is under biaxial compression, the concrete is allowed to resist the following shear:

$$V_c = \left[(N_h + N_{he})(N_v + N_{ve})\right]^{1/2}$$

Assuming, conservatively, that the maximum membrane forces and tangential shear due to seismic loads occur at the same point, the concrete allowable shear force, V_c, is calculated using the above equation. These values are also shown in table 3F-1 for the given loading combinations.

E. Evaluation of Results

Table 3F-1 shows that V_u exceeds V_c in only three cases. In accordance with the criteria 3F.1, whenever $V_u > V_c$, it is assumed that the shear carried by concrete is equal to zero. Thus, these three cases need further analysis as shown in the following paragraphs.

F. Further Analysis of Section with $V_c = 0$

In this case a total equivalent membrane force is defined as follows:

$$N_{ht} = N_h + \left[N_{he}^2 + V_u^2\right]^{1/2}$$

$$N_{vt} = N_v + \left[N_{ve}^2 + V_u^2\right]^{1/2}$$

The section is then analyzed using these equivalent membrane forces and corresponding bending moments

(table 3F-2). Results of these analyses are given in table 3F-3.

G. Final Results

Table 3F-3 shows that, in the three cases where concrete shear capacity may, conservatively, be assumed to be zero, the resulting concrete and reinforcement stresses are within the allowable limits.

Thus, it is shown that, considering the effects of tangential shear, all the sections are adequate.

Notes:

1. Notation:

   N_h, N_v = hoop and meridional membrane forces due to other loads

   N_{he}, N_{ve} = hoop and meridional membrane forces due to seismic loads

   V_c = shear carried by concrete alone

   V_u = applied tangential shear

2. V_c is zero if either or both total membrane forces are positive (tension)

3. N_h, N_v are from FINEL analysis

Table 3F-1

MEMBRANE FORCES AND TANGENTIAL SHEAR IN THE SHELL

(Sheet 2 of 2)

4. N_{he}, N_{ve}, V_u are from ASHSD analysis
5. Whenever $V_c > V_u$, concrete shear capability alone is adequate to carry tangential shear.
6. In all cases the calculated tangential shear force, V_u, is less than the total allowable shear on the section, 369 k/ft.
7. In these cases, $V_u > V_c$, and therefore further analysis is required considering tangential shear contribution to seismic membrane forces.

APPENDIX 3G

SEISMIC STRESSES IN UNDERGROUND STRUCTURES

CONTENTS

TABLE

FIGURES

APPENDIX 3G
SEISMIC STRESSES IN UNDERGROUND STRUCTURES

3G.1 SUMMARY

This appendix describes methods used for seismic analysis of buried structures such as conduits, tunnels, and well casings. The effects of earthquakes on buried structures may be broadly grouped into two classes: faulting and shaking. Faulting includes the direct, primary shearing displacement of bedrock which may carry through the overburden to the ground surface. Such direct shearing of the rock or soil is generally limited to relatively narrow zones of seismically active faults which may be identified by geological and seismological surveys. From a structural viewpoint, landsliding, ground fissuring, and consolidation of backfill soil have similar effects on buried structures. In general, it is not desirable to design structures to directly sustain such major soil displacements. However, design measures can be taken to mitigate the effects of the displacements and to identify and avoid areas prone to such displacements.

The effects of earthquake ground motion on underground conduits, in the absence of direct fault displacement or unstable soil conditions such as liquefaction, are:

1. Axial tension and compression due to traveling seismic wave
2. Shear and bending due to traveling seismic wave
3. Strain caused by dynamic differential movement at connections

Analytical procedures for evaluating these effects are described in the following sections. For very long structures, procedures are based on the assumption that there is no relative motion between the flexible structure and the ground. Seismic stresses in the conduit are estimated from the calculated strains and curvature in the surrounding soil due to the passage of seismic waves. For short structures, lippage may occur between the conduit and the soil and the calculated axial stresses are proportionately less than those assuming the conduit strain equal to the soil strain. The effects of bends and differential displacement at connections to buildings are evaluated using procedures based on equations for beams on elastic foundations. The calculated seismic stresses must be combined with stresses from other loading conditions, including pressure and surcharge loading, for final design.

The interaction of stresses and strains due to seismic wave propagation and boundary displacements, both at bends and at structures, is a complicated problem. The conservative assumption can be made that the strains due to the several sources are additive and, hence, an SRSS combination may be used. In case these resultant stresses and strains are unacceptable, the problem can be circumvented by designing discontinuities to be flexible to allow for the resultant displacements.

3G.2 STRESSES IN STRAIGHT SECTIONS

3G.2.1 GENERAL EQUATIONS FOR AXIAL AND BENDING STRAIN

The portions of a long, buried structure far from the ends and free of any external support other than the surrounding soil are assumed to be flexible and to follow essentially the displacements and deformations of the soil during seismic ground motion. Soil displacements due to the passage of shear, compression, and surface waves are calculated based on wave propagation velocities and the maximum ground particle acceleration and velocity due to the design earthquake. Stresses in the structure are calculated using the resulting strain, curvature, and modulus of elasticity of the structural material.

The assumption that relative motion between the buried structure and the surrounding soil is negligible has been shown by O'Rourke and Wang (1978) to be a valid assumption for most practical cases. For special situations where the relative motion is not negligible, and analysis techniques described by Hindy and Novak (1978) and O'Rourke and Wang (1978) can be used. Internal walls which may not follow the motion of the surrounding soil can be treated as simple oscillators subject to the design ground motion at the depth of burial.

The basic relations for calculating maximum longitudinal strain and curvature induced in a flexible, buried structure have been presented by Hall and Newmark (1978). For a compression wave propagating along the longitudinal axis of the buried structure:

$$\varepsilon_m = \pm \frac{V_{mp}}{C_p} \qquad \text{(3G-1)}$$

and for a shear wave propagating along the longitudinal axis:

$$\varepsilon_m = \pm \frac{V_{ms}}{2C_s} \qquad (3G\text{-}2)$$

$$K_m = \frac{a_{ms}}{C_s^2} \qquad (3G\text{-}3)$$

where:

ε_m = maximum longitudinal strain

K_m = maximum curvature

V_m = maximum compression wave particle velocity

V_{ms} = maximum shear wave particle velocity

a_{ms} = maximum shear wave particle acceleration

C_p = compression wave propagation velocity

C_s = shear wave propagation velocity

The maximum strain as given by equations 3G-1 and 3G-2 is an upper bound since it is limited by the pipe-soil interface friction. Slippage would occur if the computed axial force, ε_m AE, exceeds the frictional resistance as given by equation 3G-21.

The appropriate particle acceleration (a_m) for calculating maximum soil strain is the maximum ground acceleration. The maximum particle velocity should be selected for the corresponding wave type. For example, the maximum ground velocity for the compression wave portion of ground motion prior to arrival of the surface wave component is typically less than the maximum ground velocity associated with the surface wave component. Therefore, it may be unnecessarily conservative to take the maximum ground velocity in the entire

ground motion when calculating maximum soil strain due to a compression wave.

The value of wave propagation velocity to be used when calculating maximum soil strain surrounding a buried structure is the effective velocity of the ground motion disturbance past the structure. For rock or very stiff and dense soils, the effective propagation velocity is equal to the in situ wave propagation velocity as measured by field or laboratory tests. If the structure is embedded in a softer layer or at a shallow depth in uniform soils, the effective propagation velocity should be taken as the propagation velocity of the underlying competent soil or rock (Hall and Newmark, 1978). For example, the effective shear wave propagation velocity should not be taken as less than the shear wave velocity at a depth of 400 to 500 feet or, in any case, never less than about 2000 feet per second.

3G.2.2 MAXIMUM AXIAL AND BENDING STRESSES

Equations for calculating maximum axial and bending stresses as a function of angle of incidence of the various wave types have been presented by Yeh (1974). For an oblique compression wave of amplitude A_p (figure 3G-1):

$$\sigma_a = \pm \frac{Ev_{mp}}{C_p} \cos^2 \theta \qquad (3G\text{-}4)$$

$$\sigma_b = \pm \frac{ERa_{mp}}{C_p^{\ 2}} \sin \theta \cos^2 \theta \qquad (3G\text{-}5)$$

where:

σ_a = maximum axial stress

σ_b = maximum bending stress

E = modulus of elasticity for the structure

v_{mp} = maximum compression wave particle velocity

a_{mp} = maximum compression wave particle acceleration

R = distance from the cross-sectional neutral axis of the structure to the extreme fiber

θ = angle of incidence of propagating wave from the structural axis

The maximum possible values of the axial and bending stresses due to an oblique compression wave are:

$$\sigma_a = \pm \frac{Ev_{mp}}{C_p} \qquad \text{for } \theta = 0° \qquad (3G\text{-}6)$$

$$\sigma_b = \pm\, 0.385 \frac{ERa_{mp}}{C_p^{\;2}} \qquad \text{for } \theta = 35°16' \qquad (3G\text{-}7)$$

For an <u>oblique shear wave</u> of amplitude A_s (figure 3G-1):

$$\sigma_a = \pm \frac{Ev_{ms}}{C_s} \sin\theta \cos\theta \qquad (3G\text{-}8)$$

$$\sigma_b = \pm \frac{Era_{ms}}{C_s^{\;2}} \cos^3\theta \qquad (3G\text{-}9)$$

where:

v_{ms} = maximum shear wave particle velocity

a_{ms} = maximum shear wave particle acceleration

The maximum possible values of the axial and bending stresses due to an oblique shear wave are:

$$\sigma_a = \pm \frac{Ev_{ms}}{2C_s} \quad \text{for } \theta = 45° \tag{3G-10}$$

$$\sigma_b = \pm \frac{ERa_{ms}}{C_s^2} \quad \text{for } \theta = 0° \tag{3G-11}$$

For an <u>incident surface wave</u> of amplitude A_R, the motion is equivalent to the combination of a compression wave of amplitude A_{Rp} and a shear wave of amplitude A_{Rs} (figure 3G-1) and:

$$\sigma_a = \pm \frac{Ev_{mr}}{C_R} \cos^2 \theta \tag{3G-12}$$

$$\sigma_b = \pm \frac{ERa_{mr}}{C_R^2} \sin \theta \cos^2 \theta \tag{3G-13}$$

for the compressional component

$$\sigma_b = \pm \frac{ERa_{mr}}{C_R^2} \cos^2 \theta \tag{3G-14}$$

for the shear component

where:

v_{mr} = maximum surface wave particle velocity

a_{mr} = maximum surface wave particle acceleration

C_R = surface wave propagation velocity

The maximum possible values of the axial and bending stresses due to an incident surface wave are:

$$\sigma_a = \pm \frac{Ev_{mr}}{C_R} \qquad \text{for } \theta = 0° \qquad (3G\text{-}15)$$

$$\sigma_b = \pm\, 0.385 \frac{ERa_{mr}}{C_R^{\,2}} \qquad \text{at } \theta = 36°16' \qquad (3G\text{-}16)$$

for the compressional comonent

$$\sigma_b = \pm \frac{ERa_{mr}}{C_R^2} \qquad \text{at } \theta = 0° \qquad (3G\text{-}17)$$

for the shear component

3G.2.3 WAVE TYPES AND COMBINATION OF STRESSES

The maximum ground velocity and acceleration for an earthquake motion contain contributions from compressional, shear, and surface waves. The choice of wave type to be used for design depends on the location and orientation of the structure to the earthquake source, as well as on the nature of the source and local geologic conditions along the travel path.

It is not presently possible, in general, to determine the relative contributions to the total motion of each of the various wave types. The axial and bending stresses should be maximized separately according to wave type and angle of incidence, and the resulting maximums for axial and bending stress should be combined by the SRSS method since the maximum values are unlikely to occur simultaneously.

The calculated axial and bending stresses are combined to provide the total seismic design stress. The combined stress is maximized for an incident angle between 0° and 45° for each wave type using the equations provided in subsection 3G.2.2. This combined stress for each wave type will always be less than the sum of the maximum possible values of axial and bending stress which are based on different angles of incidence and, therefore, do not occur simultaneously. The maximized values of axial and bending stress for each wave type are then combined using the SRSS method to give the total seismic design stress ($\sigma_a + \sigma_b$) as follows:

$$\sigma_a = \pm \left[(\sigma_{ap})^2 + (\sigma_{as})^2 + (\sigma_{ar})^2 \right]^{1/2} \qquad \text{(3G-18)}$$

$$\sigma_b = \pm \left[(\sigma_{bp})^2 + (\sigma_{bs})^2 + (\sigma_{br})^2 \right]^{1/2} \qquad \text{(3G-19)}$$

where the subscripts p, s, and r identify the maximum axial and bending stresses due to a compressional, shear, and surface wave, respectively.

For buried piping of relatively small diameter (less than about 48 inches), the bending stresses are small compared to the calculated normal stresses. In this case, the maximum possible values of axial and bending stress for each wave type can be added directly without performing the maximizing procedure prior to combining. For buried structures of much greater dimensions, such as tunnels, and bending stress will be significant compared to the axial component and the maximizing procedure should be carried out.

If the calculated stresses exceed the allowable stresses, increasing the cross-sectional area of the structure is of no

value since the stresses are due to an imposed strain. In this case, the solution may be to either articulate the structure to make it more flexible or to isolate the structure partially or completely from the surrounding soil.

3G.2.4 SHORT SECTIONS

In case of a straight structural element embedded in soil, the transfer of soil strain as axial strain into the element depends on the end bearing of the element against the soil and the frictional resistance between the element surface and the soil. At the ends of a long, straight element, frictional resistance will develop for some length (ℓ) along which the element will displace relative to the surrounding soil due to strain incompatibility between the soil and the element (figure 3G-2). Neglecting end bearing, the minimum length of structure (L) required to develop full friction has been shown by Shah and Chu (1974) to be twice the maximum slippage length (ℓ_m) which is calculated as follows:

$$\ell_m = \frac{\varepsilon_m AE}{f} \tag{3G-20}$$

where:

ε_m = maximum soil strain

A = structure cross-sectional area

E = structure modulus of elasticity

f = friction force per unit length

For buried structures where $L < 2\ell_m$, the calculated axial stresses will be proportionately less than those calculated

assuming no relative slippage between the structure and the soil (figure 3G-2).

The frictional force (f) per unit length of a pipeline structure is given by:

$$f = \pi D p_r \mu \qquad (3G\text{-}21)$$

where:

D = pipe diameter

p_r = average radial soil pressure on pipe

μ = coefficient of friction

The average radial soil pressure on the pipe (p_r) is approximated by:

$$P_r = \frac{1 + K_o}{2} \gamma_{soil} H_d \qquad (3G\text{-}22)$$

where:

K_o = coefficient of lateral stress at rest

λ_{soil} = soil unit weight

H_d = burial depth at pipe centerline

The parameters (μ) and (K_o) are evaluated based on the type of structural material and soil conditions for a specific project. The coefficient of friction (μ) is typically in the range of 0.3 to 0.5 for a smooth pipe embedded in soil. The lateral stress coefficient (K_o) typically ranges from 0.5 to 1.0.

3G.2.5 AXIAL DISPLACEMENT OF FREE END RELATIVE TO THE SOIL

Neglecting the effect of end bearing and considering the maximum soil strain to remain constant over the length of the structure, Shah and Chu (1974) give the longitudinal displacement of the ends of a structure relative to the soil as follows:

$$\Delta = \varepsilon_m \ell_e - \frac{f\ell_e^2}{2AE} \qquad (3G\text{-}23)$$

where:

Δ = Δ (soil) - Δ(structure)

ℓ_e = effective slippage length (figure 3G-2)

In the case of a short structure where $L < 2\ell_m$, the effective slippage length equals one-half the total length ($\ell_e = L/2$) and:

$$\Delta = \frac{\varepsilon_m L}{2} - \frac{fL^2}{8AE} \qquad (3G\text{-}24)$$

For a long structure, $\ell_e = \ell_m$ and:

$$\Delta = \frac{\varepsilon_m \ell_m}{2} \quad \frac{\varepsilon_m^2 AE}{2f} \qquad (3G\text{-}25)$$

Provisions should be made in the design to accommodate this displacement at the intersection of long elements with massive embedded structures.

3G.2.6 SHEAR FORCE DUE TO AN AXIAL SHEAR WAVE

The basic relations for maximum longitudinal strain and curvature presented by Hall and Newmark (1978) can be extended to provide the rate of change of curvature of a

buried structure due to a propagating shear wave. For a shear wave propagating with wave velocity (C_s) along the x-axis, the particle dis-placement in the transverse (y) direction is:

$$y = f(x-C_s t) \qquad (3G\text{-}26)$$

The third derivative of equation 3G-26 with respect to x and t gives the following relation for the rate of change of curvature:

$$\frac{\partial^3 y}{\partial x^3} = f'''(x - C_s t) = -\frac{1}{C_s^{\,3}}\left(\frac{\partial^3 y}{\partial t^3}\right) \qquad (3G\text{-}27)$$

Defining (h) as the maximum derivative of the ground acceleration:

$$h = \frac{\partial^3 y}{\partial t^3} \qquad (3G\text{-}28)$$

and using the elementary beam relationship between the change in curvature and the shearing force (Q):

$$Q = -EI \quad \frac{\partial^3 y}{\partial x^3} \qquad (3G\text{-}29)$$

The shearing force in the buried structure is:

$$Q = EIh \, / \, C_s^{\,3} \qquad (3G\text{-}30)$$

The quantity (h) can be evaluated using the relationships between the maximum values of ground acceleration, displacement, and velocity where $a_m d_m / v_m^2 = 6$ (Hall and Newmark, 1978, Table 1) and $hv_m / a_m^2 = \beta a_m d_m / v_m^2 =$ (Newmark and Rosenblueth, 1971, p. 492). The coefficient (β) accounts for uncertainties in the relationship between the various ground motion

parameters, with a reasonable level of conservatism obtained by taking β = 1.5. Based on these assumptions:

$$h = 9a_m^2 / v_m \qquad (3G\text{-}31)$$

Combining equations 3G-30 and 3G-31 yields the following expression for the maximum shear force in the structure:

$$Q = \frac{9EIa_m^2}{C_s^3 v_m} \qquad (3G\text{-}32)$$

3G.2.7 CURVATURE

The maximum curvature (K_m) at a point can be calculated using equation 3G-3. If the calculated curvature is equal to or less than the allowable value of M/EI, the structure can be assumed to follow the ground motion without overstress and no articulation is necessary. However, some rotational capability may be required in sections where the calculated curvature exceeds the allowable value of M/EI and in the vicinity of connections to structures. The angular distortion for a given length of structure (L) can be calculated using the relation:

$$\phi = K_m L \qquad (3G\text{-}33)$$

If sections of an underground structure are effectively isolated from the surrounding component soil, the angular distortion is a function of the relative motion of the support points. The maximum relative motion in the transverse direction between two points a distance (L) apart during an earthquake can be calculated according to Yeh (1974):

$$\Delta = \frac{v_{ms} L}{C_s} \qquad (3G\text{-}34)$$

The angular distortion is then:

$$\phi = \arcsin \frac{\Delta}{L} \qquad (3G-35)$$

Sufficient rotational capability should be provided at joints and connections to permit the calculated angular distortion (ϕ) from the appropriate equation above.

3G.3 STRESSES AT BENDS

3G.3.1 GENERAL PROCEDURE

The analysis of buried structures with bends or restrained ends is based on the equations for beams on elastic foundations derived by Hetenyi (1946). In the case of a bend, the transverse leg is assumed to deform as a beam on an elastic foundation due to the axial force in the longitudinal leg (figure 3G-3). The displacement (Δ) at the bend is defined by the overall spring constant at the bend (K) where:

$$K = \frac{P}{\Delta} \qquad (3G-36)$$

The spring constant at the bend depends on the stiffness of the longitudinal and transverse legs as well as the degree of fixity at the bend and at the far ends of the legs. The approximate deformed shapes for a number of typical combinations of leg stiffness and end condition are shown in figure 3G-5. The stiffness of the leg is classified according to Hetenyi (1946) as rigid ($\lambda L < \pi/4$), intermediate ($\pi/4 < \lambda L < \pi$), and flexible ($\lambda L > \pi$) where:

$\lambda = 4\sqrt{k / 4EI}$ system characteristic

L = length of the leg

k_s = modulus of subgrade reaction for structure for width (B)

$k = k_s(B)$ where B is width of the structure

Solutions for the bend spring constant (K) for some typical configurations (cases A through E) are shown in table 3G-1. Solutions for other configurations can be derived using the appropriate equations for beams on elastic foundations.

3G.3.2 EQUATIONS FOR STRUCTURE WITH RESTRAINED END

The configuration and deformed shape of a buried structure with a bend are shown in figure 3G-4. According to Shah and Chu (1974), the maximum axial force is:

$$F_{max} = Q + f\ell_e \tag{3G-37}$$

and:

$$\Delta = \frac{Q}{K} \tag{3G-38}$$

Establishing displacement compatibility at the bend leads to the following expression:

$$\frac{F\ell_e^2}{2AE} + \ell_e\left(\frac{f}{K} - \frac{F_{max}}{AE} + \varepsilon_m\right) - \frac{F_{max}}{K} = 0 \tag{3G-39}$$

If the structure is long (L_1 or $L_2 > \ell_e + \ell_m$), $F_{max} = \varepsilon_m AE$ and equation 3G-39 reduces to:

$$\ell_e = \frac{AE}{K}\left(\sqrt{1.0 + \frac{2\varepsilon_m K}{f}} - 1.0\right) \tag{3G-40}$$

In the case of a short structure (L_1 or $L_2 < \ell_e + \ell_m$), F_{max} =

$f(L - \ell_e)$ and equation 3G-39 can be written in the form:

$$\frac{f\ell_e^2}{2AE} + \ell_e \left[\frac{f}{K} - \frac{f(L - \ell_e)}{AE} + \varepsilon_m\right] - \frac{f(L - \ell_e)}{K} = 0 \qquad (3G\text{-}41)$$

Equation 3G-41 can be solved by trial and error for the effective slippage length (ℓ_e). Having the effective slippage length, the displacement (Δ) at the bend can then be calculated. With the displacement (Δ), the shear (Q) and moment (M) in the transverse leg can then be calculated for the appropriate configuration (cases A through E) in table 3G-1. More complicated cases can be handled by discretizing the structure as described by Hindy and Novak (1978).

3G.4 STRESSES AT CONNECTIONS TO BUILDINGS

3G.4.1 AXIAL MOVEMENT

Stresses are induced in buried structures at penetrations to buildings due to relative movement between the building and the soil. In the case of relative movement in the axial direction of an underground structure with the far end unrestrained, the maximum axial force (P) in a long structure ($L > \ell_e$) is given by Yeh (1974):

$$P = \sqrt{2EAf\Delta_x} \qquad (3G\text{-}42)$$

Table 3G-1

BEND CHARACTERISTICS

Case	Spring Constant At Bend (K)	Shear In Transverse Leg (Q)	Moment In Transverse Leg (M)	Remarks
(A)	$K = \frac{k}{2\lambda}$	$Q = \frac{k\Delta}{2\lambda}$	$M = \frac{0.1662k\Delta}{\lambda^2}$ @ $X = \frac{\pi}{4\lambda}$	
(B)	$K = \frac{3k}{4\lambda}$	$Q = \frac{3k\Delta}{4\lambda}$	$M = \frac{k\Delta}{4\lambda^2}$	Equal moment of inertia (I) in longitudinal and transverse legs
(C)	$K = \frac{k}{\lambda}$	$Q = \frac{k\Delta}{\lambda}$	$M = \frac{k\Delta}{2\lambda^2}$	
(D)	$K = \frac{k}{\lambda C_1}$	$Q = \frac{k\Delta}{\lambda C_1}$	$M = \frac{k\Delta c_2}{\lambda^2 C_1}$	$C_1 = \frac{\sinh(2\lambda L) - \sin(2\lambda L)}{\cosh^2(\lambda L) + \cos^2(\lambda L)}$ $C^2 = \frac{\sinh(\lambda L)\cos(\lambda L) + \cosh(\lambda L)\sin(\lambda L)}{\cosh^2(\lambda L) + \cos^2(\lambda L)}$
(E)	$K = \frac{k}{\lambda\left(2C_1 - \frac{C_2^{\,2}}{C_3}\right)}$	$Q = \frac{k\Delta}{\lambda\left(2C_1 - \frac{C_2^{\,2}}{C_3}\right)}$	$M = \frac{k\Delta C_2}{2\lambda^2\left(2C_1C_3 - C_2^{\,2}\right)}$	$C_1 = \frac{\sinh(\lambda L)\cosh(\lambda L) - \sin(\lambda L)\cos(\lambda L)}{\sinh^2(\lambda L) - \sin^2(\lambda L)}$ $C_2 = \frac{\sinh^2(\lambda L) + \sin^2(\lambda L)}{\sinh^2(\lambda L) - \sin^2(\lambda L)}$ $C_3 = \frac{\sinh(\lambda L)\cosh(\lambda L) + \sin(\lambda L)\cos(\lambda L)}{\sinh^2(\lambda L) - \sin^2(\lambda L)}$

Note: See Fig. 3G-4 for definition of cases.

where:

Δ_x = relative movement between the building and soil in the axial direction.

ℓ_e = P/f effective slippage length

For a short structure ($L<\ell_e$), the maximum axial force is limited to:

$$P = fL \qquad (3G\text{-}43)$$

If a bend in the underground structure is located near the penetration, the connection to the building will be influenced by this restraint. In this case, the following expression can be solved for the maximum axial force (F_{max}):

$$\Delta_x = \frac{F_{max}L}{AE} - \frac{fL^2}{2AE} + \frac{F_{max}}{K} - \frac{fL}{K} \qquad (3G\text{-}44)$$

where K is evaluated for the appropriate configuration (figure 3G-4).

3G.4.2 LATERAL MOVEMENT

In the case of relative movement between the building and soil in the direction transverse to the buried structure, stresses are determined assuming the structure to be a semi-infinite beam supported on an elastic foundation with a fixed or hinged end at the connection to the building (Yeh, 1974).

For a fixed connection to the building:

$$\sigma_b = \pm \frac{KR}{2\lambda^2 I}(\Delta_y) \qquad (3G\text{-}45)$$

$$\tau = \frac{\alpha K}{\lambda A}(\Delta_y) \qquad (3G\text{-}46)$$

where:

σb = maximum bending stress at the connection

τ = maximum shear stress at the connection

Δ_y = relative movement between the building and soil in the transverse direction

α = shape factor for the structural cross-section and is equal to 2 for a thin circular section

For a hinged connection to the building:

$$\sigma_b = \pm 0.161 \frac{KR}{\lambda^2 I} (\Delta_y) \quad (3G\text{-}47)$$

$$\tau = \frac{\alpha K}{2\lambda A} (\Delta_y) \quad (3G\text{-}48)$$

where:

σ_b = maximum bending stress located at a distance $\pi/4\lambda$ from the connection

τ = maximum shear stress at the connection

3G.5 DESIGN EXAMPLE

Given An underground steel pipeline connecting two buildings as shown in plan view in figure 3G-6. The properties of the pipe and supporting soil, and the earthquake motion are as follows:

Pipe

30-inch ID

$t = 3/8 - \text{inch}$

$I = 4130 \text{ in.}^4$

$A = 35.8 \text{ in.}^2$

$E = 30x10^6$ psi

$L_1 = 500$ ft

$L_2 = 100$ ft

Soil

$\gamma_{soil} = 118$ pcf

$C_p = 7500$ fps

$C_s = C_R = 3000$ fps

$K_o = 0.7$

$H_d = 6.0$ ft

$\mu = 0.4$

$k_s = 98 \text{ lb / in.}^3$

Earthquake

$a_m = 120 \text{ in./sec}^2$

$v_{mp} = 5$ in. / sec

$v_{ms} = v_{mr} = 14$ in. / sec

Find

(a) Seismic design stresses in the straight sections of the pipeline away from the bend and connections to the buildings.

(b) Design condition at the bend, including:

- stresses in the pipeline if restrained at the bend
- maximum axial displacement of the ends of the pipeline if unrestrained at the bend
- maximum angular distortion at the bend.

(c) Design condition at the building connection, including

- stresses in the pipeline assuming a hinged or fixed connection and 0.5 inch relative movement in the axial or lateral direction
- maximum axial displacement of the ends of the pipeline at the connections assuming no restraint
- maximum angular distortion at the connections

Solution

Since the pipeline is of relatively small diameter, the maximum values of axial and bending stress for each wave type will be added directly without maximizing for angle of incidence as discussed in subsection 3G.2.3. The maximum axial and bending stresses due to individual compression, shear, and surface waves for a pipeline following the ground motion are determined from the appropriate equations of subsection 3G.2.2:

Compression wave

$$\sigma_a = \pm \frac{Ev_{mp}}{C_p} = \pm 1667 \text{ psi}$$

$$\sigma_b = \pm \frac{0.385\ ERa_{mp}}{C_p^2} = \pm 2.6 \text{ psi}$$

Shear wave

$$\sigma_a = \pm \frac{EV_{ms}}{2C_s} = \pm 5833 \text{ psi}$$

$$\sigma_b = \pm \frac{ERa_{ms}}{C_s^2} = \pm 42.7 \text{ psi}$$

Surface wave

$$\sigma_a = \pm \frac{Ev_{mr}}{C_r} = \pm 11{,}667 \text{ psi}$$

$$\sigma_b = \pm \frac{ERa_{mr}}{C_r^2} = \pm 42.7 \text{ psi}$$

(a) Seismic design stresses in the long, straight section (L_1) are obtained from stresses for the individual wave types using the SRSS method:

$$\sigma_a = \pm\left[(1667)^2 + (5833)^2 + (11{,}667)^2\right]^{1/2}$$
$$= \pm\ 13{,}100 \text{ psi}$$

$$\sigma_b = \pm\left[(2.6)^2 + (42.7)^2 + (42.7)^2\ \right] = \pm\ 60 \text{ psi}$$

Design stresses in the shorter section (L_2) can be reduced to account for slippage between the pipeline and the soil as discussed in subsection 3G.2.4:

$$\varepsilon_m = \frac{\sigma_a + \sigma_b}{E} \quad \frac{13{,}096 + 60}{30 \times 10^6} = 0.438 \times 10^{-3}$$

$$P_r = \left(\frac{1 + K_o}{2}\right)\ \gamma_{soil}\ \ (H_d) = 602 \text{ psf}$$

$$f = \pi D p_r \mu = 1935 \text{ 1b / ft}$$

$$\ell_m = \frac{\varepsilon_m AE}{f} = 243 \text{ ft}$$

For the shorter section, $L_2 < 2\ell_m$ and the seismic design stresses can be reduced in accordance with figure 3G-2:

$$\sigma_a = \frac{f}{A}\left(\frac{L_2}{2}\right) = 2700 \text{ psi}$$

(b) If the pipeline is restrained at the bend by a rigid elbow or other structure, shear and bending stresses will be induced in the pipeline in addition to an axial stress as discussed in section 3G.3. For displacement at the bend in the east-west direction (axial force in L_1):

$$\lambda = \left[\frac{k_s B}{4EI}\right]^{1/4} = 8.83 \times 10^{-3}$$

Both pipeline sections (L_1 and L_2) can be considered as infinitely long for purposes of calculating the spring constant at the bend since both λL_1 and $\lambda L_2 > \pi$.

The appropriate spring constant at the bend is case (B) of table 3G-1:

$$K = \frac{3k}{4\lambda} = 2.56 \times 10^5 \text{ lb / in.}$$

The effective slippage length along section L_1 is calculated from equation 3G-40:

$$\ell_e = \frac{AE}{K}\left(\sqrt{1.0 + \frac{2\varepsilon_m K}{f}} - 1.0\right) = 2291 \text{ in.}$$

The shear, moment, and transverse displacement induced in section L_2 at the bend are:

$$Q_2 = F_{max} - f\ell_e = \varepsilon_m AE - f\ell_e = 101{,}000 \text{ lb}$$

$$\Delta_2 = \frac{Q_2}{K} = 0.39 \text{ in.}$$

$$M_2 = \frac{k\ \Delta_2}{4\lambda^2} = 3.77 \times 10^6 \text{ in. lb}$$

For displacement at the bend in the north-south direction (axial force in L_2), one-half the section length (600 inches) is less than the effective slippage length (ℓ_e) = 2291 inches) calculated using equation 3G-40. In this case, equation 3G-41 must be solved for the effective slippage length by trial and error:

$$\ell_e = 470 \text{ in.}$$

The shear, moment, and transverse displacement induced in section L_1 at the bend are:

$$Q_1 = F_{max} - f\ell_e = f(L_2 - \ell_e) - f\ell_e = 41{,}860 \text{ lb}$$

$$\Delta_1 = \frac{Q_1}{K} = 0.16 \text{ in.}$$

$$M_1 = \frac{k\Delta_1}{4\lambda^2} = 1.55 \times 10^6 \text{ in. lb}$$

If the pipeline is not restrained at the bend, the longitudinal displacement of the ends relative to the soil can be calculated by equations 3G-23 and 3G-25. The displacement of the end of the long section (L_1) is:

$$\Delta_1 = \frac{\varepsilon_m{}^2 AE}{2f} = 0.64 \text{ in.}$$

The displacement of the end of the short section (L_2) is:

$$\Delta_2 = \frac{\varepsilon_m L_2}{2} - \frac{fL_2^2}{8AE} = 0.24 \text{ in.}$$

The angular distortion of the pipeline can be calculated by equation 3G-33:

$$\phi = K_m \ (L) = \frac{a_m (L)}{C_s{}^2}$$

For the long section (L_1), ϕ_1 = 0.03 deg.; for the shorter section (L_2), ϕ_2 = 0.01 deg.

(c) Connection at Point (A)

The axial force induced in the longer section (L_1) due to the design axial relative movement (Δ_x) of 0.5 inch is:

$$P_1 = \sqrt{2EAf\Delta_x} = 415{,}800 \text{ lb}$$

for a long structure where $L_1 = 500$ ft > $\frac{P}{f} = 215$ ft

Assuming a fixed connection, the maximum bending and shear stresses in the pipeline at the connection due to the design lateral relative movement (Δ_x) of 0.5 inch are:

$$\sigma_b = \pm \frac{kR}{2\lambda^2 I}(\Delta_y) = \pm\ 35{,}100 \text{ psi}$$

$$\tau = \frac{\alpha k}{\lambda A}(\Delta_y) = 9500 \text{ psi}$$

Assuming a hinged connection, the maximum bending and shear stresses are:

$$\sigma_b = \pm \frac{0.161kR}{\lambda^2 I}(\Delta_y) = \pm\ 11{,}300 \text{ psi at a}$$

distance $\frac{\pi}{4\lambda} = 89$ in. from the connection and

$$\tau = \frac{\alpha k}{2\lambda A}(\Delta_y) = 4800 \text{ psi}$$

<u>Connection at Point (C)</u>

For the shorter section, $L_2 = 100$ ft < $\frac{P}{f} = 215$ ft and equation 6-44 can be solved to obtain the maximum axial force due to the design axial relative displacement (Δ_x) of 0.5 inch:

$$F_{max} = 271{,}000 \text{ lb}$$

The maximum bending and shear stresses in the pipeline at the connection due to the design lateral relative movement

(Δ_y) of 0.5 inch are the same as for the connection at point (A).

Angular Distortion

The design angular distortion at the connections is the same as for the bend:

ϕ_1 = 0.03 deg

ϕ_2 = 0.01 deg

The calculated seismic stresses and displacements at various locations along the pipeline must be combined with stresses due to all other loading conditions to obtain total design stresses (Goodling, 1978). If the total calculated stresses exceed the allowable stresses, the overstressed section can be made more flexible or isolated partially or completely from the surrounding soil. In the vicinity of the connections to the buildings, for example, a fixed connection would result in very high bending stresses which could be greatly reduced by use of a hinged connection.

APPENDIX 3H

LATERAL EARTH PRESSURE ON FOUNDATION AND RETAINING WALLS

APPENDIX 3H

LATERAL EARTH PRESSURE ON FOUNDATIONS AND RETAINING WALLS

The total lateral earth pressure on foundation and retaining walls shall be based on the sum of the appropriate static and dynamic lateral forces. Static forces shall be based either on the active case (P_A) for the case of a retaining wall free to rotate and translate, or on the compacted backfill case (P_B) for the case of a rigid foundation wall. Dynamic forces shall be based on the dynamic increment for a level backfill condition (P_{AE}) plus the surcharge effect (P_{AES}), if applicable.

A. Static Conditions

Case	Equivalent Fluid Unit Weight (lb/ft^3) (Horizontal Backfill) Above Water Table	Below Water Table
Active (P_A)	36	19
Passive (P_P)	228	118
Backfill (P_B)	90	47

The increment of lateral pressure due to adjacent surcharge for the case of a rigid foundation wall shall be computed using figure 3H-1.

The increment of lateral pressure due to adjacent surcharge for the case of a retaining wall free to rotate and translate shall be computed using figure 3H-2.

B. Dynamic Conditions

The dynamic lateral force increment due to seismic effects shall be computed in accordance with figure 3H-3.[(1),(2)]

The total dynamic lateral force increment, P_{AE} or P_{AE} + P_{AES}, shall be added to the lateral force calculated for either the active case or the compacted backfill case.

The lateral force is calculated in the usual manner and includes hydrostatic pressure if a water table is present. The dynamic lateral force increments are independent of the water table.

4. REACTOR

4.1 SUMMARY DESCRIPTION

The reactor is of the pressurized water type using two reactor coolant loops. A vertical cross section of the reactor is shown in figure 4.1-1. The reactor core is composed of 241 fuel assemblies and 89 or more control element assemblies (CEAs). The fuel assemblies are arranged to approximate a right circular cylinder with an equivalent diameter of 143.6 inches and an active length of 150 inches. The fuel assembly, which provides for 236 fuel rod positions (16 x 16 array), consists of 5 guide tubes welded to spacer grids and is closed at the top and bottom by end fittings. The guide tubes each displace four fuel rod positions and provide channels which guide the CEAs over their entire length of travel. In-core instrumentation is installed in the central guide tube of selected fuel assemblies. The in-core instrumentation is routed into the bottom of the fuel assemblies through the bottom head of the reactor vessel.

Each fuel rod consists of slightly enriched uranium in the form of sintered uranium dioxide pellets, enclosed in a pressurized Zircaloy or ZIRLO™ tube that forms a hermetic enclosure. Burnable absorber rods are provided in selected fuel assembly locations, and are mechanically similar to fuel rods. The original design of PVNGS fuel assemblies utilized aluminum oxide-boron carbide pellets for the burnable adsorber, whereas reload designs have utilized erbium oxide. The erbium oxide is admixed with slightly enriched uranium in the form of sintered fuel-poison rods. The use of the rare earth element erbium may

provide significant advantages in terms of reduced core power peaking, increased core operating margin, and reduced fuel cycle costs. Reload fuel assemblies also include other incremental design improvements that improve fuel reliability, lower fabrication or fuel cycle costs, or contribute to flexibility in reactor core design or operation.

Fuel assemblies conform with fuel designs that have been analyzed with applicable NRC staff approved codes and methods, and shown by tests or analyses to comply with all fuel safety design bases. Various fuel assembly configurations may be used within the same reactor core when such use is evaluated on a reload-specific basis. A limited number of lead test assemblies that have not completed representative testing may be placed in non-limiting core regions; however, other cladding material may be used only with an NRC approved exemption as required by the PVNGS operating license.

The reactor coolant enters the inlet nozzles of the reactor vessel, flows downward between the reactor vessel wall and the core barrel, and passes through the flow skirt section where the flow distribution is equalized, and into the lower plenum. The coolant then flows upward through the core, removing heat from the fuel rods. The heated coolant enters the core outlet region where the coolant flows around the outside of control element assembly shroud tubes to the reactor vessel outlet nozzles. The control element assembly shroud tubes protect the individual neutron absorber elements of the CEAs from the effects of coolant cross-flow above the core.

The reactor internals support and orient the fuel assemblies, control element assemblies, and in-core instrumentation, and guide the reactor coolant through the reactor vessel. They also absorb static and dynamic loads and transmit the loads to the reactor vessel flange. They will safely perform their functions during normal operating, upset, and faulted conditions. The internals are designed to safely withstand forces due to dead weight, handling, temperature and pressure differentials, flow impingement, vibration, and seismic acceleration. All reactor components are considered Category I for seismic design. The design of the reactor internals limits deflection where required by function. The stress values of all structural members under normal operating and expected transient conditions are not greater than those established by Section III of the ASME Code. The effect of neutron irradiation on the materials concerned is included in the design evaluation. The effect of accident loadings on the internals is included in the design analysis.

Reactivity control is provided by three independent systems: the control element drive mechanism control system (CEDMCS), the chemical and volume control system (CVCS), and the Safety Injection System (SIS). The CEDMCS controls short-term reactivity changes and is used for rapid shutdown. The CVCS is used to compensate for long-term reactivity changes and can make the reactor subcritical without the benefit of the CEDMCS. The SIS provides reactivity control for certain postulated design basis events, such as steam line breaks and Loss of Coolant Accidents (LOCA). The design of the core and the

reactor protective system prevent fuel damage limits from being exceeded for any single malfunction in any of the reactivity control systems.

4.2 FUEL SYSTEM DESIGN

4.2.1 DESIGN BASES

4.2.1.1 Fuel Assembly

The fuel assemblies are required to meet design criteria for each design condition listed below to assure that the functional requirements are met. Except where specifically noted, the design bases presented in this section are consistent with those used for previous designs.

A. Nonoperation and Normal Operation (Condition I)

Condition I situations are those which are planned or expected to occur in the course of handling, initial shipping, storage, reactor servicing, and power operation (including maneuvering of the plant). Condition I situations must be accommodated without fuel assembly failure and without any effect which would lead to a restriction on subsequent operation of the fuel assembly. The guidelines stated below are used to determine loads during Condition I situations:

1. Handling and Fresh Fuel Shipping

Loads correspond to the maximum possible axial and lateral loads and accelerations imposed on the fuel assembly by shipping and handling equipment during these periods, assuming that there is no abnormal contact between the fuel assembly and any surface, nor any equipment malfunction. Irradiation effects on material properties are

considered when analyzing the effects of handling loads which occur during refueling. Additional information regarding shipping and handling loads is contained in paragraph 4.2.3.1.5.

2. Storage

Loads on both new and irradiated fuel assemblies reflect storage conditions of temperature, chemistry, means of support, and duration of storage.

3. Reactor Servicing

Loads on the fuel assembly reflect those encountered during refueling and reconstitution.

4. Power Operation

Loads are derived from conditions encountered during transient and steady-state operation in the design power range. (Hot operational testing, system startup, hot standby, operator-controlled transients within specified rate limits, and system shutdown are included in this category.)

5. Reactor Trip

Loads correspond to those produced in the fuel assembly by control element assembly (CEA) motion and deceleration.

B. Upset Condition (Condition II)

Condition II situations are unplanned events (such as those discussed in chapter 15 and the operating basis

earthquake (OBE)) which may occur with moderate frequency during the life of the plant. The fuel assembly design should have the capability to withstand any upset condition with margin to mechanical failure and with no permanent effects which would prevent continued normal operation.

C. Emergency Conditions (Condition III)

Condition III events are unplanned incidents as discussed in chapter 15 and minor fuel handling accidents which might occur infrequently during plant life. Rod mechanical failure must be prevented for any Condition III event in any area not subject to extreme local conditions (e.g., in any rod not immediately adjacent to the impact surface during a fuel handling accident).

D. Faulted Conditions (Condition IV)

Condition IV incidents are postulated events from chapter 15 and the safe shutdown earthquake (SSE), LOCA (mechanical excitation only), combined SSE and LOCA, and major fuel handling accident whose consequences are such that integrity and operability of the nuclear energy system may be impaired. Mechanical fuel failures are permitted, but they must not impair the operation of the engineered safety features (ESF) systems to mitigate the consequences of the postulated event.

4.2.1.1.1 Fuel Assembly Structural Integrity Criteria

The criteria that apply to the structural integrity of fuel assembly components, with the exception of fuel rods, are presented below. These criteria include the allowable primary stresses and functional requirements for each design condition. As required, limits for secondary stress may be obtained from methods similar to those given in Section III of the ASME Boiler and Pressure Vessel Code. When evaluating secondary stress, all functional requirements, including the stated assumptions regarding material properties and limits, still apply. Criteria for fuel rods are discussed separately in paragraph 4.2.1.2.

A. Design Conditions I and II

$P_m \leq S_m$

$P_m + P_b \leq F_s S_m$

Under cyclic loading conditions, stresses must be such that the cumulative fatigue damage factor does not exceed 0.8. Cumulative damage factor is defined as the sum of the ratios of the number of cycles at a given cyclic stress (or strain) condition to the maximum number permitted for that condition. The selected limit of 0.8 is used in place of 1.0 (which would correspond to the absolute maximum damage factor permitted) to provide additional margin in the design.

During the OBE, fuel assembly deflections must be such that permanent deformations are limited to a value allowing the CEAs to scram.

B. Design Condition III

$P_m \leq 1.5\ S_m$

$P_m + P_b \leq 1.5\ F_s S_m$

C. Design Condition IV

$P_m \leq S_m'$

$P_m + P_b \leq F_s S_m'$

where S_m' = smaller value of 2.4 S_m or 0.7 S_u.

1. If the equivalent diameter pipe break in the LOCA does not exceed 0.5 square foot, the fuel assembly deformation shall be limited to a value not exceeding the deformation which would preclude satisfactory insertion of the CEAs.

2. For pipe break sizes greater than 0.5 square foot, deformation of structural components is limited to maintain the fuel in a coolable array. CEA insertion is not required for these events as the appropriate safety analyses do not take credit for CEA insertion.

3. For the upper end fitting springs, calculated shear stress must not exceed the minimum yield stress in shear.

4. For the spacer grids, the predicted impact loads must be less than the tested grid capability, as defined in reference 1.

5. During the SSE, fuel assembly deflections must be such that permanent deformations are limited to a value allowing the CEAs to scram.

D. Nomenclature

The symbols used in defining the allowable stress levels are as follows:

P_m = Calculated general primary membrane stress[a]

P_b = Calculated primary bending stress

S_m = Design stress intensity value as defined by Section III, ASME Boiler and Pressure Vessel Code[b]

S_u = Minimum unirradiated ultimate tensile strength

F_s = Shape factor corresponding to the particular cross-section being analyzed[c]

---

a. P_m and P_b are defined by Section III, ASME Boiler and Pressure Vessel Code.

b. With the exception of zirconium base alloys, the design stress intensity values, S_m, of materials not tabulated by the Code are determined in the same manner as those in the Code. The design stress intensity of zirconium base alloys shall not exceed two-thirds of the unirradiated minimum yield strength at temperature. Basing the design stress intensity on the unirradiated yield strength is conservative because the yield strength of Zircaloy or ZIRLO™ increases with irradiation. The use of the two-thirds factor ensures 50% margin to component yielding in response to primary stresses. This 50% margin, together with its application to the minimum unirradiated properties and the general conservatism applied in the establishment of design conditions, is sufficient to ensure an adequate design.

c. The shape factor, F_s, is defined as the ratio of the "plastic" moment (all fibers just at the yield stress) to the initial yield amount (extreme fiber at the yield stress and all other fibers stressed in proportion to their distance from the neutral axis). The capability of cross- sections loaded in bending to sustain moments considerably in excess of that required to yield the outermost fibers is discussed in Timoshenko.[2]

S_m' = Design stress intensity value for faulted conditions

The definition of S_m' as the lesser value of 2.4 S_m and 0.7 S_u is contained in the ASME Boiler and Pressure Vessel Code, Section III.

4.2.1.1.2 Material Selection

The original fuel assembly grid cage structure design consists of ten Zircaloy-4 spacer grids, one Inconel 625 spacer grid (at the lower end), five Zircaloy-4 guide tubes, two stainless steel end fittings, and four Inconel X-750 coil springs. Beginning with Batch P3R, reload assemblies incorporate an Inconel 625 top grid, resulting in nine Zircaloy-4 spacer grids and two Inconel 625 spacer grids. Zircaloy-4, selected for fuel rod cladding, guide tubes, and spacer grids, has a low neutron absorption cross-section, and high corrosion resistance to reactor water environment. Also, there is little reaction between the cladding and fuel or fission products. ZIRLO™ material is also used for fuel rod cladding in selected fuel assemblies. As described in subsection 4.2.3, Zircaloy-4 has demonstrated its ability as a cladding, CEA guide tube, and spacer grid material. Reload fuel assemblies have incorporated laser welded Zircaloy ZIRLO™ also has a history of successful use as a cladding material spacer grids.

The original bottom spacer grid is of Inconel 625 and is welded to the lower end fitting. Beginning with Batch P3R, reload assemblies incorporate an Inconel 625 top spacer grid that is held in place by two Zircaloy-4 split rings welded directly to

each guide tube. Inconel 625 was selected rather than Zircaloy-4 to provide additional strength and relaxation resistance for regions of local flow turbulence (bottom grid) and fretting potential (top grid). Inconel 625 is a very strong material with good ductility, corrosion resistance, and stability under irradiation at temperatures below 1000F. Reload fuel assemblies have incorporated a laser welded Inconel grid design, the Guardian™ grid, manufactured by Westinghouse.

The fuel assembly upper and lower end fitting are of cast 304 stainless steel, and the upper and lower end fitting posts are type 304 stainless steel machined components. This material was selected based on considerations of adequate strength and high corrosion resistance. Also, type 304 stainless steel has been used successfully in almost all pressurized water reactor environments, including all currently operating Westinghouse reactors.

4.2.1.1.3 Control Element Assembly Guide Tubes

CEA guide tubes are manufactured in accordance with ASTM B353, Wrought Zirconium and Zirconium Alloy Seamless and Welded Tubes for Nuclear Service, with the following exceptions and/or additions:

A. Chemical Properties

   Additional limits are placed on oxygen, carbon, and silicon.

B. Mechanical Properties

Tensile Properties. Minimum values are specified for the tensile strength, yield strength, and total elongation at room temperature and high temperature.

4.2.1.1.4 Zircaloy-4 Bar Stock

Zircaloy-4 bar stock is fabricated in accordance with ASTM B351, Standard Specification for Hot-Rolled and Cold-Finished Zirconium and Zirconium Alloy Bars, Rod and Wire for Nuclear Application, with the following exceptions and/or additions:

A. Chemical Properties

Additional limits are placed on oxygen and silicon content.

B. Metallurgical Properties

Grain Size. The maximum average grain size is restricted.

4.2.1.1.5 Zircaloy-4 Strip Stock

Zircaloy-4 strip stock is fabricated in accordance with ASTM B352, Standard Specification for Zirconium and Zirconium Alloy Sheet, Strip and Plate for Nuclear Application, with the following exceptions and/or additions:

A. Chemical Properties

Additional limits are placed on oxygen and silicon content.

B. Metallurgical Properties

Grain Size. The maximum average grain size is restricted.

C. Mechanical Properties

Spacer and perimeter strips for spacer grids are to be free of cracks. Strips from each material lot are penetrant inspected in accordance with a quality control plan that ensures, with 95% confidence, that at least 95% of the strips are free of cracks. The method used is capable of detecting known cracks in a standard specimen grid strip. All strips found to have cracks shall be rejected.

4.2.1.1.6 Stainless Steel Castings

Stainless steel castings are fabricated in accordance with Westinghouse specification MACASS01 "Austenitic Stainless Steel Castings". Controls on acceptable ferrite levels are maintained at or less than 30%.

4.2.1.1.7 Stainless Steel Tubing

Stainless steel tubing is fabricated in accordance with ASTM A269, Seamless and Welded Austenitic Stainless Steel Tubing for General Service, with the following addition:

Chemical Properties:

Carbon content is limited on tubing to be welded. Cobalt content is limited.

4.2.1.1.8 Inconel X-750 Compression Springs

Inconel springs are fabricated in accordance with AMS 5699, Alloy Wire, Corrosion and Heat Resistant, with the following addition:

Chemical Properties:

Cobalt content is limited.

4.2.1.1.9 Inconel 625 Spacer Grid Strip Material

Inconel spacer grid strip material is procured in accordance with the Standard Specification for Nickel-Chromium-Molybdenum-Columbium Alloy (UNS N06625) Plate, Sheet, and Strip, Specification ASTM B443, with the following additional requirements:

A. Chemical check analysis is required. Cobalt content is limited.

B. Spacer and perimeter strips shall be free of cracks upon inspection.

4.2.1.2 Fuel Rod

4.2.1.2.1 Fuel Cladding Design Limits

The fuel cladding is designed to sustain the effects of steady-state and expected transient operating conditions without exceeding acceptable levels of stress and strain. Except where specifically noted, the design bases presented in this section are consistent with those used for previous core designs. The fuel rod design accounts for cladding irradiation growth, external pressure, differential expansion of fuel and

clad, fuel swelling, densification, clad creep, fission and other gas releases, initial internal helium pressure, thermal stress, pressure and temperature cycling, and flow-induced vibrations. The structural criteria discussed below are based on the following for the normal upset, and emergency loading combinations identified in paragraph 4.2.1.1. For a discussion of the thermal/hydraulic criteria, see subsection 4.4.1.

A. During normal operating and upset conditions, the maximum primary tensile stress in the ZIRLO™ and/or Zircaloy 4 clad shall not exceed two-thirds of the minimum unirradiated yield strength of the material at the applicable temperature. The corresponding limit under emergency conditions is the material yield strength. The use of the unirradiated material yield strength as the basis for allowable stress is conservative because the yield strength of ZIRLO™ and Zircaloy 4 increases with irradiation. The use of the two-thirds factor ensures 50% margin to component yielding in response to primary stresses. This 50% margin, together with its application to the minimum unirradiated properties and the general conservatism applied in the establishment of design conditions, is sufficient to ensure an adequate design.

B. Net unrecoverable circumferential strain shall not exceed 1% as predicted by computations considering clad creep and fuel-clad interaction effects.

   Data from O'Donnell[3] and Weber[4] were used to determine the present 1% strain limit. O'Donnell

developed an analytical failure curve for Zircaloy cladding based upon the maximum strain of the material at its point of plastic instability. O'Donnell compared his analytical curve to circumferential strain data obtained on irradiated coextruded Zr-U metal fuel rods tested by Weber. The correlation was good, thus substantiating O'Donnell's instability theory. Since O'Donnell performed his analysis, additional data have been derived at Bettis(5)(6)(7) and AECL.(8)(9)

These new data are shown in figure 4.2-1, along with O'Donnell's curve and Weber's data. This curve was then adjusted because of differences in anisotropy, stress states, and strain rates, and the design limit was set at 1%.

The conservatism of the clad strain calculations is provided by the selection of adverse initial conditions and material behavior assumptions, and by the assumed operating history. The acceptability of the 1.0% unrecoverable circumferential strain limit is demonstrated by data from irradiated Zircaloy-clad fuel rods which show no cladding failures (due to strain) at or below this level, as illustrated in figure 4.2-1. Similar results for ZIRLO™ cladding are supported by reference 71.

C. The clad will be initially pressurized with helium to an amount sufficient to prevent gross clad deformation under the combined effects of external pressure and

long-term creep. Modified design criteria for fuel rod pressurization were proposed by C-E in a topical report that justified rod internal pressure exceeding RCS pressure.[10] This report received NRC staff approval and may be used for reload core design, provided core design evaluations consider the potential effects of increased rod pressure on LOCA calculations and DNB propagation in postulated accidents.

D. Cumulative strain cycling usage, defined as the sum of the ratios of the number of cycles in a given effective strain range ($\Delta\varepsilon$) to the permitted number (N) at that range, as taken from figure 4.2-2, will not exceed 0.8.

The cyclic strain limit design curve shown on figure 4.2-2 is based upon the Method of Universal Slopes developed by S. S. Manson[11] and has been adjusted to provide a strain cycle margin for the effects of uncertainty and irradiation. The resulting curve has been compared with known data on the cyclic loading of Zircaloy and ZIRLO™ and has been shown to be conservative. Specifically, it encompasses all the data of O'Donnell and Langer.[12]

As discussed in paragraph 4.2.1.2.5, the fatigue calculation method includes the effect of clad creep to reduce the pellet to clad diametral gap during that portion of operation when the pellet and clad are not in contact. The same model is used for predicting clad fatigue as is used for predicting clad strain. Therefore, the effects of creep and fatigue loadings

are considered together in determining end-of-life clad strain (see figure 4.2-2).

E. There is no specific limit on lateral fuel rod deflection for structural integrity considerations, except that which is brought about through application of cladding stress criteria. The absence of a specific limit on rod deflection is justified because it is the fuel assembly structure, and not the individual fuel rod, that is the limiting factor for the fuel assembly lateral deflection.

F. Fuel rod internal pressure increases with increasing burnup and toward end-of-life the total internal pressure, due to the combined effects of the initial helium fill gas and the released fission gas, can approach values comparable to the external coolant pressure. The maximum predicted fuel rod internal pressure will be consistent with the following criteria.

1. The primary stress in the cladding resulting from differential pressure will not exceed the stress limits specified earlier in this section.

2. The internal pressure will not cause the clad to creep outward from the fuel pellet surface while operating at the design peak linear heat rate for normal operation. In determining compliance with this criterion, internal pressure is calculated for the peak power rod in the reactor, including accounting for the maximum computed fission gas

release. In addition, the pellet swelling rate (to which the calculated clad creep rate is compared) is based on the observed swelling rate of "restrained" pellets (i.e., pellets in contact with clad), rather than on the greater observed swelling behavior of pellets which are free to expand.

The criteria discussed above do not limit fuel rod internal pressure to values less than the primary coolant pressure, and the occurrence of positive differential pressures would not adversely affect normal operation if appropriate criteria for cladding stress, strain, and strain rate were satisfied. Modified design criteria for fuel rod pressurization were proposed by C-E in a topical report that justified rod internal pressure exceeding RCS pressure.[(10)] This report received NRC staff approval and may be used for reload core design, provided core design evaluations consider the potential effects of increased rod pressure on LOCA calculations and DNB propagation in postulated accidents.

G. The design limits of the fuel rod cladding, with respect to vibration considerations, are incorporated within the fuel assembly design. It is a requirement that the spacer grid intervals, in conjunction with the fuel rod stiffness, be such that fuel rod vibration, as a result of mechanical or flow-induced excitation, does not result in excessive wear of the fuel rod cladding at the spacer grid contact areas.

The use of ZIRLO fuel cladding is limited to a maximum allowable corrosion of 100 microns. The corrosion thickness is calculated using the best estimate model described in Reference 71. Contained in reference 71 is a letter from P.W. Richardson (WEC) to J.S. Cushing (NRC), "Response to Requests for Additional Information on Topical Report CENPD-404-P, Rev. 0", LD-2001-0045, Rev. 0, August 10, 2001. This letter specifically addresses the best estimate models for predicting corrosion limits.

The use of ZIRLO fuel cladding is also limited to a maximum radial integrated rod burnup of 60 GWD/MTU.

4.2.1.2.2 Fuel Rod Cladding Properties

4.2.1.2.2.1 Mechanical Properties

A. Modulus of Elasticity

The Modulus of Elasticity is evaluated as a function of temperature, using a Westinghouse proprietary formula.

B. Poisson's Ratio

Poisson's Ratio is evaluated as a function of temperature, using a Westinghouse proprietary formula.

C. Thermal Coefficient of Expansion

Diametral direction Thermal Coefficient of Expansion is evaluated as a function of temperature, using a Westinghouse proprietary formula.

D. Yield Strength

Yield strength in the non-irradiated condition is evaluated as a function of temperature, using a

Westinghouse proprietary formula. Yield strength in the irradiated condition is evaluated as a function of fluence.

The cladding stress limits identified in paragraph 4.2.1.2.1 are based on values taken from the minimum yield strength curve at the appropriate temperatures. The limits are applied over the entire fuel lifetime, during conditions of reactor heatup and cooldown, steady state operation, and normal power cycling. Under these conditions, cladding temperatures and fast fluences can range from 70 to 750F and from 0 to 1 x 10^{22}nvt, respectively.

E. Ultimate Strength

Ultimate tensile strength in the non-irradiated condition is evaluated as a function of temperature, using a Westinghouse proprietary formula. Ultimate tensile strength in the irradiated condition is evaluated as a function of fluence.

F. Uniform Tensile Strain

The uniform tensile strain in the irradiated condition is evaluated as a function of temperature, using a Westinghouse proprietary formula. Uniform tensile strain in the irradiated condition approaches 1% and remains relatively constant.

G. Hydrostatic Burst Test

The Zircaloy-4 cladding specification requires that two samples from each lot of cladding be subjected to room

temperature hydrostatic burst tests. To be acceptable, the burst pressure must exceed a minimum value, based on the cladding geometry and specified tensile properties, and the circumferential elongation must exceed a prescribed minimum value.

Where the use of ZIRLO™ cladding is part of the design, the ZIRLO™ cladding specification includes the requirement for Contractile Strain Ratio (CSR) testing. CSR testing is employed in place of burst testing to quantify the effects of texture on the mechanical properties.

4.2.1.2.2.2 Dimensional Requirements

A. Tube straightness is limited to 0.010 in./ft, and inside diameter and wall thickness are tightly controlled.

B. Ovality is measured as the difference between maximum and minimum outside diameters and is acceptable if within the diameter tolerances.

C. Outside diameter is specified as 0.382 ± 0.002 inches.

D. Inside diameter is specified as 0.332 ± 0.0015 inches.

E. Eccentricity is defined as the difference between maximum and minimum wall thickness at a cross-section, and is specified as 0.004 inches maximum.

F. Wall thickness is specified as 0.023 inches minimum (the nominal value reported in Table 4.2-1 is based on the nominal OD and ID).

4.2.1.2.2.3 Metallurgical Properties

Hydride Orientation. A restriction is placed on the hydride orientation factor for any third wall thickness of the tube cross-section (inside, middle, or outside). The hydride orientation factor, defined as the ratio of the number of radially oriented hydride platelets to the total number of hydride platelets, shall not exceed 0.3. The independent evaluation of three portions of the cross-section is included to allow for the possibility that hydride orientation may not be uniform across the entire cross-section.

4.2.1.2.2.4 Chemical Properties. Fuel rod cladding is manufactured in accordance with ASTM B353, Wrought Zirconium and Zirconium Alloy Seamless and Welded Tubes for Nuclear Service, or ASTM B811, Wrought Zirconium Alloy Seamless Tubes for Nuclear Reactor Fuel Cladding, except additional limits are placed on oxygen, silicon, carbon, iron, and tin content.

4.2.1.2.3 Fuel Rod Component Properties

4.2.1.2.3.1 Zircaloy-4 Bar Stock. Zircaloy-4 bar stock is fabricated in accordance with ASTM B351, Standard Specification for Hot-Rolled and Cold-Finished Zirconium and Zirconium Alloy Bars, Rod and Wire for Nuclear Application, with the following exception and/or additions:

A. Chemical Properties

Additional limits are placed on oxygen, carbon, and silicon content.

B. Metallurgical Properties

The maximum average grain size is restricted.

C. Nondestructive Testing

Ultrasonic inspection is required.

4.2.1.2.3.2 Stainless Steel Compression Springs. Stainless steel springs are fabricated in accordance with AMS 5688, Steel, Corrosion Resistant, Wire 18Cr-9.0Ni (SAE 30302) Spring Temper.

4.2.1.2.4 UO_2 Fuel Pellet Properties

4.2.1.2.4.1 Chemical Composition. Salient points regarding the structure, composition, and properties of the UO_2 fuel pellets are discussed in the following paragraphs. Where the effect of irradiation on a specific item is considered to be of sufficient importance to warrant reflection in the design or analyses, that effect is also discussed.

A. Chemical analyses are performed for the following constituents:

1. Total uranium
2. Carbon
3. Nitrogen
4. Fluorine
5. Chlorine and Fluorine
6. Iron
7. Thorium

8. Nickel

9. Aluminum

10. Silicon

11. Calcium and Magnesium

B. The oxygen-to-uranium ratio is maintained between 1.99 and 2.02.

C. The sum of the cross-sections of the following constituents shall not exceed a specified equivalent thermal-neutron capture cross-section of natural boron:

1. Boron

2. Silver

3. Cadmium

4. Gadolinium

5. Europium

6. Samarium

7. Dysprosium

8. Erbium

D. The total hydrogen content of finished ground pellets is restricted.

E. The nominal enrichment of the fuel pellets will be specified in a manufacturing order.

F. Erbium oxide (Er_2O_3) may be admixed with UO_2 as a burnable poison pellet for reload core designs, in lieu

of the original Al_2O_3-B_4C poison described in section 4.2.1.3.

4.2.1.2.4.2 Microstructure

The average grain size shall exceed a specified minimum size.

4.2.1.2.4.3 Density

A. The density of sintered pellets is determined on a geometric basis, based on a UO_2 theoretical density of 10.96 g/cm^3. The density of UO_2-Er_2O_3 pellets may differ slightly from that of UO_2 pellets, as described in Reference 27.

B. The in-pile stability of the fuel is ensured by the use of NRC-approved out-of-pile tests during production. The details of one of these tests, and the associated rationale, are presented in reference 13.

C. The effects of irradiation on the density of sintered UO_2 pellets are treated by the NRC-approved model for fuel evaluation presented in references 13 and 14.

4.2.1.2.4.4 Thermal Properties of UO_2

A. Thermal expansion

The thermal expansion of UO_2 is described by the following temperature-dependent equations:(15)(16)

From 25C up to 2200C

$$\% \text{ Linear Expansion} = (-1.723 \times 10^{-2}) + (6.797 \times 10^{-4} T) + (2.896 \times 10^{-7} T^2)$$

Above 2200C

$$\% \text{ Linear Expansion} = 0.204 + (3 \times 10^{-4} T) + (2 \times 10^{-7} T^2) + (10^{-10} T^3)$$

where T = temperature, °C

B. Thermal Emissivity

A value of 0.85 is used for the thermal emissivity of UO_2 over the temperature range 800 to 2600K.(17)(18)(19)

C. Melting Point and Thermal Conductivity

The temperature required to incur melting of UO_2 is linearly dependent on local burnup as given by:

$$T_{melt} = 5080 - (290)\left(\frac{\text{Burnup}}{50{,}000}\right)$$

where T_{melt} is in °F and burnup is in MWd/Mtu. This equation is based on UO_2 melt data given by reference 20.

The variation of the thermal conductivity of UO_2 with burnup is not explicitly treated, but is implicitly taken from the porosity relationship discussed in Section 2.2.5 of reference 13.

The melting point and thermal conductivity of UO_2-Er_2O_3 is slightly lower than that of UO_2, as described in Reference 27.

D. Specific Heat of UO_2

The specific heat of UO_2 is described by the following temperature-dependent equations:[21]

For T < 2240F

$$C_p = 49.67 + 2.2784 \times 10^{-3}T - \frac{3.2432 \times 10^6}{(T + 460)^2}$$

For T ≥ 2240F

$$C_p = -126.07 + 0.2621T - 1.399 \times 10^{-4}T^2 + 3.1786 \times 10^{-8}T^3 - 2.489 \times 10^{-12}T^4$$

where:

C_p = specific heat, Btu/ft^3-°F

T = temperature, °F

The specific heat of UO_2-Er_2O_3 is slightly higher than that of UO_2, as described in Reference 27.

4.2.1.2.4.5 Mechanical Properties

A. Young's Modulus of Elasticity

The static modulus of elasticity of unirradiated UO_2 of 97% TD and deformed under a strain rate of 0.097 hr^{-1} is given by:[22]

$E = 14.22 (1.6715 \times 10^6 - 924.4T)$

where:

E = modulus of elasticity, psi

T = temperature, °C, in the range of 1000 to 1700C

B. Poisson's Ratio

The Poisson's Ratio of polycrystalline $UO_{(2)}$ has a value of 0.32 at 25C based on reference 23. The same reference notes a 10% decrease in value over the range of 25 to 1800C. Assuming the decrease is linear, the temperature dependence of the Poisson's ratio is given by

$\upsilon = 0.32 - 1.8 \times 10^{-5} (T-25)$

where:

υ = Poisson's Ratio

T = temperature, °C, in the range of 25 to 1800C

At temperatures above 1800C a constant value of 0.29 is used for Poisson's Ratio.

C. Yield Stress (not applicable)

D. Ultimate Stress (not applicable)

E. Uniform Ultimate Strain (not applicable)

4.2.1.2.5 Fuel Rod Pressurization

Fuel rods are initially pressurized with helium for two reasons:

A. To preclude clad collapse during the design life of the fuel. The internal pressurization, by reducing stresses from differential pressure, extends the time required to produce creep collapse beyond the required service life of the fuel.

B. To improve the thermal conductivity of the pellet-to-clad gap within the fuel rod. Helium has a higher coefficient of thermal conductivity than the gaseous fission products.

In unpressurized fuel, the initially good helium conductivity is eventually degraded through the addition of the fission product gases released from the pellets. The initial helium pressurization results in a high helium-to-fission products ratio over the design life of the fuel, with a corresponding increase in the gap conductivity and heat transfer. The effect of fuel rod power level and pin burnup on fuel rod internal pressure has been studied parametrically.

The initial helium fill pressure for the original fuel design was 380 psig. This initial fill pressure was sufficient to produce a maximum EOL internal pressure consistent with the criteria of paragraph 4.2.1.2.1. The calculational methods employed to generate internal pressure histories are discussed in references 13, 14, 24, and 25. Modified design criteria for fuel rod pressurization were proposed by C-E in a topical report that justified rod internal pressure exceeding RCS pressure.[10] This report received NRC staff approval and may be used for reload core design, provided core design evaluations consider the potential effects of increased rod

pressure on LOCA calculations and DNB propagation in postulated accidents.

4.2.1.2.5.1 Capacity for Fission Gas Inventory. The greater portion of the gaseous fission products remains either within the lattice or the microporosity of the UO_2 fuel pellets, and does not contribute to the fuel rod internal pressure. However, a fraction of the fission gas is released from the pellets by diffusion and pore migration and thereafter contributes to the internal pressure.

The determination of the effect of fission gas generated in and released from the pellet column is discussed in paragraph 4.2.3.2.2. The rod pressure increase which results from the release of a given quantity of gas from the fuel pellets depends upon the amount of open void volume available within the fuel rod and the temperature associated with the various void volumes. In the fuel rod design, the void volumes considered in computing internal pressure are:

- Fuel rod upper-end plenum
- Fuel-clad annulus
- Fuel pellet-end dishes and chamfers
- Fuel pellet open porosity

These volumes are not constant during the life of the fuel. The model used for computing the available volume as a function of burnup and power level accounts for the effects of fuel and clad thermal expansion, fuel pellet densification, clad creep,

clad growth, and irradiation-induced swelling of the fuel pellets.

4.2.1.2.5.2 Fuel Rod Plenum Design. The fuel rod upper-end plenum is required to serve the following functions:

- Provide space for axial thermal expansion and burnup swelling of the pellet column.
- Contain the pellet column holddown spring.
- Act as a plenum region to ensure an acceptable range of fuel rod internal pressure.

Of these functions, the last one is expected to be the most limiting constraint on plenum length selection, since the range of temperatures in the fuel rod, together with the effects of swelling, thermal expansion, and fission gas release, produces a wide range of internal pressure during the life of the fuel. The fuel rod plenum pressure will be consistent with the pressurization and clad collapse criteria specified in paragraph 4.2.1.2.1.

4.2.1.2.5.3 Outline of Procedure Used to Size the Fuel Rod Plenum

A. A parametric study of the effects of plenum length on maximum and minimum rod internal pressure is performed. Because the criteria pertaining to maximum and minimum rod internal pressure differ, the study is divided into two sections:

1. Maximum Internal Pressure Calculation

   Maximum rod pressure is limited by the criteria specified in paragraph 4.2.1.2.1. Maximum end-of-life pressure is determined for each plenum length by including the fission gas released, selecting conservative values for components' dimensions and properties, and accounting for burnup effects on component dimensions. The primary cladding stress produced by each maximum pressure is then compared to the stress limits to find the margin available with each plenum length. Stress limits are listed in paragraph 4.2.1.2.1.

2. Minimum Internal Pressure/Collapse Calculation

   Minimum rod pressure is limited by the criterion that no rod will be subject to collapse during the design lifetime. The minimum pressure history for each plenum length is determined by neglecting fission gas release, selecting a conservative combination of component dimensions and properties, and accounting for dimensional changes during irradiation, including the effects of cladding creep, cladding growth, pellet densification, pellet swelling, and thermal expansion.

B. For each plenum length, there is a resultant range of acceptable initial fill pressures. The optimum plenum length is generally considered to be the shortest which satisfies all criteria related to maximum and minimum rod internal pressure, including a range sufficient to

accommodate a reasonable manufacturing tolerance on initial fill pressure.

C. Additional information on those factors which have a bearing on determination of the plenum length are discussed below:

1. Creep and dimensional stability of the fuel rod assembly influence the fission gas release model and internal pressure calculations, and are accounted for in the procedure for sizing the fuel rod plenum length. Creep in the cladding is accounted for in a change in clad inside diameter, which in turn influences the fuel/clad gap. The gap change varies the gap conductance in the FATES computer code(13)(14)(24)(72), with resulting changes in annulus temperature, internal pressure, and fission gas release. In addition, the change in clad inside diameter causes a change in the internal volume, with its resulting effect on temperature and pressure. Dimensional stability considerations affect the internal volume of the fuel rod, causing changes in internal pressure and temperature. Fuel pellet densification reduces the stack height and pellet diameter. Irradiation-induced radial and axial swelling of the fuel pellets decreases the internal volume within the fuel rod. In-pile growth of the fuel rod cladding contributes to the internal volume. Axial and radial elastic deformation calculations for the cladding are based on the differential pressure the

cladding is exposed to, resulting in internal volume changes. Thermal relocation, as well as differential thermal expansion of the fuel rod materials, also affects the internal volume of the fuel rods.

2. The maximum expected fission gas release in the peak power rod is calculated using the FATES computer code.(13)(14)(24)(72) Rod power history input to the code is consistent with the design limit peak linear heat rate set by LOCA considerations, and therefore the gas release used to size the plenum represents an upper limit. Because of time-varying gap conductance, fuel temperature and depletion, and expected fuel management, the release rate varies as a function of burnup.

4.2.1.2.6 Fuel Rod Performance

Steady-state fuel temperatures are determined by the FATES computer program.(13)(14)(24)(72) The calculational procedure considers the effect of linear heat rate, fuel relocation, fuel swelling, densification, thermal expansion, fission gas release, and clad deformations. The model for predicting fuel thermal performance, including the specific effects of fuel densification on increased LHGR and stored energy, is discussed in references 13, 14, 24, and 72.

Significant parameters such as cold pellet and clad diameters, gas pressure and composition, burnup and void volumes are calculated and used as initial conditions for subsequent

calculations for stored energy during the ECCS analysis. The coupling mechanism between FATES calculations and the ECCS analysis is described in detail in reference 26.

Discussions of uncertainties associated with the model, and of comparative analytical and experimental results, are also included in references 13, 14, 71 and 72.

4.2.1.3 Burnable Poison Rod

UFSAR Section 4.2.1.3 describes the aluminum oxide-boron carbide (Al_2O_3-B_4C) poison rods that were incorporated into the original Combustion Engineering System 80 fuel design for PVNGS. Although this poison is no longer favored for core design, these poison rods are present in many fuel assemblies stored at PVNGS, and are still acceptable for use in operating reactor cores. Therefore, this UFSAR section is retained primarily for historical purposes. Reload core designs may utilize erbium oxide (Er_2O_3) as a poison or absorber, in lieu of Al_2O_3-B_4C poison rods. The erbium oxide is admixed with slightly enriched uranium dioxide (UO_2) fuel in the form of sintered pellets, and the pellets are enclosed in pressurized Zircaloy or ZIRLO™ tubes. These rods are mechanically similar to fuel rods and are manufactured to the same specifications as the UO_2 fuel rods described in Section 4.2.1.2, except that the erbium oxide may constitute several weight percent of the pellets. The UO_2-Er_2O_3 fuel-poison rods meet all of the fuel mechanical design criteria described in Section 4.2.1.2. Reload designs that utilize UO_2-Er_2O_3 rods conform to a

proprietary Combustion Engineering design methodology topical report that has received NRC staff approval.[27]

4.2.1.3.1 Burnable Poison Rod Cladding Design Limits

The burnable poison rod design accounts for external pressure, differential expansion of pellets and clad, pellet swelling, clad creep, helium gas release, initial internal helium pressure, thermal stress, and flow-induced vibrations. Except where specifically noted, the design bases presented in this section are consistent with those used for previous designs. The structural criteria for the normal, upset, and emergency loading combinations identified in paragraphs 4.2.1.1 and 4.2.1.2 are highlighted as follows:

A. During normal operating and upset conditions, the maximum primary tensile stress in the clad shall not exceed two-thirds of the minimum unirradiated yield strength of the material at the applicable temperature. The corresponding limit under emergency conditions is the material yield strength.

B. Net unrecoverable circumferential strain shall not exceed 1% as predicted by computations considering clad creep and poison pellet swelling effects.

C. The clad will be initially pressurized with helium to an amount sufficient to prevent gross clad deformation under the combined effects of external pressure and long-term creep.

4.2.1.3.2 Burnable Poison Rod Cladding Properties

Cladding tubes for burnable poison rods are purchased under the specification for fuel rod cladding tubes. Therefore, the mechanical, metallurgical, chemical, and dimensional properties of the cladding are as discussed in paragraph 4.2.1.2.2.

4.2.1.3.3 Al_2O_3-B_4C Burnable Poison Pellet Properties

The Al_2O_3-B_4C burnable poison pellets used in C-E-designed reactors consist of a relatively small volume fraction of fine B_4C particles dispersed in a continuous Al_2O_3 matrix. The boron loading is varied by adjusting the B_4C concentration in the range from 0.7 to 4.0 wt% (1 to 6.0 v/o). The bulk density of the Al_2O_3-B_4C pellets is specified to be greater than 93% of the calculated theoretical density. Typical pellets have a bulk density of about 95% of the theoretical value. Many properties of the two-phase Al_2O_3-B_4C mixture, such as thermal expansion, thermal conductivity, and specific heat are very similar to the properties of the Al_2O_3 major constituent. In contrast, properties such as swelling, helium release, melting point, and corrosion are dependent on the presence of B_4C. The operating centerline temperature of burnable poison is less than 1150F, with maximum surface temperatures close to 1090F.

4.2.1.3.3.1 Thermal-Physical Properties

A. Thermal Expansion

The mean thermal expansion coefficients of Al_2O_3[28] and B_4C[29] from 0 to 1850F are 4.9 and 2.5 in./in. F x 10^{-6},

respectively. The thermal expansion of the Al_2O_3-B_4C two-phase mixture can be considered to be essentially the same as the value for the continuous Al_2O_3 matrix since the dispersed B_4C phase has a lower expansion coefficient and occupies only 5 v/o of the available volume. The low temperature (80 to 250F) thermal expansion coefficient of Al_2O_3 irradiated at 480, 900, and 1300F does not change as a result of irradiation.[30] The expansion of a similar material, beryllium oxide, up to 1900F has also been reported to be relatively unchanged by irradiation.[31] It is therefore appropriate to use the values of thermal expansion measured for Al_2O_3[28] for the burnable poison pellets:

Temperature Range (°F from 70F to)	Linear Expansion (%)
400	0.12
600	0.23
800	0.30
1000	0.40

B. Melting Point

The melting points of Al_2O_3 (3710F)[32] and B_4C (4400F)[33] are higher than the melting point of the Zr-4 cladding. No reactions have been reported between

the components which would lower the melting point of the pellets to any significant extent. As the B_4C burns up, the lithium atoms formed occupy interstitial sites randomly distributed within the B_4C lattice, rather than forming a lithium-rich phase.[34] The solid solution of lithium in B_4C should not appreciably influence the melting point of the Al_2O_3-B_4C pellets, as only a small quantity of lithium compounds (0.5 wt%) forms during irradiation. It is concluded that the melting point of Al_2O_3-B_4C will remain considerably above the maximum 1150F operating temperature.

C. Thermal Conductivity

The thermal conductivity of Al_2O_3-B_4C was calculated from the measured values for Al_2O_3 and B_4C using the Maxwell-Eucken relationship[35] for a continuous matrix phase (Al_2O_3) with spherical dispersed phase (B_4C) particles. Because of the high Al_2O_3 content of these mixtures and the similarity in thermal conductivity, the resultant values for Al_2O_3-B_4C were essentially the same as the values for Al_2O_3. The measured, unirradiated values of thermal conductivity at 750F are 0.06 cal/s-cm-°K for B_4C and 0.05 cal/s-cm-°K for Al_2O_3.

The thermal conductivity of Al_2O_3 after irradiation decreases rapidly as a function of burnup to values of about one-third the unirradiated values.[30] The irradiated values of Al_2O_3-B_4C calculated from the above

relationships are given below as a function of temperature.[30][36]

Temperature (°F)	Thermal Conductivity (cal/s-cm-°K)
400	0.015
600	0.013
800	0.010
1000	0.008

D. Specific Heat

The specific heat of the Al_2O_3-B_4C mixture can be taken to be essentially the same as pure Al_2O_3 since the concentration of B_4C is low (6.0 v/o maximum). In addition, the effect of irradiation on specific heat is expected to be small based on experimental evidence from similar materials which do not sustain transmutations as a function of neutron exposure.

The values for Al_2O_3 measured on unirradiated samples[36][37] are given below:

Temperature (°F)	Specific Heat (cal/gm-°F)
250	0.12
450	0.13
800	0.14
1000 and above	0.15

4.2.1.3.3.2 Irradiation Properties

A. Swelling

Al_2O_3-B_4C consists of B_4C particles dispersed in a continuous Al_2O_3 matrix, which occupies more than 95% of the poison pellet. The swelling of Al_2O_3-B_4C depends primarily upon the neutron fluence on the continuous Al_2O_3 matrix and, secondarily, on the B^{10} burnup of the dispersed B_4C phase. Recent measurements performed on material containing about 2 wt% B_4C irradiated in a C-E PWR to 100% B^{10} burnup at a fluence of 2.4 x 10^{21} nvt (E > 0.8 MeV) revealed a diametral swelling of about 1%. Pellets similar to the burnable poison used in C-E reactors with up to 3 wt% B_4C also sustained about 100% B^{10} burnup. Experimental data(38) on Al_2O_3 reveal a diametral swelling of about 0.7% at a fluence of 2.4 x 10^{21} nvt (E > 0.8 MeV). Swelling of Al_2O_3 increases linearly with fluence to 1.8% diametral after an exposure of 6 x 10^{21} nvt (E > 0.8 MeV).

These data show that Al_2O_3-B_4C swells somewhat more than Al_2O_3 up to a burnup of $\underset{\sim}{~}$ 90% B^{10} depletion (about 2 x 10^{21} nvt, E > 0.8 MeV).

The C-E design value of Al_2O_3-B_4C swelling rate for fluences less than 2 x 10^{21} nvt is greater than the swelling rate of Al_2O_3, while after 2 x 10^{21} nvt fluence

the swelling rate for Al_2O_3-B_4C is considered equal to that of Al_2O_3.

The data and considerations presented above result in best-estimate diametral swelling values at end-of-life (7×10^{21} nvt, E > 0.8 MeV) of about 2% for Al_2O_3 and from 2 to 3% for Al_2O_3-B_4C loading.

B. Helium Release

Experimental measurements reveal that less than 5% of the helium formed during irradiation will be released.[39] These measurements were performed on Al_2O_3-B_4C pellets irradiated at temperatures to 500F and subsequently annealed at 1000F for 5 days. The helium release in a burnable poison rod which operated for one cycle in a C-E PWR was calculated from internal pressure measurements to be less than 5%.

4.2.1.3.3.3 Chemical Properties

A. Al_2O_3-B_4C Coolant Reaction

Should irradiated B_4C particles be exposed to reactor coolant, the primary corrosion products that would be formed are boric acid (which is soluble in water), hydrogen, free carbon, and a small amount of lithium compounds. The presence of these products in the reactor coolant would not be detrimental to the operation of the plant.

Observations of Al_2O_3-B_4C poison shims have revealed that long-term exposure of this material to reactor coolant can result in gradual leaking out of boron and eventual eroding away of the Al_2O_3 matrix. However, the rate of reaction is such that any resultant changes in reactivity are very gradual.

B. Chemical Compatibility

Chemical compatibility between Al_2O_3-B_4C pellets and the burnable poison rod cladding during long-term normal operation has been demonstrated by examination of a burnable poison rod from the Maine Yankee reactor. The rod had been exposed to an axial average fluence in excess of 2×10^{10} nvt (E > 0.821 MeV). No evidence of a chemical reaction was observed on the cladding I.D.

Short-term chemical compatibility during upset and emergency conditions is demonstrated by the fact that conditions favorable to a chemical reaction between Zr-4 and Al_2O_3 are not present at temperatures below 1300F.[40] This temperature is higher than that which will occur at burnable poison pellet surfaces during Condition II and III occurrences (paragraph 4.2.1.1). The reaction between Zr-4 and Al_2O_3 described by Idaho Nuclear[41] was observed to occur rapidly only at temperatures in excess of 2500F, well above the peak Zr-4 temperatures in the higher-energy fuel rods described in chapter 15.

4.2.1.4 Control Element Assemblies (CEAs)

The mechanical design of the control element assemblies is based on compliance with the following functional requirements and criteria.

A. To provide for or initiate short-term reactivity control under all normal and adverse conditions experienced during reactor startup, normal operation, shutdown, and accident conditions.

B. Mechanical clearances of the CEA within the fuel and reactor internals are such that the requirements for CEA positioning and reactor trip are attained under the most adverse accumulation of tolerances.

C. Structural material characteristics are such that radiation-induced changes to the CEA materials will not impair the functions of the reactivity control system.

4.2.1.4.1 Thermal-Physical Properties of Absorber Material

The primary control rod absorber materials in the Feltmetal® full strength CEAs consist of boron carbide (B_4C) pellets. The control rod absorber material in the AIC full strength CEAs consists of B_4C pellets, and hollow Silver-Indium-Cadmium (AIC) slugs. Alloy 625 is used as the absorber in the part-strength rods. Refer to figures 4.2-3, 4.2-4, and 4.2-5 for the specific application and orientation of the absorber materials. The significant thermal and physical properties used in mechanical analysis of the absorber materials are listed below:

A. Boron Carbide (B_4C)

Configuration	Right cylinder	
Outside diameter, inches	(a) 0.737 ± 0.001 (b) 0.664 ± 0.001, or 0.674[a] ± 0.001	
Pellet length, inches	0.5 to 2.0	
Density, gm/cc	1.84	
Weight % boron, minimum	77.5	
% open porosity in pellet	27	
Ultimate tensile strength, lb/in^2	N/A	
Yield strength, $lb/in.^2$	N/A	
Elongation, %	N/A	
Young's Modulus, psi	N/A	
Thermal conductivity,		
cal/cm-s-°C	Irradiated	Unirradiated
at 800F	8.3×10^{-3}	28×10^{-3}
at 1000F	7.9×10^{-3}	24×10^{-3}

(a) Nominal tip B_4C pellet diameter is 0.664 inches. The 0.674 inch diameter pellet remains in the UFSAR to allow use of existing spares if necessary.

Melting point, °F	4440
% thermal linear expansion	0.23% @ 1000F

B. Silver-Indium-Cadmium (AIC)

Configuration	Hollow right cylinder
Outside diameter, inches	0.734 ± 0.003
Inside diameter, inches	0.250 ± 0.016
Slug length, inches	8.250 ± 0.062
Density, gm/cc	10.17
Young's Modulus, psi	11.52 @ 25°C 9.86 @ 300°C
Thermal Conductivity, cal/CM-s-°C	0.137 irradiated 0.182 unirradiated
Melting Point, °F	1470 ± 18
Thermal linear expansion, in/in/°F (77°F to 932°F)	13.1×10^{-6} irradiated 12.5×10^{-6} unirradiated
Yield Strength, MPa	190 irradiated
Ultimate Strength, MPa	345 irradiated

C. Type 347 Stainless Steel Felt Metal

Configuration	Cylindrical sleeves formed from sheets
Thickness, inches	0.032 ± 0.002
Length of sheet, inches nominal	20

Density, $lbs/in.^3$	0.059
Ultimate tensile strength, $lb/in.^2$	N/A

Young's Modulus, $lb/in.^2$	N/A
Thermal conductivity, cal/s-cm-°C	
at 500F	1.26×10^{-3}
at 1000F	1.41×10^{-3}

D. Alloy 625

Configuration (as absorber)	Solid Cylindrical bar (a.k.a., Slug)
Outside diameter, inches	0.737 ± 0.001
Inside diameter, inches	Solid
Length of each absorber slug, inches	7.450 ± 0.020 (part-strength CEA)
Total length of absorber slugs, inches	149.0 (part-strength CEA)
Density, $lb/in.^3$	0.305
Ultimate tensile strength, $lb/in.^2$	120-150

Specified minimum yield strength @ 650F, ksi	65
Elongation in 2 inches, %	30
Young's Modulus, lb/in.^{2}	
at 70F	29.7×10^6
at 650F	27.0×10^6
Thermal conductivity, Btu/h-ft-°F	
at 70F	5.7
at 600F	8.2
Linear thermal expansion, in./in.-°F	7.4×10^{-6} (70 to 600F)

4.2.1.4.2 Compatibility of Absorber and Cladding Materials

The cladding material used for the control elements is Alloy 625. The selection of this material for use as cladding is based on considerations of strength, creep resistance, corrosion resistance, and dimensional stability under irradiation, and also upon the acceptable performance of this material for this application in other Westinghouse reactors currently in operation.

A. B_4C/Alloy 625 Compatibility

Studies have been conducted by HEDL[42] on the compatibility of Type 316 stainless steel with B_4C under irradiation for thousands of hours at temperatures between 1300 and 1600F. Carbide formation to a depth of about 0.004 inch in the 316 stainless steel was measured after 4400 hours at 1300F. Similar compound formation depths were observed after ex-reactor bench testing. After testing at 1000F, only 0.001 in./yr of penetration was measured. Since Alloy 625 is more resistant to carbide formation than 316 stainless steel, and the expected pellet/clad interfacial temperature in the standard design is below 800F, it is concluded that B_4C is compatible with Alloy 625.

B. Silver-Indium-Cadmium (AIC)/Alloy 625 Compatibility

AIC is a corrosion resistant alloy whose compatibility with Alloy 625 has been demonstrated in numerous control rod applications.

4.2.1.4.3 Cladding Stress-Strain Limits

The stress limits for the Alloy 625 cladding are as follows:

A. Nonoperation, Normal Operation, and Upset Design Conditions

$$P_m \leq S_m$$

$$P_m + P_b \leq F_s S_m$$

The net unrecoverable circumferential strain shall not exceed 1% on the cladding diameter, considering the effects of pellet swelling and cladding creep. Near the CEA tip, plastic strain cannot be accommodated; therefore, strain must remain in the elastic range, taken as the proportional limit or 2/3 of the yield stress for irradiated material.

B. Emergency Design Conditions

$$P_m \leq 1.5\ S_m$$

$$P_m + P_b \leq 1.5\ F_s S_m$$

C. Faulted Design Conditions

$$P_m \leq S_m'$$

$$P_m + P_b \leq F_s S_m'$$

where S_m' is the smaller of 2.4 S_m or $0.7S_u$.

For definition of P_m, P_b, S_m, S_m', S_u, and F_s, see paragraph 4.2.1.1.1. For the Alloy 625 CEA cladding, the value of S_m is two-thirds of the minimum specified yield strength at temperature.

For Alloy 625, the specified minimum yield strength is 65,000 lb/in.^{2} at 650F.

F_s = Mp/My where Mp is the bending moment required to produce a fully plastic section and My is the bending moment which first produces yielding at the extreme fibers of the cross-section. The capability of cross-sections loaded in bending to

sustain moments considerably in excess of that required to yield the outermost fiber is discussed in reference 1. For the CEA cladding dimensions, $F_s = 1.33$.

The values of uniform and total elongation of Alloy 625 cladding are estimated to be as follows:

Fluence (E > 1 MeV), nvt	1×10^{22}	3×10^{22}
Uniform elongation, %	3	1
Total elongation, %	6	3

4.2.1.4.4 Irradiation Behavior of Absorber Materials

A. Boron Carbide Properties

1. Swelling. The linear swelling of B_4C increases with burnup according to the relationship

$$\%\Delta L = (0.1)\ B^{10} \text{ burnup, a/o}$$

This relationship was obtained from experimental irradiations on high density (> 90% TD) wafers[43] and pellets with densities ranging between 71 and 98% TD.[42][44] Dimensional changes were measured as a function of burnup, after irradiating at the temperature expected in the design.

2. Thermal Conductivity. The thermal conductivity of unirradiated 73% dense B_4C decreases linearly with temperatures from 300 to 1600F, according to the relationship:

$$\lambda = \frac{1\ \text{cal/cm-°K-s}}{2.17\ (6.87 + 0.017\ T)}$$

where T = temperature, °K

This relationship was obtained from measurements performed on pellets ranging from 70 to 98% TD.[45]

The relationship between the thermal conductivity of irradiated 73% TD B_4C pellets and temperature given below was derived from measured values[45] on higher density pellets irradiated to fluences out to 3 x 10^{22} nvt (E > 1 MeV).

$$\lambda = \frac{1\ \text{cal/cm-°K-s}}{2.17\ (38 + 0.025\ T)}$$

where T = temperature, °K

Thermal conductivity measurements of 17 B_4C specimens with densities ranging from 83 to 98% TD, irradiated at temperatures from 930 to 1600F showed that thermal conductivity decreased significantly after irradiation. The rate of decrease is high at the lower irradiation temperatures, but saturates rapidly with exposure.

3. Helium Release. Helium is formed in B_4C as B^{10} burnup progresses. The fraction of the helium released from the pellets is important for determining rod internal gas pressure. The relationship between helium release and irradiation temperature given below was developed at ORNL[46] to

fit experimental data obtained from thermal reactor irradiations.

$$\%\text{He release} = e^{(C-1.85D)} e^{\frac{-Q}{RT}}$$

where:

C = constant, 6.69 for pellets

D = fractional density, 0.73 for C-E pellets

Q = activation energy constant, 3600 cal/mole

R = gas constant, 1.98 cal/mole-°K

T = pellet temperature, °K

This expression becomes

$$\%\ \text{He release} = 208\, e^{\frac{-1820}{T}} + 5$$

when the above parameters are substituted. In this form, design values for helium release as a function of temperature are generated. The 5% helium release allowance (the last term in the expression) was added to ensure that design values lie above all reported helium release data. Calculated values of helium release obtained from the recommended design expression lie above all experimental data points(42)(47)(48) obtained on B_4C pellet specimens irradiated in thermal reactors.

4. Pellet Porosity. Experimental evidence is available(49) which shows that for pellet densities below 90%, essentially all porosity is open at

beginning-of-life. Irradiation-induced swelling does not change the characteristics of porosity, but only changes the bulk volume of the specimens. Therefore, the amount of porosity available at end-of-life is the same as that present at beginning-of-life.

B. Silver-Indium-Cadmium

1. Swelling. Available data on swelling of AIC in CEA applications (Reference 73) gives a bounding volumetric swelling rate:

$$\frac{\%V}{V} = 0.21\frac{\phi t}{10^{21}} \qquad \text{(E>1MeV)}$$

Diametral swelling is taken as 1/3 volumetric swelling:

$$\frac{\%D}{D} = 0.07\frac{\phi t}{10^{21}} \qquad \text{(E>1MeV)}$$

2. Creep Strength. Creep strength and yield strength of AIC both increase due to irradiation; however, both the creep strength and yield strength remain well below the irradiated yield strength of the Alloy 625 cladding.

3. Helium Release and Pellet Porosity. The AIC slugs do not undergo the same neutron activation reaction as B_{10}; therefore, no helium is generated as a result of irradiation. The AIC slugs are not a ceramic material as B_4C is; therefore, there is no porosity associated with the AIC structure.

C. Alloy 625

1. Swelling. Available information indicates that Alloy 625 is highly resistant to radiation swelling. Exposure of Alloy 625 to a fluence of 3×10^{22} nvt (E > 0.1 MeV) at a temperature of 400C (725F) showed no visible cavities in metallographic examinations(50) so that swelling, if any, would be very minor. Direct measurements made after exposure of Alloy 625 to a fluence 5×10^{22} nvt (E > 0.1 MeV) at LMFBR conditions showed no evidence of swelling.(51) Further exposure to 6 to 10^{22} nvt (E > 0.1 MeV) at 500C (932F) showed essentially no swelling as measured by immersion density, but did show small cavities. Thus, Alloy 625 after fluences of 3×10^{22} nvt (E > 1 MeV) is not expected to swell.

2. Ductility. The ductility of Alloy 625 decreases after irradiation. Extrapolation of lower fluence data on Alloy 625 and 500 indicates that the values of uniform and total elongation of Alloy 625 after 1×10^{22} nvt (E > 1 MeV) are 3 and 6%, respectively.

3. Strength. The value of yield strength of Alloy 625 increases after irradiation in the manner typical for metals. However, no credit is taken for increases in yield strength in the design analyses above the value initially specified.

4.2.1.5 Surveillance Program

4.2.1.5.1 Requirements for Surveillance and Testing of Irradiated Fuel Rods

High burnup performance experience, as described in subsection 4.2.3, has provided evidence that the fuel will perform satisfactorily under design conditions. In addition, C-E conducted a detailed fuel assembly performance evaluation program at the Arkansas Nuclear One - Unit 2 (ANO-2) reactor. Due to the similarity in the ANO-2 and System 80 designs, the evaluation is applicable to System 80 fuel.

A surveillance program has also been performed to evaluate the performance of System 80 fuel in Palo Verde. The program included end-of-cycle visual inspections, dimensional measurements to characterize fuel rod growth, and cladding oxide measurements on precharacterized fuel to track corrosion behavior. A CEA guide tube wear measurement program has been performed on Units' 1 and 2 fuel, at end-of-cycle 1, which indicates wear is within acceptable limits. Results from these surveillance programs indicate the fuel is behaving as expected with no indications that would alter the planned fuel management scheme for System 80 fuel.

A limited, random sample of fuel assemblies is visually inspected during or after each refueling outage, as described in section 4.2.4.

4.2.2 DESCRIPTION AND DESIGN DRAWINGS

This subsection summarizes the mechanical design characteristics of the fuel system and discusses the design parameters which are of significance to the performance of the reactor. A summary of typical mechanical design parameters is presented in table 4.2-1. These data are intended to be descriptive of the design and, in some cases, are approximate values. Limiting values of these and other parameters are discussed in the appropriate sections, and specific values are determined for each core reload.

4.2.2.1 Typical Fuel Assembly

The fuel assembly (figure 4.2-6) consists of 236 fuel and poison rods, 5 guide tubes, 11 fuel rod spacer grids, upper and lower end fittings, and a holddown device. The outer guide tubes, spacer grids, and end fittings form the structural frame of the assembly.

The fuel spacer grids (figure 4.2-7) maintain the fuel rod array by providing positive lateral restraint to the fuel rod but only frictional restraint to axial fuel rod motion. The grids are fabricated from preformed Zircaloy or Inconel strips (the top and bottom spacer grid material is Inconel) interlocked in an egg-crate fashion and welded together. Each cell of the spacer grid contains leaf springs and arches. The leaf springs press the rod against the arches to restrict relative motion between the grids and the fuel rods. The perimeter strips contain features designed to prevent hangup of grids during a refueling operation.

The spacer grids are fastened to the Zircaloy-4 guide tubes by welding to form a grid cage assembly. The Zircaloy-4 spacer grids are fastened directly to the guide tubes while the Inconel 625 top grid is held in place by two Zircaloy-4 split rings welded to each guide tube. In the original design, the lowest spacer grid (Inconel) was not welded to the guide tubes due to material differences. It was supported by an Inconel 625 skirt which was welded to the spacer grid and to the perimeter of the lower end fitting. In reload designs, the proprietary GUARDIAN™ grid replaces the lowest Inconel grid, and the perimeter strip is welded to the lower end fitting, in lieu of a skirt.

The upper end fitting is an assembly consisting of two cast 304 stainless steel plates, five machined posts, and four helical Inconel X-750 springs. The end fitting attaches to the guide tubes to serve as an alignment and locating device for each fuel assembly and has features to permit lifting of the fuel assembly. The lower cast plate locates the top ends of the guide tubes and is designed to prevent excessive axial motion of the fuel rods.

The Inconel X-750 springs are of conventional coil design. Inconel X-750 was selected for this application because of its previous use for coil springs and good resistance to relaxation during operation.

The upper cast plate of the assembly, called the holddown plate, together with the helical compression springs, comprise the holddown device. The holddown plate is movable, acts on the underside of the tube sheet tubes, and is loaded by the

compression springs. Since the springs are located at the upper end of the assembly, the spring load combines with the fuel assembly weight to counteract upward hydraulic forces. The determination of upward hydraulic forces includes factors accounting for flow maldistribution, fuel assembly component tolerances, crud buildup, drag coefficient, and bypass flow. The springs are sized and the spring preload selected such that a net downward force will be maintained for all normal and anticipated transient flow and temperature conditions. The design criteria limit the maximum stress under the most adverse tolerance conditions to below yield strength of the spring material. The maximum stress occurs during cold conditions and decreases as the reactor heats up. The reduction in stress is due to a decrease in spring deflection resulting from differential thermal expansion between the Zircaloy fuel bundles and the stainless steel internals.

During normal operation, a spring will never be compressed to its solid height. However, if the fuel assembly were loaded in an abnormal manner such that a spring were compressed to its solid height, the spring would continue to serve its function when the loading condition returned to normal.

The lower end fitting assembly is a simple stainless steel casting consisting of a plate with flow holes and a support leg at each corner (total of four legs) that aligns the lower end of the fuel assembly with the core support structures' alignment pins. Alignment pins are required to position the corners of the lower end fittings. A center post is threaded into the central portion of the flow plate and welded into position. Reload assemblies may have a lower end fitting

design whereby the center post is an integral part of the lower end fitting casting.

The four outer guide tubes have a widened region at the upper end which contains an internal thread. Connection with the upper end fitting is made by passing the externally threaded end of the guide posts through holes in the lower cast flow plate and into the guide tubes. When assembled, the flow plate is secured between flanges on the guide tubes and on the guide posts. The connection with the upper end fitting is locked with a mechanical crimp. Each outer guide tube has, at its lower end, a welded Zircaloy fitting. This fitting has a threaded portion which passes through a hole in the fuel assembly lower end fitting and is secured by either a Zircaloy nut or a stainless steel bolt. This joint is secured with a stainless steel locking ring welded to the lower end fitting.

The central instrumentation guide tube inserts into a socket and a sleeve in the upper and lower end fittings, respectively, and is thus retained laterally by the relatively small clearance at these locations. The upper end fitting socket is created by the center guide tube post which is threaded into the lower cast flow plate and tack-welded in two places. The lower end fitting sleeve is an extension from the center post of the lower end fitting assembly. There is no positive axial connection between the central guide tube and the end fittings.

The five guide tubes have the effect of ensuring that bowing or excessive swelling of the adjacent fuel rods cannot result in

obstruction of the control element pathway. This is so because:

A. There is sufficient clearance between the fuel rods and the guide tube surface to allow an adjacent fuel rod to reach rupture strain without contacting the guide tube surface.

B. The guide tube, having considerably greater diameter and wall thickness (and also, being at a lower temperature) than the fuel rod, is considerably stiffer than the fuel rods and would, therefore, remain straight, rather than be deflected by contact with the surface of an adjacent fuel rod.

Therefore, the bowing or swelling of fuel rods would not result in obstruction of the control element channels such as could hinder CEA movement.

The fuel assembly design enables reconstitution, i.e., removal and replacement of fuel and poison rods, of an irradiated fuel assembly. Reconstitution of fuel assemblies is done in accordance with Reference 70. Reference 70 describes a methodology of using inert replacement rods (solid stainless steel rods) to replace failed or damaged fuel rods, including burnable poison rods, during reconstitution of fuel assemblies for core reloads. The inert replacement rods require mechanical, neutronic, and thermal-hydraulic analyses to demonstrate that the inclusion of the inert replacement rods in fuel assemblies with the specific configurations and core locations chosen for a specific fuel cycle is acceptable with respect to the overall fuel performance and safety conclusions.

These analyses were performed in Reference 70, with generic bounding results achieved if the placement of stainless steel rods is limited to certain locations within the assembly. In fact, if the placement rules of Reference 70 are followed, then no further cycle specific analyses are required. Further, placement outside of the guidelines was not reviewed and approved. The fuel and poison rod lower end caps are conically shaped to ensure proper insertion within the fuel assembly grid cage structure. The lower end caps used with the Guardian™ grid in reload assemblies are longer than the end caps used in the original System 80 fuel design for PVNGS. The upper end caps are designed to enable grappling of the fuel and poison rod for purposes of removal and handling. Threaded joints which mechanically attach the upper end fitting to the control element guide tubes will be properly torqued and locked during service, but may be removed to provide access to the fuel and poison rods.

Loading and movement of the fuel assemblies are conducted in accordance with strictly monitored administrative procedures and, at the completion of fuel loading, an independent check as to the location and orientation of each fuel assembly in the core is required.

The serial number provided on the fuel assembly upper end fitting enables verification of fuel enrichment and orientation of the fuel assembly. The serial number is also provided on the lower end fitting to ensure preservation of fuel assembly identity in the event of upper end fitting removal.

During the manufacturing process, each fuel rod is marked to provide a means of maintaining a record of pellet enrichment, pellet lot, and fuel stack weight. In addition, the Westinghouse quality control program requires that measures be established for the identification and control of materials, components, and partially fabricated subassemblies. These means provide assurance that only acceptable items are used and also provide a method of relating an item or assembly from initial receipt through fabrication, installation, repair, or modification to an applicable drawing, specification, or other pertinent technical document.

Starting with reload Batch N, fuel rod fabrication was moved from Hematite, MO, to the Columbia, SC, facility. Fuel rod changes that resulted from this move include:

A. In reload assemblies prior to Batch N, the fuel rod end cap to cladding tube weld is a Magnetic Force (i.e., resistance) Weld whose outer surface is subsequently machined (i.e., deflashed). Beginning with Batch N, the joint was converted to Tungsten Inert Gas (TIG) welding. The latter also utilizes a separate (TIG) seal weld to close the opening through which the rod is pressurized.

B. The upper and lower end caps were redesigned to make them compatible with the TIG welding process.

C. The cladding tube was modified to make it compatible with the TIG welding process.

D. The fuel rod spring was redesigned for compatibility with the TIG welding process.

E. The alumina spacer between the pellet stack and the lower end cap was eliminated.

F. The combined effect of redesigning the lower end cap and eliminating the alumina spacer is to lower the active fuel region by 0.355 inch. This change in core elevation is relative to the Batch M design.

G. The combined effect of redesigning the plenum spring and eliminating the alumina spacer is to increase the rod's internal void volume by 0.032 cubic inch, relative to the Batch M design.

H. Reload rods for Batches N and later are fabricated at the Columbia facility, which builds its pellet stacks directly in the cladding tubes. Their stacks are built up, 25 at a time, from a series of shorter preassembled segments that are fed into a like number of tubes by a vibratory feeder. Before feeding the last row of segments into the tubes, the distance from the end of the tube to the end of the pellet stack is checked with a guage. If necessary, an appropriate number of pellets are added to or removed from each segment in the row. The gamma scanning system is used to certify dimensions related to stack lengths.

4.2.2.2 Fuel Rod

The fuel rods consist of slightly-enriched UO_2 or OO_2-Er_2O_3 cylindrical ceramic pellets, a round wire Type 302 stainless steel compression spring, and an alumina spacer disc located at each end of the fuel column, all encapsulated within a Zircaloy-4 or ZIRLO™ tube seal-welded with Zircaloy-4 end

caps. Reload assemblies may be manufactured without the alumina spacer discs. The fuel rods are internally pressurized with helium during assembly. Figure 4.2-8 depicts the fuel rod design. Figure 4.2-8a compares the Batch M and N urovia rods.

Each fuel rod assembly is marked to ensure traceability of the fabrication history of each fuel rod component.

The fuel cladding is cold-worked and stress-relief-annealed Zircaloy-4 or ZIRLO™ tubing 0.025 inch thick. The actual tube forming process consists of a series of cold-working and annealing operations, the details of which are selected to provide the combination of properties discussed in paragraph 4.2.1.2.2.

The UO_2 pellets are dished at both ends in order to better accommodate thermal expansion and fuel swelling. The density of the sintered pellets is determined on a geometric basis, based on a UO_2 theoretical density of 10.96 grams per cubic centimeter. The allowable range of pellet density is controlled by Westinghouse specification, and may vary slightly between batches of fuel. Furthermore, because the pellet dishes and chamfers constitute a small portion of the volume of the pellet stack, the average density of the pellet stack is lower than that of the individual pellets. This reduced value, the stack density, may likewise vary between batches of fuel.

The compression spring located at the top of the fuel pellet column maintains the column in its proper position during handling and shipping. The alumina spacer disc at the lower end of the fuel rod (prior to Batch N) reduces the lower end cap temperature. The fuel rod plenum, which is located above

the pellet column, provides space for axial thermal differential expansion of the fuel column and accommodates the initial helium loading and evolved fission gases. (See paragraphs 4.2.1.2.5.1 and 4.2.1.2.5.2.) The specific manner in which these factors are taken into account, including the calculation of temperatures for the gas contained within the various types of rod internal void volume, is discussed in references 13 and 14.

4.2.2.3 Burnable Poison Rod

The original burnable neutron absorber (poison) rods, figure 4.2-9, were included in selected fuel assemblies to reduce the beginning-of-life moderator coefficient. They replaced fuel rods at selected locations. The poison rods were mechanically similar to fuel rods, but contained a column of burnable poison pellets instead of fuel pellets. The poison material was alumina with uniformly-dispersed boron carbide particles. The balance of the column consisted of Zircaloy-4 spacers, with the total column length the same as the column length in fuel rods. The burnable poison rod plenum spring was designed to produce a smaller preload on the pellet column than that in a fuel rod, because of the lighter material in the poison pellets.

Each burnable poison rod assembly includes a serial number, to record fabrication information of each component in the rod assembly.

Reload assemblies may use UO_2-Er_2O_3 fuel-poison pellets, as described in Section 4.2.1.3. Figure 4.2-9a compares the Batch N and M erbia rods

4.2.2.4 Control Element Assembly Description and Design

The control element assemblies consist of either four or twelve neutron absorber elements arranged to engage the peripheral guide tubes of fuel assemblies. The neutron absorber elements are connected by a spider structure which couples to the control element drive mechanism (CEDM) drive shaft extension. The neutron absorber elements of a four-element CEA engage the four corner guide tubes in a single fuel assembly. The four-element CEAs are used for power shaping functions and make up the first control rod group to be inserted at high power. The twelve-element CEAs engage the four corner guide tubes in one fuel assembly and the two nearest corner guide tubes in adjacent fuel assemblies. The twelve-element CEAs make up the balance of the control groups of CEAs and provide a bank of strong shutdown rods. The control element assemblies are shown in figures 4.2-3 through 4.2-5. The pattern of CEAs (total of 89) is shown in figure 4.2-10. Note that up to eight additional CEAs may be installed if desired for additional flexibility or future use.

Part-strength CEAs are differentiated from full-strength CEAs by using alphanumeric serialization (i.e., P-XXX vs. F-XXX).

The control elements of a Feltmetal® full-strength CEA consist of an Alloy 625 tube loaded with a stack of cylindrical absorber pellets. The absorber material consists of 73% TD

boron carbide (B_4C) pellets, with the exception of the lower portion of the elements, which contains reduced diameter B_4C pellets wrapped in a sleeve of type 347 stainless steel felt metal.

The design objective realized by the use of felt metal and reduced diameter B_4C pellets in the element tip zones is that as the B_4C pellets swell due to irradiation, the felt metal sleeve compresses as a result of the applied loading. This compression limits the amount of induced strain in the cladding. Therefore, buffering of the CEA following scram, which occurs when the element tips enter a reduced diameter portion of the fuel assembly guide tubes, is not affected with long-term exposure of the CEA to reactor operating conditions.

The control elements of an AIC full-strength CEA consist of an Alloy 625 tube loaded with a stack of cylindrical B_4C absorber pellets and cylindrical AIC hollow absorber slugs. The B_4C pellets are 73% TD boron carbide material. The design objective realized by the use of hollow AIC slugs in the element tip zones is that as the AIC slugs swell due to thermal expansion and irradiation, the low AIC creep strength relative to the Alloy 625 cladding yield strength results in the AIC filling the central hole, which limits the amount of induced strain in the cladding. Therefore, buffering of the CEA following scram, which occurs when the element tips enter a reduced diameter portion of the fuel assembly guide tubes, is not affected with long-term exposure of the CEA to reactor operating conditions.

During normal power operation, most of the CEAs are expected to be in the fully withdrawn position. Thus, the local B-10 burnup progresses at a lower rate, and CEA life is prolonged.

Above the poison column is a plenum which provides expansion volume for helium released from the B_4C. The plenum volume contains a Type 302 stainless steel holddown spring, which restrains the absorber material against longitudinal shifting with respect to the clad, while allowing for differential expansion between the absorber and the clad. The spring develops a load sufficient to maintain the position of the absorber material during shipping and handling.

Each full-strength control element is sealed by welds which join the tube to an Alloy 625 nose cap at the bottom, and an Alloy 625 connector at the top which makes up part of the end fitting at the top. The end fittings, in turn, are threaded and crimped in place by a locking nut to the spider structure which provides rigid lateral and axial support for the control elements. The spider hub bore is specially machined to provide a point of attachment for the CEA extension shaft.

Thirteen of the 89 CEAs are part-strength CEAs. The control elements of a part-strength CEA consist of solid Alloy 625 slugs over their entire active length. A holddown spring, similar to the spring in the full-strength rods, maintains the orientation of the Alloy 625 slugs. The FSCEA/PSCEA pattern is shown in figure 4.2-10.

Each full-strength or part-strength CEA is positioned by a magnetic jack control element drive mechanism (CEDM) mounted on the reactor vessel closure head. The extension shaft joins

with the CEA spider and connects the CEA to the CEDM. Full and part-strength CEAs may be connected to any extension shaft depending on control requirements. Mechanical reactivity control is achieved by positioning groups of CEAs by the CEDMs.

In the outlet plenum region, all FSCEAs/PSCEAs are enclosed in CEA shrouds which provide guidance and protect the FSCEA/PSCEA and extension shaft from coolant cross flow. Within the core, each element travels in a Zircaloy guide tube. The guide tubes are part of the fuel assembly structure and ensure proper orientation of the control elements with respect to the fuel rods.

When the extension shaft is released by the CEDM, the combined weight of the shaft and CEA causes the CEA to insert into the fuel assembly.

The lower ends of the four outer fuel assembly guide tubes are tapered gradually to form a region of reduced diameter which, in conjunction with the control element on the CEA, constitutes an effective hydraulic buffer for reducing the deceleration loads at the end of a trip stroke. This purely hydraulic damping action is augmented by a spring and plunger arrangement on the CEA spider. When fully inserted, full- and part-strength CEAs rest on the upper guide structure support plate.

The capability of the CEAs to scram within the allowable time is demonstrated as part of the tests discussed in paragraph 4.2.4.4.

4.2.3 DESIGN EVALUATION

4.2.3.1 Fuel Assembly

4.2.3.1.1 Vibration Analyses

Four sources of periodic excitation are recognized in evaluating the fuel assembly susceptibility to vibration damage. These sources are as follows:

A. Reactor Coolant Pump Blade Passing Frequency

Precritical vibration monitoring on previous C-E reactors indicates that peak pressure pulses are expected at the pump blade passing frequency (120 Hz), and a lesser but still pronounced peak at twice this frequency.

B. Lower Support Structure Motion

Random lateral motion between the fuel assembly and the lower support structure is expected to occur with an amplitude similar to that of other C-E reactors in the frequency range of between 2 and 10 Hz.

C. Fuel Rod Vibration

Flow-induced fuel rod vibration resulting from coolant flow through the fuel assembly. The expected amplitude of such vibration is 0.004 inch or less.

D. Flow-Induced Control Element Vibration

System-80 incorporates design features that ensure that the vibration of CEAs is such as to produce no significant wear in the guide tubes.

These sources of periodic motion are not expected to have an adverse effect on the performance of the Standard System 80 fuel assembly.

The capability of the Standard System 80 fuel assembly to sustain the effects of flow-induced vibration without adverse effects has been demonstrated in the dynamic flow tests as reported in Section 4.2.3.1.8.

4.2.3.1.2 CEA Guide Tube

The CEA guide tubes are evaluated for structural adequacy using the criteria given in paragraph 4.2.1.1 in the following areas:

A. Steady axial load due to the combined effects of axial hydraulic forces and upper end fitting holddown forces.

   For normal operating conditions, the resultant guide tube stress levels are significantly less than the design limits.

B. Short-term axial load due to the impact of the spring-loaded CEA spider against the upper guide structure support plates at the end of a CEA trip.

   For trips occurring during normal power operation, solid impact is not predicted to occur due to the kinetic energy of the CEA being dissipated in the hydraulic buffer and by the CEA spring.

C. Short-term differential pressure load occurring in the hydraulic buffer regions of the outer guide tubes at the end of each trip stroke.

The buffer region slows the CEA during the last few inches of the trip stroke. The resultant differential pressure across the guide tube in this region gives rise to circumferential stresses which are significantly less than the design limits. The trip is assumed to be repeated daily. However, the resultant stress is too small to have a significant effect on fatigue usage.

For conditions other than normal operation, the additional mechanical loads imposed on the fuel assembly by an OBE (equivalent to one-half DBE), DBE, and large break LOCA and their resultant effect on the control element guide tubes are discussed in the following paragraphs.

4.2.3.1.2.1 Operating Basis Earthquake (OBE). During the postulated OBE, the fuel assembly is subjected to lateral and axial accelerations which, in turn, cause the fuel assembly to deflect from its normal shape. The method of calculating these deflections is described in paragraph 3.7.3.14. The magnitude of the lateral deflections and resultant stresses were evaluated for acceptability. The method for calculating stresses from deflected shapes is described in reference 1. The fuel assembly is designed to be capable of withstanding the axial loads without buckling and without sustaining excessive stresses. The results of the stress analysis demonstrate that the component stresses are less than the allowable values discussed in section 4.2.1.1.

4.2.3.1.2.2 Safe Shutdown Earthquake (SSE). The axial and lateral loads and deformation sustained by the fuel assembly during a postulated SSE have the same origin as those discussed above for the OBE, but they arise from initial ground accelerations twice those assumed for the OBE. The analytical methods used for the SSE are identical to those used for the OBE. The predicted component stresses were less than the allowable values discussed in reference 1.

4.2.3.1.2.3 Loss-of-Coolant Accident (LOCA). In the event of a large break LOCA, there will occur rapid changes in pressure and flow within the reactor vessel. Associated with the transient are relatively large axial and lateral loads on the fuel assemblies. The response of a fuel assembly to the mechanical loads produced by a LOCA is considered acceptable if the fuel rods are maintained in a coolable array, i.e., acceptably low grid crushing. The methods used for analysis of combined seismic and LOCA loads and stresses are described in reference 1. The results of the LOCA analysis were that component stresses were within the limits established in reference 1.

4.2.3.1.2.4 Combined SSE and LOCA. It is not considered appropriate to combine the stresses resulting from the SSE and LOCA events. Nevertheless, for purposes of demonstrating margin in the design, the maximum stress intensities for each individual event were derived by a square root of sum of the squares (SRSS) method. This was performed as a function of fuel assembly evaluation and position, e.g., the maximum stress intensities for the center guide tube at the upper grid

elevation (as determined in the analysis discussed in the above paragraphs for SSE and LOCA) were combined by the SRSS method. The results demonstrated that the allowable stresses described in reference 1 were not exceeded for any position along the fuel assembly even under the added conservatism provided by this load combination.

To qualify the complete fuel assembly, full-scale hot loop testing has been conducted. These tests evaluated fretting and wear of components, refueling procedures, fuel assembly uplift forces, holddown performance, and compatibility of the fuel assembly with interfacing reactor internals, CEAs, and CEDMS under conditions of reactor water chemistry, flow velocity, temperature, and pressure. The details of the System 80 hot loop testing are reported in Section 4.2.3.1.8.

4.2.3.1.3 Spacer Grid Evaluation

The function of the spacer grids is to provide lateral support to fuel and burnable poison rods in such a manner that the axial forces are not sufficient to buckle or bow the rods, and that the wear resulting at the grid-to-clad contact points will be limited to acceptably small amounts. It is also a criterion that the grid be capable of withstanding the lateral loads imposed during the postulated seismic and LOCA events.

Fuel assemblies are designed such that the combination of fuel rod rigidity, grid spacing, and grid preload will not result in significant fuel rod deformation under axial loads, and the long-term effects of clad creep (reduction in clad OD), the reduction of grid stiffness with temperature, and the partial relaxation of the grid material during operation ensure that

this criterion is also satisfied during all operating conditions. Moreover, inspection of irradiated fuel assemblies from the Maine Yankee (14 x 14), Arkansas (16 x 16), Calvert Cliffs (14 x 14), Palisades (15 x 15), and Omaha (14 x 14) reactors has not shown significant bowing of the fuel rods. In view of these factors and the similarity of these designs to the Standard System 80 designs, it is concluded that the axial forces applied by the grids on the cladding will not result in a significant degree of fuel rod bow. The influence of fuel rod lateral deflection is discussed further in paragraph 4.2.3.2.6. Additional discussion of the causes for and effects of fuel rod bowing are contained in paragraph 4.2.3.2.6 and in reference 52.

The capability of the grids to support the clad without excessive clad wear is demonstrated by out-of-pile flow testing on the Standard System 80 assembly design, and by the results of post-irradiation examination of grid-to-clad contact points in Maine Yankee fuel assemblies which showed only negligible clad wear (reference 53).

The capability of the grid to withstand the lateral loads produced during the postulated seismic and LOCA events is demonstrated by impact testing the reference grid design, and comparing the test results with the analytical predictions of the seismic and LOCA loads.

The Zircaloy spacer grid material is of similar composition as the fuel rods and guide tubes with which it is in contact, thereby obviating any problem of chemical incompatibility with those components. For the same reason, adequate resistance to

corrosion from the coolant is assured (see paragraph 4.2.3.2.3, listing A, for additional information relative to the corrosion-resistance of Zircaloy-4 in the primary coolant environment).

The Inconel 625 material used for the lowest and uppermost spacer grid is in contact with the coolant, the 304 stainless steel lower end fitting (to which the lowest spacer grid is welded), the Zircaloy-4 split rings (top grid), the Zircaloy-4 or ZIRLO fuel rods, the poison rods, and the Zircaloy-4 guide tubes. The mutual chemical compatibility of these materials in a reactor environment has been demonstrated by Westinghouse use of these materials in fuel assemblies that have been operated in other Westinghouse reactors and for which post-irradiation examination has yielded no evidence of chemical reaction between these components. In addition, experiments have also been performed at Westinghouse of Inconel-type alloys and Zircaloy-4 which showed that eutectic reactions did not occur below 2200F, a temperature far in excess of that anticipated at the lower grid location in the event of a LOCA.

4.2.3.1.4 Dimensional Stability of Zircaloy or ZIRLO™

Zircaloy components and ZIRLO™ cladding are designed to allow for dimensional changes resulting from irradiation-induced growth. Extensive analyses of in-pile growth data have been performed to formulate a comprehensive model of in-pile growth.[54] [71] The in-pile growth equations are used to determine the minimum axial differential growth allowance which must be included in the axial gap between the fuel rods and the

upper end fitting. For determining the gap between the fuel rods and the upper end fitting, the growth correlations for fuel rod and guide tube growth are combined statistically, such that the minimum initial gap is adequate to accommodate the upper 95% probability level of differential growth between fuel rods and guide tubes in the peak burnup fuel assembly. For the purpose of predicting axial and lateral growth of the fuel assembly structure (thereby establishing the minimum initial clearance with interfacing components), the equations are used in a conservative manner to ensure adequate margins to interference are maintained. The manner in which the in-pile growth equations are used in design is described in reference 55.

4.2.3.1.5 Fuel Handling and Shipping Design Loads

Three specific design bases have been established for shipping and handling loads. These are as follows:

A. The fuel assembly, when supported in the new fuel shipping container, shall be capable of sustaining the effect of 5g axial, lateral, or vertical acceleration without sustaining stress levels in excess of those allowed for normal operation. The 5g criterion was originally established experimentally, and its adequacy is continually confirmed by the presence of impact recorders, as discussed in the following paragraph.

   Impact recorders, included with each shipment, indicate if loadings in excess of 5g are sustained. A record of shipping loads in excess of 5g indicates an unusual

shipping occurrence in which case the fuel assembly is inspected for damage prior to releasing it for use.

The axial shipping load path is through either end fitting to the guide tubes. A 5g axial load produces a compressive stress level in the guide tubes less than the two-thirds yield stress limit that is allowed for normal condition events. The fuel assembly is prevented from buckling by being clamped at grid locations. For lateral or vertical shipping loads, the grid spring tabs have an initial preload which exceeds five times the fuel rod weight. Therefore, the spring tabs see no additional deflection as a result of 5g lateral or vertical acceleration of the shipping container. In addition, the side load on the grid faces produced by a 5g lateral or vertical acceleration is less than the measured impact strength of the grids.

B. The fuel assembly shall be capable of sustaining a 5000-pound axial load applied at the upper end fitting by the refueling grapple (and resisted by an equal load at the lower end fitting) without sustaining stress levels in excess of those allowed for normal operation. The 5000-pound load was chosen in order to provide adequate lift capability should an assembly become lodged. This load criterion is greater than any lift load that has been encountered in service.

C. The fuel assembly shall be capable of withstanding a 0.125-inch deflection in any direction whenever the fuel assembly is raised or lowered from a horizontal

position without sustaining a permanent deformation beyond the fuel assembly inspection envelope.

Fuel handling procedures required the use of a strongback to limit the fuel assembly deflection to a maximum of 0.125-inch in any direction whenever the fuel assembly is raised or lowered to a horizontal position. This limits the stress and strain imposed upon the fuel assembly to values well below the limits set for normal operating conditions. The adequacy of the 0.125-inch criterion is based on the inclusion of this limitation in specifications and procedures for fuel handling equipment, which is thereby constrained to provide support such that lateral deflection is limited to 0.125 inches.

4.2.3.1.6 Fuel Assembly Analysis Results

The results of the fuel assembly analyses confirm that the design criteria of paragraph 4.2.1.1, regarding stress, strain, and strain fatigue, are satisfied.

4.2.3.1.7 Fuel Assembly Lift-off Analysis

The results of the analysis confirm that the fuel assembly will not lift off during reactor operation. This analysis considers the appropriate combination of forces as described in paragraph 4.2.2.1.

4.2.3.1.8 Hot Loop Flow Testing

4.2.3.1.8.1 Summary

Hot loop flow testing for System 80 was completed during 1980 and 1981. Test components included an array of five fuel assemblies, a twelve rod control element assembly (CEA) and supporting structures. Pressure drops and CEA scram times were measured for a range of temperature and flowrate settings. Results were nearly as predicted based on analyses and the results of hot loop tests preceding those for System 80. A 1300 hour wear test was run, finding no fretting wear on fuel rods and no other wear on fuel exterior surfaces. Some wear occurred inside rodded CEA guide tubes, but at acceptable rates.

4.2.3.1.8.2 Test Facility Description

Tests were performed in the 36" ID main section of the C-E TF-2 hot loop. The piping arrangement in this loop is shown in Figure 4.2-11. The loop is rated at 15000 gpm, 650°F, 2500 psia. System 80 wear tests were near loop limits, at 14000 gpm, 620°F, 2250 psia. The loop includes systems which maintain steady temperature and pressure and normal reactor water chemistry.

4.2.3.1.8.3 Test Components

4.2.3.1.8.3.1 Stackup

The test component stackup is shown in Figure 4.2-12. The support structures were bolted to lugs and a support ring at the bottom of the test vessel. The fuel assemblies and CEA were

enclosed within lower and upper support structures which were joined by bolts at the fuel alignment plate.

4.2.3.1.8.3.2 Fuel Assemblies

4.2.3.1.8.3.2.1 Details of Design

Fuel assemblies closely matched the production reactor fuel design. Differences include:

A. Fuel rod loading - 46% of the fuel rods (544) were of prototype construction, with depleted UO_2 pellets. 54% (636) were dummy rods of solid stainless steel. Prototype rods were used in all positions of concern with respect to fretting wear.

B. Lower end fitting leg braces - Braces are deleted between legs of the lower end fitting. The test design, with braces, is considered less favorable with respect to fretting wear.

C. Inside dimension of guide tubes and upper end fitting posts - The I.D. in upper ends of guide tubes and in UEF posts for production fuel will be enlarged slightly as a precaution, allowing use of wear sleeves if needed. The tube enlargement should have little effect on guide tube wear tendency, and will speed CEA scrams very slightly.

4.2.3.1.8.3.2.2 Spacer Grid Spring Settings

All spacer grip springs were set for the minimum restraint of fuel rods expected during the fuel lifetime.

4.2.3.1.8.3.2.3 Fuel Array in Test

The array of five fuel assemblies is shown in Figure 4.2-13, with relationships to the fuel shroud and CEA.

4.2.3.1.8.3.3 Control Element Assembly

System 80 reactors utilize both 4 rod and 12 rod control element assemblies. The twelve rod CEA was chosen for hot loop tests because it has a lower weight per rod ratio (hence slower scrams) and is a more complex structure. The test CEA was functionally identical to that shown in Figure 4.2-4.

4.2.3.1.8.3.4 Support Structures

The support structures were prototypical sections of a System 80 reactor and provided support and alignment of the fuel assemblies and CEA. The lower ends of the fuel assemblies engages alignment pins on an open grid beam array. The fuel shroud cross section is noted in Figure 4.2-13. All possible corner shapes and fuel to shroud clearances were included. Shroud tubes in the upper guide structure were held by the upper guide structure support plate (UGSSP) and fuel alignment plate (FAP), and engaged the four posts of each fuel upper end fitting. The region between the FAP and the UGSSP is an outlet plenum, where flow passes up around the shroud tubes and exits the outlet nozzle. Effects of a pressure gradient across the reactor outlet plenum were included in tests. The gradient causes flow circulation through small holes in the UGSSP upward near the reactor centerline and downward near the outlet nozzles. In TF-2 the flow circulation was driven through

external piping, employing a CEA shroud and seal assembly above the UGSSP.

4.2.3.1.8.4 Test Results

4.2.3.1.8.4.1 Scram Time vs Acceptance Curve

Hot loop tests previewed the scram performance checks that will be required for every reactor CEA, during pre-operation functional tests. Measured position vs. time for reactor scrams must fall below an acceptance curve applied in safety analyses. The reactor scram tests are run at approximately 525°F with all pumps running. The TF-2 scram for this condition is plotted in Figure 4.2-14, along with the acceptance curve.

4.2.3.1.8.4.2 Pressure Drops in Fuel

Fuel assembly pressure drops were measured over a range of flow Reynolds Number. Results are in good agreement with measurements for similar fuel in prior TF-2 tests. The test results support the flow resistances used in design analyses for System 80 and based on the prior measurements. Those analyses include fuel holddown spring design requirements, support structure hydraulic loadings and the prediction of system flow rate.

4.2.3.1.8.4.3 Fuel Rod Fretting

The test for fuel rod fretting ran 1300 hours, at 620°F, with flow ≥13,400 gpm through the fuel. The setting was based on worst case reactor conditions at full power, with 116% design flow. Test fluid velocities exceeded those expected in any

System 80 reactor. No fretting was found on any of the fuel rod surfaces.

4.2.3.1.8.4.4 Guide Tube Wear

In view of observed CEA motion dependence on upper guide structure flow, a sequence of different flow conditions was set during the wear test. With each change of flow conditions the CEA was raised to a new position. Conditions included the maximum pressure differences expected across the reactor UGSSP, both upward and downward, and an intermediate equalized condition. Following the tests all CEA guide tubes were inspected with an eddy current probe. Four tubes which gave the largest indications were removed and sectioned longitudinally (clamshelled) for precise inspection. Greatest wear occurred for the UGSSP upflow condition, at points of CEA rod tip contact in guide tubes. Guide tube wear at the highest rate observed in tests will not contribute to violation of stress limits in Section 4.2.3.

4.2.3.2 Fuel Rod Design Evaluation

The evaluations discussed in this section are based on assumed fuel rod operation within certain linear heat rate limits related to avoiding excessive fuel and clad temperatures. Information concerning the bases for these limits is contained in section 4.4.

4.2.3.2.1 Results of Vibration Analyses

Four sources of periodic excitation are recognized in evaluating the fuel rod susceptibility to vibration damage. These sources are as described in paragraph 4.2.3.1.1.

These sources of periodic motion are not expected to have an adverse effect on the performance of the fuel rod. Paragraph 4.2.3.2.4 includes additional information on fuel rod response to the sources.

4.2.3.2.2 Fuel Rod Internal Pressure and Stress Analysis

A fuel rod cladding stress analysis is conducted to determine the circumferential stress and strain resulting from normal, upset, and emergency conditions. The analysis includes the calculation of cladding temperatures and rod internal pressures during each of the occurrences listed in paragraph 4.2.1.1. The design criteria to be used to evaluate the analytical results are specified in paragraph 4.2.1.2.1. Fuel rod stresses resulting from seismic events are calculated using the methodology described in reference 1.

The results of the fuel rod analyses confirm that the design criteria of paragraph 4.2.1.2.1, regarding stress, strain, and strain fatigue, are satisfied.

4.2.3.2.3 Potential for Chemical Reaction

A. Corrosion

Zircaloy-4 fuel rod tubing has been visually examined in the spent fuel pool after six reactor cycles at Ft. Calhoun, five reactor cycles at Calvert Cliffs, and

others at Palo Verde 1 and 2, ANO-2, and Maine Yankee. In addition, oxide thicknesses were measured in the hot cell after one cycle at Maine Yankee, five cycles at Calvert Cliffs, and six cycles at Ft. Calhoun. The oxide appearance and oxide thickness measured were similar to that from autoclave behavior for that time and temperature.

Coolant chemistry parameters have been specified that minimize corrosion product release rates and their mobility in the primary system. Specifically, the precore hot functional environment is controlled (pH and oxygen) to provide a thin, tenacious, adherent, protective oxide film. This approach minimizes corrosion product release and associated inventory on initial startup and subsequent operation. During operation, the recommended lithium concentration range effects a chemical potential gradient or driving force between hot and cooler surfaces (fuel cladding and steam generator tubing, respectively), such that soluble iron and nickel species will preferentially deposit on the steam generator surfaces. The associated pH also minimizes general corrosion product release rates from primary system surfaces. Moreover, the specified hydrogen concentration's range insures reducing conditions in the core, thereby avoiding low solubility Fe^{3+}. Additionally, dissolved hydrogen promotes rapid recombination of oxidizing species. (Recall, oxidizing species and a fast neutron flux are

synergistic prerequisites to accelerated Zircaloy-4 corrosion.)

During operation lithium, dissolved oxygen, and dissolved hydrogen will be monitored at a frequency consistent with maintaining these parameters within their specifications.

Post-operational examinations of fuel cladding that has operated within these specifications has shown no significant chemical or corrosive attack of the Zircaloy cladding. ZIRLO™ cladding corrosion characteristics are found to be equally acceptable as discussed in Section 4.5 of Ref. 71.

B. External Hydriding

During operation of the reactor with exposure to high temperature, high pressure water, Zircaloy-4 or ZIRLO™ cladding will react to form a protective oxide film in accordance with the following equation:

$$Zr + 2H_2O \rightarrow ZrO_2 + 2H_2$$

Approximately 20% of the hydrogen is absorbed by the Zircaloy. Based on data described in WAPD-MRP-107, the cladding would be expected to contain up to 250 ppm of hydrogen following three years of exposure.

A series of burst tests were performed on Zircaloy-2 tubes containing 340 ppm and 460 ppm of hydrogen precipitated as hydride platelets in a circumferential manner.(56) Burst tests at 660F showed that the burst test specimens with 340 ppm had normal burst ductility

of 12%. Therefore, hydrogen normally absorbed in Zr-4 tubing will not prove deleterious to the cladding integrity. This is also true of the ZIRLO™ tubing as discussed in Section 4.4.2.5 of Ref. 71.

C. Internal Hydriding

A number of reported fuel rod failures have resulted from excessive moisture available in the fuel. Under operation, this moisture oxidizes the Zircaloy.

The hydrogen, which was not absorbed during normal oxidation, would then be absorbed into the Zircaloy through a scratch in the oxide film. This localized hydrogen absorption by the cladding would shortly result in a localized fuel rod failure. Work performed at the Institute for Atomenergi, Halden, Norway, demonstrated that a threshold value of water moisture is required for hydride sunbursts to occur.[57] Through a series of in-pile experiments, the level of this threshold value was established. The allowable hydrogen limit in the fuel complies with this requirement, ensuring that hydride sunbursts will not occur.

D. Crud

Crud layers on zirconium oxide films are usually porous and non-insulating. As an example, heavy but non-insulating crud layers have been found in Yankee Rowe (WCAP-3317-6094, Yankee Core Evaluation Program, Final Report, 1971). With porous crud, water is free to flow through the crud and provide heat transfer by

convection. Under these conditions, crud-enhanced corrosion should not occur.

Water chemistry monitoring is a continuous process and should ensure no dense crud buildup.

E. Fuel-Cladding Chemical Reaction

An in-depth post-irradiation examination has been conducted wherein fuel-cladding chemical reactions were among those items studied.[26] This study concluded that early unpressurized elements containing unstable fuel were more susceptible to stress corrosion attack than is the current design that utilizes stable fuel and pressurized cladding. By carefully monitoring the primary coolant activity of operating reactors, it has been concluded that the current fuel designs are not susceptible to stress corrosion (or other types of corrosion) during normal plant operation. Since stress corrosion attack is the result of a combination of stress imposed by the fuel on the cladding and the corrosive chemical species available to the cladding, irradiation programs have been pursued to define the conditions under which pellet-clad interaction will damage the cladding. These programs have been conducted at Halden, at Petten in the Netherlands, and at Studsvik in Sweden, and have confirmed that current fuel designs are not susceptible to failure by stress corrosion cracking during normal plant operation.

4.2.3.2.4 Fretting Corrosion

The phenomenon of fretting corrosion, particularly in Zircaloy clad fuel rods supported by Zircaloy spacer grids, has been extensively investigated. Since irradiation-induced stress relaxation causes a reduction in grid spring load, spacer grids must be designed for end-of-life conditions as well as beginning-of-life conditions to prevent fretting caused by flow-induced tube vibrations.

Examination of Zircaloy-clad fuel rods after six cycles of exposure in Ft. Calhoun, five cycles in Calvert Cliffs-1, and four cycles in Arkansas Nuclear One-Unit 1 indicates fuel rod fretting between the fuel rod and spacer grid is rare. The usual result of the contact between grid components and fuel rods is a small cladding surface mark with no appreciable depth. The grid to rod fretting issue for ZIRLO™ cladding is discussed in Section 5.4.7 of Ref. 71 and concludes that fretting failures with ZIRLO™ cladding will remain at the low levels seen with Zircaloy-4 clad.

4.2.3.2.5 Fuel Rod Bowing

Experience has proven that any specific criterion on allowable deflections (bowing), with respect to the effects which such deflections might have on thermal-hydraulic performance, is not necessary beyond the initial fuel rod positioning requirements required of the grids. This variation in spacing is accounted for in thermal-hydraulic analysis through the introduction of hot channel factors in calculating the maximum enthalpy rise in calculating DNBR. This adjustment is called the Pitch, Bowing,

and Clad Diameter Factor, which is conservatively applied to simulate a reduced flow area along the entire channel length. The value of this factor is given in table 4.4-2 and its application in defining overall uncertainty penalty factors is discussed in section 4.4.

The subject of fuel rod bowing is discussed in reference 52 and 71.

4.2.3.2.6 Irradiation Stability of Fuel Rod Cladding

The combined effects of fast flux and cladding temperature are considered in three ways as discussed below:

A. Cladding Creep Rate

The in-pile creep performance of Zircaloy-4 and ZIRLO™ is dependent upon both the local material temperature and the local fast neutron flux. The functional form of the dependencies is presented in references 13, 14, and 24 for gap conductance calculations, and in reference 58 for cladding collapse time predictions.

B. Cladding Mechanical Properties

The yield strength, ultimate strength, and ductility of Zircaloy-4 and ZIRLO™ are dependent upon temperature and accumulated fast neutron fluence. The temperature and fluence dependence are discussed in paragraph 4.2.1.2.2.1. Unirradiated properties were used depending upon which is more restrictive for the phenomenon being evaluated.

C. Irradiation-Induced Dimensional Changes

Zircaloy-4 and ZIRLO™ have been shown to sustain dimensional changes (in the unstressed condition) as a function of the accumulated fast fluence. These changes are considered in the appropriate clearances between the various core components. The irradiation-induced growth correlation method is discussed in reference 54.

Zircaloy-4 and ZIRLO™ fuel cladding have been utilized in pressurized water reactors at temperatures and burnups anticipated in current designs with no failures attributable to radiation damage. Mechanical property tests on Zircaloy-4 cladding exposed to neutron irradiation of 4.7×10^{21} nvt (E > 1 MeV) (estimated) have revealed that the cladding retains a significant amount of ductility (in excess of 4% elongation). Typical results are shown in table 4.2-2. It is believed that the fluence of 4.7×10^{21} nvt (E > 1 MeV) is at saturation so that continued exposure to irradiation will not change these properties.[(59)]

4.2.3.2.7 Cladding Collapse

Reference 60 presents the results of a study which deals with the phenomena of interpellet gap formation and clad collapse in modern PWR fuel. The conclusion drawn from this report[(61)] is that clad collapse analyses are not necessary for modern Westinghouse manufactured fuel because of the absence of large axial gaps between pellets. These same conclusions apply to

the use of ZIRLO™ cladding as discussed in Section 5.4.1 of Ref. 71.

4.2.3.2.8 Fuel Dimensional Stability

Fuel swelling due to irradiation (accumulation of solid and gaseous fission products) and thermal expansion results in an increase in the fuel pellet diameter. The design makes provision for accommodating both forms of pellet growth. The fuel-clad diametral gap is more than sufficient to accommodate the thermal expansion of the fuel. To accommodate irradiation-induced swelling, it is conservatively assumed that the fuel-clad gap is used up by the thermal expansion and that only the fuel porosity and the dishes on each end of the pellets are available. Thermal and irradiation-induced creep of the restrained fuel results in redistribution of fuel so that the swelling due to irradiation is accommodated by the free volume. These conclusions also apply to the use of ZIRLO™ cladding.

Table 4.2-2

TENSILE TEST RESULTS ON IRRADIATED

SAXTON CORE III CLADDING[59]

Fluence (>1 MeV) 4.7×10^{21} n/cm^2 (estimated)						
Rod ID	Location From Bottom (in.)	Testing Temp. (°F)	0.2% Yield Stress (lb/$in.^2$ x 10^3)	Ultimate Tensile Strength (lb/$in.^2$ x 10^3)	Uniform Strain in 2-in. Gage Length (%)	Total Strain in 2-in. Gage Length
BO	11-17	650	61.4	65.6	2.2	6.8
BO	26-32	650	58.1	68.9	2.4	11.3
RD	3-9	650	62.2	70.0	2.0	4.2
RD	12-18	650	60.5	65.4	1.7	5.8
MQ	12-18	675	70.4	77.4	1.9	6.1
MQ	28-34	675	66.0	75.1	1.6	6.2
FS	28-34	675	57.2	71.4	3.9	12.9
GL	12-18	675	60.5	71.5	2.4	9.3

For such restrained pellets, and at a total fission-product-induced swelling rate of 0.4% $\Delta V/V$ per 10^{20} fiss/cm^3, 0.24% would be accommodated by the fuel porosity and dishes through fuel creep, and 0.16% would increase the fuel diameter. Assuming peak burnup, this would correspond to using up a void volume equal to 3.30% of the fuel volume and increasing the fuel rod diameter by a maximum of < 0.0025 inch (< 0.7% clad strain). When these numbers were compared to the minimum available volume and the maximum allowable strain, it was concluded that sufficient accommodation volume has been provided even under the most adverse burnup and tolerance conditions.

Early work on the swelling rates for UO_2 is described in references 6, 55, 56, 57, 62 and 63. The experiments were conducted using fuel materials made prior to the discovery of densification and would be appropriate for some of C-E's early production. The incorporation of pore-formers that provide more representative fuel microstructures makes a more recent set of data from a C-E-conducted program more appropriate for swelling rates.

Fuel pellets were fabricated by C-E and irradiated for four cycles to burnup levels up to 50 GWd/Mtu.[(64)] Immersion density measurements taken from pellets of various burnups were plotted to determine the rate of volume increase with burnup. The rate derived from these measurements was 1.0% $\Delta V/V$ per 10 GWd/Mtu. Since the levels of burnup were after cladding contact, the swelling value obtained is a restrained swelling rate. The

0.4% value per 4 GWd/Mtu is approximately equal to 0.4% $\Delta V/V$ per 10^{20} fiss/cm^3 used for the calculation above.

4.2.3.2.9 Potential for Waterlogging Rupture and Chemical Interaction

The potential for waterlogging rupture is considered remote. Basically, the necessary factors, or combination of factors, include the presence of a small opening in the cladding, time to permit filling of the fuel rod with water, and finally, a rapid power transient. The size of the opening necessary to cause a problem falls within a fairly narrow band. Above a certain defect size, the rod can fill rapidly, but during a power increase it also expels water or steam readily without a large pressure buildup. Defects which could result in an opening in cladding are scrupulously checked for during the fuel rod manufacturing process by both ultrasonic and helium leak testing. Clad defects which could develop during reactor operation due to hydriding are also controlled by limiting those factors; e.g., hydrogen content of fuel pellets, which contributes to hydriding.

The most likely time for a waterlogging rupture incident would be after an abnormally long shutdown period. After this time, however, the startup rate is controlled so that even if a fuel rod were filled with coolant, it would "bake out," thus minimizing the possibility of additional cladding rupture. The combination of control and inspection during the manufacturing process and the limits on the rate of power change restrict the potential for waterlogging rupture to a very small number of fuel rods.

The UO_2 fuel pellets are highly resistant to attack by reactor coolant in the event cladding defects should occur. Extensive experimental work and operating experience have shown that the design parameters chosen conservatively account for changes in thermal performance during operation and that coolant activity buildup resulting from cladding rupture is limited by the ability of uranium dioxide to retain solid and gaseous fission products.

4.2.3.2.10 Fuel Burnup Experience

The Westinghouse fuel rod design is based on an extensive experimental data base and by an extension of experimental knowledge through design application of Westinghouse fuel rod evaluation codes. The experimental data base includes data from C-E or C-E/Kraftwerk Union (KWU) joint irradiation experiments, from C-E, Westinghouse and KWU operating commercial plant performance, and from many basic experiments conducted in various research reactors which are available in the open literature. Some of these sources will be discussed below. Evidence currently available indicates that Zircaloy (or ZIRLO™) and UO_2 fuel performance is satisfactory to exposures in excess of 60,000 MWd/Mtu.

A. Public Information

   General fuel performance information available in the open literature has provided part of the Westinghouse fuel rod design data base. Particular experiments that have been cited in the past as key references are:

1. Determination of the effect of fuel-cladding gap on the linear heat rating to melting for UO_2 fuel rods, conducted in the Westinghouse test reactor.
2. Shippingport irradiation experience.
3. Saxton irradiation experience.
4. Combined Vallencitos boiling water reactor (VBWR) - Dresden irradiation.
5. Large Seed Blanket Reactor (LSBR) rod experience
6. Joint U.S.-Euratom Research and Development Program to evaluate central fuel melting in the Consumers Power Co. Big Rock Point reactor.

Since the information from these programs is available in the open literature, they will not be described here. However, details as to the significance of the results to Westinghouse fuel burnup experience are presented in reference 65.

B. C-E/KWU Technical Exchange

C-E entered into a technical agreement with KWU beginning in 1972 for the complete exchange of information and technology relating to pressurized water reactor systems including fuel. This agreement made available to C-E the total experience of 10 years successful operation of commercial PWR fuel in systems designed and fabricated by KWU and is the most advanced of its type in the world. An essential part of this broad-based exchange involves joint sponsorship of numerous fuel testing programs.

C. Operating Fuel Experience

C-E and KWU have fabricated more than 1,335,000 Zircaloy-clad fuel rods, both internally pressurized and unpressurized. Of this total, 530,000 rods remain in operation, some with average burnups in excess of 40,000 MWd/Mtu. Overall performance of this fuel has been excellent. The fuel rod reliability level, estimated from coolant activities, has been excellent. Reliability levels are continually validated by extensive pool-side fuel inspection programs conducted by C-E at reactor sites during refueling shutdowns.

D. Fuel Irradiation Programs

C-E is involved in diversified fuel irradiation test programs to confirm the adequacy of the C-E fuel rod design bases and models by experimental means. Some of these programs involve safety-related research, while other programs provide confirmatory data on performance capability or evaluate design and fabrication variables or methods which may improve and extend our current knowledge of fuel rod performance.

Some of the key fuel performance evaluation programs that will be summarized below include:

- Fuel densification experiments at the Battelle Research Reactor (BRR).
- Joint C-E/KWU fuel densification experiments including tests in the MZFR reactor at Karlsruhe,

West Germany, and the EEI experiments in the General Electric Test Reactor (GETR).

- Direct participation in the Halden Project in Norway with access to all Halden base program fuel test data.
- Irradiation of special instrumented fuel rods to obtain dynamic in-reactor measurements in Halden experimental rigs.
- Ramp test programs on fuel rods to evaluate fuel load-follow capabilities and the pellet clad interaction/stress corrosion phenomenon in both the Studsvik and Petten test reactors. Other in-reactor experiments have been conducted in Obrigheim pressurized water reactor.
- Irradiation of special test and surveillance assemblies in operating C-E reactors.
- Similar irradiation programs are in operation for ZIRLO™ fuel rods as discussed in Ref. 71.

E. C-E Fuel Densification Experiments

C-E has conducted several experiments which provided data on the in-reactor densification behavior of various UO_2 fuel types. These include the BRR, EEI, and MZFR densification experiments.

F. BRR Fuel Densification Experiment

The object of this program was to examine the in-pile densification behavior of various fuel types and

microstructures fabricated with and without pore-formers. The non-pore-former fuel types had initial densities of 93% to 94% theoretical with a grain size of less than six microns, with a large fraction of pores less than four microns in diameter. The pore-former fuel types had initial densities of 93% to 95% and were characterized by a combination of large grain size and/or large pore size. Fuel pellets of each experimental type were irradiated in six BRR capsules at linear heat ratings between 2.8 and 4.6 kW/ft for periods of up to 1500 hours. Post-irradiation examination of the BRR results showed significant differences in the densification behavior between pore-former and non-pore-former fuel. The pore-former fuel showed little change in density (high stability) while the non-pore-former fuel densified rapidly. A trend towards increased densification with lower initial density was apparent in the non-pore-former fuel. It was concluded that UO_2 microstructure played a dominant role in the kinetics and extent of in-reactor densification. Consequently, fuel exhibiting the desirable microstructural features to reduce in-reactor densification (i.e., large fraction of the pore volume in the large pore size range) became part of the standard C-E fuel design.

G. C-E/KWU Fuel Densification Experiment (MZFR)

As a follow-on to the C-E experiment in the BRR, a joint C-E/KWU program has been conducted in the German MZFR to evaluate the performance of several

non-densifying fuel types at higher power levels for longer times and to higher burnups.

Sixteen full-length fuel rods each containing a different fuel type were irradiated at powers up to 11 kW/ft for burnups up to 4000 MWd/Mtu. Included in these rods are UO_2 and UO_2-PuO_2 fuels, most of which were fabricated using techniques intended to minimize densification. Six rods employed C-E fabricated UO_2 fuels, five of which included pore-former additives and one fabricated without a pore-former to serve as a referenceable control sample. Eight rods were fabricated using KWU experimental fuel representing a wide range of sintering times and temperatures, initial densities, and enrichments. The remaining two rods were fabricated using UO_2-PuO_2 fuels of two different densities, with and without a pore-former additive. Each of the fuel pellet types and fuel rods was extensively characterized prior to testing to permit comparison with similar post-irradiation measurements.

The results of the post-irradiation examination showed that fuel types fabricated with pore-formers (similar to current production fuel) experienced significantly less in-pile densification compared to those fabricated without pore-formers. The data also support use of a standardized out-of-pile resintering test developed by C-E to characterize expected in-pile densification at the time of fabrication. This simulation test has been

submitted to the NRC and approved for use by C-E in LOCA calculations.

H. EEI Fuel Densification Experiment

The prime objective of the EEI Fuel Irradiation Test Program conducted in the General Electric Test Reactor (GETR) was to isolate and characterize the in-reactor densification behavior of pore-former (or stable) fuel types. C-E and KWU were among 11 participants in the program.

This program entitled C-E to obtain densification data on nine base program fuel pellet types with varying microstructures. An additional four fuel types were fabricated by C-E and KWU. These included C-E fuel types, two with and one without a pore-former additive, and a KWU standard production fuel. The pellets in the program were well characterized prior to irradiation. Four of the fuel types were irradiated in one pressurized (53 atmospheres) capsule. Two of the fuel types were also irradiated in a separate non-pressurized capsule (one atmosphere). Each of the capsules contained thermocouples to continuously monitor capsule power generation during irradiation to assure that the desired operating conditions were maintained. Post-irradiation examination of these test capsules confirmed that UO_2 fuel with specific ranges of microstructural characteristics, such as produced by pore-former additives, are stable with respect to densification. The largest in-reactor density changes

occurred for those types having a combination of the smallest pore size, the largest volume percent of porosity m less than 4 microns in the smallest initial grain size, and the lowest initial density.[66]

I. Halden Program Participation

The experimental facilities and programs of the OECD Halden Reactor Project in Norway represent one of the most advanced efforts in quantifying the effects and interaction of the various design parameters of Zircaloy-clad fuel rods through measurements made in-reactor. C-E has been a member of the project since 1973. C-E reviews the data generated by the project in considerable detail and utilizes the results in various fuel development programs.

The Halden test reactor has unique capability for measuring fuel rod operation during irradiation. This capability has been utilized by C-E with specific experiments to provide information in the following areas:

1. Fuel densification phenomenon, including measurements of the rate of fuel column shortening as a function of the initial fuel density, power level, and fuel fabrication process.

2. Fuel clad mechanical interaction involving studies of the effects of pellet design (shape and density) and operating parameters on cladding deformation.

3. Modeling of fuel rod behavior with emphasis on heat transfer characteristics.

The first three test assemblies sponsored jointly by C-E and KWU contained 24 well-characterized fuel rods. These assemblies included the following range of design and operating parameters:

- Helium fill pressures from 22 to 35 atmospheres.
- Initial fuel densities from 91 to 96% TD.
- Linear heat ratings to 15 kW/ft.
- U_{235} enrichments from 6 to 12%; 9 rods fabricated with mixed-oxide fuel.

The objectives of these tests were to determine the dynamic changes in fuel rod internal pressure, fuel centerline temperature, and fuel stack length during operation as a function of burnup. Two of these assemblies (six test rods each) were discharged from the reactor after receiving a peak burnup of ~24,000 MWd/Mtu. The third rig (12 rods) was irradiated to a peak burnup of approximately 40,000 MWd/Mtu so that fuel swelling and gas release behavior could be evaluated to high burnups. The objectives of a fourth six-rod test assembly were to evaluate the effects of such design variables as pellet-clad gap, fill-gas composition, and linear heat rating (to 15 kW/ft) on heat transfer characteristics. This experiment also provided gap conductance data on UO_2 and mixed-oxide fuel. This test was discharged

from the reactor after reaching a peak burnup of ~4000 MWd/Mtu.

Instrumentation used to measure fuel behavior during irradiation included centerline thermocouples, internal pressure transducers, linear variable differential transformers (LVDTs) for fuel column length changes, and flux monitors for axial and radial power profiles.

Fuel column length change data obtained support data generated by the EEI, BRR, and MZFR experiments and confirm the in-reactor stability of C-E pore-former fuel types. In addition, the internal pressure monitor and centerline thermocouple data have confirmed the adequacy of the C-E thermal performance design models.

In addition to these C-E/KWU assemblies, C-E has designed and irradiated three rods in the Halden high temperature, high pressure loop to simulate PWR coolant temperature and pressure conditions. The purpose of these experiments was to distinguish the effects of pellet configuration on the formation of circumferential ridging and on the elongation of the rods. Each rod contained three pellet types with one type as a standard. This program, in combination with the results of other experiments, gives C-E a firm basis upon which to optimize fuel rod design with respect to dimensional changes, and to improve fuel performance models developed to predict rod dimensional stability.

J. Power Ramp Programs

C-E and KWU participated in the Studsvik and Petten/Pathfinder programs to evaluate fuel rod performance(67) under ramp conditions to power levels not recently attained. These can occur either after refueling or after extended periods of low power operation or during control rod maneuvers. The effects of various fuel rod design variables on power ramp limits were also investigated as a means to further optimize design. The Petten/Pathfinder program which began in 1973 was conducted jointly by C-E and KWU in the Obrigheim PWR reactor and Petten test reactor facilities. One special test assembly has been irradiated each year from 1973 to 1980 in the Obrigheim reactor. Included in this assembly, which is designed to facilitate fuel rod removal and replacement, are well-characterized segmented rods or "rodlets" which are axially connected to form a complete fuel rod. These rodlets were "pre-irradiated" in the Obrigheim reactor for one to four operating cycles, and then separated and irradiated in a test reactor to evaluate performance under ramp conditions. Ninety-nine of these rodlets irradiated in Obrigheim have been discharged and ramped in Petten. An additional 40 of these rodlets have been tested at the R2 reactor at Studsvik. Post-irradiation, hot-cell examination programs form an integral part of both the Petten/Pathfinder and Studsvik experiments to characterize fuel rod behavior, particularly with

respect to dimensional stability and fission product release. These test programs are designed to distinguish between fuel rod power ramps which occur on start-up and those which might occur during reactor power maneuvering operations.

Operating flexibility of a plant requires that the fuel rods maintain integrity during periodic changes in power. Power cycling tests of this type have been jointly conducted by C-E/KWU in Obrigheim and Petten. In the Petten test, a single unpressurized fuel rod was power cycled between 9 kW/ft and 17 kW/ft at a power change rate of about 3 kW/ft/min. The fuel rod successfully completed 400 cycles and achieved a burnup of 8000 MWd/Mtu. Power cycling tests were then conducted in Obrigheim on eight short pressurized and unpressurized fuel rods. The test fuel rods were attached to a control rod drive mechanism and driven from the low power to a high power position on a nominal cycle. Power changes from 50% to 100% at rates of 20% per minute for 880 cycles were included. After successfully completing the experiment, the test rods achieved a peak burnup of 30,000 MWd/Mtu without substantial cladding deformation or fuel rod perforation.

K. Fuel Surveillance Programs

C-E has conducted a number of fuel surveillance programs on fuel in operating plants. Thus far, a total of more than 38 pool-side fuel inspection

programs of varying detail have been performed by C-E (see table 4.2-3). A large number of assemblies have been visually examined, and dimensional measurements have also been obtained on a large number of these assemblies. Fuel bundle disassembly operations have been conducted either to obtain information of particular aspects of performance of interest or as part of test assembly surveillance programs. A listing of these programs and a summary of the results are found in reference 68. The results of the C-E pool-side inspection program have been used to verify fuel assembly operation and provide data in support of design. A pool-side fuel surveillance program was performed for C-E's first System 80 fuel at Palo Verde.

4.2.3.2.11 Temperature Transient Effects Analysis

4.2.3.2.11.1 Waterlogged Fuel. The potential for a fuel rod to become waterlogged during normal operation is discussed in paragraph 4.2.3.2.9. In the event that a fuel rod does become waterlogged at low or zero power, it is possible that a subsequent power increase could cause a buildup of hydrostatic pressure. It is unlikely that the pressure would build up to a level that could cause cladding rupture because a fuel pin with the potential for rupture requires the combination of a very small defect together with a long period of operation at low or zero power.

Tests which have been conducted using intentionally waterlogged fuel pins (capsule drive core at SPERT)[62][69] showed that the resulting failures did eject some fuel material from the rod and greatly deformed the test specimens. However, these test rods were completely sealed, and the transient rates used were several orders of magnitude greater than those allowed in normal operation.

In those instances where waterlogged fuel rods have been observed in commercial reactors, it has not been clear that waterlogging was the cause, and not just the result, of associated cladding failures; and C-E has not observed and is not aware of any case in which material was expelled from waterlogged fuel rods or in which the fuel cladding was significantly deformed in a normal power reactor.

It is therefore concluded that the effect of normal power transients on waterlogged fuel rods is not likely to result in cladding rupture, and even if rupture does occur it will not produce the sort of postulated burst failures that would expel fuel material or damage adjacent fuel rods or fuel assembly structural components.

4.2.3.2.11.2 Intact Fuel. The thermal effects of anticipated operational occurrences on fuel rod integrity are discussed in the following paragraphs.

A. Fuel rod thermal transient effects are basically manifested as the change in internal pressure, the changes in clad thermal gradient and thermal stresses, and the differential thermal expansion between pellets

and clad. These effects are discussed in paragraphs 4.2.3.2.2 and 4.2.3.2.11.

B. Another possible effect of transients would be to cause an axial expansion of the pellet column against a flattened (collapsed) section of the clad. However, the fuel rod design includes specific provisions to prevent clad flattening, and, therefore, such interactions will not occur.

4.2.3.2.12 Energy Release During Fuel Element Burnout

The reactor protective system provides fuel clad protection so that the probability of fuel element burnout during normal operation and anticipated operational occurrences is extremely low. Thus, the potential for fuel element burnout is restricted to faulted conditions. The LOCA is the limiting event since it results in the larger number of fuel rods experiencing burnout; thus, the LOCA analysis, which is very conservative in predicting fuel element burnout, provides an upper limit for evaluating the consequences of burnout. The LOCA analysis explicitly accounts for the additional heat release due to the chemical reaction between the Zircaloy clad and the coolant following fuel element burnout in evaluating the consequences of this accident. LOCA analysis results are discussed in sections 6.3.3 and 15.6.5.

4.2.3.2.13 Energy Release on Rupture of Waterlogged Fuel Elements

A discussion of the potential for waterlogging fuel rods and for subsequent energy release is presented in paragraph 4.2.3.2.9.

4.2.3.2.14 Fuel Rod Behavior Effects from Coolant Flow Blockage

An experimental and analytical program was conducted to determine the effects of fuel assembly coolant flow maldistribution during normal reactor operation. In the experimental phase, velocity and static pressure measurements were made in cold, flowing water in an oversize model of a C-E 14 x 14 fuel assembly in order to determine the three-dimensional flow distributions in the vicinity of several types of flow obstruction. The effects of the distributions on thermal behavior were evaluated, where necessary, with the use of a preliminary version of the TORC thermal and hydraulic code.(63) Subjects investigated included:

A. The assembly inlet flow maldistribution caused by blockage of a core support plate flow hole. Evaluation of the flow recovery data indicated that even the complete blockage of a core support plate flow hole would not produce a W-3 DNBR of less than 1.0, even though the reactor might be operating at a power sufficient to produce a DNBR of 1.3 without the blockage.

B. The flow maldistribution within the assembly caused by complete blockage of one to nine channels. Flow distributions were measured at positions upstream and downstream of a blockage of one to nine channels. The influence of the blockage diminished very rapidly in the upstream direction. Analysis of the data for a single channel blockage indicated that such a blockage would not produce a W-3 DNBR of less than 1.0 downstream of the blockage, even though the reactor might be operating at a power sufficient to produce a DNBR of 1.3 without the blockage.

The results presented above were obtained through flow-testing an oversize model of a standard 14 x 14 fuel assembly. Because of the great similarity in design between the Standard System 80, 16 x 16 assembly, and the earlier 14 x 14 array, these test results also constitute an adequate demonstration of the effects that flow blockage would have on the 16 x 16 assembly. This conclusion is also supported by the fact that the 16 x 16 assembly has been demonstrated to have a greater resistance to axial flow than would occur with the 14 x 14 array. The effect of the higher flow resistance to produce more rapid flow recovery, i.e., more nearly uniform flow, is analogous to the common use of flow resistance devices (screens or perforated plates) to smooth non-uniform velocity profiles in ducts or process equipment.

4.2.3.2.15 Fuel Temperatures

Steady-state fuel temperatures are determined by the FATES computer program. The calculational procedure considers the

effect of linear heat rate, fuel relocation, fuel swelling, densification, thermal expansion, fission gas release, and clad deformations. The model for predicting fuel thermal performance is discussed in detail in references 13, 14, 24, 71 and 72.

Two sets of burnup and axially-dependent linear heat rate distributions are considered in the calculation. One is the hot rod, time averaged, distribution expected to persist during long-term operation, and the other is the envelope of the maximum linear heat rate at each axial location. The long-term distributions are integrated over selected time periods to determine burnup, which is in turn used for the various burnup-dependent behavioral models in the FATES computer program. The envelope accounts for possible variations in the peak linear heat rate at any elevation which may occur for short periods of time, and is used exclusively for fission gas release calculations.

The power history used assumes continuous 100% reactor power from beginning-of-life. Using this history, the highest fuel temperatures occur at beginning-of-life. It has been shown that fuel temperatures for a given power level at any burnup are insensitive to the previous history used to arrive at the given power level.

Fuel thermal performance parameters are calculated for the hot rod. These parameters for any other rod in the core can be obtained by using the axial location in the hot rod, whose local power and burnup correspond to the local power and burnup in the rod being examined. This procedure will yield

conservatively high stored energy in the fuel rod under consideration.

The maximum power density, including the local peaking as affected by anticipated operational occurrences, is discussed in sections 4.3 and 4.4, and chapter 15.

4.2.3.3 Al_2O_3-B_4C Burnable Poison Rod

4.2.3.3.1 Burnable Poison Rod Internal Pressure and Cladding Stress

A poison shim cladding analysis was performed to determine the stress and strain resulting from the various normal, upset, and emergency conditions discussed in paragraph 4.2.1.1. Specific accounting was made for differential pressure, differential thermal expansion, cladding creep, and irradiation-induced swelling of the Al_2O_3-B_4C burnable poison material. Owing to the very low linear heat generation rates in these rods (maximum local is less than 1.5 kW/ft), the stress analysis can be accomplished using conventional strength of materials formulae.

The results of the burnable poison rod analyses confirm that the design criteria of paragraph 4.2.1.3.1, regarding stress, strain, and strain fatigue, are satisfied.

4.2.3.3.2 Potential for Chemical Reaction

A discussion of possible chemical reaction between the poison material and the coolant was presented in paragraph 4.2.1.3.3.3, along with information on chemical compatibility between poison material and cladding. Since the cladding

material is identical to that of the fuel rod (paragraph 4.2.1.3.2), the description of potential chemical reactions between cladding and coolant in paragraph 4.2.3.2.3 is applicable to both fuel and poison rods.

The potential for waterlogging rupture in poison rods is much lower than that in fuel rods because of the smaller thermal and dimensional changes that occur in a poison rod during reactor power increases. Refer to paragraph 4.2.3.2.10 for a discussion of the potential for waterlogging rupture in fuel rods.

4.2.3.4 Control Element Assembly

The Feltmetal® full-strength CEAs are designed for a lifetime of 8-EFPY (i.e., about 5 cycles) based on estimates of neutron absorber burnup and B_4C pellet swelling, allowable plastic strain of the Alloy 625 cladding, and the resultant dimensional clearances of the elements within the fuel assembly guide tubes.

The AIC full-strength CEAs are designed for a lifetime of 6.8×10^{20} n/cm^2 (approximately 11 EFPY) for neutrons with energies greater than 1 MeV, based on 20% filling of the central hole in the AIC slugs. This fast fluence value is a high confidence estimate of the design life since it is shown analytically that clad strain limits are satisfied beyond 40% hole fill even with a 5X multiplier on available AIC creep strength data.

A. Internal Pressure

The value of internal pressure in the control elements is dependent on the following parameters:

1. Initial fill gas pressure

2. Gas temperature

3. Helium generated and released

4. Available volume including B_4C porosity

Of the absorber materials utilized in the CEA design, only the B_4C contributes to the total quantity of gas which must be accommodated within the control element. The helium is produced by the nuclear reaction $n^1 + {}_5B^{10} \rightarrow {}_3Li^7 + {}_2He^4$, and the fraction of the quantity generated which is actually released to the plenum is temperature-dependent and is predicted by the empirical equation discussed in paragraph 4.2.1.4.4, listing A.3.

Temperatures used for release fraction calculations are the maximum predicted to occur during normal operation.

The results of the CEA analyses confirm that the design criteria of paragraph 4.2.1.4, regarding stress, strain, and strain fatigue, are satisfied.

B. Thermal Stability of Absorber Materials

None of the materials selected for the control elements are susceptible to thermally-induced phase changes at reactor operating conditions. Linear thermal expansion, thermal conductivity, and melting points are given in paragraph 4.2.1.4.

C. Irradiation Stability of Absorber Materials

Irradiated properties of the absorber materials are discussed in paragraph 4.2.1.4. Irradiation-induced chemical transmutations are produced in B_4C. Neutron bombardment of B-10 atoms results in the production of lithium and helium. The percent of helium released is given by the expression in paragraph 4.2.1.4.

Irradiation-enhanced swelling characteristics of the absorber materials are given in paragraph 4.2.1.4. Accommodations for swelling of the absorbers have been incorporated in the design of the control elements and include the following measures:

1. All B_4C pellets have rounded edges to promote sliding of the pellets in the cladding due to differential thermal expansion and irradiation-enhanced swelling.
2. The creep strength of the AIC slugs used in the tip sections of AIC full-strength CEAs is substantially lower than the yield strength of the Alloy 625 cladding. Stress due to irradiation induced swelling causes the AIC material to creep into the central hole in the slug instead of causing strain in the cladding.
3. Dimensionally stable Type 304 stainless steel spacers are located at the bottom of all absorber stacks adjacent to the nose cap to minimize strain at the weld joint.

4. A felt metal sleeve containing reduced diameter B_4C pellets is located in the bottom length of the absorber stacks in Feltmetal® full-strength control elements. The felt metal sleeve laterally positions the reduced diameter B_4C pellets uniformly with respect to the clad, and in addition absorbs the differential thermal expansion and irradiation-induced swelling of the B_4C pellets, thereby limiting the amount of induced strain in the clad.

D. Potential for and Consequences of CEA Functional Failure

The probability for a functional failure of the CEA is considered to be very small. This conclusion is based on the conservatism used in the design, the quality control procedures used during manufacturing, operational history of similar designs, and on testing of similar full-size CEA/CEDM combinations under simulated reactor conditions for lengths of travel and numbers of trips greater than that expected to occur during the design life. The consequences of CEA/CEDM functional failure are discussed in chapter 15.

A postulated CEA failure mode is cladding failure. In the event that an element is assumed to partially fill with water under low or zero power conditions, the possibility exists that upon returning to power, the path of the water to the outside could be blocked. The expansion of the entrapped water could cause the

element to swell. In tests, specimens of CEA cladding were filled with a spacer representing the poison material. All but 9% of the remaining volume was filled with water. The sealed assembly was then subjected to a temperature of 650F and an external pressure of 2250 lb/in.^{2} followed by a rapid removal of the external pressure. The resulting diametral increases of the cladding were on the order of 15 to 25 mils and were not sufficient to impair axial motion of the CEA, which has a 0.084 diametral clearance with the fuel assembly guide tubes. This test result, coupled with the low probability of a cladding failure leading to a waterlogged rod, demonstrates that the probability for a CEA functional failure from this cause is low.

Another possible consequence of failed cladding is the release of small quantities of CEA filler materials, and helium and lithium (from the neutron-boron reactions). However, the amounts which would be released are too small to have significant effects on coolant chemistry.

4.2.3.5 CEA Axial Growth Analysis

Analysis has shown that adequate axial clearance exists between the bottom of the CEA finger and the fuel assembly guide tube. This clearance, representative of the limiting design condition, has been calculated on the basis of worst-case dimensional tolerances and considers the relative thermal growth between the fuel assembly and the fully inserted CEA.

4.2.4 TESTING AND INSPECTION PLAN

PVNGS shall visually inspect a limited number of randomly selected (about 10 to 15) discharged fuel assemblies during or following each refueling. The visual inspection shall be conducted with underwater viewing equipment (will include inspection of the four sides of each inspected fuel assembly) and is intended to detect gross problems of structural integrity, gross fuel rod failure, gross bowing, spacer grid strap damage, insufficient fuel rod shoulder gap spacing, or crud deposition. Underwater viewing may be accomplished with an underwater camera or binoculars.

Fuel bundle assembly and control element assembly quality assurance is attained by adherence to Westinghouse procedures during fabrication and shipping. New fuel receipt inspection is performed under the PVNGS QA Program, but is based on Westinghouse inspection guidelines and instructions.

Vendor product certification, process surveillance, inspections, tests, and material check analyses are performed to ensure conformity of all fuel assembly and control element assembly components to the design requirements from material procurement through receiving inspection at the plant site. The following are basic quality assurance measures which are performed:

4.2.4.1 Fuel Assembly

A comprehensive quality control plan is established to ensure that dimensional requirements of the drawings are met. In those cases where a large number of measurements are required

and 100% inspection is impractical, these plans provide a high statistical confidence that these dimensions are within tolerance. Sensitivity and accuracy of all measuring devices are within ±10% of the dimensioned tolerance. The basic quality assurance measures which are performed in addition to dimensional inspections and material verifications are described in the following sections.

4.2.4.1.1 Weld Quality Assurance Measures

The welded joints used in the fuel assembly design are listed below in series of paragraphs which describe the type and function of each weld, and include a brief description of the testing (both destructive and nondestructive) performed to ensure the structural integrity of the joints. The welds are listed from top to bottom in the fuel assembly.

The CEA guide tube joints (between the tube and threaded upper and lower ends) are butt welds between the two Zircaloy subcomponents. The welds are required to be full penetration welds and must not cause violation of dimensional or corrosion resistance standards.

The upper end fitting center guide post to lower cast flow plate joint has a threaded connection which is prevented from unthreading by tack welding the center guide post to the bottom of the lower cast plate using the gas tungsten arc (GTA) process. Each weld is inspected for compliance with a visual standard.

The Zircaloy spacer grid welds at the intersection of perpendicular Zircaloy-4 grid strips are made by the GTA

process. Each intersection is welded top and bottom, and each weld is inspected by comparison with a visual standard.

For the Zircaloy spacer grid to CEA guide tube weld (both components Zircaloy-4), each grid is welded to each guide tube with eight small welds, evenly divided between the upper and lower faces of the grid. Each weld is required to be free of cracks and burn-through and each weld is inspected by comparison to a visual standard. Also, sufficient testing of sample welds is required to establish acceptable corrosion resistance of the weld region. Each guide tube is inspected after welding to show that welding has not affected clearance for CEA motion.

The Inconel top spacer grid is held in place by split rings that are welded directly to each guide tube. Each ring is welded to the guide tube in four locations around its circumference, at the end of the ring away from the grid. A total of 20 welds on each side of the grid (four welds in each of five rings) provides the same number of welds used to attach the standard Zircaloy top grid to the guide tubes. Each weld is required to be free of cracks and burn-through, and each weld is inspected by comparison to a visual standard. Also, sufficient testing of sample welds is required to establish acceptable corrosion resistance of the weld region. Each guide tube is inspected after welding to show that welding has not affected clearance for CEA motion.

The lower spacer grid welds at spacer strip intersections and between spacer and perimeter strips (all components Inconel 625) have the same configuration as for the Zircaloy

and are all inspected for compliance with appropriate visual standards.

The lower spacer grid (Inconel) to Inconel skirt weld is made using the GTA process. Each weld is inspected to ensure compliance with a visual standard.

The Inconel skirt to lower end fitting (304 stainless steel) weld is made using the GTA process and each weld is inspected to ensure compliance with a visual standard.

The lower end fitting is fastened to the Zircaloy guide tubes using threaded connections. The connections are prevented from unthreading by stainless steel locking rings which are welded to the lower end fitting. Each ring is tack welded to the end fitting in four places using the GTA process, and each weld is inspected for compliance with a visual standard.

Reload assemblies may use proprietary, laser welded Guardian™ grids (lower Inconel grids), as well as laser welded spacer grids. Welds are to be free of cracks and burn-through upon inspection.

The inspection requirements and acceptance standards for each of the welds are established on the basis of providing adequate assurance that the connections will perform their required functions.

4.2.4.1.2 Other Quality Assurance Measures

All guide tubes are internally gaged ensuring free passage within the tubes including the reduced diameter buffer region.

Each upper end fitting post to guide tube joint is inspected for compliance with a visual standard.

The spacer grid to fuel rod relationship is carefully examined at each grid location. Each grid cell in the top grid and in the lower Inconel grid is inspected for proper spring preset during fuel assembly fabrication. Grid cells in all other grids are inspected for proper spring preset in accordance with a Westinghouse sampling plan. Every grid cell is checked for tightness prior to installation of the upper end fitting assembly.

The uranium concentration on the exterior surface of the fuel rods is maintained within 10 $dpm/100cm^2$.

Each completed fuel assembly is inspected for cleanliness, wrapped to preserve its cleanliness, and loaded within shipping containers.

Visual inspection of the conveyance vehicle, shipping container, and fuel assembly are performed at the reactor site. Approved procedures are provided for unloading the fuel assemblies. Following unloading, exterior portions of the fuel assembly components are inspected for shipping damage and cleanliness. If damage is detected, the assembly may be repaired onsite or returned to the manufacturing facility for repair. In the event that the repair process were other than one normally used by the manufacturing facility, or that the repaired assembly did not meet the standard requirements for new fuel, the specific process or assembly would be reviewed before the process or assembly would be accepted.

4.2.4.2 Fuel Rod

4.2.4.2.1 Fuel Pellets

During the conversion of source material to ceramic grade uranium dioxide powder, the UO_2 powder is divided into lots blended to form uniform isotopic, chemical, and physical characteristics. Two samples are tested from each powder blend to verify compliance with the specification limits for the blend. Additional finished pellets are tested for the final enrichment certification of the pellets.

Pellets are divided into lots during fabrication with all pellets within the lot being processed under the same conditions as defined per the pellet specification. Representative samples are obtained from each lot for product acceptance tests. Hydrogen content of the finished ground pellets is restricted. The pellets' diameters are inspected and certified to meet the design tolerance requirements at a 95/99 confidence level. All other pellet dimensions meet a 90/90 confidence level. Density requirements of the sintered pellets must meet a 95/95 confidence level. Sample pellets from each pellet lot are prepared for metallographic examination to ensure conformance to microstructural requirements. Surface finish of ground pellets is restricted and meets a 90/90 confidence level. Pellet surfaces are inspected for chips, cracks, and fissures in accordance with approval standards.

4.2.4.2.2 Cladding

Lots are formed from tubing produced from the same ingot, annealed in the same final vacuum annealing charge, and fabricated using the same procedures. Samples of either finished tubing or ingots are selected for chemical analysis to ensure conformance to specified chemical requirements, and to verify tensile properties and hydride orientation. Each finished tube is ultrasonically tested for internal soundness; visually inspected for cleanliness and the absence of acid stains, surface defects, and deformation; and inspected for inside dimension and wall thickness.

4.2.4.2.3 Fuel Rod Assembly

Immediately prior to loading, pellets must be capable of passing approved visual standards. Each fuel pellet stack is weighed to within 0.1% accuracy. The loading process is such that cleanliness and dryness of all internal fuel rod components are maintained until after the final end cap weld is completed. Loading and handling of pellets are carefully controlled to minimize chipping of pellets. The allowable gap between pellets, and the allowable cumulative gaps in a fuel column, are to be within specified limits.

Loaded fuel rods are pressurized with helium to a prescribed pressure as determined for the fuel batch. Impurity content of the fill gas during rod pressurization shall not exceed 0.5% by volume.

The fuel rod end cap-to-fuel rod cladding tube welds are butt welds between the Zircaloy-4 or ZIRLO™ cladding tube and the

Zircaloy-4 end cap machined from bar stock. Quality assurance on the end cap weld is as follows:

A. Radiographic examination or ultrasonic testing of all end cap welds (Batches N and later only) to certify bond length and to detect porosity or undercut.

B. Destructive examination of a sufficient number of weld samples to establish that the maximum allowable percent of unbonded wall thickness and the maximum allowable continuous unbonded region are not exceeded. An alternate process may be specified in lieu of cut samples.

C. Visual examination of all end cap welds to establish freedom from cracks, seams, inclusions, and foreign particles (Note: In Batches A through M, that examination was performed) after final machining of the weld region.

D. Helium leak checking of all end cap welds to establish that no air equivalent leak rate greater than 10^{-8} cm^3/s (STP) is present.

E. Corrosion testing of a sufficient number of samples to establish that weld zones do not exhibit excessive corrosion compared to a visual standard.

All finished fuel rods are visually inspected to ensure a proper surface finish (scratches greater than 0.001 inch in depth, cracks, slivers, and other similar defects are not acceptable).

Each fuel rod is marked to provide a means of identification.

4.2.4.3 Burnable Poison Rod

4.2.4.3.1 Burnable Poison Pellets

B_4C powder is sampled to verify particle size and wt% boron requirements prior to its use in pellet production. Finished pellets are 100% inspected for diameter and must satisfy a 90/90 confidence level on other dimensions. Samples are taken from each of the pellet lots and examined for uniform dispersion of the B_4C in Al_2O_3.

Conformance with density range requirements is demonstrated at a 95/95 confidence level and with B_4C loading requirements at a 90/90 level. Samples are drawn from each lot to verify acceptable impurity levels. Finally, all pellets are inspected for conformance with surface chip and crack standards.

4.2.4.3.2 Cladding

The testing and inspection plan for burnable poison rod cladding is identical to that for fuel rod cladding (paragraph 4.2.4.2.2).

The moisture content of poison pellets prior to loading is limited to values below that which would be required to produce primary hydride penetration of the cladding. Total moisture inventory is comparable to that which has been shown to be acceptable in fuel rods.[57] The fabrication process is such that all steps from component drying through final welding are carefully controlled so as to minimize the possibilities for excessive moisture pickup. Final verification of pellet dryness is made by moisture analysis.

The following procedure is used during fabrication to assure that there are no axial gaps in poison rods.

The operator stacks pellets onto V troughs that are gage marked to be the proper column height. When pellet stacking is completed, all column heights are overchecked by Quality Control. The pellets are subsequently loaded into tubes. After loading, the distance from the end of the tube to the end of the pellet column is checked with a gage.

Loaded poison rods are evacuated and backfilled with helium to a prescribed level. Impurity content of the fill gas must not exceed 0.5%.

End cap weld integrity and corrosion resistance are ensured by a quality control plan identical to that used in fuel rod fabrication (paragraph 4.2.4.2.3).

Each poison rod is marked to provide a means of identification.

4.2.4.4 Control Element Assemblies

The CEAs are subjected to numerous inspections and tests during manufacturing and after installation in the reactor. A general product specification controls the fabrication, inspection, assembly, cleaning, packaging, and shipping of CEAs. All materials are procured to AMS, ASTM, U.S. General Services Administration, military (MIL), or Westinghouse specifications. In addition, various CEA hardware tests have been conducted.

During manufacturing, the following inspections and tests are performed:

A. The loading of each control element is carefully controlled to obtain the proper amounts and types of filler materials for each type of CEA application (e.g., full-strength or part-strength).

B. All end cap welds are liquid penetrant examined and helium leak tested. All full penetration welds, including end cap welds, are radiographed.

C. Each CEA is serialized to distinguish it from the others. See figures 4.2-3 through 4.2-5.

Once fully assembled, the CEAs are checked for proper alignment of the neutron absorber elements using a special fixture. The alignment check ensures that the frictional force that could result from adverse tolerances is below the force which could significantly increase trip time.

In addition to the basic measures discussed above, the manufacturing process includes numerous other quality control steps for ensuring that the individual CEA components satisfy design requirements for material quality, detail dimensions, and process control.

After installation in the reactor, but prior to criticality, each CEA is traversed through its full stroke and tripped. A similar procedure will also be conducted at refueling intervals.

The required 90% insertion SCRAM time for full-strength CEAs is 4.0 seconds under worst case conditions. Verification of

adequacy has been determined by testing in the C-E TF-2 flow test facility. This test facility contained prototypical (System 80) reactor components consisting of fuel assemblies, CEA shroud, control element drive mechanism, and a simulation of surrounding core internal support components. The test conditions simulated the range of temperatures and flow rates predicted for System 80 normal plant operation.

4.2.5 REACTOR INTERFACE REQUIREMENTS

Detailed below are the interface requirements that the reactor places on certain aspects of the BOP, listed by categories. In addition, applicable General Design Criteria (GDC) and Regulatory Guides which Westinghouse utilizes in its design of the reactor are presented. The GDC and Regulatory Guides are listed only to show what Westinghouse considers to be relevant, and are not imposed as interface requirements unless specifically called out as such in a particular interface requirements.

Relevant GDC -	1, 2, 3, 4, 10, 11, 12, 14, 15, 26, 27, 28, 29, 30, 31, 32, 61, 62, 63
Relevant Reg. - Guides	1.13, 1.2, 1.20, 1.25, 1.28, 1.29, 1.31, 1.34, 1.36, 1.37, 1.38, 1.43, 1.44, 1.46, 1.48, 1.50, 1.51, 1.54, 1.60, 1.61, 1.64, 1.65, 1.68, 1.71, 1.74, 1.84, 1.85

A. Power

Not applicable

B. Protection from Natural Phenomena

1. High winds, tornado, tornado missile, and flooding requirements relating to the reactor are in accordance with Criterion 2 of 10CFR50 Appendix A.

2. The spent fuel pool shall be a seismic Category I structure.

3. The load-bearing members of the spent fuel storage racks shall withstand the forces induced by the SSE vertical and horizontal seismic loadings. These forces shall be assumed as acting simultaneously in conjunction with the combined dead weight and live loads, without exceeding minimum material yield stresses as specified by ASTM.

4. The spent fuel storage racks shall be seismic Category I.

C. Protection from Pipe Failure

1. The fuel shall be protected from the effects of pipe whip while in storage.

2. Refer to subsection 5.1.4 for protective measure requirements for the reactor.

3. Spent fuel shall be protected from the effects of pipe rupture.

D. Missiles

1. A removable structure shall be located above the reactor vessel to block any missile that could be generated by a control element drive mechanism.

2. The fuel shall be protected from the effects of missiles while in storage.

E. Separation

1. New Fuel Storage Racks

a. The new fuel storage racks shall be designed such that fuel assemblies will not be inserted in other than prescribed locations.

b. Adequate margin to criticality shall be provided for full rack loadings of fuel assemblies having a mechanical design similar to that described in chapter 4.0 and a maximum, radially averaged, U-235 enrichment up to 4.80 weight percent.

c. The degree of subcriticality provided shall be consistent with the requirements of ANSI Standard N18.2 Section 5.7.4.1.

F. Independence

Not applicable.

G. Thermal Limitations

1. Cooling air shall be provided to the CEDMs at a minimum flow rate of 700 standard ft^3/min per CEDM at a temperature in the range of 80 to 120F.

2. Drains, permanently connected systems, and other features of the spent fuel pool shall be designed so that neither maloperation nor failure can result

in loss of coolant that would uncover the stored fuel.

3. Spent fuel pool cooling shall be capable of removing the decay heat generated from one complete core of spent fuel placed in the pool 7 days after shutdown in addition to one-third of a completed core that has been in the pool 90 days after shutdown.

H. Monitoring

1. Low water level alarms shall be provided for the refueling pool and the spent fuel pool.

2. A system shall be provided to monitor the reactor coolant system for internal loose parts. The system shall have ability to detect a loose part striking the internal surface of reactor coolant system components with an energy level of one-half foot-pound or more. The system shall have alarm and recording capability. The system design shall be suitable for the temperature and humidity environment experienced in the area where the equipment normally operates.

I. Operational/Controls

Not applicable.

J. Inspection and Testing

Inservice inspection shall be performed in accordance with Section XI of the ASME Code.

K. Chemistry/Sampling

Not applicable.

L. Materials

See paragraph 5.1.4.L.3.

M. System/Component Arrangement

Not applicable.

N. Radiological Waste

Not applicable.

O. Overpressure Protection

Not applicable.

P. Related Services

1. For refueling operations, the containment building crane shall have a minimum capacity of 225 tons.

   a. A hoisting speed of 6 inches per minute or less shall be utilized during refueling operations.

   b. A load measuring device shall be provided for use during heavy lifts.

   c. A low inching speed is required during those portions of the lift when close tolerance surfaces are engaging each other.

2. An overhead crane shall be provided in the new fuel storage area to facilitate handling new fuel.

   a. The crane capacity shall be at least 1 ton to accommodate the weight of a fuel assembly.

b. A vertical hoisting speed of 6 feet/minute or less shall be provided.

c. The crane load shall be capable of being limited to prevent the hoist load from exceeding 5000 pounds when handling fuel assemblies.

3. See paragraph 5.1.4.P.3.

Q. Environmental

Not applicable.

4.2.6 CESSAR REACTOR INTERFACE REQUIREMENTS EVALUATION

The CESSAR interface requirements listed in subsection 4.2.5 are met by the PVNGS design as follows:

A. Power

Not applicable

B. Protection from Natural Phenomena

1. Refer to section 3.3 for a discussion of protection for the reactor from high winds, tornadoes, and tornado missiles. Section 3.4 discusses flood protection.

2. The spent fuel pool is located in the fuel building, which is a Seismic Category I structure as described in subsection 9.1.2.

3. The spent fuel storage racks are designed such that the load bearing members will withstand the forces induced by the SSE vertical and horizontal seismic

loadings that are assumed as acting simultaneously on this equipment in conjunction with the combined dead weight and live loads without exceeding minimum material yield stresses as specified by ASTM.

4. The spent fuel storage racks are designed as Seismic Category I.

C. Protection from Pipe Failure

1. The fuel is protected from the effects of pipe whip while in storage by routing all pressurized pipes away from the fuel storage locations.

2. Refer to section 3.6 and subsection 5.1.5 for a discussion of reactor protection from pipe failures.

3. Spent fuel is protected from the effects of pipe rupture while in storage by routing all pressurized pipes away from the spent fuel storage locations as discussed in Section 3.6. Accidental criticality is prevented by assuring that K_{eff} remains less than 1.0 assuming unborated water and by assuring that K_{eff} remains less than or equal to 0.95 taking credit for 900 ppm soluble boron in the water (which is normally at ≥ 2150 ppm). Dilution analysis has shown that the final boron concentration in the spent fuel pool would remain well above the required 900 ppm as a result of the most limiting boron dilution event.

D. Missiles

1. Refer to subsection 3.5.2.

2. There are no credible sources for missile generation that could affect the fuel while in storage since the fuel building is designed to withstand tornado missiles and there are no sources of internally generated missiles.

E. Separation

1. New Fuel Storage Racks

a. The new fuel storage racks are designed such that fuel assemblies can be inserted only in prescribed locations.

b. The new fuel storage racks are designed to provide adequate margin to criticality for full rack loadings of fuel assemblies having a mechanical design similar to that described in chapter 4.0 and a maximum radially averaged U-235 enrichment of 4.80 weight percent.

c. The degree of subcriticality provided will be consistent with the requirements of ANSI Standard N18.2 Section 5.7.4.1.

F. Independence

Not applicable.

G. Thermal Limitations

1. An adequate flow rate of cooling air is provided to the CEDMs to ensure that the CEDMs operating

service design temperature is not exceeded (refer to subsection 9.4.6).

2. Drains, permanently connected systems, and other auxiliary features are designed such that neither their malfunction nor failure would result in loss of pool coolant and expose the stored fuel to the atmosphere.

3. Spent fuel pool cooling is provided as discussed in subsection 9.1.3.

H. Monitoring

1. Low and low-low level alarms (fed from separate instrument loops) are provided for the spent fuel pool and refueling pool. However, only the low level alarm is set to alarm prior to reaching the Technical Specification LCO minimum requirement.

2. Refer to section 7.7.1.1.8 for a description of the loose parts monitoring system provided for PVNGS units.

I. Operational/Controls

Not applicable.

J. Inspection and Testing

Refer to subsection 5.1.5, listing J, for the evaluation of these interface requirements.

K. Chemistry/Sampling

Not applicable.

L. Materials

Refer to subsection 5.1.5, listing L.3, for the evaluation of these interface requirements.

M. System/Component Arrangement

Not applicable.

N. Radiological Waste

Not applicable.

O. Overpressure Protection

Not applicable.

P. Related Services

1. The containment crane has a minimum capacity of 225 tons.

   a. A hoisting speed of 6 inches per minute or less is provided.

   b. The containment crane is provided with a load measuring device.

   c. The containment crane is provided with a low inching speed.

2. A new fuel handling crane is provided.

   a. The new fuel handling crane has a 10-ton capacity.

   b. A vertical hoisting speed of 10 feet per minute, (+ 2 fpm tolerance), is provided. While this is greater than the speed

identified in Section 4.2.5, it has been evaluated to be acceptable.

c. This crane has an adjustable load limiting device that is adjusted to prevent the hoist load from exceeding 5000 pounds when handling fuel assemblies.

3. The fire protection system provided to protect the RCS is discussed in subsection 9.5.1.

Q. Environmental

Not applicable.

4.3 NUCLEAR DESIGN

4.3.1 DESIGN BASES

The bases for the nuclear design of the fuel and reactivity control systems for Units 1, 2, and 3 are discussed in the following paragraphs.

4.3.1.1 Excess Reactivity and Fuel Burnup

The excess reactivity provided for each cycle is based on the depletion characteristics of the fuel and burnable poison and the desired burnup for each cycle. The desired burnup is based on an economic analysis of the fuel cost and the projected operating load cycle for PVNGS. The average burnup is chosen to ensure that the peak rod-averaged burnup is within the limits of 60,000 MWd/Mtu (60 MWd/kgU) discussed in References 1 and 2. This design basis, along with the design basis in paragraph 4.3.1.8, satisfies General Design Criterion 10.

4.3.1.2 Core Design Lifetime and Fuel Replacement Program

The core design lifetime and fuel replacement programs are based on refueling intervals of 18 to 24 months with up to one-half of the fuel assemblies replaced at each refueling in the later cycles. Explicit evaluations are performed to assure applicability of all analyses to the previous cycle's final burnup. Explicit evaluations are also performed prior to entering Mode 4 after a refueling outage to verify that the integrated spent fuel pool heat load within the design cooling capability of the auxiliary cooling systems (Refer to

sections 9.1 and 9.2 for these cooling systems design bases and descriptions).

4.3.1.3 Negative Reactivity Feedback

In the power operating range, the net effect of the prompt inherent nuclear feedback characteristics (fuel temperature coefficient, moderator temperature coefficient, and moderator pressure coefficient) tends to compensate for a rapid increase in reactivity. The negative reactivity feedback provided by the design satisfies General Design Criterion 11.

4.3.1.4 Reactivity Coefficients

The values of each coefficient of reactivity are consistent with the design basis for net reactivity feedback (paragraph 4.3.1.3), and with analyses that predict acceptable consequences of postulated accidents and anticipated operational occurrences, where such analyses include the response of the reactor protective system (RPS).

4.3.1.5 Burnable Poison Requirements

The burnable poison reactivity worth provided in the design is sufficient to ensure that the moderator coefficients of reactivity are consistent with the design bases of paragraphs 4.3.1.1 through 4.3.1.4.

4.3.1.6 Stability Criteria

The reactor and the instrumentation and control systems are designed to detect and suppress xenon-induced power distribution oscillations that could, if not suppressed, result in conditions

that exceed the specific acceptable fuel design limits. The design of the reactor and associated systems precludes the possibility of power level oscillations. This basis satisfies General Design Criterion 12.

4.3.1.7 Maximum Controlled Reactivity Insertion Rate

The core, control element assemblies (CEAs), reactor regulating system, and boron charging portion of the chemical and volume control system are designed so that the potential amount and rate of reactivity insertion due to normal operation and postulated reactivity accidents do not result in:

A. Violation of the specified acceptable fuel design limits.

B. Damage to the reactor coolant pressure boundary.

C. Disruption of the core or other reactor internals sufficient to impair the effectiveness of emergency core cooling.

This design basis, along with paragraph 4.3.1.11, satisfies General Design Criteria 25 and 28.

4.3.1.8 Power Distribution Control

The core power distribution is controlled such that, in conjunction with other core operating parameters, the power distribution does not result in violation of the limiting conditions for operation. Limiting conditions for operation and limiting safety system settings are based on the accident analyses described in chapters 6 and 15 such that specified acceptable fuel design limits and other criteria are not exceeded

for accidents. This basis, along with paragraph 4.3.1.1, satisfies General Design Criterion 10.

4.3.1.9 Excess CEA Worth with Stuck Rod Criteria

The amount of reactivity available from insertion of withdrawn CEAs under all power conditions, even when the highest worth CEA fails to insert, will provide for at least 2% excess CEA worth after cooldown to hot zero power, plus any additional shutdown reactivity requirements assumed in the safety analysis. This basis, along with paragraph 4.3.1.10, satisfies General Design Criteria 26 and 27.

4.3.1.10 Chemical Shim Control

The chemical and volume control system (CVCS) (subsection 9.3.4) is used to adjust the dissolved boron concentration in the moderator. After a reactor shutdown, this system is able to compensate for the reactivity changes associated with xenon decay and reactor coolant temperature decreases to ambient temperature, and it provides adequate shutdown margin during the refueling. This system also has the capability of controlling, independently of the CEAs, long-term reactivity changes due to fuel burnup and reactivity changes during xenon transients resulting from changes in reactor load. This design basis, along with paragraph 4.3.1.9, satisfies General Design Criteria 26 and 27.

4.3.1.11 Maximum CEA Speeds

Maximum CEA speeds are consistent with the maximum controlled reactivity insertion rate design basis discussed in paragraph 4.3.1.7. Maximum CEA speeds are also discussed in section 4.2.

4.3.2 DESCRIPTION

The description of the nuclear design for Units 1, 2, and 3 is discussed in the following paragraphs.

4.3.2.1 Nuclear Design Description

This section summarizes the nuclear characteristics of the core and discusses the important design parameters that affect the performance of the core in steady-state and normal transient operation. A summary of typical nuclear design parameters is presented in table 4.3-1. The data is intended to be representative of a reload cycle design.

Table 4.3-1

TYPICAL NUCLEAR DESIGN CHARACTERISTICS

(Sheet 1 of 2)

Item	Value
General Characteristics	
Fuel management	3-batch, Low Leakage CENTRAL ZONE
Core average burnup (MWd/T), 10 ppm soluble boron	18,500
Core average U-235 enrichment (wt%)	4.0
Number of control element assemblies	
Full-strength	76
Part-strength	13
Burnable Poison Rods	
Number	9,500
Material	Er_2O_3
Dissolved Boron	
Dissolved boron content for criticality, ppm (CEAs withdrawn, BOC)	
Cold, 68F	2,400
Hot, zero power, 565F	2,100
Hot, full power, equilibrium Xe	1,700

Table 4.3-1

TYPICAL NUCLEAR DESIGN CHARACTERISTICS

(Sheet 2 of 2)

Item	Value
Dissolved boron content (ppm) for:	
Refueling	
5% subcritical, cold (135F) (all CEAs out)	1,850
5% subcritical, hot (564F) (all CEAs out)	2,200
Boron worth, ppm/%$\Delta\rho$ (BOC/EOC)	
Hot, 594F	140/100
Cold, 68F	85/61
Neutron parameters	
Prompt neutron generation time, ℓ^* (cycle average), microseconds	22.95
Delayed neutron fraction (cycle average)	0.0056

Cycle-specific data are calculated for each unit reload. Bounding design limit values for these and other parameters are discussed in the appropriate sections.

The cycle designs feature fuel enrichment zoning loading schemes in which the assemblies contain rods of different enrichments and Er_2O_3 integrated burnable absorber. In earlier assemblies fuel pins that exhibit tendency to experience peak power are integrated with Er_2O_3 in an effort to hold down assembly power. Fuel pins adjacent to guide tubes and water holes are specifically targeted. These unique systems of fuel enrichment zoning offer lower power peaking as well as improved

long-term control over the local assembly power distribution. A typical fuel loading pattern is shown in figure 4.3-1. Cycle-specific data are identified for each reload. Physical features of the lattice, fuel assemblies, and CEAs are described in section 4.2.

Typical enrichments, core burnup, critical soluble boron concentrations and worths, and delayed neutron fractions and neutron lifetime are shown in table 4.3-1. The soluble boron insertion rates, as discussed in subsection 9.3.4, are sufficient to compensate for the maximum reactivity addition due to xenon burnout and normal plant cooldown.

4.3.2.2 Power Distribution

4.3.2.2.1 General

At all times during operations, it is intended that the power distribution and coolant conditions be controlled so that the peak linear heat rate and the minimum departure from nucleate boiling ratio (DNBR) are maintained within operating limits supported by the safety analyses (chapters 6 and 15) with due regard for the correlations between measured quantities, the power distribution, and uncertainties in the determination of power distribution.

Methods of controlling the power distribution include the use of full- or part-strength CEAs to alter the axial power distribution; decreasing CEA insertion by boration, thereby improving the radial power distribution; and correcting off-optimum conditions which cause margin degradations (e.g., CEA misoperation).

The Core Operating Limit Supervisory System (COLSS) will indicate continuously to the operator how far the core is from the operating limits and give an audible alarm should an operating limit be exceeded. Such a condition signifies a reduction in the capability of the plant to withstand an anticipated transient, but does not necessarily imply a violation of fuel design limits. If the margin to fuel design limits continues to decrease, the RPS initiates a trip to assure that the specified acceptable fuel design conditions are not exceeded.

The COLSS, described in section 7.7 and reference 3, continually generates an assessment of the margin to linear heat rate and DNBR operating limits. The data required for these assessments include measured in-core neutron flux data, CEA positions, and coolant inlet temperature, pressure, and flow. In the event of an alarm indicating that an operating limit has been exceeded, power must be reduced unless the alarm can be cleared by improving either the power distribution or another process parameter. The validity of the COLSS calculations is verified periodically as discussed in the Technical Specifications. In addition to the monitoring performed by COLSS, the core protection calculator system (CPCS, section 7.2) continually infers the core power distribution and DNBR by processing reactor coolant data, signals from excore neutron flux detectors, each containing three axially stacked elements, and input from redundant reed switch assemblies to indicate CEA position. In the event the power distributions or other parameters are perturbed as the result of an anticipated operational occurrence that would

violate fuel design limits, the high local power density or low DNBR algorithm in the CPCS will initiate a reactor trip.

4.3.2.2.2 Nuclear Design Limits on the Power Distribution

The design limits on the power distribution stated here were employed during the design process, both as design input and as initial conditions for accident analyses described in chapters 6 and 15. However, for the monitoring system, it is the final operating limit determination that is used to assure that the consequences of an anticipated operational occurrence or postulated accident will not be any more severe than the consequences shown in chapters 6 and 15. The initial conditions used in this operating limit determination are actually stated in terms of peak linear heat generation rate and required power margin for minimum DNBR.

The design limits on power distribution are as follows:

A. The limiting three-dimensional heat flux peaking factor, F^nq, was established for full power conditions at 2.28 and 2.35 for first and equilibrium cycles, respectively. The lower value for the first cycle reflects the presence of burnable poison shims in the fuel lattice and a corresponding reduction in the number of fuel rods. F^nq is defined in paragraph 4.4.2.2.2.1, listing C, and is termed the nuclear power factor or the total nuclear peaking factor.

B. The thermal margin to a minimum DNBR of the SAFDL (using the CE-1 CHF correlation as discussed in paragraphs 4.4.2.2 and 4.4.4.1, and statistical

treatment of the core inlet flow distribution as discussed in paragraph 4.4.2.2), which is available to accommodate anticipated operational occurrences, is a function of several parameters, including:

1. The coolant conditions.
2. The axial power distribution.
3. The axially integrated radial peaking factor, $F^n r$; where $F^n r$ is the rod radial nuclear factor or the rod radial peaking factor and is defined in paragraph 4.4.2.2.2.1, listing A (referred to as rod radial power factor in that section).

The coolant conditions assumed in the safety analyses, $F^n r$, a cycle dependent radial design limit, and the set of axial shapes displayed in figure 4.4-4 constitute a set of limiting combinations of parameters for full power operation. Other combinations giving acceptable accident analysis consequences are equally acceptable. Implementation of these limits in the Technical Specification is via a power operating limit based on DNBR which maintains an appropriate amount of thermal margin to the DNBR limit. It will be shown in the following paragraphs that operation within these design limits is achievable.

4.3.2.2.3 Expected Power Distributions

The planar radial power distributions and unrodded core average axial power distributions are calculated for every reload cycle. These calculations identify conditions expected at full power for various times in the fuel cycle. It is expected that the normal operation of the reactor will be with limited CEA

insertion so that these power distributions represent the expected power distribution during most of the cycle. The uncertainty associated with these calculated power distributions is discussed in paragraph 4.3.3.1.2.2.3.

The capability of the core to follow a load transient without exceeding power distribution limitations depends on the margin to operating limits compared to the margin required for base loaded, unrodded operation.

The radial and axial power distributions and estimates of $F^{n}q$ and $F^{n}r$ are obtained from either 3D ROCS/MC, 3D SIMULATE-3, or 2D ROCS/MC with HERMITE.

The detailed radial power distribution within any assembly is a function of the location of that assembly within the core as well as the time in life, CEA insertion, etc. The normalized assembly power distribution used for the sample DNB calculation discussed in paragraph 4.4.2.2 is shown on figure 4.3-2. The accuracy of calculations of the power distribution within a fuel assembly is discussed in paragraph 4.3.3.1.2.

4.3.2.2.4 Allowances and Uncertainties on Power Distributions

In comparing the expected power distributions and implied peak linear heat generation rate (PLHGR) produced by analysis with the design limits stated in paragraph 4.3.2.2.2, consideration must be given to the uncertainty and allowances associated with on-line monitoring by COLSS, and those associated with calculational procedures.

4.3.2.2.5 Comparisons Between Limiting and Expected Power Distributions

As was discussed in paragraph 4.3.2.2.3, the maximum calculated $F^n q$ augmented by uncertainty factors provides an upper limit on $F^n q$. Additionally, the calculations described in paragraph 4.3.2.2.3 show that, with proper use of the part-strength CEAs, no appreciable increase in the peak linear heat rate occurs during these maneuvering transients. In the event that the part-strength CEAs were not moved properly, the power distribution could have become unacceptable. In this case, the monitoring system would indicate if insufficient margin to operating limits has been reached, and that action has to be taken to improve the core power distribution, to improve the coolant conditions, or to reduce core power.

Allowing for uncertainty, the maximum expected unrodded $F^n r$ that occurs at full power is typically 1.72. Again, as demonstrated by the calculations of the power distributions expected to occur during maneuvering transients, no appreciable loss in thermal margin is expected to occur during these transients.

4.3.2.3 Reactivity Coefficients

Reactivity coefficients relate changes in core reactivity to variations in fuel or moderator conditions. Subsection 4.3.3 presents comparisons of calculated and measured moderator temperature coefficients and power coefficients for various operating reactors. The good agreement shown in that subsection provides confidence that the data calculated for the current reload cycles adequately characterize the current PVNGS

reactors. Chapters 6 and 15 provide the bounding values used in the safety analyses. In these chapters each accident analysis applies suitable conservation uncertainties, as discussed in paragraph 4.3.3.1.2 and other conservatism to the calculated values. Therefore, the values used in the safety analyses may fall outside the ranges (in conservative direction) of the data presented in this section.

The calculational methods used to compute reactivity coefficients are discussed in paragraph 4.3.3.1.1. All data discussed in subsequent paragraphs were calculated with two-dimensional and three-dimensional, quarter-core nuclear models. Spatial distributions of materials and flux weighting are explicitly performed for the particular conditions at which the reactivity coefficients are calculated. The adequacy of this method is discussed in paragraph 4.3.3.1.2.

4.3.2.3.1 Fuel Temperature Coefficient

The fuel temperature coefficient is the change in reactivity per unit change in fuel temperature. A change in fuel temperature affects the reaction rates in both the thermal and epithermal neutron energy regimes. Epithermally, the principal contributor to the change in reaction rate with fuel temperature is the Doppler effect, arising from the increase in absorption widths of the resonances with an increase in fuel temperature. The ensuing increase in absorption rate with fuel temperature causes a negative fuel temperature coefficient. In the thermal energy regime, a change in reaction rate with fuel temperature arises from the effect of temperature-dependent scattering properties of the fuel matrix on the thermal neutron

spectrum. In typical PWR fuels containing strong resonance absorbers such as U-238 and Pu-240, the magnitude of the component of the fuel temperature coefficient arising from the Doppler effect is more than a factor of 10 larger than the magnitude of the thermal energy component.

Figure 4.3-3 shows a typical dependence of the calculated fuel temperature coefficient on the fuel temperature, both at the beginning and the end of cycle.

4.3.2.3.2 Moderator Temperature Coefficient

The moderator temperature coefficient relates changes in reactivity to uniform changes in moderator temperature, including the effects of moderator density changes with changes in moderator temperature. Typically, an increase in the moderator temperature causes a decrease in the core moderator density, and therefore, less thermalization, which reduces the core reactivity. However, when soluble boron is present in the moderator, a reduction in moderator density causes a reduction in the content of soluble boron in the core, thus producing a positive contribution to the moderator temperature coefficient. To limit the dissolved boron concentration, burnable poison rods (shims) are provided in the form of cylindrical pellets of integrated $U0_2$ and Er_20_3 particles. A typical number of shims is given in table 4.3-1. Cycle-specific data are identified for each reload.

The moderator temperature coefficients for various core conditions at the beginning and end of each cycle are calculated for each reload cycle. The moderator temperature coefficients are more negative at end-of-cycle because the

soluble boron in the coolant is reduced. The buildup of equilibrium xenon produces a net negative change in the moderator temperature coefficient, due mainly to the accompanying reduction in critical soluble boron. The changing fuel isotopic concentrations and the changing neutron spectrum during the fuel cycle depletion also contribute a small negative component to the moderator temperature coefficient.

The bounds of the allowed MTC are identified in each unit's Core Operating Limits Report (COLR).

4.3.2.3.3 Moderator Density Coefficient

The moderator density coefficient is the change in reactivity per unit change in the average core moderator density at constant moderator temperature. A positive moderator density coefficient translates into a negative contribution to the total moderator temperature coefficient, which is defined in paragraph 4.3.2.3.2. The density coefficient is always positive in the operating range, although the magnitude decreases as the soluble boron level in the core is increased. The density coefficients explicitly used in the accident analyses are based upon core conditions with the most limiting temperature coefficients allowed by the technical specification.

4.3.2.3.4 Moderator Nuclear Temperature Coefficient

The moderator nuclear temperature coefficient is the change in reactivity per unit change in core average moderator temperature, at constant moderator density. The source of this reactivity dependence is the variation of the spectral effects

associated with the change in thermal scattering properties of water molecules as the internal energy, represented by the bulk water temperature, is changed. The magnitude of the moderator nuclear temperature coefficient is equal to the difference between the moderator temperature coefficient, defined in paragraph 4.3.2.3.2, and the moderator density coefficient, defined in paragraph 4.3.2.3.3.

4.3.2.3.5 Moderator Pressure Coefficient

The moderator pressure coefficient is the change in reactivity per unit change in reactor coolant system pressure. Since an increase in pressure, at constant moderator temperature, increases the water density, the pressure coefficient is merely the density coefficient expressed in a different form.

4.3.2.3.6 Moderator Void Coefficient

The anticipated occurrence of small amounts of local subcooled boiling in the reactor during full power operation results in a predicted core average steam (void) volume fraction substantially less than 1%. Changes in the moderator void fraction produce reactivity changes that are quantified by the void coefficient of reactivity. An increase in voids decreases core reactivity, but the presence of soluble boron tends to add a positive contribution to the coefficient.

4.3.2.3.7 Power Coefficient

The power coefficient is the change in reactivity per unit change in core power level. All previously described coefficients contribute to the power coefficient, but only the

moderator temperature coefficient and the fuel temperature coefficient contributions are significant. The contributions of the pressure and void coefficients are negligible, because the magnitudes of these coefficients and the changes in pressure and void fraction per unit change in power level are small. The contribution of moderator density change is included in the moderator temperature coefficient contribution. In order to determine the change in reactivity with power, it is necessary to know the changes in the average moderator and effective fuel temperature with power. The average moderator (coolant) temperature is controlled to be a linear function of power.

The core average linear heat rate is also linear with power. The average effective fuel temperature dependence on the core average linear heat rate is calculated from the following semi-empirical relation:

$$T_f = TT_{MOD} + (\sum_{i=o}^{2} B_i * M^i) * P + (\sum_{j=o}^{3} C_j * M^j) * p^2 \qquad (1)$$

T_{MOD} is the average moderator temperature (°F), M is the exposure in MWd/T, P is the linear heat generation rate in the fuel in kW/ft, and T_f is the average effective fuel temperature (°F). The coefficients B_i and C_j are determined from least squares fitting of the fuel temperature generated by FATES. For a System 80 fuel pin, the following values apply:

$B_o = 146.526$

$B_1 = 0.8841 * 10^{-3}$

$B_2 = -0.2052 * 10^{-6}$

$C_o = -2.0355$

$C_1 = -0.5121 * 10^{-3}$

$C_2 = 0.5043 * 10^{-7}$

$C_3 = -0.1071 * 10^{-11}$

The basis for this relation is discussed in paragraph 4.3.3.1.2.2.1.

The total power coefficient at a given core power can be determined by evaluation, for the conditions associated with the given power level, of the following expression:

$$\frac{d\rho}{dp} = \frac{\partial\rho}{\partial T_f} * \frac{\partial T_f}{\partial p} + \frac{\partial\rho}{\partial T_m} * \frac{\partial T_m}{\partial p} \qquad (2)$$

The first term of equation (2) provides the fuel temperature contribution to the power coefficient, which is shown as a function of power in figure 4.3-4.

The first factor of the first term is the fuel temperature coefficient of reactivity discussed paragraph 4.3.2.3.1. A typical example of this dependence is shown in figure 4.3-3.

The second factor is obtained by calculating the derivative of equation (1).

$$\frac{\partial T_f}{\partial p} = \left(\sum_{i=o}^{2} B_i * M^i\right) + 2\left(\sum_{j=o}^{3} C_j * M^j\right) * P \qquad (3)$$

The second term in equation (2) provides the moderator contribution to the power coefficient. The first factor of this term, the moderator temperature coefficient, is discussed in paragraph 4.3.2.3.2. The second factor is a constant since the moderator temperature is controlled to be a linear function of power.

Since the factors $\partial p/\partial T_f$ and $\partial p/\partial T_m$ are functions of one or more independent variables, e.g., burnup, temperature, soluble boron

content, xenon worth, and CEA insertion, the total power coefficient, $d\rho/dp$, also depends on these variables.

The power coefficient tends to become more negative with burnup because the fuel and moderator temperature coefficients become more negative. The insertion of the CEAs, while maintaining constant power, results in a more negative power coefficient, because the soluble boron level is reduced and because of the spectral effects of the CEAs.

4.3.2.4 Control Requirements

There are three basic types of control requirements that influence the design of this reactor:

A. Reactivity control so that the reactor can be operated in the unrodded critical, full power mode for the design cycle length.

B. Power level and power distribution control so that (a) the reactor power may be safely varied from full-rated power to cold shutdown, and (b) the power distribution at any given power level is controlled within acceptable limits.

C. Shutdown reactivity control sufficient to mitigate the effects of postulated accidents.

Reactivity control is provided by several different means. The amount and enrichment of the fuel and burnable poison shims are design variables that determine the initial and end-of-cycle reactivity for an unrodded, unborated condition. Soluble boron and CEA poisons are flexible means of controlling long-term and short-term reactivity changes, respectively.

The following paragraphs discuss the reactivity balances associated with each type of control requirement.

4.3.2.4.1 Reactivity Control at BOC and EOC

Excess positive reactivity is available to compensate for burnup and fission product poisoning. Typical soluble boron concentrations required for criticality at various core conditions are shown in table 4.3-1. This boron is used to compensate for slow reactivity changes such as those due to burnup, changes in xenon content, etc. At EOC, the reactivity worth of the residual poison is less than 1%, and the soluble boron concentration is near zero. The reactor is to be operated in essentially an unrodded condition at power. The CEA insertion at power is limited by the power-dependent insertion limit (PDIL) for short-term reactivity changes.

4.3.2.4.2 Power Level and Power Distribution Control

The regulating CEA groups may be used to compensate for changes in reactivity associated with routine power level changes. In addition, regulating CEAs may be used to compensate for minor variations in moderator temperature and boron concentrations during operation at power, and to dampen axial xenon oscillations. The reactivity worths of various CEA control groups are calculated and measured for each cycle. Soluble boron is used to maintain shutdown reactivity at cold zero power conditions. The soluble boron can also be used to compensate for changes in reactivity due to power level changes and minor changes in reactivity which might occur during normal reactor operation. Thirteen part-strength CEAs are provided in

the design to help control the core power distribution. This function includes the suppression of xenon-induced axial power oscillations.

4.3.2.4.3 Shutdown Reactivity Control

The reactivity worth requirements of the full complement of CEAs are primarily determined by the power defect, the excess CEA worth with the stuck rod criteria discussed in paragraph 4.3.1.9. Table 4.3-2 shows typical reactivity component allowances that define the total reactivity allowance and may vary from cycle to cycle. Each allowance component is further discussed below. No CEA allowance is provided for xenon reactivity effects, e.g., Table 4.3-2

TABLE 4.3-2

TYPICAL CEA REACTIVITY ALLOWANCES (%$\Delta\rho$)

Fuel temperature variation	1.04
Moderator temperature variation	3.08
Moderator voids	0.1
CEA bite	0.3
Part-strength CEA effects	0.0
Cooldown to minimum temperature (SLB accident analysis)	3.79
Total reactivity allowance	8.31

undershoot, since these effects are controlled with soluble boron rather than with CEAs.

The worth of all CEAs except the most reactive, which is assumed stuck in the fully withdrawn position, provides more shutdown capability than required by the total reactivity allowance shown in table 4.3-2. This margin is calculated for the end of each reload cycle. The margin is more than sufficient to compensate for calculated uncertainties in the nominal design allowances and in the CEA reactivity worth. Thus, the shutdown reactivity control provided in this design is sufficient at all times in the cycle.

4.3.2.4.3.1 Fuel Temperature Variation. The increase in reactivity that occurs when the fuel temperature decreases from the full power value to the zero power value is due primarily to the Doppler effect in U-238. The CEA reactivity allowance for fuel temperature variations shown in table 4.3-2 is a conservative allowance. Measurements of first cycle power coefficients at Omaha, Calvert Cliffs, and Millstone-2 lead to a power defect of 1.2% $\Delta\rho$. The slight increase in power defect with exposure due to the presence of plutonium isotopes is offset by the reduction in the fuel temperature resulting from fuel swelling and clad creep-down.

4.3.2.4.3.2 Moderator Temperature Variation. The moderator temperature variation allowance is large enough to compensate for any reactivity increase that may occur when the moderator temperature decreases from the full power value to the zero power (hot standby) value. This reactivity increase, which is primarily due to the negative moderator temperature coefficient, is largest at the end-of-cycle when the soluble

boron concentration is near zero and the moderator coefficient is strongly negative. At beginning-of-cycle, when the moderator temperature coefficient is less negative, the reactivity change is smaller.

The CEA reactivity allowance for moderator temperature variation given in table 4.3-2 is actually the sum of three allowances. The first, and most important, is the allowance for the moderator temperature coefficient effect. The second is an allowance for the reduction in CEA worth resulting from the shorter neutron diffusion length at the zero power moderator density relative to the full power moderator density. This allowance is necessary because the CEA worths were calculated at full power. The third allowance is intended to cover the reactivity effects associated with the greatest expected axial flux redistribution, resulting from the difference in moderator temperature profile between full and zero power, and the asymmetric axial isotopic distribution at EOC.

4.3.2.4.3.3 Moderator Voids. Reducing the power level from full power to zero power causes a negligible increase in reactivity resulting from the collapsing of steam bubbles caused by local boiling at full power. The amount of void in the core is small and is estimated to be substantially less than 1% at full power. As with the moderator temperature effect, the maximum increase in reactivity from full to zero power occurs at end-of-cycle, when the least amount of dissolved boron is present. The reactivity effect is small, and allowance for this effect is shown in table 4.3-2.

4.3.2.4.3.4 Control Element Assembly Bite. The CEA bite is the amount of reactivity worth in CEAs that can be inserted in the core at full power to initiate ramp changes in reactivity associated with load changes, and to compensate for minor variations in moderator temperature, boron concentration, xenon concentration, part-strength CEA (PSCEA) movement, and power level. The reactivity allowance for this effect is shown in table 4.3-2.

4.3.2.4.3.5 Part-Strength CEA Effects. No reactivity allowance is provided or required for the PSCEAs because of the moderate negative reactivity provided by Alloy 625 used as the neutron poison as described in paragraph 4.2.2.4. During normal operation, PSCEAs are not inserted more than the PSCEA PDIL of 50% of active core height. On reactor trip, the PSCEAs insert completely.

4.3.2.4.3.6 Accident Analysis Allowance. The allowance shown in table 4.3-2 for accident analysis is consistent with that assumed under various postulated accident conditions addressed in chapter 15, which result in predicted acceptable consequences.

4.3.2.5 Control Element Assembly Patterns and Reactivity Worths

The locations of all CEAs are shown in figure 4.2-10. The FSCEAs designated as regulating control rods are divided into five groups; the shutdown CEAs are divided into two groups; and the PSCEAs are divided into two groups. These groups are

identified in figure 4.3-6. All CEAs in a group are withdrawn or inserted quasi-simultaneously. Shutdown groups are inserted after the regulating groups are inserted, and are withdrawn before the regulating groups are withdrawn. The reactivity worths of these sequentially inserted CEA groups are calculated for the beginning and end of each cycle where the maximum rod planar radial peaking factors (F_{xy}) for these configurations occur. The values of F_{xy} for these times are also calculated.

It is expected that the core will be essentially unrodded during full power steady-state operation, except for limited insertion of the first regulating group in order to compensate for minor variations in moderator temperature and boron concentration. For operation with substantial CEA insertion, the relationship between power level and the maximum permitted CEA insertion is identified in each unit's Core Operating Limits Report (COLR). The COLR limits also identify the regulating group insertion order (5-4-3-2-1) and the 40% fixed overlap between successive regulating groups. It is noted here that reduced CEA overlap is permitted. However, the order of insertion and withdrawal must be maintained. Compliance with the power-dependent insertion limits throughout the cycle insures that adequate shutdown margin is maintained and that the core conditions are no more severe than the initial conditions assumed in the accident analyses described in chapter 15.

Reactivity insertion rates for the safety analysis of the core are presented in chapter 15. Please refer to UFSAR Chapter 15 for a description of CEA worth for CEA ejections, CEA withdrawals, and CEA drops.

The typical reactivity insertion during a reactor scram is discussed in chapter 15. This reactivity insertion is computed by the HERMITE code at various scram CEA positions, and it is used for all accidents which are terminated by a scram, unless otherwise indicated. The reactivity insertion is conservative since only the minimum shutdown worth is assumed to be available at hot full power. The scram reactivity insertion for the loss of flow is implicit in the kinetic axial analysis.

4.3.2.6 Criticality of Reactor During Refueling

The Technical Specifications LCO for boron concentration requirements during refueling ensure that the k_{eff} of the core during refueling does not exceed 0.95. Typical soluble boron concentrations during refueling are shown in table 4.3-1.

4.3.2.7 Stability

4.3.2.7.1 General

Pressurized water reactors (PWRs) with negative overall power coefficients are inherently stable with respect to power oscillations. Therefore, this discussion will be limited to xenon-induced power distribution oscillations. Xenon-induced oscillations occur as a result of rapid perturbations to the power distribution which cause the xenon and iodine distributions to be out of phase with the perturbed power distribution. This results in a shift in the iodine and xenon distribution that causes the power distribution to change in an opposite direction from the initial perturbation, and thus an oscillatory condition is established. The magnitude of the power distribution oscillation can either increase or decrease

with time. Thus, the core can be considered to be either unstable or stable with respect to these oscillations. Discussed below are the methods of analyzing the stability of the core with respect to xenon oscillations. The tendency of certain types of oscillations to increase or to decrease is calculated, and the method of controlling unstable oscillations is presented.

4.3.2.7.2 Method of Analysis

Xenon oscillations may be analyzed by two methods. The first method consists of an explicit analysis of the spatial flux distribution accounting for the space-time solution of the xenon concentrations. Such a method is useful for testing various control strategies and evaluating transitional effects (such as power maneuvers). The second method consists of modal perturbation theory analysis, which is useful for the evaluation of the sensitivity of the stability to changes in the reactor design characteristics, and for the determination of the degree of stability for a particular oscillatory mode.

The stability of a reactor can be characterized by a stability index or a damping factor, which is defined as the natural exponent which describes the growing or decaying amplitude of the oscillation. A xenon oscillation may be described by the following equation.

$$\phi(\bar{r},t) = \phi_o(\bar{r}) + \Delta\phi_o(\bar{r})\, e^{bt} \sin(\omega t + \delta)$$

where

$\phi(\bar{r},t)$ is the space-time solution of the neutron flux

$\phi_o(\bar{r})$ is the initial fundamental flux

$\Delta\phi_o(\bar{r})$ is the perturbed flux mode

b is the stability index

ω is the frequency of the oscillation

δ is a phase shift

Modal analysis consists of an explicit solution of the stability index b using known fundamental and perturbed flux distributions. A positive stability index b indicates an unstable core, and a negative value indicates stability for the oscillatory mode being investigated. The stability index is generally expressed in units of inverse hours, so that a value of -0.01/h would mean that the amplitude of each subsequent oscillation cycle decreases by about 25% (for a period of about 30 hours for each cycle).

Xenon oscillation modes in PWRs can be classified into three general types: radial, azimuthal, and axial. To analyze the stability for each oscillation mode, only the first overtone needs to be considered since higher harmonic modes decay more rapidly than the first overtone. Furthermore, since the first overtone of a radial oscillation decays more rapidly than the first overtone of an azimuthal oscillation, only the latter of these two modes will be considered in detail.

4.3.2.7.3 Expected Stability Indices

4.3.2.7.3.1 Radial Stability. A radial xenon oscillation consists of a power shift inward and outward from the center of the core to the periphery. This oscillatory mode is generally more stable than an azimuthal mode. This effect is illustrated in figure 4.3-9, which shows that for a bare cylinder, the radial mode is more stable than the azimuthal mode.

4.3.2.7.3.2 Azimuthal Stability. An azimuthal oscillation consists of an X-Y power shift from one side of the reactor to the other. Modal analysis for this type of oscillation is performed for a range of expected reactor operating conditions.

The expected variation of the azimuthal oscillation stability index during the first cycle is shown in figure 4.3-10. These results are obtained from analyses which consider the spatial flux shape changes during the cycle, the changes in the moderator and Doppler coefficient during the cycle, and the change in xenon and iodine fission yield due to plutonium buildup during the cycle. As is shown on the figure, the expected stability index is no greater than $-0.04h^{-1}$ at any time during the cycle for the expected mode of reactor operation. Comparison of the predicted stability index with those actually measured on operating cores, as discussed in paragraph 4.3.3.2.3, provides a high confidence level in the prediction of azimuthal stability. Measurements of xenon spatial stability in large cores have been made(4) which provide confidence in the methods that are used to predict the azimuthal stability of this core.

4.3.2.7.3.3 Axial Stability. An axial xenon oscillation consists of a power shift toward the top and bottom of the reactor core. This type of oscillation may be unstable during the first cycle. Table 4.3-3 shows the calculated variation of the axial stability index during the first cycle. It is anticipated that control action with part-strength rods and/or full-strength rods may be required to limit the magnitude of the oscillation. As discussed in paragraph 4.3.2.2, the axial power distribution is monitored by COLSS and the RPS. Based on the COLSS measurement of the axial power distribution, the operator may move either the full-strength or the part-strength CEAs so as to control any axial oscillations.

Table 4.3-3

TYPICAL VARIATION OF THE AXIAL STABILITY INDEX DURING THE FIRST CYCLE[a] (h^{-1})

Power Level (% of Full Power	BOC	EOC
100	-.006	+.115

a. Equilibrium xenon conditions

4.3.2.7.4 Control of Axial Instabilities

The control of axial oscillations during a power maneuver is accomplished through the use of full-strength and/or part-strength control element assemblies (CEAs). CEAs are used throughout these maneuvers to limit the change in the power distribution. The difference between an uncontrolled and a controlled xenon oscillation is illustrated in figure 4.3-11. It was assumed in the calculation of the controlled oscillation

that the CEAs were moved in such a way as to preserve the initial axial shape in the core prior to the initiating perturbation. The calculations were performed at the end of the first cycle, which corresponds to the expected least stable condition for axial xenon oscillations.

4.3.2.7.5 Summary of Special Features Required by Xenon Instability

The RPS described in subsection 7.2.2 is designed to prevent exceeding acceptable fuel design limits and to limit the consequences of postulated accidents. In addition, a means is provided to assure that under all allowed operating modes, the state of the reactor is confined to conditions not more severe than the initial conditions assumed in the design and analysis of the protective system.

Since the reactor is predicted to be stable with respect to radial and azimuthal xenon oscillations, no special protective system features are needed to accommodate radial or azimuthal mode oscillations. Nevertheless, a maximum quadrant tilt is prescribed in the Technical Specifications along with prescribed operating restrictions in the event that the tilt is exceeded. The azimuthal power tilt is determined by COLSS and included in the COLSS determination of core margin. The azimuthal power tilt limit is accounted for in the RPS.

4.3.2.7.5.1 Features Provided for Azimuthal Xenon Effects

A. Administrative limits on azimuthal power tilt.

B. Monitoring and indicating the azimuthal power tilt in COLSS as well as accounting for this tilt in the COLSS determination of core margin.

C. Accounting for azimuthal power tilt limit in the RPS.

4.3.2.7.5.2 Features Provided for Axial Xenon Effects and Power Distribution Effect and Control

A. PSCEAs or regulating CEAs for control of the axial power distribution, if required.

B. Monitoring and accounting for changes in the axial power distribution in COLSS.

C. Monitoring and accounting for the axial power distribution in the RPS.

4.3.2.8 Vessel Irradiation

The design of reactor internals and of the water annulus is such that the vessel fluence greater than 1 MeV is estimated to be less than 3.29E+19 neutrons per square centimeter for a 40-year lifetime. This estimate is confirmed periodically during plant lifetime by a material surveillance program.

4.3.3 ANALYTICAL METHODS

4.3.3.1 Reactivity and Power Distribution

4.3.3.1.1 Method of Analysis

The nuclear design analysis of low enrichment PWR cores is based on either of the multigroup two-dimensional transport codes, DIT or CASMO-4 which provide cross-sections appropriately averaged over a few broad energy groups, for the whole assembly or individual cells and few-group one, two, and three dimensional diffusion theory calculations of integral and differential reactivity effects and power distributions. Comparisons between calculated and measured data that validate the design procedures are presented in paragraph 4.3.3.1.2. As improvements in analytical procedures are developed and improved data become available, they are incorporated into the design procedures after validation by comparison with related experimental data.

4.3.3.1.1.1 Cross Section Generation Using DIT. Few-group cross sections for coarse-mesh and fine-mesh diffusion theory codes are prepared by the DIT lattice code. These cross sections are used in ROCS (coarse-mesh) and in MC (fine-mesh). The ROCS/DIT code system is documented in an NRC-approved Topical Report.[5]

The essential components of the DIT lattice code are:

A. Spectrum calculations using integral transport theory in up to 85 energy groups for typical portions of the assembly geometry (e.g., fuel cell, fuel cell and burnable absorber, fuel cell and water-hole).

B. Few-group spatial calculations in exact assembly geometry followed by a leakage calculation to maintain a critical spectrum.

C. Isotopic depletion calculations for every cell in the assembly.

Thus, the use of the two-dimensional integral transport theory code DIT ensures that the effects of lattice heterogeneities are explicitly treated. Few-group cross sections for coarse-mesh spatial calculations are obtained without laborious intermediate fine-mesh calculations to perform accurate weighting of the various types of fuel, absorber, and waterhole cells.

The assembly calculation, which is performed in several broad energy groups (ranging from 2 to 12), is preceded by spectrum calculations performed in the basic cross section library energy group structure of up to 85 groups. The geometries used in the spectrum calculations are replicas of portions of the true assembly geometry. Boundary conditions recycled from the assembly calculation are used for each spectrum geometry.

Group condensation based on the spectra calculated for all the different types of cells and subregions within them is performed to obtain few-group macroscopic cross sections that are passed on directly to the assembly calculations. Since the accuracy of the spectrum calculations is high, the group condensation can normally be performed with a standard four-group structure. In cases where conventional group condensation methods break down, more groups can be (and are) used in the assembly calculation.

The assembly calculation as well as the spectrum calculations are performed by integral transport theory with multi-group interface current used to couple adjacent cells.

This entire sequence of calculations is normally performed assuming that there is no net leakage from the assembly geometry. Following the assembly calculation, fine-group spectra are constructed for all subregions in the assembly based on the spatial distribution of the few-group assembly flux and on the energy and space distribution of the fine-group flux from the spectrum calculations. A correction for the influence of global leakage is then made on the basis of a B1 calculation with the fine energy group structure for the homogenized assembly to maintain criticality of the assembly. The ROCS code uses Assembly Discontinuity Factors (ADF's) in order to provide improved internal agreement between ROCS and DIT codes. ADF's are a standard method used in the nuclear industry to eliminate homogenization errors in nuclear design analysis where the heterogenous solution is known.

Few-group microscopic cross sections for use in the depletion stage of DIT are formed using the basic cross section library and the spectrum calculated as described. Spatial averages of microscopic and macroscopic cross sections are performed for editing purposes and are passed on to ROCS and MC.

The above calculations are performed in one single job step without manual intervention. Few-group coarse-mesh cross sections are prepared in the HARMONY format[6] for ROCS by the editing code CESAW, and fine-mesh cross sections are input to MC via the editing code MCXSEC.

The DIT code utilizes a data library containing multigroup cross sections, fission spectra, fission product yields, and other supplemental data. The principal source of data for the library is ENDF/B-IV. Three adjustments to the library data have been made to reflect changes to ENDF/B-IV recommended by the Cross Sections Evaluations Working Group (CSEWG) for incorporation into ENDF/B-V.

These adjustments include:

A. A reduction of about 3% in the shielded resonance integral of U-238.

B. The adaption of the harder Watt fission spectra for U-235 and PU-239, later incorporated in ENDF/B-V.

C. A moderate upward adjustment of U-235 and Pu-239 thermal $\bar{y}$-values of about 0.1% improving the $\bar{y}$, h discrepancy but not going as far as ENDF/B-V.

In the epithermal region, the ENDF/B-IV files are processed with ETOG[7] to provide cross section resonance parameters and scattering matrices for the isotopes contained in the library. ETOG prepares this data in 99 energy groups spanning the range from 14.9 MeV to 0.414 eV. The GAM portion of GGC-3[8] is used to condense the 99 group data into 50 energy groups spanning the energy range 14.8 MeV to 1.855 eV weighted with a spectrum representative of that in a PWR assembly.

In the resolved energy region (9.1 KeV to 1.855 eV), the capture and fission cross sections of resonant absorbers are replaced with resonance tables.

In the thermal region, the ENDF/B-IV files are processed with FLANGE-II[9] to provide cross sections and full scattering matrices in the thermal region (1.855 eV to 0.00025 eV). The cross sections of isotopes containing resonances in the thermal region are Doppler broadened. For hydrogen, scattering matrices are prepared with FLANGE-II using ENDF/B-IV thermal scattering low parameters for $H_2 0$.

The cross sections and scattering matrices are tabulated on the library for a sufficient number of temperatures to span the range expected during power reactor operation and to permit linear interpolation.

Cross sections for the resolved resonance region (9.1 KeV to 1.855 eV) are prepared with C-E RABBLE, an extension of the RABBLE[10] code using resolved resonance parameters from ENDF/B-IV. The cosine current approximation in RABBLE was replaced with an integral transport routine. Group averaged resonance cross sections are generated with the modified RABBLE code which performs a space-dependent calculation of the slowing down sources. The cross sections from the C-E RABBLE calculations are corrected to include the proper group-dependent smooth calculations which are derived from the ETOG/GGC-3 calculations. RABBLE is also used to validate interference effects among resonance absorbers as calculated by the DIT algorithm.

Following the assembly spectrum calculation, a depletion time step takes place for each individual pin in the assembly and, when required, for subdivisions of a pin. At the end of the depletion step, new isotopic compositions are defined for use

in the spectrum calculation of the next time step. This process is extended over the expected life of the fuel assembly.

4.3.3.1.1.2 Coarse Mesh Methods Using ROCS. Static and depletion-dependent reactivities and nuclide concentration flux, and power distribution in two- and three-dimensional representation of the core are determined by a diffusion-depletion program, ROCS-MC. The ROCS code is designed to perform two- or three-dimensional coarse-mesh reactor core calculations based on two-group higher order difference (HOD) or nodal expansion (NEM) methods with full-, half-, or quarter-core symmetric geometries. The use of HOD or NEM methods is determined by the version of ROCS used. Before using ROCS-NEM for nuclear design analysis for Palo Verde, Combustion Engineering performed extensive verification to confirm that the calculational biases and uncertainties obtained with both methods were equivalent. The mesh consists of rectangular parallelepiped "nodes" arranged contiguously in the xy-plane, with one or more axial meshes (or planes) in the z-direction. In most applications, only the active core region is represented, with albedo-like boundary conditions[11] assigned to exterior nodes. A typical ROCS core geometry uses four nodes per assembly in the xy-plane and 20 to 30 axial planes depending upon core height and in-core instrument locations.

The nodal macroscopic group constants used in the neutronics calculation are constructed from detailed isotopic concentrations and microscopic cross sections processed by the

code. The isotopes specified include fixed depletable isotopes and a lumped residual representing nondepletable isotopes. The depletable isotopes include fission chain isotopes, fission products, and burnable absorbers. Control rods are represented by macroscopic cross sections specific to different rod banks.

The ROCS system performs coarse-mesh depletion calculations for each node in a two- or three-dimensional core configuration. The allowed depletion chains are internally modeled with fixed completion equations so that beyond the input cross section data the user need supply only such data as initial concentrations, decay constants, and fission yields for each depletion nuclide.

These include the principal uranium and plutonium isotopes, a fuel exposure chain, xenon and samarium fission product chains, and boron and gadolinium burnable absorber chains. The fixed depletion equations used in the ROCS code are derived through the standard procedure of analytically integrating the coupled linear rate equations which represent each chain.

The depletion equations are solved using the flux and microscopic cross section values based on the neutronics and thermal-hydraulic feedback calculations preceding the depletion time step. The initial flux and cross sections are assumed constant over the depletion time step. Cross section information used in the ROCS system is derived from microscopic cross sections supplied by DIT for each nuclide in two energy groups. This information is utilized in two basic forms. First, two-group macroscopic cross sections are used in the basic flux and eigenvalue calculation. The macroscopic

contributions due to thermal-hydraulic feedbacks, xenon, soluble boron, and control rods are added prior to the flux calculation. Second, two-group microscopic cross sections are used explicitly in the depletion and xenon short-term time-stepping calculations.

The two-group microscopic cross sections for each nuclide are supplied in table form. Represented for each nuclide and energy group are:

σ_{tr} = transport cross section (b)

σ_a = absorption cross section (b)

σ_R = removal cross section (b)

σ_f = fission cross section (b)

ν = average number of neutrons released per fission

κ = average energy release per fission (watt-sec)

The tables represent the above values as nonlinear functions of important independent variables (e.g., exposure, initial enrichment, soluble boron concentration) evaluated for nominal thermal-hydraulic conditions. In addition, multipliers (called G-factors) may be included in the table for any of the cross sections. The G-factors may also be represented as functions of pertinent independent variables. Thus a typical cross-section table interpolation can be represented symbolically by:

$$\sigma(\rho_o, T_{Mo}, T_{Fo}) = (N_1, N_2, N_3) G(N_4, N_5, N_6),$$

$$\rho_o, T_{Mo}, T_{Fo}$$

where

ρ_o, T_{Mo}, T_{Fo} = nominal moderator density, moderator temperature, and fuel temperature

$N_1, ..., N_6$ = independent variables for table interpolation

The cross sections are assumed to vary with moderator temperature, moderator density, and the square root of the fuel temperature for small changes about the nominal. The dependence of the cross sections on the thermal-hydraulic parameters is usually approximated by the inclusion of the first derivative of the cross section, for example:

$$\sigma(\rho, T_M, T_F) = \sigma(\rho_o, T_{Mo}, T_{Fo}) + \frac{\partial\sigma}{\partial\rho}\Delta\rho + \frac{\partial\sigma}{\partial T_M}\Delta T_M + \frac{\partial\sigma}{\partial (T_F)^{1/2}}\Delta(T_F)^{1/2}$$

where

$\Delta\rho = \rho - \rho_o$ = change in density from nominal value

$\Delta T_M = T_M - T_{Mo}$ = change in moderator temperature from nominal value

$\Delta(T_F)^{1/2} = (T_F)^{1/2} - (T_{Fo})^{1/2}$ = change in square root of fuel temperature from nominal value

The ROCS neutronics calculation is linked to optional independent feedback calculations for thermal-hydraulic parameters (moderator density, moderator temperature, fuel temperature[(12)(13)] and for equilibrium I-135 - Xe-135 distributions. The thermal-hydraulic calculation is performed

iteratively with the flux calculation when any combination of thermal-hydraulic feedbacks is specified. For each feedback variable specified, the macroscopic cross sections used in the flux calculation are updated through the appropriate feedback term. In the case of xenon, the macroscopic cross sections are updated each iteration cycle using calculated I-135 and Xe-135 equilibrium concentrations based on the two-group flux distribution from the previous iteration. The number of feedback iterations is governed by independent convergence criteria for each feedback parameter, so that the final flux solution is obtained after all specified feedbacks have converged.

In addition to the above feedback models, the ROCS code contains optional eigenvalue search models for the following control variables: control rod bank insertion, soluble boron concentration, reactor power level, and inlet moderator temperature. The search calculations employ numerical iteration techniques which update the specified control variable to obtain convergence on the search eigenvalue, and are generally used along with feedback calculations. The power level and inlet temperature searches require use of thermal-hydraulic feedbacks. These latter search calculations are performed after alternate feedback iterations, while the boron and rod search calculations are performed after each feedback iteration.

4.3.3.1.1.3 Fine-Mesh Methods Using MC. The MC code performs pin peaking calculations for each node in two- or three-dimensional core geometries. MC uses an imbedded

fine-mesh diffusion theory method for obtaining pin power distributions from coarse-mesh calculations.

A method has been developed for determining diffusion coefficients which, when combined with the finite difference formulation of MC, permits the inclusion of transport effects in a rigorous fashion. The diffusion coefficients have the property of conserving cell-averaged fluxes, reaction rates, and net leakages across cell boundaries. Thus, MC has the capability to effectively reproduce DIT local power distributions.

Having determined diffusion coefficients that exactly reproduce average fluxes, reaction rates, and net currents from transport theory for a particular geometry, it is then asserted that they are universally applicable independent of the size of the flux gradients seen in the core.

The nodal diffusion equations are solved as a boundary source problem for the imbedded calculation. The partial in-currents on each nodal face and the global eigenvalue are supplied by the ROCS coarse-mesh calculation.

After completion of the fine-mesh imbedded calculation, the fine-mesh power distribution is renormalized to the coarse-mesh power level to assure that coarse-mesh and fine-mesh node average powers and burnups will remain the same during depletion.

The MC-imbedded calculation uses a macroscopic cross section model based upon interpolation of multi-dimensional macroscopic tables. These tables are created by the MCXSEC code which processes DIT results for all assembly types, and are typically

burnup-, enrichment-, moderator-, and fuel temperature-dependent for each fine-mesh pin type. Lagrange linear interpolations are performed to obtain the macroscopic cross sections. The interpolated absorption cross section is then corrected for soluble boron and xenon changes by using boron and xenon microscopic cross sections along with number densities obtained from the core soluble boron and local xenon equilibrium concentrations. In addition, axial leakage is represented by adding a DB^2 term to the absorption cross section.

4.3.3.1.1.4 Cross Section Generation Using CASMO-4. The multigroup, two-dimensional transport theory code, CASMO-4, prepares cross sections for the two-group nodal diffusion code, SIMULATE-3. The CASMO-4/SIMULATE-3 code system is documented in an NRC-approved Topical Report.[30] As stated in PVNGS letter 102-04518-CDM/SAB/JAP, dated 1/3/2001, to NRC, and the NRC's Safety Evaluation for the issuance of amendments on CASMO-4/SIMULATE-3 (TS Amendment #132), dated 3/20/2001, PVNGS agreed to certain limitations associated with its application of CASMO-4/SIMULATE-3. Specifically, the NRC Safety Evaluation wording stating limiting the use of CASMO-4/SIMULATE-3 to, "the range of fuel configurations and core design parameters as stated and referenced by the June 8, 2000, application (reference 30). Introduction of significantly different or new fuel designs will require further validation of the above stated physics methods for application to PVNGS by the licensee and will require review by the NRC staff." In the NRC Safety Evaluation, the NRC staff further stated that, "It is clear

that interpolation between or modest extrapolations from cases implicitly analyzed in the topical report are not "significantly different" or "new fuel designs." However, a new fuel design would involve physics components which are not benchmarked in the topical report." Additional discussion on interpreting these limitations are contained in reference 31.

Features of CASMO-4 are listed below:

A. Nuclear data are collected in a library containing microscopic cross sections in 70 energy groups. Up to 40 energy groups are allowed in the two-dimensional transport theory calculation.

B. Effective resonance cross sections are calculated individually for each fuel pin.

C. The calculation sequence starts in a simplified geometry. Energy groups are then collapsed as spatial detail is increased. The two-dimensional calculation is performed in the true heterogeneous geometry using the KRAM characteristics module. The intermediate macro-group calculation is performed in two dimensions using a response matrix method.

D. A fundamental mode calculation is performed to account for leakage effects.

E. The microscopic depletion is calculated in each fuel pin and burnable absorber pin.

F. In the depletion calculation a predictor-corrector approach is used which greatly reduces the number of burnup steps necessary for a given accuracy.

G. Output gives few-group cross sections and reaction rates for any region of the assembly for use in overall reactor calculations.

H. Discontinuity factors are calculated at the boundary between bundles and for reflector regions.

The flow of calculations in CASMO-4 starts with the calculation of effective resonance cross sections for important resonance absorbers. The effective cross sections in the resonance energy region for important resonance absorbers are calculated using an equivalence theorem, which relates tabulated effective resonance integrals for each resonance absorber in each resonance group to the particular heterogeneous problem. The resonance integrals obtained from the equivalence theorem are used to calculate effective absorption and fission cross sections. The screening effect between different pins is considered by the use of Dancoff factors.

Macroscopic group cross sections are calculated for the succeeding micro group calculations. Microscopic cross sections in the library group structure are read from the data library. Macroscopic cross sections for any spatial region are directly calculated from the densities, geometries, etc. given in the input. The cross sections thus prepared are used in a series of micro group calculations to obtain detailed neutron energy spectra to be used for energy condensation of the pin cells.

The library contains cross sections tabulated for different temperatures. Data for the actual temperature are obtained by use of linear interpolation.

The nodal data is dependent on the flux distribution used to homogenize and collapse the cross sections. Using the true heterogeneous nature of the lattice in the energy group structure in the nuclear data library would result in prohibitively long execution times on some machines. To simplify the problem, the lattice calculations are performed in a smaller number of energy groups. The cross sections in the smaller group must be representative of those from the original group structure. Therefore, the cross sections must be condensed with an appropriate flux spectrum.

The condensation scheme in CASMO-4 consists of one-dimensional pin cell calculations followed by a two-dimensional response matrix (RM) calculation, where all regions of each pin cell are homogenized into an equivalent single region cell. The pin cell calculations are performed in the micro group structure of the cross section library (40 or 70 groups). Cross sections for each region of the lattice are then condensed to the macro group structure (typically 40 groups), where the RM calculation is performed. The spatial distribution of neutrons across each pin cell is obtained from the pin cell calculations, while the energy distribution of neutrons within each pin cell is updated by the RM calculation.

Normally, a micro group calculation is performed for each pin type in the fuel assembly. Collision probabilities are determined in a simplified geometry consisting of the different material regions of the pin type. Normal fuel pins are typically modeled using either three or four regions (i.e., fuel, air, canning, and coolant). For inert rods (e.g., water rods, guide tubes, etc.), a fuel-containing

“buffer” region is added to the outside of the coolant and is used to drive the flux across the cell. Burnable absorber rods, specifically fuel rods containing Gadolinium or Erbium, are modeled using a geometry similar to that used for inert rods. The fuel region of the burnable absorber rod, however, is automatically split into many annular subregions, used to represent the strong variations in the number density of the burnable absorber across the fuel region once the pin begins to deplete.

The macro group calculation is used to adjust the energy distribution of neutrons in all regions of the lattice to account for the effects of the surroundings. The calculation is performed on the entire lattice using homogenized pin cell regions. The macro group calculation is performed using a response matrix method.

In the response matrix method, the regions of the lattice are coupled together using their surface currents, rather than their scalar fluxes. An outgoing current is calculated along each surface of each mesh. This current will become the incoming current to the neighboring mesh.

Both the pin cell spectral calculations, described above, and the response matrix method solve the integral transport equation.

Following the two-dimensional macro group calculation, the neutron energy distribution throughout each macro region in the assembly is updated to include the effects of the surroundings. Since the macro group calculation is performed using homogenized pin cell regions, it is incapable of modifying the

distribution of neutrons in space across a cell. In order to account for the effects of the surroundings on the shape of the flux across the various regions of each pin cell, CASMO-4 performs a two-dimensional, heterogeneous calculation on the entire lattice in the 2D-group energy structure. Cross sections for each micro region of the lattice are condensed to the 2D-group structure using the updated spectrum from the macro group calculation. The flux distribution throughout the lattice is determined by solving the Boltzmann transport equation using the method of characteristics (KRAM module).

In single bundle calculations, a fundamental buckling mode is used for modifying the infinite lattice results obtained from the transport calculation to include the effects of leakage. This calculation is normally made in diffusion theory. The fundamental mode calculation should be bypassed in calculations on two by two segments, reflectors and fuel storage racks.

The burnup calculation is carried out in two steps. In going from the time t_{n-1} to t_n a "predictor" step is first taken using the fluxes obtained from the neutron calculation at t_{n-1}. The predictor step provides predicted number densities at t_n. The cross sections are then updated and the new spectrum calculation gives fluxes to be used in a "corrector" step after which final number densities at t_n are given by the average value of the results from the predictor and corrector steps.

The SIMULATE-3 code uses Assembly Discontinuity Factors (ADFs). CASMO-4 calculates ADFs at the boundary between bundles and for reflector regions.

The CASLIB code produces a binary neutron cross section library for input to CASMO-4 from a card-image, formatted library. The card-image, formatted library, supplied with CASMO-4, is based mainly on data from ENDF/B-IV, although some data come from other sources. It contains cross sections for 108 materials, most of which are individual nuclides. A few materials are either elements of natural composition or mixtures of elements.

Microscopic cross sections are tabulated in 70 energy groups. The group structure was taken over from the WIMS code with the addition that a boundary has been put in at 1.855 eV. The group structure of the library fulfills the following requirements:

A. The 14 fast groups give enough detail in the fast energy region to calculate the leakage and fast fission accurately.

B. The 13 resonance groups provide correct flux levels as a function of energy for the calculation of resonance absorption.

C. The 43 thermal groups (below 4 eV, which is the cut off for up-scattering) make the thermal cross sections independent of the weighting spectrum used for their generation. Groups are concentrated around the 0.3 eV resonance in Pu-239 and the 1 eV resonance in Pu-240.

The library contains absorption, fission, nufission, transport and scattering cross sections. Data are tabulated as a function of temperature when needed. Shielded resonance integrals versus potential background cross section and

temperature are tabulated for resonance absorbers. The library also contains yields and decay constants for fission products.

Typically, each unique PWR fuel assembly type (defined by geometry, enrichment, and burnable poison pins) is separately modeled in CASMO-4 (usually with octant symmetry). Enrichment zoning among fuel pins, burnable poison pins, and guide tubes are explicitly modeled. The water gap between assemblies in the reactor core is included in the CASMO-4 model. The spacer grid material is also included.

Several depletion cases are needed to generate each fuel assembly type’s average cross section data. First, the fuel assembly is depleted at hot full power, no control rods, reactor average conditions. Moderator temperature, fuel temperature, and soluble boron concentration are set to constant average values for the complete depletion. Next, depletions called history depletions are performed at various other moderator temperatures, fuel temperatures, and boron concentrations. Each fuel assembly type is depleted to burnups which bracket licensed burnup limits.

Branch cases are performed to calculate instantaneous effects. The branch cases are executed from the hot full power reactor average conditions and from the history conditions discussed above at a selection of exposures. Branch cases are run for a range of boron concentrations, moderator temperatures, control rodded conditions, and fuel temperatures. Both isothermal and non-isothermal cases are performed.

CASMO-4 also generates top, bottom, and radial reflector cross sections. Reflector cross sections are typically modeled as a

function of soluble boron concentration and moderator temperature.

TABLES-3 is a data processing program that links CASMO-4 to SIMULATE-3. The program processes the following types of data from CASMO-4:

A. two-group cross sections,

B. discontinuity factors,

C. fission product data,

D. in-core instrument response data,

E. pin power reconstruction data,

F. kinetics data, and

G. isotopics data.

TABLES-3 reads the CASMO-4 card image files and functionalizes the data into a one-, two-, or three-dimensional, master binary cross section library for SIMULATE-3. CMS-LINK is a modern version of TABLES-3, which performs all of the above functions in a more automated manner. In addition, CMS-LINK processes additional CASMO data for (future) use with space-time kinetics calculations.

Typically, data from the following CASMO-4 card image files are combined into binary cross section libraries for input to SIMULATE-3:

A. HFP Reactor Average Depletion + Branches + History Depletions,

- Fuel Temperature Branches

- Moderator Temperature Branches
- Soluble Boron Concentration Branches
- Control Rod Insertion Branches
- Cold Branches (293 K < T < 569 K)
- Boron History
- Fuel Temperature History
- Moderator Temperature History

B. Bottom Reflector

C. Top Reflector

D. Radial Reflector

4.3.3.1.1.5 Coarse-Mesh Methods Using SIMULATE-3. SIMULATE-3 is a two- or three-dimensional (2-D or 3-D), two-group coarse mesh diffusion theory reactor simulator program. Homogenized cross sections and discontinuity factors are applied to the coarse mesh nodal model to solve the two-group diffusion equation using the QPANDA neutronics model. QPANDA employs fourth order polynomial representations of the intranodal flux distributions in both the fast and thermal groups. The equations are derived by subdividing the spatial domain of the reactor into a set of rectangular parallelepipeds, referred to as nodes. Each node will typically represent a full assembly or a quarter assembly in the radial plane and a 15 - 30 cm axial region of an assembly. A typical SIMULATE-3 core geometry for Palo Verde uses four nodes per assembly in the xy-plane and 25 axial nodes.

Early generation nodal models related the currents between nodes to the difference between fluxes in neighboring nodes using simple finite-difference or modified coarse-mesh finite-difference approximations. The QPANDA nodal model does not make this approximation, and the coupling relationships are derived directly from the neutron diffusion equation.

Traditionally, nodal codes have relied on user-adjusted albedos to treat the neutron reflection and the fuel/baffle interface. SIMULATE-3 explicitly models the baffle/reflector region, eliminating the need to normalize to higher-order fine mesh calculations such as PDQ.

The SIMULATE-3 program performs a macroscopic depletion, as opposed to using isotopic number densities and microscopic cross sections. Individual Uranium, Plutonium, and lumped fission product isotopic concentrations are not computed. However, microscopic depletion of Iodine, Xenon, Promethium, and Samarium is included to model typical reactor transients. Microscopic cross sections for boron are also used in SIMULATE-3.

The nodal thermal hydraulic properties are calculated based on the inlet temperature, RCS pressure, coolant mass flow rate, and the heat addition along the channels.

4.3.3.1.1.6 Fine-Mesh Methods Using SIMULATE-3. The pin-by-pin power distributions, on a 2-D or 3-D basis, are constructed from the inter- and intra-assembly information from the coarse mesh solution and the pin-wise assembly power distribution from CASMO-4. The SIMULATE-3 pin power reconstruction method is based on the assumption of

separability of the global flux (homogeneous intranodal flux) and local flux shapes (heterogeneous form functions). If the separability approximation is made, detailed pin-by-pin flux (and power) within an assembly can be approximated by the product of a global homogenized distribution and a local heterogeneous form function.

The SIMULATE-3 pin power reconstruction method is motivated by two observations: 1) if the intranodal power distribution can be very accurately modeled, it should be possible to compute accurate pin power distributions by using form functions from single-assembly (zero-leakage) spectrum/depletion calculations, and 2) since the fast group contribution to the intra-assembly pin power is relatively smooth, it should be possible to use total power (not group-wise) form functions.

Intranodal power distributions are computed from group-wise nodal (homogenized) fission cross sections and flux distributions.

The SIMULATE-3 intranodal fast flux distribution is accurately represented by a non-separable polynomial expansion.

However, the same polynomial flux shapes cannot accurately model the large localized thermal flux gradients which occur at assembly interfaces. SIMULATE-3 approximates the intranodal thermal flux distribution by assuming the thermal flux to be composed of an asymptotic term and a surface transition term.

The QPANDA nodal model provides accurate node-averaged fluxes, surface-averaged fluxes, and surface-averaged currents which can be used as constraints on the flux expansions. Additional constraints are obtained by requiring the flux expansions to

preserve fluxes at nodal corner points, and estimates of the corner-point fluxes are obtained by an interpolation method.

The corner-point fluxes provide four constraints (in addition to the node-averaged flux, 4 surface-averaged fluxes, 4 surface-averaged currents) for the homogeneous flux expansion. The complete flux expansion requires 25 constraints, and only 13 are directly available. However, it has been determined that accurate intranodal flux distributions can be determined without these additional constraints. Consequently, 12 of the cross terms in the flux expansions are neglected, and the 13 expansion coefficients are determined directly from the aforementioned constraints.

nce depletion has occurred, the intranodal distribution of homogenized cross section must be known. The exposure-induced variation of intranodal cross sections is modeled using separable biquadratic expansions which preserve the node-averaged and surface-averaged exposures. The biquadratic exposure distribution is integrated over each pin location and the resulting pin-wise homogeneous exposures are used to evaluate pin-wise homogenized fission cross sections.

The use of flux and power form functions from single assembly (zero leakage) spectrum/depletion calculations leads to an additional complication because of spectral interactions at assembly interfaces. These spectral interactions produce significantly different plutonium buildup and uranium depletion rates at assembly interfaces than those implicit in the single assembly spectrum/depletion calculation.

It is assumed that the differences between the local (intranodal) homogenized cross sections and the single assembly cross sections are proportional to the difference between the local two-group spectrum and the single assembly spectrum. This can be manipulated to obtain an approximate expression for the cross-section variations as a function of spectral history. Spectral history is a function of the local and single assembly fast to thermal flux ratios.

Since CASMO-4 history depletion calculations are evaluated during generation of the macroscopic cross-section library, the same data is interpreted to evaluate the spectral variation of cross sections as a function of spectral history. The difference in the homogenized cross section between a branch (from base depletion to history condition) and a history depletion is assumed to be a function of the exposure-integrated ratio of spectra, and the change in the cross section-per-unit-of spectral history is approximated by a function of spectral history. Spectral history is approximated by a function of the history and base depletion fast to thermal flux ratios.

The actual changes in cross sections are computed from the local value of spectral history and exposure. Since the spectral-induced variations in homogenized cross sections are driven by assembly spectrum interactions, the actual values of spectral history need only be retained for nodal surfaces; and the spatial distribution of change in cross sections is assumed to have the shape of the local thermal flux expansion.

The treatment of cross-section variation with spectral history permits direct evaluation of spectral-interaction effects within the nodal code.

Explicit modeling of intranodal exposure and spectral-history distributions allows evaluation of pin-by-pin distribution of fission cross sections.

4.3.3.1.1.7 Other Analysis Methods. As the size of large power reactors increases, space-time effects during reactor transients become more important. In order not to penalize reactor performance unduly with overly conservative design methods, it is desirable to have the capability of performing detailed space-time neutronics calculations for both design and off-design transients.

The HERMITE(14) computer code has been developed to meet this objective. It solves the few-group, space- and time-dependent neutron diffusion equation including feedback effects of fuel temperature, coolant temperature, coolant density, and control rod motion. The neutronics equations in one, two, and three dimensions are solved by the nodal expansion method. The fuel temperature model explicitly represents the pellet, gap, and clad regions of the fuel pin, and the governing heat conduction equations are solved by a finite difference method. Continuity and energy conservation equations are solved in order to determine the coolant temperature and density. In the one-dimensional mode, HERMITE also has the option of finding the axial-dependent poison distribution required to produce a particular user-specified axial power shape. This option is often used to produce conservative axial power shapes

corresponding to the LCO limits on axial power shape, from which simulations of core transients are subsequently initiated.

4.3.3.1.2 Comparisons with Experiments

NOTE: This UFSAR section is retained for historical purposes, because it describes critical experiments that supported the initial license for PVNGS. Further, more recent information on critical experiments involving UO_2-Er_2O_3 may be found in a proprietary C-E topical report approved by NRC staff.[29] See also the ROCS topical report, Reference 5. For information on the CASMO-4/SIMULATE-3 code system and benchmark, see APS CASMO-4/SIMULATE-3 topical report, Reference 30.

The nuclear analytical design methods in use for SYSTEM 80 have been checked against a variety of critical experiments and operating power reactors. In the first type of analysis, reactivity and reaction rates and power distribution calculations are performed, which lead to information concerning the validity of the basic fuel cell calculation. The second type of analysis consists of a core follow program in which power distributions, reactivity coefficients, reactivity depletion rate, and CEA worths are analyzed to provide a global verification of the nuclear design package.

4.3.3.1.2.1 Critical Experiments. Selected critical experiments have been analyzed with the DIT code. Selection of criticals is based on the following criteria:

- Applicability to C-E PWR fuel and assembly designs,
- Self-consistency of measured parameters, and
- Availability of adequate data to model the experiments.

Two groups of critical experiments using rod arrays representative of the 14 x 14 assembly have been employed in this evaluation. The first is a series of clean experiments with UO_2 fuel carried out in 1967[15], and the second is a set of experiments carried out in 1969.[16] Tables 4.3-4 and 4.3-5 give the principal parameters for each of the experimental configurations. The moderator-to-fuel volume ratios were varied by changing the cell pitch of the fuel rod arrangement. The moderator and reflector material for all cores was H_20.

Measurements included the criticality parameters and the fission rate distributions in selected fuel rods. This section addresses the comparisons between measured and calculated criticality, as well as between measured and calculated fissions rate distributions done to establish calculative biases and uncertainties in predicting intra-assembly power peaking for both 14 x 14 and 16 x 16 arrays.

4.3.3.1.2.1.1 Description of the Experiments.

A. Combustion Engineering Sponsored UO_2 Critical Experiments

A series of critical experiments were performed for Combustion Engineering by Westinghouse Corporation at the Westinghouse Reactor Evaluation Center (WREC) employing the CRX reactor. The experimental program consisted of approximately 70 critical configurations of fuel rods. The basic core configuration was a 30 x 30 square, fuel rod array of Zr-4 clad UO_2 fuel having an enrichment of 2.72 w/o U-235. Fuel rods were removed to create internal water holes or channels to accommodate

control rods or to simulate control rod channels and water gaps representative of the C-E 14 x 14 fuel assembly design.

The majority of the experiments employed a lattice pitch of 0.600 inches with several experiments repeated with a lattice pitch of 0.575 inches. These values of 0.600 and 0.575 inches, together with the fuel pellet dimensions and enrichment and the rod diameter, resulted in hydrogen-to-fuel ratios representative of the 14 x 14 design at room and at operating temperatures, respectively.

B. KRITZ Experiments

A program of critical experiments, sponsored jointly by Combustion Engineering and KWU, was performed at the KRITZ CRITICAL FACILITY of AB Atomenergi, Studsvik, Sweden. The program consisted of analyzing a number of core configurations of interest to C-E and KWU. The C-E configurations were representative of the 14 x 14 fuel assembly, including the 5 large control rod channels. A basic cell pitch of 0.5650 inches was used for all lattices. The cores were relatively large, both in cross-sectional area and height. Each core contained about 1450 rods 265 cm in length. The core was reflected with water on the four sides and the bottom. Soluble boron was employed for gross reactivity control.

4.3.3.1.2.1.2 Results of Analyses. The results of the analyses of the six critical experiments are summarized in Table 4.3-6. The average K_{eff} is 1.0016.

As part of the C-E Criticals and the KRITZ CRITICALS experiment programs, pin-by-pin power distributions were also measured, to provide a data base with which to define biases and uncertainties in predicted water hole peaking factors. This analysis is described in detail in reference 17. The bias and 95/95 tolerance limit in assembly-wise peaking factor are 0.0 and + 2.4%, respectively.

4.3.3.1.2.2 Power Reactors. The accuracy of the calculational system in its entirety can only be assessed through the analysis of experimental data collected on operating power reactors. The data under investigation consists of critical conditions, reactivity coefficients, and rod worths measured during the startup period, and of critical conditions, power distributions, and reactivity coefficients measured throughout the various cycles.

4.3.3.1.2.2.1 Startup Data. Measured data obtained during reactor start-up are the most reliable, because they consist of well-controlled conditions. Eleven cores have been analyzed, covering four cycles of fuel management.

Table 4.3-7 shows the measured and predicted hot, zero power, xenon free, all rods out critical boron concentrations for each cycle. Over the eleven points of the data base, the critical soluble boron concentration is underestimated by an average of 14 ppm, with tolerance limits of ± 25 ppm at a 95/95 probability/confidence level. In terms of reactivity, this corresponds to an underprediction by 0.18% $\Delta\rho$ with two-sided tolerance limits of ± 0.31% $\Delta\rho$.

A. Isothermal Temperature Coefficient

   The Isothermal Temperature Coefficient (ITC) is the change in core reactivity resulting from a 1°F change in moderator and fuel temperatures.

   Isothermal Temperature Coefficients have been measured for a number of reactors and cycles, both at power and at zero power, and for a wide range of soluble boron

concentrations (83 to 1342 ppm). Three-dimensional ROCS calculations were performed at the same conditions as the measurements using concentration files taken from core follow depletions. This data base contains 37 comparisons which are shown in table 4.3-8. Included in the table are the calculated and measured ITCs, their differences, and the respective power level and soluble boron concentration.

Measured and calculated ITCs were found to be linear functions of the measured soluble boron concentration (ppm). The ITC calculated - measured differences were also a linear function of ppm; therefore, a least squares linear fit was used to determine a ppm-dependent bias.

The deviations of the ITC calculated - measured differences about this least squares fit were found to be normally distributed. The plant-by-plant variances about the overall linear fit to PPM passed the Bartlett test for poolability. The calculated - measured differences showed no statistically significant dependence on power level, fuel exposure, or assembly design. Thus the final results of this analysis consisted of a ppm-dependent bias curve and the associated tolerance band of $0.18 \times 10^{-4}/°F$ in 95/95 confidence level about that curve (figure 4.3-12).

B. Control Rod Bank Worths

Sequential insertions of regulating and shutdown control rod banks from start-up tests were simulated with three-dimensional ROCS calculations. Homogenized macroscopic cross sections for rodded nodes in the coarse-mesh calculations may also be obtained using pairs (rodded and unrodded) of assembly calculations performed with DIT. The paired DIT calculations for individual assembly types are over a range of conditions of burnup, moderator temperature, and soluble boron concentration applicable to reactor start-up and operating conditions. The effects of rod insertions in the ROCS models are represented using two-group delta-macroscopic cross sections in rodded nodes, which are the direct differences in flux- and volume-averaged macroscopic cross sections obtained from the paired DIT assembly calculations. The ROCS CEA cross sections are functionalized with burnup, soluble boron, moderator temperature, and enrichment.

The comparisons of ROCS calculated control rod bank worths to the measured values are shown in tables 4.3-9 and 4.3-10.

The estimated calculative tolerance intervals, $\pm kS_c$, for the difference between ROCS/DIT and truth are ± 6% for first cycles and at most ± 9% for reload cycles. Thus the accuracy of ROCS/DIT with both methods of calculating control rod cross sections is comparable to

currently approved C-E methods and is acceptable for the calculation of control rod worths.

C. Dropped, Ejected and Net Rod Worths

Reactivity worths for some non-sequential asymmetric rod configurations are calculated and compared to measured values. The results for these anomalous rod configurations are then related to those for normal control rod operation.

All the data analyzed were obtained during the start-up test programs of first cycles.

The dropped, ejected, and net rod worth comparisons all showed similar good results which are consistent with the previous analysis of control rod bank worths. This is demonstrated in Table 4.3-11 where the means and standard deviations for the upset rod configurations are compared with reactivity results for normal sequential insertions of control rod banks. The normal rod bank reactivity results are taken from the first

cycle only calculations because all upset rod calculations here were for first cycles.

D. Power Coefficient

The power coefficient is the change in core reactivity due to a 1% change in power level. In addition to proper functionalization of the temperature-dependence of the microscopic cross sections, accurate calculation of power coefficients depends on the model used for the effective fuel temperature. All current ROCS models employ fuel temperature correlations that are both local (nodal) power density and fuel exposure dependent. Direct fits to FATES[13] fuel temperature data are used for each fuel type.

Table 4.3-12 shows 15 calculated and measured power coefficients and the differences between them. The average bias was small and slightly positive and therefore conservative. That is, the calculated power coefficients were about 10% less negative than the measured values.

Table 4.3-12

COMPARISON OF POWER COEFFICIENTS

Mean Difference + .10

Standard Deviation ± .07

a. Units of 10^{-4} $\Delta\rho$/%P.

The uncertainty in ROCS/DIT power coefficients is characterized by tolerance limits of ± 0.18 x 10^{-4} $\Delta\rho$/%power on a 95/95 probability/confidence level.

4.3.3.1.2.2.2 Depletion Data. The two quantities which are monitored on a continuing basis during nominal full power

operation are the reactivity depletion rate and the power distributions. The constant monitoring of these quantities establishes the validity of the nuclear design. The reactivity depletion rate is monitored by comparing measured critical steady states conditions with corresponding calculated conditions. These conditions are characterized by exposure, power level, boron concentration, inlet temperature, and control rod insertion.

Since the measured and the calculated critical conditions most likely differ in some respects, an interpolation scheme was devised to infer a calculated reactivity at each measured condition. The results are displayed in Figure 4.3-13 for five later cycles of the 14 x 14 fuel assembly type core. It shows a small and consistent burnup independent reactivity bias of -0.25% $\Delta\rho$, with a 95/95 probability level of $\pm$ 0.22% $\Delta\rho$. This bias is in good agreement with the hot zero power bias given earlier, demonstrating that Doppler and thermal hydraulics reactivity effects, as well as fission product worth, are correctly treated throughout life by the ROCS/DIT system.

For cores of the 16 x 16 assembly type such as System 80, the experimental data base is not as large. Figure 4.3-14 shows a composite picture of the reactivity bias for both reactor types. This demonstrates that the reactivity predictive capabilities for System 80 are comparable to those for current reload cycles of the earlier design.

4.3.3.1.2.2.3 Assembly Power Distributions. The uncertainty to be attributed to calculated fuel assembly power distributions can be obtained by comparing detailed three-dimensional calculations of the assembly powers with those inferred from in-core measurements with the CECOR[18] system using fixed in-core rhodium detectors. The resulting differences are a reflection of both measurement and calculational errors. In order to determine the uncertainty to be attributed to the calculation, the measurement uncertainty has been subtracted out from these difference distributions as described below. The measurement uncertainty was taken from an evaluation of the uncertainty associated with the CECOR system.[17]

Estimates have been made of σ^{c}_{FR}, σ^{c}_{FXY}, and σ^{c}_{FQ}, for the standard deviations of the differences between calculated and true assembly power. The data base included Arkansas Nuclear One Unit 2 (ANO2) cycle 1, Calvert Cliffs Unit I (BGE I) cycles 1-2, Calvert Cliffs Unit 2 (BGE II) cycles 1-2, and St. Lucie Unit 1 (FPL) cycles 1-3. ANO2 is a 177-assembly core with a 16 x 16 fuel pin lattice, while the other cores have 217 assemblies with a 14 x 14 lattice. Overall, comparisons were made for these 8 cycles over 112 time points with about 40 instrument strings each, resulting in about 20,000 data points.

Table 4.3-13 summarizes the calculational uncertainties.[19]

Table 4.3-13

SUMMARY OF ROCS/DIT CALCULATIVE UNCERTAINTIES

ROCS Calculational Uncertainty	F_{XY}	F_Q	F_R
Percent deviation, S_C	1.88%	2.89%	1.47%
95/95 Confidence internal, KS_C(%)	4.94%	5.25%	3.44%

4.3.3.2 Spatial Stability

4.3.3.2.1 Methods of Analysis

An analysis of xenon-induced spatial oscillations may be done by two classes of methods: time-dependent spatial calculations and linear modal analysis. The first method is based on computer simulation of the space-, energy-, and time-dependence of neutron flux and power density distributions. The second method calculates the damping factor based on steady-state calculations of flux, importance (adjoint flux), xenon and iodine concentrations, and other relevant variables.

The time-dependent calculations are indispensable for studies of the effects of CEAs on core margin, out-of-core, and in-core detector responses, and are performed in one, two, and three dimensions with few-group diffusion theory, using tested computer codes and realistic modeling of the reactor core. The linear modal analysis methods are used to calculate the effect on the damping factors of changes in fuel zoning, enrichment, CEA patterns, operating temperature, and power levels. These methods, using information at a single point in time, are particularly suited to survey-type calculations. Methods are based on the work of Randall and St. John[20] as

extended by Stacey.[21] These methods are verified by comparison with time-dependent calculations.

4.3.3.2.2 Radial Xenon Oscillations

To confirm that the radial oscillation mode is extremely stable, a space-time calculation was run for a reflected, zoned core representative of System 80 without including the damping effects of the negative power coefficient. The initial perturbation was a poison worth of 0.4% in reactivity placed in the central 20% of the core for 1 hour. Following removal of the perturbation the resulting oscillation was followed in 4-hour time steps for a period of 80 hours. The resulting oscillation died out very rapidly with a damping factor of about -0.06 per hour. When this damping factor is corrected for a finite-time step size by the formula in Reference 22, a more negative damping factor is obtained indicating an even more strongly convergent oscillation. On this basis, it is concluded that a radial oscillation instability will not occur.

4.3.3.2.3 Azimuthal Xenon Oscillations

Two-dimensional modal analysis techniques were used to calculate the damping factor for azimuthal oscillations, and included both the fuel-temperature and moderator-temperature components of the total power coefficient. These calculational techniques were used to predict the results of azimuthal oscillation tests at Maine Yankee at 75% power. The predicted damping factor of -0.045 per hour for azimuthal oscillations was found to agree well with the measured value of -0.047 % 0.005 per hour.

4.3.3.2.4 Axial Xenon Oscillations

To check and confirm the predictions of the linear modal analysis approach, numerical space-time calculations were performed for both beginning and end-of-cycle. The fuel and poison burnup distributions were obtained by depletion with soluble boron control, so that the power distribution was strongly flattened. Spatial Doppler feedback was included in these calculations. In figure 4.3-15, the time variation of the power distribution along the core axis is shown for the end-of-cycle with reduced Doppler feedback.

The initial perturbation used to excite the oscillations was a 50% insertion into the top of the core of a 1.5% reactivity CEA bank for 1 hour. The damping factor for this case was calculated to be about 0.02 per hour; however, when corrected for finite-time step intervals by the methods of Reference 22, the damping factor is increased to approximately +0.04. When this damping factor is plotted on figure 4.3-16 at the appropriate eigenvalue separation for this mode at end-of-cycle, it is apparent that good agreement is obtained with the modified Randall-St. John distribution of the moderator coefficient about the core midplane, and its consequent flux and adjoint weighted integrals of approximately zero.

Axial xenon oscillation experiments performed at Omaha at a core exposure of 7000 MWd/T and at Stade at beginning of cycle and at 12000 MWd/T[23] were analyzed with a space-time one-dimensional axial model. The results are given in table 4.3-14 and show no systematic error between the experimental and analytical results.

Table 4.3-14

AXIAL XENON OSCILLATIONS

Reactor	Exposure (MWd/T)	Period (h)		Damping (h_{-1})	
		Measured	Calculated	Measured	Calculated
Omaha	7075	29	32	-0.027	-0.030
Stade	BOC	36	36	-0.096	-0.090
Stade	12200	27	30	-0.021	-0.019

4.3.3.3 Reactor Vessel Fluence Calculation Model

The general method for calculation of fluence to the reactor vessel uses results obtained from two dimensional transport calculations with the DORT code, which is a routine within the Oak Ridge National Laboratory's DOORS code suite.[(24)] The DORT model uses a r, r,θ, and r,z coordinate system to represent the geometry of the core, surrounding water, internals, and vessel and follows the guidance of Regulatory Guide 1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence."[(26)]

The preliminary vessel fluence data given in paragraph 4.3.2.8 is calculated by a more approximate one dimensional subset of this method using ANISN.[(25)] The calculated vessel fluence was obtained by applying a one-dimensional cylindrical geometry model for the core and vessel configuration based upon the azimuthal location of the peak vessel fluence.

The calculated vessel fluence is validated in part by comparisons between calculation and measurements of surveillance capsule data.

4.4 THERMAL AND HYDRAULIC DESIGN

This section presents the steady-state thermal and hydraulic analysis of the reactor core, the analytical methods, and the experimental work done to support the analytical techniques. Discussions of the analyses of anticipated operational occurrences and accidents are presented in chapter 15. The prime objective of the thermal and hydraulic design of the reactor is to ensure that the core can meet steady-state and transient performance requirements without violating the design bases.

The thermal and hydraulic design of the reactor coolant system are discussed in subsection 4.4.3. The line lengths and sizes of the safety injection lines are given in table 4.4-1 and a simplified safety injection piping diagram is provided in figure 4.4-1.

4.4.1 DESIGN BASES

Avoidance of thermally or hydraulically induced fuel damage during normal steady-state operation and during anticipated operational occurrences is the principal thermal hydraulic design basis. The design bases for accidents are specified in chapter 15. In order to satisfy the design basis for steady-state operation and anticipated operational occurrences, the following design limits are established, but violation of these will not necessarily result in fuel damage. The reactor protective system (RPS) provides for automatic reactor trip or other corrective action before these design limits are violated.

Table 4.4-1

4.4.1.1 Minimum Departure from Nucleate Boiling Ratio (DNBR)

The minimum DNBR shall be such as to provide at least a 95% probability with 95% confidence that departure from nucleate boiling (DNB) does not occur on a fuel rod having that minimum DNBR during steady-state operation and anticipated transients of moderate frequency. A value of 1.34 provides this probability and confidence, as described in paragraph 4.4.2.2.1.

4.4.1.2 Hydraulic Stability

Operating conditions shall not lead to flow instability during steady-state operation or anticipated operational occurrences.

4.4.1.3 Fuel Design Bases

A. The peak temperature of the fuel shall be less than the melting point (5080F unirradiated, reduced by 58F per 10,000 MWd/Mtu for burnup and adjusted for burnable poisons per CENPD-382-P-A) during steady-state operation and anticipated occurrences of moderate frequency.

B. The fuel design bases for fuel clad integrity and fuel assembly integrity are given in subsection 4.2.1. Thermal and hydraulic parameters that influence the integrity include maximum linear heat rate, core coolant velocity, coolant temperature, clad temperature, fuel-to-clad gap conductance, fuel burnup, and UO_2 temperature. Other than the design limits already specified, no limits need to be applied to these parameters directly. Conformance with the design limits

specified here and conformance with the design bases specified in subsection 4.2.1 are sufficient to ensure fuel clad integrity, fuel assembly integrity, and the avoidance of thermally or hydraulically induced fuel damage for steady-state operation and anticipated occurrences of moderate frequency.

4.4.1.4 Coolant Flow, Velocity, and Void Fraction

The primary coolant flow with all four pumps in operation shall be neither less than the design minimum nor greater than the design maximum. A percentage of the flow entering the reactor vessel is not effective for cooling the core. This percentage is called the core bypass flow. The design minimum value for the calculated core flow is obtained by subtracting the design maximum value for the calculated core bypass flow from the design minimum primary coolant flow. For thermal margin analyses, the design minimum value for the calculated core flow is used. The design minimum primary coolant flow is listed in table 4.4-2.

The design pre-core and post-core maximum primary coolant flows are equal to 1.22 and 1.16 times the design minimum primary coolant flow, respectively. The design maximum primary coolant flow is used in the determination of design hydraulic loads in the manner described in paragraph 4.4.2.6.3.

Design of the reactor internals provides for the coolant flow to be distributed to the core such that the core is adequately cooled during steady-state operation and anticipated

operational occurrences. Therefore, no specific orificing configuration is used.

Although the coolant velocity, its distribution, and the coolant voids affect the thermal margin, design limits need not be applied to these parameters because they are not in themselves limiting. These parameters are included in the thermal margin analyses and thus affect the thermal margin to the design limits.

Table 4.4-2
TYPICAL THERMAL HYDRAULIC PARAMETERS AT FULL POWER
(Sheet 1 of 2)

General Characteristics	Units	PVNGS Units[d] 1, 2, & 3	Waterford Steam Electric Station Unit 3

Core average heat flux (accounts for fraction of heat generated in fuel rod and axial densification factor)	Btu/hr-ft^2	192,203[b]	182,400

a. Licensed minimum flow rate.

b. Representative value; depends on the number of non-fuel rods. This value assumes all rod locations are fuel rods, except for 100 non-fuel rods for the purposes of fuel reconstitution.

Table 4.4-2
TYPICAL THERMAL HYDRAULIC PARAMETERS AT FULL POWER
(Sheet 2 of 2)

General Characteristics	Units	PVNGS Units[d] 1, 2, & 3	Waterford steam Electric Station Unit 3
Total heat transfer area (accounts for axial densification factor)	ft^2	68,323[b]	62,000
Average linear heat rate of undensified fuel rod (accounts for fraction of heat generated in fuel rod)	kW/ft	5.62[b]	5.34
Average core enthalpy rise	Btu/lbm	90.1	81
Engineering heat flux factor	--	1.03[c]	1.03
Engineering enthalpy rise factor	--	1.03[c]	1.03
Rod pitch, bowing, and clad diameter factor	--	1.05[c]	1.05
Maximum augmentation factor	--	1.0	1.041

c. These factors have been combined statistically with other uncertainty factors as described in reference 1 to define overall uncertainty penalty factors to be applied in the DNBR calculations in COLSS and CPC which, when used in conjunction with the appropriate DNBR limit for that cycle, provide assurance at the 95/95 confidence/probability level that the hot rod will not experience DNB.

d. These values are typical (Generic) design operating conditions that do not necessarily reflect any specific unit and cycle.

Table 4.4-3
TYPICAL THERMAL AND HYDRAULIC PARAMETERS FOR FSAR ANALYSES

Reactor Parameters	PVNGS Units 1, 2, & 3	Waterford Steam Electric Station Unit 3 (Docket No. 50-382)
Design maximum core bypass flow, % of primary	3.0	3.5
Power distribution factors:		
Rod radial power factor	1.55	1.55
Nuclear power factor	2.28	2.28
Total heat flux factor	2.35	2.35
Engineering factor on linear heat rate	1.03	1.03
Fuel densification factor (axial)	1.002	1.002
Characteristics of rod and channel with minimum DNBR:		
Maximum fuel rod heat flux, Btu/hr-ft^2	447,000	428,000
Maximum fuel rod linear heat rate, kW/ft	13.1	12.5
UO_2 maximum steady state temperature, °F	3,200	3,180
Outlet temperature, °F	652	642
Outlet enthalpy, Btu/lbm	699	680
Minimum DNBR at nominal conditions (CE-1 correlation)	1.79	2.07

4.4.2 DESCRIPTION OF THERMAL AND HYDRAULIC DESIGN OF THE REACTOR CORE

4.4.2.1 Summary Comparison

Typical thermal and hydraulic parameters for the reactor are listed in tables 4.4-2 and 4.4-3. A comparison of these parameters with those for the Waterford Steam Electric Station Unit 3 (Docket No. 50-382) is included in these tables.

The principal difference between the two reactors is the total core heat output.

4.4.2.2 Critical Heat Flux Ratios

4.4.2.2.1 Departure from Nucleate Boiling Ratio

The margin to DNB in the core is expressed in terms of the departure from nucleate boiling ratio (DNBR). The DNBR is defined as the ratio of the heat flux required to produce departure from nucleate boiling at the calculated local coolant conditions to the actual heat flux.

The DNB correlation used for design of the core is the CE-1 correlation.(2)(3) Based on statistical evaluation of the CE-1 correlation and relevant data for 14 x 14 and 16 x 16 fuel assemblies, Combustion Engineering concluded that the appropriate minimum DNBR is 1.13.(2)(3) NRC evaluation of the uniform axial power distribution data for 16 x 16 assemblies resulted in their concluding that the CE-1 critical heat flux correlation, when coupled with the TORC code, provided an acceptable correlation of uniform axial CHF data and that the minimum acceptable DNBR was 1.19.(4) Statistical combination of

uncertainties (SCU) methods were later used to statistically combine the uncertainties of the thermal hydraulic code input parameters (system parameters) as described in reference 5. Using this SCU methodology, the following uncertainties were statistically combined with CE-1 CHF correlation statistics at 95/95 confidence/probability level to yield a 1.231 DNBR limit for Cycle 1:

- Systematic variation on fuel rod pitch
- Systematic variation on fuel clad OD
- Engineering enthalpy rise factor
- Engineering heat flux factor
- Penalty on minimum DNBR due to fuel rod bowing
- Statistics associated with the NRC-approved 1.19 DNBR limit

Also included in this MDNBR limit are a 0.01 penalty[6] for the use of HID spacer grid, the penalty due to the CHF correlation uncertainty and penalties imposed by the NRC to account for CHF correlation "prediction uncertainty" and TORC code uncertainty. Beginning with cycle 2, the MDNBR limit was increased from 1.231 to 1.24 due to the increase in rod bow penalty from 0.8% in cycle 1 to 1.75% starting with cycle 2. The DNBR limit was used in safety analysis, CPC trip set points, and COLSS power operating limit calculations in conjunction with a CETOP model based on a nominal geometry.

Beginning with Unit 3 Cycle 5, a topical report supplement[7] was utilized that treats the core inlet flow distribution data

in a statistical manner, as opposed to a deterministic manner, for use with SCU methodology for assessing core thermal margin. Utilizing this statistical approach removes conservatism inherent in the deterministic approach and results in a gain of additional calculated core thermal margin. The MDNBR was increased from 1.24 to 1.30 due to using the statistical treatment of the core inlet flow distribution data with the SCU methodology.

Beginning with U2C11, the DNBR Safety Limit was increased from 1.30 to 1.34. This change accommodated increased DNBR sensitivity to uncertainties in inlet flow to the hot assembly and adjacent assemblies. This increased sensitivity was attributed to the flatter power distributions of the more efficient present day erbium core designs.

This increased DNBR sensitivity to inlet flow was first encountered in Unit 1 Cycle 7. Since the NRC Safety Evaluation (issued May 26, 1994 for PVNGS Units 1, 2, and 3) for the then current 1.30 DNBR limit stated "Uncertainties in inlet flow to the hot assembly and adjacent assemblies can be accounted for statistically by either increasing DNBR [Limit] or applying a thermal margin penalty using approved SCU methods." it was chosen to account for the increased DNBR sensitivity by applying a thermal margin penalty to COLSS and CPC. This approach was also used for the subsequent cycles in Units 1 and 3. Prior to U2C11 a new bounding DNBR limit (1.34) had been calculated. It took into account the increased DNBR sensitivity to inlet flow. Implementing the new bounding DNBR limit moved the accounting for the increased DNBR sensitivity to inlet flow from a thermal margin penalty on COLSS and CPC to

an increase in the DNBR limit. This change modified the reload safety analysis and setpoint design bases to make them less confusing thus simplifying their human interface with respect to DNBR limit (since the Safety Limit and effective DNBR trip setpoint are the same again) to avoid possible future errors.

When required, additional increases in DNBR sensitivity to flow uncertainties will continue to be addressed as a thermal penalty in accordance with the May 26, 1994 NRC Safety Evaluation.

A historical comparison of the minimum DNBRs computed using different correlations for the same power, flow, coolant temperature and pressure, and power distribution is presented in table 4.4-4. The minimum DNBR values in both the limiting matrix subchannel and the limiting subchannel next to the guide tube are presented. The correlations compared are the CE-1 correlation, the original W-3 correlation,[8] the revised W-3 correlation,[9] and the B&W-2 correlation.[9] The differences between the original and revised W-3 correlations as used here are in the Tong F-factor (which accounts for the effects of nonuniform axial heat flux distributions) and cold wall correction factor (which accounts for the effects of different heated and wetted equivalent diameters). The Tong F-factor is also known as a "C-factor" or "shape factor" in the referenced correlation source documents.

Table 4.4-4

COMPARISON OF THE DEPARTURE FROM NUCLEATE BOILING RATIOS COMPUTED WITH DIFFERENT CORRELATIONS[a]

	DNBRs for Nominal Reactor Conditions		DNBRs for Reactor Conditions Giving a 1.19 CE-1 Minimum DNBR in Matrix Subchannel	
Correlation	Matrix Subchannel	Subchannel Next to Guide Tube	Matrix Subchannel	Subchannel Next to Guide Tube
CE-1	1.99	1.79	1.19	1.15
Original W-3[8]	1.95	2.04	1.08	1.16
Revised W-3[9]	1.95	1.90	1.08	1.21
B&W-2[9]	2.41	2.62	1.42	1.68

(a) This comparison is based on the Cycle 1 MDNBR limit of 1.19. The overall comparison would be similar to the current MDNBR limit of 1.34.

Additional comparisons are contained in CENPD-162-A.[2] In general, the CE-1 correlation predicts lower values of CHF than the B&W-2 correlation, with the differences increasing with increasing inlet subcooling. In comparison with the W-3 correlation, the CE-1 correlation tends to predict lower values of CHF with high inlet subcooling, and higher values of CHF with low inlet subcooling.

The TORC and the CETOP computer codes[10][11] are used to compute the local coolant conditions in the core and thereby the minimum DNBR. A discussion of the CE-1 DNB correlation and the analytical methods is presented in paragraphs 4.4.4.1 and 4.4.4.5.2, respectively. The parameter ranges over which the CE-1 correlation is valid are presented in paragraph 4.4.4.1.

4.4.2.2.2 Application of Power Distribution and Engineering Factors

Distribution of power in the core is expressed in terms of factors that define the local power per unit length produced by the fuel relative to the core average power per unit length produced by the fuel. The method used to compute these factors, which describe the core power distribution, is discussed in section 4.3. The energy produced in the fuel deposits in the fuel pellets, fuel cladding, and the moderator, and results in the generation of heat in those places. The fraction of energy deposited in the fuel pellet and cladding is called the fuel rod energy deposition fraction. Accordingly, the core average heat flux from the fuel rods is determined by multiplying the core power by the average fuel rod energy deposition fraction, and then dividing by the total heat transfer area.

The effects on local heat flux and subchannel enthalpy rise of within tolerance deviations from nominal dimensions and specifications are included in thermal margin analyses by certain factors called engineering factors. These factors are applied to increase the local heat flux at the location of minimum DNBR and to increase the enthalpy rise in the subchannel adjacent to the rod with the minimum DNBR. Diversion cross-flow and turbulent interchange mixing are not input as factors on subchannel enthalpy rise but are explicitly treated in the TORC and CETOP codes' analytical models.

Uncertainties in the power distribution factors are discussed in paragraph 4.4.2.9.4.

4.4.2.2.2.1 Power Distribution Factors

A. Rod Radial Power Factor

The rod radial power factor is the ratio of the average power per unit length produced by a particular fuel rod to the average power per unit length produced by the average powered fuel rod in the core. The maximum rod radial power factor is the ratio of the average power per unit length produced by the highest powered rod in the core to the average power per unit length produced by the average powered fuel rod in the core. Radial power distributions are dependent upon a variety of parameters (control rod insertion, power level, fuel exposure, etc.). The core wide and hot assembly radial power distributions used for a typical DNB analysis are shown in figures 4.4-2 and 4.4-3. The maximum rod radial power factor for those figures is selected as 1.55 for better comparison with the Waterford Station Unit 3. The actual maximum rod radial power reactor in the core is not limited to a maximum value of 1.55. The only limits are those specified in subsection 4.4.1. The protection system, in conjunction with the reactor operator maintaining Technical Specification limiting conditions for operation (LCOs), ensures that those design limits are not violated.

B. Axial Power Factor

The axial power factor is the ratio of the local power per unit length produced by a fuel rod to the average power per unit length produced by the same fuel rod.

The maximum axial power factor is the ratio of the maximum local power per unit length produced by a rod to the average power per unit length produced by the same fuel rod. The axial power distribution directly affects DNBR.

Typically, the farther the location of the peak heat flux is from the core inlet, the lower the value of the peak heat flux needed to reach the DNBR limit. On the other hand, fuel temperature is almost independent of the location of the peak heat flux and is principally dependent on the value of the peak heat flux or linear heat rate. Section 4.3 describes the power distributions and their control. Figure 4.4-4 shows several axial power distributions used for this analysis. The minimum DNBR in table 4.4-3 is determined using the 1.26 peaked axial power distribution, whereas the maximum heat fluxes are determined using the 1.47 peaked axial power distribution.

C. Nuclear Power Factor

The nuclear power factor is the ratio of the maximum local power per unit length produced in the core to the average power per unit length produced by the average powered fuel rod in the core. It is conservatively calculated as the product of the maximum axial and radial power factors. For better comparisons with Waterford Station Unit 3, a value of 2.28 is selected for computing maximum heat fluxes. The actual value of

the nuclear power factor is not limited to a maximum value of 2.28. The design limits are those specified in subsection 4.4.1. The protection and supervisory system and Technical Specification LCOs assure that those design limits are not violated.

D. Total Heat Flux Factor

The total heat flux factor is the ratio of the local fuel rod heat flux to the core average fuel rod heat flux. The effects of fuel densification are not included in this factor. To determine the maximum local heat flux including the effect of gaps occurring between the fuel rod pellets, the augmentation factor should be applied. From this definition, the total heat flux factor is the product of the nuclear power factor, the engineering heat flux factor, and the ratio of the hot to the average rod energy deposition fractions. The total heat flux factor is given in table 4.4-3.

E. Augmentation Factor

The densification of the fuel may lead to axial gaps in the fuel pellets stacks and can cause increased localized power peaking. This effect is expressed in terms of the augmentation factor which is defined as the ratio of the local heat flux to the unperturbed heat flux. The axial length over which the localized power perturbation is considered to occur is called the gap length. The augmentation factor is given in

table 4.4-2. The effect of this factor on DNBR is discussed in paragraph 4.4.2.2.3.

4.4.2.2.2.2 Engineering Factors

A. Engineering Heat Flux Factor

The effect on local heat flux due to normal manufacturing deviations from nominal design dimensions and specifications is accounted for by the engineering heat flux factor. Design variables that contribute to this engineering factor are initial pellet density, pellet enrichment, pellet diameter, and clad outside diameter.

These variables are combined statistically to obtain the engineering heat flux factor. The design value used for the engineering heat flux factor is based on deviations obtained from fuel manufacturing inspection data for over 25 batches of fuel for previous reactor cores. Similar tolerances and quality control procedures are used for the PVNGS cores. The engineering heat flux factor is applied to the rod with the minimum DNBR and increases the heat flux when calculating DNBR. It does not affect the enthalpy rise in the subchannel; the effect on the enthalpy rise in the subchannel due to normal manufacturing deviations from normal design dimensions and specifications is accounted for by the engineering enthalpy rise factor.

B. Engineering Factor on Linear Heat Rate

The effect of deviations from nominal fuel rod design dimensions and specifications of fuel temperature is accounted for by the engineering factor on linear heat rate. An engineering factor of 1.03 conservatively bounds the established fuel rod design dimensional tolerances and specifications.

C. Engineering Enthalpy Rise Factor

The engineering enthalpy rise factor accounts for the effects of normal manufacturing deviations in fuel fabrication from nominal dimensions and specifications on the enthalpy rise in the subchannel adjacent to the rod with the minimum DNBR. Tolerance deviations (average over the length of the fuel rods that adjoin the subchannel) for fuel pellet density, enrichment, and diameter contribute to this factor.

The engineering enthalpy rise factor is applied by multiplying by the factor, the rod radial power factor of each of the fuel rods adjacent to the subchannel adjoining the rod with the minimum DNBR. This increases the enthalpy rise in the subchannels which adjoin the same fuel rods.

D. Pitch and Bow Factor

The pitch and bow factor is an allowance for the effect of enthalpy rise or the possible decreased flowrate in the subchannel resulting from a smaller than nominal subchannel flow area.

The pitch and bow factor is applied by multiplying by the factor, the incremental enthalpy rise in the limiting subchannel adjacent to the rod with the minimum DNBR. This increases the enthalpy rise in that subchannel in the same manner as does the engineering enthalpy rise factor, but does not directly affect the heat input into the surrounding subchannels. The combined effects of diversion cross-flow and turbulent interchange resulting from the higher heat input and enthalpy rise are computed by the TORC code. The pitch and bow factor to account for the effects of fuel rod bowing has been superseded by an explicit rod bow DNBR penalty. Based on CENPD-225,[12] a 0.8% rod bow penalty for fuel bundle burnups up to 20,000 MWd/Mtu was used in cycle 1. Starting with cycle 2, a 1.75% penalty for burnups up to 30,000 MWd/Mtu was used. Bundles having burnups in excess of 30,000 MWd/Mtu are not limiting with respect to DNB margin due to the lower radial peaks in higher burnup bundles. The rod bow penalty is included in the minimum DNBR limit as discussed in paragraph 4.4.2.2.1. Additional discussions of fuel and poison rod bowing are presented in CENPD-225.[12]

4.4.2.2.3 Fuel Densification Effect on DNBR

The perturbation in local heat flux due to fuel densification is given in table 4.4-3.

As shown in CENPD-207[3] (see paragraph 4.4.4.1), even much larger local heat flux variations have no significant adverse effect on DNB in San Onofre Units 2 and 3 fuel assemblies.

Therefore, no specific allowance is made or required for the effect on DNBR of local heat flux variations due to densification of the fuel.

4.4.2.3 Linear Heat Generation Rate

The core average and maximum fuel rod linear heat generation rates are given in tables 4.4-2 and 4.4-3. The maximum fuel rod linear heat generation rate is determined by multiplying the core average fuel rod linear heat generation rate by the product of the nuclear power factor, the engineering factor on linear heat rate, and the ratio of the hot to the average fuel rod energy deposition fractions. The effects of fuel densification are not included in the maximum fuel rod linear heat generation rate presented in table 4.4-3; although, to determine the maximum local linear heat generation rate including the effect of gaps occurring between the fuel pellets, the augmentation factor is applied.

4.4.2.4 Void Fraction Distribution

The core average void fraction and the maximum void fraction are calculated using the Maurer method.(13) The void fractions discussed below are values for the reactor operating conditions and engineering factors given in tables 4.4-2 and 4.4-3, for the radial power distribution in figures 4.4-2 and 4.4-3, and for the 1.26 peaked axial power distribution in figure 4.4-4. For these conditions, only subcooled boiling occurs in the core.

The core average void fraction is less than 0.1%. The local maximum void fraction is 10% and occurs at the exit of the

subchannel adjacent to the rod with the minimum DNBR. The average exit void fractions and qualities in different regions of the core are shown in figure 4.4-5 for the core radial power distribution shown in figure 4.4-2. The axial distribution of void fraction and quality in the subchannel adjacent to the rod with the minimum DNBR is shown in figure 4.4-6. The average void fraction in that subchannel is 0.5%.

4.4.2.5 Core Coolant Flow Distribution

The core inlet flow distribution is required as input to the TORC thermal margin code (refer to paragraph 4.4.4.5.2). The inlet flow distribution for four-loop operation was determined from flow tests. Descriptions of the tests and the resulting core inlet flow distribution are given in paragraph 4.4.4.2.1.

4.4.2.6 Core Pressure Drops and Hydraulic Loads

4.4.2.6.1 Reactor Vessel Flow Distribution

The design minimum coolant flow entering the four reactor vessel inlet nozzles is given in table 4.4-2. The main coolant flow path in the reactor vessel is down the annulus between the reactor vessel and the core support barrel, through the flow skirt, up through the core support region and the reactor core, through the fuel alignment plate, and out through the two reactor vessel outlet nozzles. A portion of this flow leaves the main flow path as shown schematically in figure 4.4-7. Part of the bypass flow is used to cool the reactor internals in the areas not in the main coolant flow path and to cool the CEAs. Table 4.4-5 lists the bypass flow paths and the percent of the total vessel flow that enters and leaves these paths.

Table 4.4-5
BEST ESTIMATE REACTOR COOLANT FLOWS IN BYPASS CHANNELS

Bypass Route	Percent of Total Vessel Flow
Outlet nozzle clearances	1.0
Alignment keyways	0.4
Core shroud annulus	0.3
Guide tubes	0.6
Total Bypass	2.3

The thermal margin calculations conservatively use the design bypass flow of 3.0% of the total vessel flow shown in table 4.4-3 as compared to the calculated bypass flow of 2.3% shown in table 4.4-5.

4.4.2.6.2 Reactor Vessel and Core Pressure Drops

The irrecoverable pressure losses from the inlet to the outlet nozzles are calculated using standard loss coefficient methods and information from flow model tests. These pressure losses have been verified by results from flow tests for the System 80 reactor, as described in section 4.4.4.2.1.1.

Pressure losses at 100% power, the design minimum primary coolant flow, and an operating pressure of 2250 lb/in^2 are listed in table 4.4-6 together with the coolant temperature used to calculate each pressure loss. The calculated pressure losses include both geometric and Reynolds number dependent effects.

Table 4.4-6
REACTOR VESSEL BEST ESTIMATE
PRESSURE LOSSES AND COOLANT TEMPERATURES[(a)]

Component	Pressure Loss (lb/in.^{2})	Temperature (°F)
Inlet nozzle and 90° turn	9.6	565
Downcomer, lower plenum, and support structure	12.3	565
Fuel assembly	16.4	595
Fuel assembly outlet to outlet nozzle	14.8	625
Total pressure loss	53.1	

(a) Note: Best estimate pressure losses are evaluated on a cycle-by-cycle basis to consider the effect of fuel mechanical design and other changes in plant design or operation. For example, the best estimate pressure loss across the Unit 1 Cycle 8 core is 16.3 psid, and the total pressure loss is 52.6 psid, or within 1% of the values in this table.

4.4.2.6.3 Hydraulic Loads on Internal Components

The significant hydraulic loads which act on the reactor internals during steady state operation are listed in table 4.4-7. These loads are determined from analytical methods and from results of reactor flow model and components test programs (refer to paragraphs 4.4.4.2.1 and 4.4.4.2.2, respectively). The design hydraulic loads consist of steady-state drag and impingement loads, and the fluctuating loads induced by pump-induced pressure pulsations, vortex shedding, and turbulence.

The hydraulic loads are initially evaluated on a best estimate basis with a flow rate equal to the design maximum flow rate minus expected measurement uncertainty. The effects of uncertainties in the input, such as flow rates, force coefficients, and dimensional tolerances, are added to the best estimate loads. Finally, where appropriate, the effect of a six psi increase in core Δp due to crudding is added to arrive at the final design hydraulic loads.

In evaluating the design hydraulic loads, consideration is given to the particular pump operating configuration and coolant temperature that maximize the hydraulic load for a given internal component.

All hydraulic loads in table 4.4-7 are based on the design maximum primary coolant flow and a coolant temperature of 500F. When other coolant conditions result in more limiting loading for individual components, the loads in table 4.4-7 are adjusted in the detailed design analysis.

Hydraulic loads for postulated accident conditions are discussed in paragraph 3.9.2.5.

Table 4.4-7
DESIGN STEADY STATE HYDRAULIC LOADS
ON VESSEL INTERNALS AND FUEL ASSEMBLIES[(a)]

Component	Steady State Load Description	Load Value
Core support barrel	Radial pressure differential directed inward opposite inlet duct Uplift load Lateral load	95 lb/in^2 1.5×10^6 lb 0.36×10^6 lb
Upper guide structure	Uplift load Lateral load	0.7×10^6 lb 0.42×10^6 lb
Flow skirt	Radial pressure differential directed inward Axial load directed downward	68 max. psi 27 avg. psi 3050 max. lb/ft of circ. 1400 avg. lb/ft of circ.
Instrumentation plate supports	Lateral drag load directed inward	380 lb, max. support
Instrumentation support plate	Uplift load	3300 lb
Instrumentation tube	Lateral drag load directed inward	1200 lb, max. tube
Bottom plate	Drag load directed upward	111,600 lb
Lower support structure beams	Drag load directed upward Lateral load	1,900 lb 7,500 lb
Fuel assembly	Uplift load	2270 lb
Core shroud	Radial pressure differential directed outward	40 lb/in^2 at bottom 0 lb/in^2 at top
Fuel alignment plate	Drag load directed upward	320,600 lb
CEA shroud tubes	Lateral drag load	2400 lb, max. tube
Upper guide plate	Load directed downward	278,800 lb

a. Load values at 500F. Actual values may vary.

4.4.2.7 Correlations and Physical Data

4.4.2.7.1 Heat Transfer Coefficients

The correlations used to determine cladding temperatures for nonboiling forced convection and nucleate boiling are discussed here. The surface temperature of the cladding is dependent on the axial and radial power distributions, the temperature of the coolant, and the surface heat transfer coefficient.

The surface heat transfer coefficient for nonboiling forced convection is obtained from the Dittus-Boelter correlation[14] where fluid properties are evaluated at the bulk condition.

$$h_{db} = \frac{0.023k}{De} \left(N_R\right)^{0.8} \left(N_{Pr}\right)^{0.4}$$

where:

h_{db} = heat transfer coefficient, Btu/h-ft^2-°F

k = thermal conductivity, Btu/h-ft-°F

De = equivalent diameter = $4A/P_w$, ft

N_R = Reynolds number, based on the equivalent diameter and coolant properties evaluated at the local bulk coolant temperature

N_{Pr} = Pradtl number, based on coolant properties evaluated at the local bulk coolant temperature

A = cross-sectional area of flow subchannel, ft^2

P_w = wetted perimeter of flow subchannel, ft

No specific allowance is made or considered necessary for the uncertainties associated with the Dittus-Boelter correlation because the Dittus-Boelter correlation is not used directly in computing thermal margin, but rather plays a part in determining pressure drop and cladding temperature. The validity of the overall scheme for predicting pressure drop is shown by the excellent agreement between predicted and experimental values obtained during the DNB test program and described in paragraph 4.4.4.1. The uncertainty associated with the cladding temperatures calculated for single phase heat transfer is not a major concern because the limiting fuel and cladding temperatures occur where the cladding-to-coolant heat transfer is by nucleate boiling.

The temperature drop across the surface film is calculated from:

$$\Delta T_{film} = q''/h_{db}$$

where:

q'' = fuel rod surface heat flux, Btu/h-ft^2

The maximum fuel rod heat flux is the product of the core average fuel rod heat flux and the total heat flux factor (refer to tables 4.4-2 and 4.4-3 and paragraph 4.4.2.2.2). Nucleate boiling may occur on the clad surface. In the nucleate boiling regime, the surface temperature of the cladding is determined from the Jens and Lottes correlation:[15]

$$T_{wall} = T_{sat} + 60\ (q'' \times 10^{-6})^{0.25}\ [\exp\ (-P/900)]$$

where:

P = pressure, psia

q" = defined above

T_{sat} = saturation temperature, °F

Nucleate boiling is assumed to exist if T_{wall} is less than the sum of $T_{coolant}$ plus ΔT_{film}.

The cladding surface temperature is calculated by summing the temperature of the coolant at the particular location and the temperature drop across the surface film; or if nucleate boiling is occurring, it is calculated directly from the Jens and Lottes correlation.

4.4.2.7.2 Core Irrecoverable Pressure Drop Loss Coefficients

Irrecoverable pressure losses through the core result from friction and geometric changes. The pressure losses through the lower and upper end fittings were initially calculated using the standard loss coefficient method and then verified by test (refer to paragraph 4.4.4.2.2). The correlations used to determine frictional and geometric losses in the core are presented in paragraph 4.4.4.2.3.

4.4.2.7.3 Void Fraction Correlations

There are three separate void regions to be considered in flow boiling. Region 1 is highly subcooled in which a single layer of bubbles develops on a heated surface and remains attached to the surface. Region 2 is a transition region from highly subcooled to bulk boiling where the steam bubbles detach from the heated surface. Region 3 is the bulk boiling regime.

The void fraction in regions 1 and 2 is predicted using the Maurer Method.[13] The calculation of the void fraction in the bulk boiling regime is discussed in paragraph 4.4.4.2.3.

4.4.2.8 Thermal Effects of Operational Transients

Design basis limits on DNBR and fuel temperature are established so that thermally-induced fuel damage will not occur during steady-state operation and during the anticipated operational occurrences. The COLSS provides information to the operator so he can assure that proper steady-state conditions exist. The RPS ensures that the design limits are not violated. The COLSS provides the reactor operator with a comparison of the actual core operating power to the licensed power, and to the limiting power based on DNBR and linear heat rate. If the operating power reaches one of the limiting powers, an alarm is sounded. These limits are maintained by LCO using COLSS, or CPC when COLSS is out of service, to provide sufficient margin not to exceed the design basis limits in the event the most limiting anticipated operational occurrence occurs simultaneously with the operating power being at the limiting power in steady state.

The COLSS thermal margin algorithm is an analytical approximation to the standard thermal margin design methods described in paragraph 4.4.4.5.2.

4.4.2.9 Uncertainties in Estimates

4.4.2.9.1 Pressure Drop Uncertainties

The reactor vessel pressure losses in table 4.4-6 are the best-estimate values calculated for the design minimum flow with standard loss coefficient methods. The uncertainties in the correlations for the loss coefficients and the dimensional uncertainties on the reactor vessel and internals are accounted for when determining maximum and minimum vessel hydraulic resistance. The uncertainties at the 2σ level are estimated to be equivalent to approximately ± 12% of the best estimate vessel pressure loss.

4.4.2.9.2 Hydraulic Load Uncertainties

When determining the design hydraulic loads for normal operation (refer to paragraph 4.4.2.6.3), the effects of uncertainties in the input are considered. The uncertainties in items such as flow rate, force and pressure coefficients, and dimensional tolerances are evaluated at the 2.33σ level.

4.4.2.9.3 Fuel and Clad Temperature Uncertainty

Uncertainty in the ability to predict the maximum fuel temperature is a function of gap conductance, thermal conductivities, peak linear heat rate, and heat generation distribution. Uncertainties in gap conductance and thermal conductivity are taken into account in the analytical model. Uncertainties in the peak linear heat rate are accounted for by including the uncertainty in estimating the total nuclear peak. Uncertainties in fuel pellet density, enrichment, pellet

diameter, and clad diameters are expressed by the engineering factor on linear heat rate (paragraph 4.4.2.2.2).

Uncertainty in predicting the cladding temperature at the location of maximum heat flux is the uncertainty in the film temperature drop, which is minimal at this location where nucleate boiling occurs.

4.4.2.9.4 DNBR Calculation Uncertainties

A. The uncertainty in the calculation of minimum DNBR is divided into:

   1. The uncertainty in the input to the core analytical model, the TORC code. This includes the core geometry, power distribution, inlet flow and temperature distribution, exit pressure distribution, single phase friction factor constants, spacer grid loss coefficients, diversion cross-flow resistance and momentum parameters, turbulent interchange constants, and hot fuel rod energy deposition fraction.

   2. The uncertainty in the analytical model to compute the actual distribution of flow and the local subchannel coolant conditions.

   3. The uncertainty in the CE-1 correlation to predict DNB.

B. The following paragraphs discuss the above uncertainties and the allowances for them, if needed, in the thermal margin analysis of the core:

1. Uncertainty in the input to the core analytical model:

a. Uncertainty in core geometry, as manifested by manufacturing variations within tolerances, is considered by the inclusion of engineering factors in the DNBR analyses; see paragraph 4.4.2.2.2 for discussion of the method used to compute conservative values.

b. Uncertainties on the power distribution factors are applied in the COLSS and RPS (see Chapter 7).

c. The core inlet flow distribution is obtained from flow model testing discussed in section 4.4.4.2. Uncertainties in the core flow distribution are included in the design method for TORC analyses.

d. Uncertainties in the core inlet temperature distribution and core exit pressure distribution are included in the design method for TORC analyses.

e. The Blasius single-phase friction factor equation for smooth rods is given and shown to be valid in paragraph 4.4.4.2.3. The spacer grid loss coefficient for the high impact grid

is obtained from pressure drop data discussed in paragraph 4.4.4.2.3.

f. The value of minimum DNBR is relatively insensitive to cross-flow resistance and momentum parameters.[10]

g. Paragraph 4.4.4.1 describes the testing to determine the inverse Peclet number which is indicative of the turbulent flow interchange between subchannels. The inverse Peclet number is input to the TORC code and is used to determine the effect of turbulent interchange on the enthalpy rise in adjacent subchannels. From the testing, a value of 0.0035 is justified.

h. The same fuel rod energy deposition fraction used for the hot rod is used for the average rod. The hotter the rod, the lower the actual value of energy deposition fraction is with respect to that for the average rod. A lower energy deposition fraction reduces the hot rod heat flux and thereby increases its DNBR. The use of the average rod energy deposition fraction for the hot rod is therefore conservative. See section 4.3 for a discussion of the calculation of the energy deposition fractions.

2. Uncertainty in the analytical model:

   The ability of the TORC code to accurately predict subchannel local conditions in rod bundles is described in CENPD-161.[10] The ability of the code to accurately predict the core-wide coolant conditions is described in CENPD-206.[16]

3. Uncertainty in the DNB correlation:

   The uncertainty in the DNB correlation is determined by a statistical analysis of DNB test data. A value of 1.34 has been shown to provide a 95% probability with 95% confidence that DNB will not occur on a fuel rod having that minimum DNBR.[1][2][3]

   A discussion on the method of Statistical Combination of Uncertainties (SCU) to combine uncertainties into minimum DNBR limit is provided in paragraph 4.4.2.2.1.

4.4.2.10 Flux Tilt Considerations

An allowance for degradation in the power distribution in the x-y plane (commonly referred to as flux tilt) is provided in the protection limit set points even though little, if any, tilt in the x-y plane is expected.

The tilt, along with other pertinent core parameters, is continually monitored during operation by the COLSS (described in section 7.7). If the core margins are not maintained, the

COLSS actuates an alarm, requiring the operator to take corrective action.

The thermal margin calculations used in designing the reactor core are performed using the TORC and CETOP codes. The TORC and CETOP codes, which are described in paragraph 4.4.4.5.2, are based on an open core analytical method for performing such calculations and treat the entire core on a three-dimensional basis. Thus, any asymmetry or tilt in the power distribution is analyzed by providing the corresponding power distribution in the TORC and CETOP input.

4.4.3 DESCRIPTION OF THE THERMAL AND HYDRAULIC DESIGN OF THE REACTOR COOLANT SYSTEM (RCS)

A summary description of the RCS is given in section 5.1.

4.4.3.1 Plant Configuration Data

4.4.3.1.1 Configuration of the RCS

An isometric view of the RCS is given in figure 4.4-8. Dimensions are shown on general arrangement drawings in Chapter 5. Table 4.4-8 lists the valves and pipe fittings which form part of the RCS.

Table 4.4-9 lists the design minimum flow through each flowpath in the RCS.

Table 4.4-10 provides the estimated volume, minimum flow area, flowpath length, height and liquid level of each volume, and bottom elevation for each component within the RCS.

The line lengths and sizes of the safety injection lines are given in table 4.4-1.

4.4.3.2 Operating Restrictions on Pumps

The minimum RCS pressure at any given temperature is limited by the required net positive suction head (NPSH) for the reactor coolant pumps during portions of plant heatup and cooldown. To ensure that the pump NPSH requirements are met under all possible operating conditions, operating curves are used which gives permissible RCS pressure as a function of temperature, for each of the allowed RCP combinations.

The reactor coolant pump NPSH restrictions on these curves are determined by using the NPSH requirement for one pump operation (maximum flow, hence, maximum required NPSH) and correcting it for pressure and temperature instrument errors, pressure drop, and pressure measurement location. The NPSH required versus pump flow is supplied by the pump vendor. Plant operation below these curves is prohibited. At low reactor coolant temperature and pressure, other considerations require that the minimum pressure versus temperature curve be above the NPSH curve.

4.4.3.3 Power Flow Operating Map (BWR)

This subsection is not applicable to Palo Verde Nuclear Generating Station.

Table 4.4-8
RCS VALVES AND PIPE FITTINGS

Pressure Boundary Valves

Valve	Valve No.	Size (in.)	Quantity
Pressurizer safety Valves	RC-200, RC-201 RC-202, RC-203	6 x 8	4
Pressurizer spray control valves	RC-100E, RC-100F	3	2
Spray bypass needle valves	RC-236, RC-237	3/4	2
Refueling level indicator connection isolation valve	RC-214	3/4	1
Reactor vessel head vent isolation valve	RC-212	3/4	1

RCS Pipe Fittings

45°	30	45	4
90°	30	45	8
44°9'	30	45	4

Table 4.4-9
RCS DESIGN MINIMUM FLOWS

Flow Path	Flow (lbm/hr)
Total minimum RCS flow	155.8×10^6
Core bypass flow (design maximum)	4.7×10^6
Core flow	151.1×10^6
Hot leg flow	77.9×10^6
Cold leg flow	38.95×10^6

4.4.3.4 Temperature - Power Operating Map (PWR)

RCS temperature and pressure limits are discussed in Chapter 5 and the Technical Specification.

The adequacy of natural circulation for decay heat removal after reactor shutdown has been verified analytically and by tests on the Palisades reactor (Docket No. 50-255) and Calvert Cliffs I (Docket No. 50-317). The core ΔT in the analysis has been shown to be lower than the normal full power ΔT; thus the thermal and mechanical loads on the core structure are less severe than normal design conditions. In addition, St. Lucie Unit I (Docket No. 50-335) successfully performed a cooldown from full power conditions using only natural circulation cooling following a reactor trip.

Heat removed from the core during natural circulation may be rejected either by dumping steam to the main condenser or to the atmosphere. The rate of heat removal may be controlled to maintain core ΔT within allowable limits.

4.4.3.5 Load Following Characteristics

The design features of the RCS influence its load following and transient response. The RCS is capable of following the normal transients identified in paragraph 3.9.1.1. These requirements are considered when designing the pressurizer spray and heater systems, charging/letdown system, reactor regulating system (RRS), and feedwater regulating system. Finally, these transients are included in the equipment specification for each RCS component to ensure the structural integrity of the system.

When load changes are initiated, the RRS senses a change in the turbine power and positions CEAs to attain the programmed coolant average temperature. RCS boron concentration can also be adjusted to attain the appropriate coolant temperature. The feedwater system employs a controller which senses changes in steam flow, feedwater flow, and water level, and acts to maintain steam generator level at the desired point. The pressurizer pressure and level control systems respond to deviations from preselected setpoints caused by the expansion or contraction of the reactor coolant, and actuate the spray or heaters and the charging or letdown systems as necessary to maintain pressurizer pressure and level.

4.4.3.6 Thermal and Hydraulic Characteristics Table

Typical thermal and hydraulic characteristics of the RCS components are listed in table 4.4-11. Specific values may vary between the PVNGS units or between reloads.

4.4.4 EVALUATION

4.4.4.1 Critical Heat Flux

The margin to critical heat flux (CHF) or DNB is expressed in terms of the DNBR. The DNBR is defined as the ratio of the heat flux required to produce DNB at the calculated local coolant conditions to the actual heat flux.

The CE-1 correlation[2][3] is used with the TORC and CETOP computer codes[10][11] to determine DNBR values for normal operation and anticipated operational occurrences. The CE-1 correlation is used specifically for DNB margin predictions for fuel assemblies with standard spacer grids similar to those in System 80.

Topical Reports CENPD-162[2] and CENPD-207[3] provide detailed information on the CE-1 correlation and source data, and also provide comparisons with other data and correlations. In brief, the correlation is based on data from tests conducted for Combustion Engineering at the Chemical Engineering Research Laboratories of Columbia University. Those tests used electrically-heated 5 x 5 array rod bundles corresponding dimensionally to a portion of a 16 x 16 or 14 x 14 assembly with standard spacer grids. The test programs conducted for the 16 x 16 and 14 x 14 assembly geometries each included tests to determine the effects on DNB of the CEA guide tube, bundle heated length, axial grid spacing, and lateral and axial power distributions.

e. These values are typical (Generic) design operating conditions that do not necessarily reflect any specific unit and cycle.

The uniform axial power CE-1 correlation[2] was developed from DNB data for six test sections with the following characteristics:

Fuel Assembly Geometry	No. Heated Rods	Lateral Power Distr.	Heated Length (ft)	Axial Grid Spacing (in.)
16 x 16	25	Uniform	7	16.0
16 x 16	21	Nonuniform	7	18.3
16 x 16	21	Nonuniform	12.5	17.4
14 x 14	25	Uniform	7	14.3
14 x 14	21	Nonuniform	7	14.3
14 x 14	21	Nonuniform	12.5	14.3

Local coolant conditions at the DNB location were determined by using the TORC code in a manner consistent with the use of the code for reactor thermal margin calculations. The uniform axial power CE-1 correlation was developed from 731 DNB data points, and was determined to predict the source data with a mean and standard deviation of the ratio of measured and predicted DNB heat fluxes of 1.000 and 0.068, respectively.[2] However, the NRC has approved the use of a 1.19 minimum DNBR for the 16 x 16 assembly based on a subset of the 731 source data as reported in the SER for CENPD-162.[4] The 1.19 limit was increased to 1.20 for CE's HID fuel design to account for the small differences between the HID fuel and the standard fuel simulated in the CE-1 CHF test. The validity of the CE-1 correlation for predicting DNB for 16 x 16 fuel assemblies was further verified by the analysis of data obtained by repeating

one of the tests for the 16 x 16 assembly geometry at the Winfrith Laboratory of the UKAEA.

For nonuniform axial power distributions, the uniform axial power CE-1 correlation is modified by the Tong F-factor.[9] The conservatism of that method of predicting DNB for 16 x 16 fuel assemblies with nonuniform axial flux shapes was demonstrated in CENPD-207.[3] CENPD-207 presents measured and predicated DNB heat fluxes for a series of tests using nonuniform axial power rod bundles representative of 16 x 16 or 14 x 14 fuel assemblies with standard spacer grids. Those test sections had the following characteristics.

Fuel Assembly Geometry	No. Heated Rods	Lateral Power Distr.	Axial Power Distr.	Heated Length (ft)	Axial Grid Spacing (in.)
16 x 16	21	Nonuniform	1.46 symmetric	12.5	14.2
16 x 16	21	Nonuniform	1.47 top peak	12.5	14.2
14 x 14	21	Uniform	1.68 top peak	12.5	17.4
14 x 14	21	Nonuniform	1.68 bottom peak	12.5	17.4

The DNB data from those tests were evaluated using the CE-1 correlation modified by the Tong F-factor, and the TORC code was used in a manner consistent with the use of the code for reactor calculations. It was found that the mean and standard deviation of the ratio of measured and predicted DNB heat fluxes were 1.229 and 0.125, respectively, for the 369 DNB data points obtained from these tests.

Testing was also conducted with rod bundles representative of the 16 x 16 fuel assembly to determine the effect on DNB of local perturbations in heat flux. Results are presented in CENPD-207[3] for two nonuniform axial power rod bundles which were similar except that one test bundle had a heat flux spike (23% higher heat flux for a 4-inch length) at the location where DNB was anticipated. The results show that there is no significant adverse effect on DNB due to that flux spike. Therefore, it is concluded that no allowance is required for the effect on DNB of local heat flux perturbations less severe than that tested.

The CE-1 CHF correlation that is utilized by the CETOP and TORC computer codes is empirical in nature, because it is derived from the series of tests described above. The correlation equation includes proprietary coefficients that were determined by nonlinear least-squares regression analysis of test data within the following parameter ranges:

Pressure (psia)	1785 to 2415
Inlet temperature (°F)	382 to 644
Local coolant quality	-0.16 to 0.20
Local mass velocity (lb/hr-ft^2)	0.87×10^6 to 3.21×10^6
Subchannel heated equivalent diameter (inches)	0.4713 to 0.7837
Subchannel wetted equivalent diameter (inches)	0.3588 to 0.5447
Heated length (inches)	84 and 150

The CE-1 correlation is therefore valid throughout these parameter ranges.

One important factor in the prediction of DNB and local coolant conditions is the treatment of coolant mixing or turbulent exchange. The effect of turbulent interchange on enthalpy rise in the subchannels of 16 x 16 fuel assemblies with standard spacer grids is calculated in the TORC code by

$$\hat{Pe} = \frac{w'}{\overline{G}\,\overline{D}_e} = 0.0035$$

where:

$\hat{Pe}$ = inverse Peclet number

w' = turbulent interchange between adjacent subchannels, lb/h-ft

$\overline{D}_e$ = average equivalent diameter of the adjacent subchannels, ft

$\overline{G}$ = average mass velocity of the adjacent subchannels, lb/h-ft^2

The value of 0.0035 for the inverse Peclet number for use with the 16 x 16 fuel assembly with standard spacer grids was originally chosen based on cold water dye mixing tests conducted for the 14 x 14 assembly and for a "prototype" of the Palisades reactor fuel assembly. The validity of the inverse Peclet number of 0.0035 for the 16 x 16 assembly with standard

grids was verified with data obtained in the tests conducted at Columbia University.[2]

The design basis requires that the minimum DNBR for normal operation and anticipated operational occurrences be chosen to provide a 95% probability at the 95% confidence level that DNB will not occur on a fuel rod having that minimum DNBR. Statistical evaluation of the CE-1 correlation and relevant data shows that the appropriate minimum DNBR is 1.13.[2][3]

Based on review of CENPD-162[2], the NRC required use of a minimum DNBR of 1.19 for CE standard grid fuel assemblies and 1.20 for CE HID fuel. This minimum DNBR has been increased to 1.34 to account for system parameter uncertainties as described in paragraph 4.4.2.2.1.

4.4.4.2 Reactor Hydraulics

4.4.4.2.1 Reactor Flow Model Tests

The hydraulic design of the System 80 reactor vessel and internals is supported by a three-phase flow test program with geometrically scaled models. In the first phase, 1/8-scale air-flow model tests were conducted at Kraftwerk Union (KWU) to refine the geometry of the lower plenum and core support structure to attain an acceptable core inlet flow distribution. In these tests, geometric scaling was maintained up to the core inlet. The reactor core was represented by a single orifice plate matching the flow resistance through the lower end fitting and lower-most spacer grid, housed in a core shroud envelope. The core inlet flow distribution was mapped by velocity probe measurements downstream of the orifice plate.

Because of the simplified core modeling and measurement technique, the KWU test results are considered to be preliminary.

In the second phase, 3/16-scale water-flow tests were conducted in the C-E Nuclear Laboratories to refine the hydraulic performance of the upper plenum region, with respect to pressure drop and structure hydraulic loading. In these tests there was no representation of the reactor core.

In the third phase, a 3/16-scale water-flow model of the entire reactor and internals was tested to verify the design hydraulic parameters based on analysis and results of earlier tests. This reactor flow model incorporates the minor design changes made after completion of the earlier model tests. Model components are geometrically similar to reactor components, except for the core.

Individual fuel assemblies are represented in the third test model by an array of square tubes. An axial distribution of orifice plates and of cross-flow holes in the double-wall boundaries between adjoining core tubes are sized to provide the axial and lateral flow hydraulic resistances of the reactor core. This "open-core" flow modeling technique is a continuation of testing methods applied for the C-E 3400-series reactors (San Onofre Units 2 and 3, Forked River Unit 1, Waterford Unit 3, Pilgrim Unit 2), as described in CENPD-206.[16] Details of the 3/16 scale System 80 reactor flow model test and portions of the test results are presented in section 4.4.4.2.1.1.

Subsequent tests were also performed on the Yonggwang 177-assembly model, and provided further data on the relationship between the lower core support structure and inlet flow distribution.

Hydraulic design parameters derived from reactor flow model test results included:

- The core inlet flow distribution and core exit pressure distribution.
- Pressure drops in the reactor vessel.
- Hydraulic loads on reactor internal components.

A. Core Inlet Flow and Core Exit Pressure Distributions

The core inlet flow and the core exit pressure distributions are required as input to the TORC code for core thermal margin analysis (refer to paragraph 4.4.4.5.2).

The four-loop core inlet flow distribution used in the TORC analysis is based on the results from flow tests. The core exit pressure distribution is based on an extrapolation of the pressure distribution measured in the 3410 MWt class reactor flow model test program described in CENPD-206.[16]

These core hydraulic boundary conditions were verified by the results from the 3/16-scale System 80 reactor flow model test and subsequent Yonggwang test.

B. Reactor Pressure Losses

Reactor vessel pressure drop predictions other than for the core region were verified by flow model test results. Where appropriate, corrections are made to flow model test results to account for differences in Reynolds number and surface relative roughness between model and reactor. Reactor pressure drop predictions for the core region are based on data from C-E 16 x 16 fuel assembly components tests (see paragraph 4.4.4.2.2). Best estimate reactor vessel pressure drop predictions are given in table 4.4-6 (see paragraph 4.4.2.6.2).

C. Hydraulic Loads on Reactor Internal Components

Design hydraulic loads on reactor internal components for normal operating conditions are based on analytical methods which utilize available flow model and components test nondimensionalized experimental data (see paragraph 4.4.2.6.3). Flow model measurements related to derivation of design hydraulic loads include incremental pressure drops, surface static pressure distributions, wall pressure differentials, and fluid velocity distributions.

4.4.4.2.1.1 SYSTEM 80 REACTOR FLOW MODEL TEST PROGRAM

4.4.4.2.1.1.1 INTRODUCTION

Flow model tests have been conducted to determine the hydraulic performance of the System 80 class reactors. Tests in 1973-1975 at Kraftwerk Union (KWU) with a 1/8 scale model of

the downcomer and lower support structure, and in 1975-1976 at C-E with a 3/16 scale model of the outlet plenum region, were conducted to refine basic hydraulic design. Objectives were to produce an acceptable core inlet flow distribution, and to minimize hydraulic loadings and resistance to flow. The reactor core was not represented in these tests, except for simplified provisions to represent a portion of the core inlet resistance for inlet flow distribution mapping in the KWU lower plenum tests. The test results obtained through 1976 were treated as preliminary in view of the simplified core modelling. Results were used in design analyses of core thermal margin, system pressure drop, and component hydraulic loading.

Final verification of reactor design hydraulic parameters is based on tests with a 3/16 scale model having all structures in the main flow paths, including a dynamically scaled core. This model was constructed in 1976-1977 and tested in 1978, in the C-E Nuclear Laboratories.

4.4.4.2.1.1.2 DESCRIPTION OF FLOW MODEL

4.4.4.2.1.1.2.1 PRESSURE VESSEL AND CORE SUPPORT STRUCTURES

A cross-sectional view of the flow model is presented in Figure 4.4-9. Geometric similarity to the reactor main flow paths is maintained, with a scaling factor of 3/16, except in the model core. Relatively stagnant regions at the top of the downcomer and in the upper guide structure and closure head volume are truncated for ease and economy of model assembly.

4.4.4.2.1.1.2.2 MODEL CORE

The model core consists of an array of 241 square tubes, each representing one fuel assembly. Six levels of flow resistor plates match the axial flow resistance of reactor fuel assemblies, and approximately match the axial distribution of axial flow resistance over the length of the assembly. Aligned round holes through adjoining tube walls match the resistance to cross-flow between reactor fuel assemblies. Model and reactor fuel assemblies are compared in Figure 4.4-10. The model core design and associated "open-core" flow model testing technique follow the methodology of flow model tests for the C-E 3400-Series reactors, as described in CENPD-206-P[16].

4.4.4.2.1.1.2.3 MODEL INSTRUMENTATION

Model instrumentation consists of wall static pressure taps in the inlet and outlet ducts, at the top and bottom of the downcomer, on the flow skirt and bottom plate, in the inlet and outlet of each core tube, at several points on the upper guide structure, and in the closure head volume. These taps provide for assessment of the breakdown of reactor vessel pressure drop, component steady state hydraulic loading, and for measurement of core inlet and core outlet pressure boundary conditions. A detailed summary of pressure tap locations is provided in Figure 4.4-11.

4.4.4.2.1.1.3 DESCRIPTION OF TEST FACILITY

4.4.4.2.1.1.3.1 TEST FACILITY AND OPERATING CONDITIONS

Testing was conducted in the C-E Large Scale Hydraulic Test Facility, TF-15. For the configuration representing full flow with four operating reactor coolant pumps, model flow was set at 11,000 gpm. All tests were conducted at approximately 80°F fluid temperature. At these conditions flow in the model is fully turbulent, with an outlet duct Reynolds Number of 2.6×10^6. The corresponding reactor Reynolds Number at full power is 1.5×10^7. It is expected that non-dimensionalized pressure drops and flow distributions do not change at the higher reactor Reynolds Numbers.

4.4.4.2.1.1.3.2 TEST LOOP

The TF-15 test loop, as used for System 80 Flow Model full flow testing is depicted in Figure 4.4-12. Three circulating pumps are required to provide the 11,000 gpm model flow rate. Individual inlet and outlet duct flow settings are established with flow control valves and calibrated flow meters. Flow meter signals are continuously fed to the data acquisition system to verify constancy of flow settings.

4.4.4.2.1.1.3.3 DATA ACQUISITION SYSTEM

The data acquisition system used for this test is depicted in Figure 4.4-13. Model point pressures are sequentially connected through computer-operated solenoid valves to a series of differential pressure transducers. Point pressures are read against an internal reference pressure at mid-elevation in the

model core. Electrical output is repeatedly scanned and averaged for each point after a dwell period in which pressure differences are allowed to stabilize. Switching and digital voltmeter readout is controlled by a computer. Operator control of test progress and screening of measurements is accomplished with a teletypewriter. Data is recorded on magnetic tape for further reduction with a digital computer.

4.4.4.2.1.1.3.4 CALIBRATION STANDARDS

Calibration of the instruments is made utilizing fixed water columns or variable height mercury columns, as appropriate for the range of each instrument. Calibrations are made at the beginning of each test run, and are confirmed upon completion of each test run.

4.4.4.2.1.1.4 DATA ANALYSIS

4.4.4.2.1.1.4.1 MODEL POINT PRESSURES

Model point pressures, measured relative to an internal reference pressure at core mid-elevation, are converted to Euler numbers of one of several forms.

a. For the planar pressure distributions at the core inlet and core outlet, Pin and Pout:

$$Ei = \left(Pi - \overline{Pi}\right) / \left(\overline{Pin} - \overline{Pout}\right)$$

b. For other point and spatially averaged pressures:

$$Ei = \left(Pi - \overline{Pin}\right) / VH_{ref}$$

where VH_{ref} is a reference model inlet velocity head.

c. For point-to-point pressure differentials:

$$Ei = (P\ \text{upstream} - P\ \text{downstream}) / VH_{ref}$$

Euler numbers are readily converted to desired pressure drop loss coefficient and hydraulic loading coefficient forms, considering averaged data from repeat runs.

4.4.4.2.1.1.4.2 CORE INLET FLOW DISTRIBUTION

The core inlet flow distribution for the normal condition with four operating reactor coolant pumps is provided in Figure 4.4-14. At each fuel assembly location, the inlet flow is expressed as a fraction of the average fuel assembly flow rate in the core. Flow model test data, in the form of the core inlet pressure distribution, is scaled to reactor conditions and used in a TORC-HERMITE simulation of the System 80 core to determine the core inlet flow field. This technique for determining the core inlet flow distribution is discussed further in CENPD-206-P[16].

Figure 4.4-14 also provides the revised flow distribution based on subsequent tests at Yonggwang.

4.4.4.2.1.1.4.3 CORE OUTLET PRESSURE DISTRIBUTION

The reactor core outlet pressure distribution is provided in Figure 4.4-15, for the normal condition with four operating reactor coolant pumps. Euler numbers at fuel assembly locations express the core outlet pressure distribution in a non-dimensional form which is defined as,

$$E_i)_{outlet} = \frac{P_i - \overline{P}\ \text{outlet}}{k_{core}\ \overline{q}_{core}}$$

where: P_i = local static pressure, core outlet

$\overline{P}$ = core average static pressure, core outlet

K_{core} = core overall loss coefficient, based on core flow area

$\overline{q}_{core}$ = average core outlet velocity head, based on core flow area

The core outlet pressure distribution is obtained as a result of interfacing two analytical simulations: the first simulation is a representation of the core region, using the TORC code; the second is a multi-flow-path simulation of the upper plenum region between the core exit and the outlet nozzles. Input to the TORC code contains the core inlet flow distribution as determined earlier from flow model test data. Input to the upper plenum simulation contains the flow resistances found in flow model tests for this region. Matching of the interface conditions between the two simulations provides the core outlet flow and pressure distributions.

Uncertainty in core outlet pressure distribution takes into account the uncertainty in the TORC representation of the core and the uncertainty in the analytical model of the outlet plenum and core exit regions. The typical uncertainty in core outlet pressure distribution (ΔE_i) is 0.008 at the 1σ level.

4.4.4.2.1.1.4.4 REACTOR VESSEL PRESSURE DROP

Best estimate reactor vessel incremental loss coefficients and pressure drops, are provided in Table 4.4-6.

4.4.4.2.1.1.4.5 COMPONENT HYDRAULIC LOADING

Reactor internal component design steady state hydraulic loads which have been verified using scale model flow test data include the following:

a. Core support barrel and upper guide structure uplift forces.

b. Differential pressure loadings on the:

- Flow skirt
- Bottom plate
- Fuel alignment plate
- Upper guide structure support barrel

c. Steady state drag loading on the cylindrical shroud tubes in the outlet plenum and instrument nozzles in the lower plenum.

Design values for these hydraulic loads based on earlier flow model test results and on analytical methods are in all cases shown to be conservative, on the basis of final model test results.

4.4.4.2.2 Components Testing

Components test programs have been conducted in support of all C-E reactors. The tests subject a full-size reactor core module comprising one to five fuel assemblies, control rod assembly and extension shaft, control element drive mechanism, and reactor internals to reactor conditions of water chemistry, flow velocity, temperature, and pressure under the most adverse

operating conditions allowed by design. Two objectives of the programs are to confirm the basic hydraulic characteristics of the components and to verify that fretting and wear will not be excessive during the components' lifetime.

Thus, components tests have been run on the Palisades design, the cruciform control rods, on the Fort Calhoun design with CEAs and rack-and-pinion control element drive mechanisms (CEDMs), on the Maine Yankee design with a duel CEA and a magnetic jack CEDM, and on the Arkansas design with a 16 x 16 fuel assembly, a CEA, and magnetic jack CEDM.

During the course of the tests, information is obtained on fuel rod fretting, on CEA/CEDM trip behavior, and on fuel assembly uplift and pressure drop. The first two subjects are discussed in section 4.2. The third is discussed below.

As part of the assessment of fuel assembly margin to uplift in the reactor, measurements are made of the flow rate required to produce fuel assembly lift-off over a temperature range of 150 to 600F at a system pressure of 350 to 2250 psia. To obtain the desired information, the point of fuel assembly lift-off is determined with load beams or lift-off conductivity probes. With the first approach, one of the fuel assemblies of the module is mounted on the load beam so that the assembly net weight can be monitored as a function of flow rate and temperature. Fuel assembly lift-off is established when the net weight goes to zero. With the second approach, the lift-off probes are mounted to contact the bottom of the fuel assembly. When the fuel assembly is seated, the contact between the assembly and lift-off probes complete an electrical

circuit. The point of lift-off is indicated by a large step change in the circuit resistance caused by the break in contact between the probes and the fuel assembly.

Data reduction involves the calculation of an uplift coefficient, describing the hydraulic uplift force acting on the assembly; the coefficient is defined as follows:

$$Kup = Wo/\rho V^2 A/2gc$$

where:

Wo = wet weight of assembly, lb

V = flow velocity in assembly at the point of lift-off, ft/sec

A = envelope area of assembly, ft^2

ρ = water density, lb/ft^3

A plot of the Kup data shows that they can be fitted by the relation:

$$Kup = \alpha N_R^{-B}$$

where α and B are peculiar to the particular components test being run and the standard error of estimate is typically 4%, including the replication and instrument error.

The uplift coefficient and its associated uncertainty are employed in the analysis of the uplift forces on the fuel assemblies in the reactor. The force is determined for the most adverse assembly location for startup and normal operating conditions. Additional input to the calculation includes analytical corrections to the coefficient for the absence of

the CEA, for crud information, and for small geometrical differences among the fuel assemblies for the different reactor designs all nominally describable by the same components test.

Pressure measurements are also made during the components test to verify the accuracy of the calculated loss coefficients for various fuel assembly components. Direct reduction of the pressure drop data yields the loss coefficients for the lower and upper end fitting region, while the spacer grid loss coefficient is evaluated by subtracting a calculated fuel rod friction loss from the measured pressure drop across the fuel rod region.

Experience has shown that the experimental end fitting loss coefficients are essentially independent of the Reynolds number and, with their sample standard deviations, are in reasonable agreement with the predicted values used in the calculation of core pressure drop (paragraph 4.4.2.6). The design value for the 16 x 16 fuel assembly high impact design spacer grid is based upon experimental results from the 16 x 16 fuel assembly design components test program.

As described in section 4.2, a components test was performed on the System 80 reactor design. The test hardware consists of five fuel assemblies, core support structure, CEA shroud, control rod assembly, and drive mechanism. Component pressure drop measurements for the fuel assemblies were taken during the tests to verify pressure loss and fuel assembly uplift design values.

4.4.4.2.3 Core Pressure Drop Correlations

The total pressure drop along the fuel rod region of the core is computed as the sum of the individual losses resulting from friction, acceleration of the fluid, the change in elevation of the fluid, and spacer grids. The individual losses are computed using the momentum equation and the consistent set of empirical correlations presented in the TORC code.[10]

In the following paragraphs, the correlations used are summarized and the validity of the scheme is demonstrated with a comparison of measured and predicted pressure drops for single-phase and two-phase flow in rod bundles with CEA-type geometry.

For isothermal, single phase flow, the pressure drop due to friction for flow along the bare rods is based on the equivalent diameter of the bare rod assembly and the Blasius friction factor:

$$f = 0.184\ N_R^{\ -0.2}$$

The pressure drop associated with the spacer grids is computed using a grid loss coefficient (K_{SG}) given by a correlation which has the following form:

$$K_{SG} = D_1\ (N_R)^{D_2} \pm \text{Standard Error of Estimate}$$

The constants, D_n, are determined from pressure drop data obtained for a wide range of Reynolds numbers for isothermal flow through a CEA-type rod bundle fitted with the high impact design spacer grids. The data come from a components test program on a 16 x 16 fuel assembly design (paragraph 4.4.4.2.2). The standard error of estimate

associated with the loss coefficient relation includes replication and instrument error.

To compute pressure drop either for heating without boiling or for subcooled boiling, the friction factor given above for isothermal flow is modified through the use of the multipliers given in Pyle.[17] It is important to recognize that the multipliers were developed in such a way as to incorporate the effects of subcooled voids on the acceleration and elevation components of the pressure drop, as well as the effect on the friction losses. Consequently, it is not necessary to compute specifically either a void fraction for subcooled boiling or the individual effects of subcooled boiling on the friction, acceleration, or elevation components of the total pressure drop.

The effect of bulk boiling on the friction pressure drop is computed using a curve fit to the Martinelli-Nelson data[18] above 2000 psia, or the Martinelli-Nelson correlation[18] with the modification given in Pyle[17] below 2000 psia. The acceleration component of the pressure drop for bulk boiling conditions is computed in the usual manner for the case of two-phase flow where there may be a nonunity slip ratio.[19] The elevation and spacer grid pressure drops for bulk-boiling are computed as for single phase flow except that the bulk coolant density ($\bar{\rho}$) is used, where:

$$\bar{\rho} = \alpha\rho_{\upsilon} + (1 - \alpha)\rho_{\ell}$$

and

α = bulk boiling void fraction

ρ_{υ} = density of saturated vapor, lb/ft^3

ρ_{ℓ} = density of saturated liquid, lb/ft^3

The bulk boiling void fraction used in computing the elevation, acceleration, and spacer grid losses is calculated by assuming a slip ratio of unity if the pressure is greater than 1850 psia, or by using the Martinelli-Nelson void fraction correlation(18) with the modifications presented in Pyle(17) if the pressure is below 1850 psia.

To verify that the scheme described above accurately predicts pressure drop for single-phase and two-phase flow through the 16 x 16 assembly, geometry comparisons have been made of measured pressure drop and the pressure drop predicted by TORC,(10) for the rod bundles used in the DNB test program at Columbia University (refer to paragraph 4.4.4.1). Figure 6.7 of CENPD-161(10) shows some typical results for a 21-rod bundle of the 16 x 16 fuel assembly geometry (5 x 5 array with four rods replaced by a control rod guide tube). The excellent agreement demonstrates the validity of the methods described above.

4.4.4.3 Influence of Power Distributions

The reactor operator will restrict operation of the plant such that power distributions which are permitted to occur will have adequate margin to satisfy the design bases during anticipated operational occurrences. A discussion of the methods of controlling the power distributions is given in paragraph 4.3.2.4.2. A discussion of the expected power

distributions is given in paragraph 4.3.2.2.3. The full-power maximum rod radial power factor is used in the calculations of the core thermal margins.

If CEAs or PLCEAs are inserted in the core, the same planar radial power distribution does not exist at each axial elevation of the core, nor does the same axial power distribution exist as each radial location in the core. From the analysis of many three-dimensional power distributions, the important parameters which establish the thermal margin in the core are the maximum rod power and its axial power distribution.[16] Examination of many axial power distributions shows the 1.26 peaked axial power distribution in figure 4.4-4 to be among those giving the lowest DNBRs. The combination of that axial shape and the maximum rod radial power factor is therefore a meaningful combination for DNB analyses. The maximum linear heat rate at a given power is determined directly from the core average fuel rod linear heat rate and the nuclear power factor. The typical value of 2.28 for the nuclear power factor is selected and corresponds to a 1.55 rod radial power factor combined with the 1.47 peaked axial shape shown in figure 4.4-4.

4.4.4.4 Core Thermal Response

Steady-state core parameters are summarized in tables 4.4-2 and 4.4-3 for normal four-pump operation. Figure 4.4-16 shows the sensitivity of the minimum DNBR to small changes in pressure, inlet temperature and flow. The same 1.26 peaked axial power distribution and 1.55 maximum rod radial power factor are used.

The response of the core to anticipated operational occurrences is discussed in chapter 15. The response of the core at the design overpower cannot be presented with any meaning. The concept of a design overpower is not applicable for the PVNGS core since the RPS prevents the design basis limits from being exceeded.

4.4.4.5 Analytical Methods

4.4.4.5.1 Reactor Coolant System Flow Determination

The design minimum flow to be provided by the reactor coolant pumps is established by the required mass flow to result in no violation of the design limits in subsection 4.4.1 during steady-state operation and anticipated operational occurrences. This design minimum flow is specified in table 4.4-2.

The reactor coolant pumps are sized to produce a flow greater than or equal to the design minimum flow for the maximum expected system flow resistance. The maximum system flow resistance is determined by adding an allowance for uncertainty to the best estimate system flow resistance. From this maximum system flow resistance, the required minimum reactor coolant pump head is determined.

Upon completion of the manufacturing and testing of the pumps, the characteristic pump head or performance curve is established. The expected maximum, best estimate, and minimum reactor coolant system flow rates are determined as follows:

A. Best Estimate Expected Flow

   The best estimate expected RCS flow is determined by equating the head loss around the reactor coolant flow

path to the head rise supplied by the reactor coolant pumps (subsection 5.4.1 provides a description of the pumps).

B. Maximum Expected Flow

The maximum expected flow is determined in a manner analogous to the best estimate expected flow, except that statistical techniques are employed. A pump performance curve probability distribution for each pump is calculated by statistically combining measurement uncertainties in flow and head. The uncertainties are based on performance and acceptance testing done at the pump vendor's facility. The system head loss uncertainty distributions are evaluated by statistically combining the uncertainties in the correlations for loss coefficients and normal manufacturing tolerances about nominal dimensions. The expected flow rate probability distribution is determined from the statistical combination of the respective pump curve probability distributions and the probability distributions for the system resistances. This probability distribution for the expected flow rate is used in turn to define the maximum and minimum expected flow rates. The maximum expected flow rate is defined by the upper flow rate limit on the expected flow rate probability distribution, above which the actual flow rate has only a 2.3% probability of existing. This maximum expected flow rate will be equal to or less than the design maximum flow.

C. Minimum Expected Flow

The minimum expected flow is also determined by using the expected flow rate probability distribution discussed above. The minimum expected flow rate is defined as the lower flow rate limit on the expected flow rate probability distribution, below which the actual flow rate has only a 2.3% chance of existing. This minimum expected flow rate will be equal to or greater than the design minimum flow.

Upon installation of the pumps in the reactor coolant system, the operating flow is determined by one or more of the following flow measurement techniques:

A. Pump casing differential pressure method, using a correlation between pump casing differential pressure and flow rate.

B. Calorimetric methods (may be a heat balance performed on either the primary or secondary coolant).

C. By other nonintrusive flow measurement methods such as ultrasonic flow meters.

The uncertainties included in the calculation of the operating flow are those uncertainties associated with the measurement technique or techniques used above. These uncertainties are statistically combined to give the overall uncertainty in primary coolant flow as determined from onsite tests. The best estimate flow reduced for uncertainties shall be greater than the design minimum flow.

Any significant formation of crud buildup is detected by continuous monitoring of the reactor coolant system flow. A significant buildup of crud is not anticipated, however, due to the design of the water chemistry.

4.4.4.5.2 Thermal Margin Analysis

Thermal margin analyses of the reactor core are performed using the TORC and the CETOP codes which are based on the open core analytical method of the COBRA-IIIC code.[20] A complete description of the TORC code and application of the code for detailed core thermal margin analyses is contained in CENPD 161.[10] The CETOP code is used for design thermal margin calculations. CETOP is described in detail in reference 11. A brief description of the codes and their uses is given here.

The COBRA-IIIC code solves the conservation equations for mass, axial and lateral momentum, and energy for a collection of parallel flow channels that are hydraulically open to each other. Since the size of a channel in design varies from the size of fuel assembly or more to the size of a subchannel within a fuel assembly, certain modifications were necessary to enable a realistic analysis of thermal-hydraulic conditions in both geometries. The principal revisions to arrive at the TORC code, which leave a basic structure of COBRA-IIIC unaltered, are in the following areas:

A. Modification of the lateral momentum equation for core-wide calculations where the smallest channel size is typically that of a fuel assembly.

B. Addition of the capability for handling nonzero lateral boundary conditions on the periphery of a collection of parallel flow channels. This capability is particularly important when analyzing the group of subchannels within the hot fuel assembly.

C. Addition of the capability to handle nonuniform core exit pressure distributions.

D. Insertion of standard C-E empirical correlations and the ASME fluid property relationships.

Details of the lateral momentum equations and the empirical correlations used in the TORC code are given in CENPD-161.[10]

The application of the TORC code for detailed core thermal margin calculations typically involves two or at most three stages. In the two stage TORC, stage one represents the coarse-mesh quarter core layout with one node per quarter of an assembly. In stage two, each fuel pin and sub channel in the limiting assembly are modeled. The three stage approach is discussed below.

The first stage consists of calculating coolant conditions throughout the core on the coarse-mesh basis. The core is modeled such that the smallest unit represented by a flow channel is a single fuel assembly. The three-dimensional power distribution in the core is superimposed on the core coolant inlet flow and temperature distributions. The core inlet flow and core exit static pressure distribution are obtained from flow model tests discussed in paragraph 4.4.4.2, and the inlet temperature for normal four-loop operation is assumed uniform. The axial distributions of flow and enthalpy in each fuel

assembly are then calculated on the basis that the fuel assemblies are hydraulically open to each other. Also determined during this stage are the transport quantities of mass, momentum, and energy which cross the lateral boundaries of each flow channel.

In the second state, typically the hot assembly and adjoining fuel assemblies are modelled with a coarse mesh. The hot assembly is typically divided into four to five partial assembly regions. One of these regions is centered on the subchannels adjacent to the rod having the minimum DNBR. The three-dimensional power distribution is superimposed on the core coolant inlet flow and temperature distributions. The lateral transport of mass, momentum, and energy from the stage one calculations is imposed on the peripheral boundary enclosing the hot assembly and the neighboring assemblies. The axial distributions of flow and enthalpy in each channel are calculated as well as the transport quantities of mass, momentum, and energy which cross the lateral boundary of each flow channel.

The third stage involves a fine-mesh modelling of the partial assembly region which centers on the subchannel adjacent to the rod having the minimum DNBR. All of the flow channels used in this stage are hydraulically open to their neighbors. The output from the stage two calculations, in terms of the lateral transport of mass, momentum, and energy, is imposed on the lateral boundaries of the stage three partial assembly region. Engineering factors are applied to the minimum DNBR rod and subchannel to account for uncertainties on the enthalpy rise and heat flux due to manufacturing tolerances. The local

coolant conditions are calculated for each flow channel. These coolant conditions are then input to the DNB correlation and the minimum value of DNBR in the core is determined.

A more detailed description of this procedure with example is contained in CENPD-161.[10] This procedure is used to analyze in detail any specific three-dimensional power distribution superimposed on an explicit core inlet flow distribution. The detailed core thermal margin calculations are used primarily to develop and to support the CETOP[11] design core thermal margin calculational scheme discussed below. The CETOP code, a variant of the TORC code, is used as a design code for thermal margin analyses. The CETOP code uses transport coefficients for improved prediction of diversion cross flow and turbulent mixing between adjoining channels. Furthermore, a prediction-correlation method is used to solve the conservation equations, replacing the iterative method used in the TORC code. CETOP is benchmarked against TORC DNBR data to ensure that CETOP DNBR results are accurate or conservative relative to TORC.

The method used for design calculations using CETOP is discussed in detail in reference 11. In summary, the method is to use one limiting hot assembly radial power distribution for all analyses, to raise or lower the hot assembly power to provide the proper maximum rod radial power factor, and to use the core average mass velocity in all fuel assemblies except the hot assembly. The appropriate reduction for the hot assembly mass velocity was determined after completion of the System 80 flow model tests (see paragraph 4.4.4.2.1). This

methodology is used in the thermal margin analyses of the System 80 reactors.

4.4.4.5.3 Hydraulic Instability Analysis

Flow instabilities leading to flow excursions or flow oscillations have been observed in some boiling flow systems containing one or more closed, heated channels. Flow instability phenomena are a concern primarily because they may lead to a reduction in the DNB heat flux relative to that observed during a steady flow condition. Flow instabilities are not, however, expected to reduce thermal margin in C-E PWRs during normal operation or anticipated operational occurrences. This conclusion is based upon available literature, experimental evidence, and the results of core flow stability analyses.

Review of the available information on boiling systems has resulted in the following qualitative observations. Flow instabilities which have been observed have occurred almost exclusively in closed channel systems operating at pressures low relative to PWR operating pressures. Increasing pressure has been found to have a stabilizing influence in many cases where flow instabilities have been observed(21), and the high operating pressure characteristics of PWRs minimize the potential for flow instability. For PWR operating pressures, experimental results(22) have shown that, even with closed channel systems, operating limits due to the occurrence of Critical Heat Flux (CHF) are encountered before the flow stability threshold is reached. It would be expected that the low resistance to coolant cross-flow among subchannels of C-E

PWR fuel assemblies would have a stabilizing effect, and that expectation is confirmed by experimental results[23][24][25], which show that flow stability in parallel heated channels is enhanced by cross connections between the channels.

Experimental evidence that flow instabilities will not adversely affect thermal margin is provided by the data from the rod bundle DNB tests conducted by C-E[2][3]; many rod bundles have been tested over wide ranges of operating conditions with no evidence of premature DNB or of inconsistent data which might be indicative of flow instabilities in the rod bundle.

Analytical support for the conclusion that flow instabilities will not reduce the thermal margin of C-E PWRs is provided in reference 26. That document presents an assessment of core flow stability for a typical C-E PWR. The assessment was made using the CE-HYDNA code, the C-E version of the HYDNA flow stability code presented in reference 27. In addition to the C-E PWR flow stability assessment, reference 26 contains:

- A description of the CE-HYDNA flow stability code.
- A user's manual and Fortran listing of the CE-HYDNA code.
- Results of sensitivity studies and of code verification through comparison with experimental data.

The CE-HYDNA code provides the fundamental analytical tool for the assessment of flow stability in C-E PWRs. The code has the capability of analyzing transient one-dimensional flow phenomena in several groups of laterally closed channels with common entrance and exit plena. The use of CE-HYDNA for

analysis of open-array C-E PWR cores is conservative because the stabilizing effects of interchannel communication(17)(21)(22) are neglected.

The results presented in reference 26 are for a C-E 3450 MWt class reactor but those results are representative of all C-E PWRs. It was found that, for nominal coolant conditions, the flow is stable throughout the range of reactor power levels examined (100 to 250% rated power). Additional calculations were performed covering a wide range of operating conditions. These calculations showed that, even under severely adverse operating conditions, the flow is stable at greater than 100% of rated power. The results provide additional evidence that flow instabilities will not adversely affect core thermal margin during normal operation or anticipated operational occurrences.

4.4.5 TESTING AND VERIFICATION

Data descriptive of thermal and hydraulic conditions within the reactor vessel were obtained as part of the startup program described in Chapter 14.

4.4.6 INSTRUMENTATION REQUIREMENTS

In-core instrumentation is used to confirm core power distributions and assist in the calibration of the ex-core flux measurement system. Further information is provided in Chapter 7.

4.5 REACTOR MATERIALS

4.5.1 CONTROL ELEMENT DRIVE STRUCTURAL MATERIALS

4.5.1.1 Material Specifications

A. The materials used in the control element drive mechanism (CEDM) reactor coolant pressure boundary components are as follows:

1. Motor housing assembly

   SA 182, Type 347 (austenitic stainless steel)

   SA 182, Grade F6, and Code Case N-4-11 (Modified Type 403 martensitic stainless steel)

   SB 166 (nickel-chromium alloy)

2. Upper pressure housing

   SA 213, Type 316 (austenitic stainless steel)

   SA 479, Type 316 (austenitic stainless steel)

The above listed materials are also listed in Section III of the ASME Boiler and Pressure Vessel Code (1998 Edition through 2000 Addenda). In addition, the materials comply with Section II and IX of the ASME Boiler and Pressure Vessel Code.

The functions of the above listed components are described in Section 3.9.4.1.

B. The materials in contact with the reactor coolant used in the CEDM motor assembly components are as follows:

1. Latch guide tubes

   ASTM A269, Type 316 (austenitic stainless steel)

Chrome Oxide (plasma spray treatment)

2. Magnet and spacer

   ASTM A276, Type 410 (martensitic stainless steel)

3. Latch housing and insert

   ASTM A276, Type 316 (austenitic stainless steel)

   QQ-C-320a, Class 2B (chrome plating)

   ASTM A276 Type 440C (martensitic stainless steel)

4. Lift Spacer

   ASTM A240, 300 Series austenitic stainless steel

5. Alignment Tab

   ASTM A276 Type 440 (martensitic stainless steel)

6. Spring

   AMS 5698, Inconel X-750 (nickel base alloy)

7. Pin

   Haynes Stellite No. 6B (cobalt base alloy)

8. Dowel pin

   300 Series Austenitic stainless steel

9. Spacer and screw

   ASTM A240, 300 Series austenitic stainless steel

10. Stop

    ASTM A276, Type 410 (martensitic stainless steel)

11. Latch and pin

    Haynes Stellite No. 36 (cobalt base alloy)

12. Locking cup and screws

    300 Series austenitic stainless steel

13. Lower Lift

    300 Series austenitic stainless steel

The functions of the CEDM motor assembly components are described in Section 3.9.4.1.

C. The materials in contact with the reactor coolant used in the extension shafts are listed below:

1. Shafts, rod, and plunger

   ASTM A276, Type 304 (austenitic stainless steel)

   ASTM A264, Type 304 (austenitic stainless steel)

2. Gripper

   ASTM B446, Alloy 625 (nickel-chromium-molybdenum-columbium alloy)

   QQ-C-320a, Class 2B (chrome plating)

3. Spring

   AMS 5699, Inconel X-750 (nickel base alloy)

4. Pin

   304 austenitic stainless steel

The functions of the extension shaft components are described in Section 3.9.4.1.

D. The weld rod filler materials used with the above listed components are 308 stainless steel, 316 stainless steel and Inconel 52.

The material in the above listings, A through D, are similar to those used in an extensively tested CEDM assembly that exceeded lifetime requirements, as described in Section 3.9.4.4.1.

4.5.1.2 Control of the Use of 90 ksi Yield Strength Material

The only control element drive structural material identified in Section 4.5.1.1 which has a yield strength greater than 90 ksi is ASTM A276, Type 440, martenistic stainless steel. Its usage is limited to the steel ball in the vent valve on the top of the CEDM and bearing inserts in the motor assembly. The ball is used as a seal and is not a primary load bearing member of the pressure boundary while the inserts are 440 for surface hardness, see little stress and are not part of the safety release mechanism in the motor assembly. This material was tested and exceeded lifetime requirements. Also, this material has been used in reactors such as Maine Yankee (Docket 50-209), Calvert Cliffs (Docket 50-317) and St. Lucie Unit I (Docket 50-335) and has performed satisfactorily for the same application.

4.5.1.3 Control of the Use of Sensitized Austenitic Stainless Steel

Control of the use of sensitized austenitic stainless steel is consistent with the recommendations of Regulatory Guide 1.44, as described in Sections 4.5.1.3.1 through 4.5.1.3.3, except for the criterion used to demonstrate freedom from sensitization. The ASTM A708 Strauss Test is used in lieu of the ASTM A262 Method E, Modified Strauss Test, to demonstrate freedom from sensitization in fabricated unstablized austenitic

stainless steel. The former test has shown, through experimentation, excellent correlation with the type of corrosion observed in severely sensitized austenitic stainless steel.

4.5.1.3.1 Solution Heat Treatment Requirements

All raw austenitic stainless steel, both wrought and cast, employed in the fabrication of the control element drive mechanism structural components is supplied in the solution annealed condition.

4.5.1.3.2 Material Inspection Program

Extensive testing on stainless steel mockups, fabricated using production techniques, has been conducted to determine the effect of various welding procedures on the susceptibility of unstabilized 300 series stainless steels to sensitization-induced intergranular corrosion. Only those procedures and/or practices demonstrated not to produce a sensitized structure are used in the fabrication of control element drive mechanism structural components. The ASTM Standard A708 (Strauss Test) is the criterion used to determine susceptibility to intergranular corrosion. This test has shown excellent correlation with a form of localized corrosion preculiar to sensitized stainless steels. As such, ASTM A708 is utilized as a go/no-go standard for acceptability.

4.5.1.3.3 Avoidance of Sensitization

Homogeneous or localized heat treatment of unstabilized austenitic stainless steel in the temperature range 800 to 1500 F is prohibited.

Weld heat affected zone sensitized austenitic stainless steel (which will fail in the Strauss Test, ASTM A708), is avoided in control element drive mechanism structural components by careful control of:

a. Weld heat input to less than 60 kJ/in

b. Interpass temperature to 350 F maximum

c. Carbon content

4.5.1.4 Control of Delta Ferrite in Austenitic Stainless Steel Welds

The austenitic stainless steel, primary pressure retaining welds in the control element drive mechanism structural components are consistent with the recommendations of Regulatory Guide 1.31 as follows:

The delta ferrite content of A-No. 8 (Table QW-442 of the ASME Code, Section IX) austenitic stainless steel welding materials is controlled to 5FN-23FN. The delta ferrite determination is carried out using a calibrated magnetic measuring instrument and undiluted weld deposits produced in accordance with the American Welding Society Specification AWS A.5.4 or another comparable procedure for other than coated electrodes. The ferrite requirement is met for each heat, lot or heat/lot combination of weld filler material.

Delta ferrite contents of consumable inserts, rod or wire filler metal used with the gas tungsten are welding process, and deposits made with the plasma are welding process may be determined from their chemical compositions using a constitutional diagram for austenitic stainless steel welding material.

As an alternative, the delta ferrite determination may be carried out on production welds by magnetic measurement methods. The average delta ferrite content must be 3FN or more, with no single reading less than 1FN when measured at four equally spaced positions. Each production weld greater than one inch in thickness is examined while welds of thicknesses one inch and less are tested in accordance with a sampling plan.

4.5.1.5 Cleaning and Contamination Protection Procedures

The procedure and practices followed for cleaning and contamination protection of the control element drive mechanism structural components are in compliance with the recommendations of Regulatory Guide 1.37 and are described below:

Specific requirements for cleanliness and contamination protection are included in the equipment specifications for components fabricated with austenitic stainless steel. The provisions described below indicate the type of procedures utilized for components to provide contamination control during fabrication, shipment, and storage.

Contamination of austenitic stainless steels of the 300 type by compounds that can alter the physical or metallurgical structure and/or properties of the material is avoided during all stages of fabrication. Painting of 300 series stainless steels is prohibited. Grinding is accomplished with resin or rubber-bonded aluminum oxide or silicon carbide wheels that have not previously been used on materials other than 300 series stainless alloys.

Internal surfaces of completed components are cleaned to the extent that grit, scale, corrosion products, grease, oil, wax, gum, adhered or embedded dirt, or extraneous material are not visible to the unaided eye.

Cleaning is effected by either solvents (acetone or isopropyl alcohol) or inhibited water (30-100 ppm hydrazine). Water will conform to the following requirements:

Halides	
Chloride, ppm	< 0.60
Fluoride, ppm	< 0.40
Conductivity, μhos/cm	< 5.0
pH	6.0 - 8.0
Visual clarity	No turbidity, oil or sediment

To prevent halide-induced intergranular corrosion that could occur in an aqueous environment with significant quantities of dissolved oxygen, flushing water may be inhibited with hydrazine. Experiments have proven this to be effective. Operational chemistry specifications for halides and oxygen are described in section 9.3.4.3.

4.5.2 REACTOR INTERNALS MATERIALS

4.5.2.1 Material Specifications

The materials used in fabrication of the reactor internal structures are primarily Type 304 stainless steel. The flow skirt is fabricated from Inconel. Welded connections are used where feasible; however, in locations where mechanical connections are required, structural fasteners are used which are designed to remain captured in the event of a single failure. Structural fastener material is typically a high strength austenitic stainless steel; however, in less critical applications Type 316 stainless steel is employed. Hardfacing of Stellite material is used at wear points. The effect of irradiation of the properties of the materials is considered in the design of the reactor internal structures. Work hardening properties of austenitic stainless steels are not used.

The following is a list of the major components of the reactor internals together with their material specifications:

A. Core support barrel assembly

   1. Type 304 austenitic stainless steel to the following specification:

      a. ASTM-A-182

      b. ASTM-A-213

      c. ASTM-A-240

      d. ASTM-A-479

2. Precipitation hardening stainless steel to the following specifications:

   a. ASTM-A-453, Grade 660

   b. ASTM-A-638, Grade 660

B. Upper guide structure assembly

1. Type 304 austenitic stainless steel to the following specifications:

   a. ASTM-A-182

   b. ASTM-A-240

   c. ASTM-A-213

   d. ASTM-A-479

2. Precipitation hardening stainless steel to the following specifications:

   a. ASTM-A-638, Grade 660

   b. Core shroud assembly

1. Type 304 austenitic stainless steel to the following specifications:

   a. ASTM-A-182

   b. ASTM-A-240

D. Holddown ring

ASTM-A-182, modified to ASME Code Case 1747

E. Bolt and pin material

ASTM-A-453 and ASTM-A-638, Grade 660 material (trade name A-286) is used for bolting and pin applications. This

alloy is heat treated to a minimum yield strength of 85,000 lb/in.^{2}. Its corrosion properties are similar to those of the 300 series austenitic stainless steels. It is austenitic in all conditions of fabrication and heat treatment. This alloy was used for bolting in previous reactor systems and test facilities in contact with primary coolant and has proven completely satisfactory.

F. Chrome plating and hardfacing

Chrome plating or hardfacing are employed on reactor internals components or portions thereof where required by function. Chrome plating complies with Federal Specification No. QQ-C-320b. The hardfacing material employed is Stellite 25.

All of the materials employed in the reactor internals and in-core instrument support system have performed satisfactorily in reactors such as Palisades (Docket 50-255), Fort Calhoun (Docket 50-285) and Maine Yankee (Docket 50-309).

4.5.2.2 Welding Acceptance Standards

Welds employed on reactor internals and core support structures meet the acceptance standards delineated in article NG-5000, Section III, Division I, and control of welding is performed in accordance with Sections III, Division I, and IX of the ASME Code. In addition, consistency with the recommendations of Regulatory Guides 1.31 and 1.44 is described in Section 4.5.2.3.

4.5.2.3 Fabrication and Processing of Austenitic Stainless Steel

The following information applies to unstabilized austenitic stainless steel as used in the reactor internals.

4.5.2.3.1 Control of the Use of Sensitized Austenitic Stainless Steel

The recommendations of Regulatory Guide 1.44, as described in Sections 4.5.2.3.1.1 through 4.5.2.3.1.5, are followed except for the criterion used to demonstrate freedom from sensitization. The ASTM A708 Strauss test is used in lieu of the ASTM A262 Method E, Modified Strauss Test, to demonstrate freedom from sensitization in fabricated unstabilized austenitic stainless steel, since the former test has shown, through experimentation, excellent correlation with the type of corrosion observed in severely sensitized austenitic stainless steel.

4.5.2.3.1.1 Solution Heat Treatment Requirements

All raw austenitic stainless steel material, both wrought and cast, employed in the fabrication of the reactor internals is supplied in the solution annealed condition, as specified in the pertinent ASTM or ASME B&PV Code material specification; viz, 1900 to 2050 F for 1/2 to 1 h/in of thickness and rapidly cooled to below 700F. The time at temperature is determined by the size and the type of component.

Solution heat treatment is not performed on completed or partially fabricated components. Rather, the extent of

chromium carbide precipitation is controlled during all stages of fabrication as desired in Section 4.5.2.3.1.4.

4.5.2.3.1.2 Material Inspection Program

Extensive testing of stainless steel mockups, fabricated using production techniques, was conducted to determine the effect of various welding procedures on the susceptibility of unstabilized 300 series stainless steels to sensitization-induced inter-granular corrosion. Only those procedures and/or practices demonstrated not to produce a sensitized structure are used in the fabrication of reactor internals components. The ASTM Standard A708 (Strauss Test) is the criterion used to determine susceptibility to intergranular corrosion. This test has shown excellent correlation with a form of localized corrosion peculiar to sensitized stainless steel. As such, ASTM A708 is utilized as a go/no-go standard for acceptability.

As a result of the above tests, a relationship was established between the carbon content of Type 304 stainless steel and weld heat input. This relationship is used to avoid weld heat affected zone sensitization as described in Section 4.5.2.3.1.4.

4.5.2.3.1.3 Unstabilized Austenitic Stainless Steels

The unstabilized grade of austenitic stainless steel with a carbon content greater than 0.03% used for components of the reactor internals is Type 304. This material is furnished in the solution annealed condition, The acceptance criterion used for this material, as furnished from the steel supplier, is ASTM A262, Method E.

Exposure of completed or partially fabricated components to temperatures ranging from 800 to 1500 F is prohibited except as described in Section 4.5.2.3.1.5.

Duplex, austenitic stainless steels containing more than 5FN delta ferrite (weld metal, cast metal, weld deposit overlay), are not considered unstabilized since these alloys do not sensitize; i.e., form a continuous network of chromium-iron carbides. Specifically, alloys in this category are:

-F8M	Cast stainless steel (delta ferrite controlled to 5FN-33FN)
-CF8	Cast stainless steel (5FN-33FN)
-Type 308	Singly and combined
-Type 309	stainless steel weld filler metals
-Type 312	(delta ferrite controlled to
-Type 316	5FN-23FN as deposited)

In duplex austenitic/ferritic alloys, chromium-iron carbides are precipitated preferentially at the ferrite/austenite interfaces during exposure to temperatures ranging from 800-1500°F. This precipitate morphology precludes intergranular penetrations associated with sensitized 300 series stainless steels exposed to oxygenated or otherwise faulted environments.

4.5.2.3.1.4 Avoidance of Sensitization

Exposure of unstabilized ustenitic 300 series stainless steels to temperatures ranging from 800 to 1500F will result in carbide precipitation. The degree of carbide precipitation or sensitization depends on the temperature, the time at that temperature, and also the carbon content. Severe sensitization is defined as a continuous grain boundary chromium-iron carbide

network. This condition induces susceptibility to intergranular corrosion in oxygenated aqueous environments, as well as those containing halides. Such a metallurgical structure will readily fail the Straus Test, ASTM A708. Discontinuous precipitates (i.e., an intermittent grain boundary carbide network) are not susceptible to intergranular corrosion in a PWR environment.

Weld heat affected zone sensitized austenitic stainless steels are avoided (which will fail the Strauss Test, ASTM A708) by careful control of:

- Weld heat input to less than 60 kJ/in
- Interpass temperature to 350 F maximum
- Carbon content

A weld heat input of less than 60 kJ/in is used during most fabrication stages of the Type 304 stainless steel core support structure. Higher heat inputs are used in some heavy section weld joints. Freedom from weld heat affected zone sensitization in those higher heat input weldments is demonstrated with weld runoff samples produced at the time of component welding in material having a carbon content equal to or greater than the highest carbon content of those heats of steel being fabricated. Specimens so provided are subjected to the Strauss Test, ASTM A708.

4.5.2.3.1.5 Retesting Unstabilized Austenitic Stainless Steels Exposed to Sensitizing Temperature

Sensitization, which may be susceptible to intergranular corrosion, is avoided during welding as described in

Section 4.5.2.3.1.4. Homeneous or localized heat treatment of unstabilized stainless steels in the temperature range 800 to 1500 F is avoided. Complex substructures may be thermally stabilized after fabrication and prior to final machining. Such treatment produces only minor, discontinuous precipitates. In addition to thermocouple records during this heat treatment, a sample of Type 304 stainless steel, having a carbon content equal to or greater than the highest carbon heat of material present in the structure, is included as a monitor sample. After heat treatment, the monitor sample is subjected to the Strauss Test, ASTM A708, as well as a metallographic examination to verify freedom from sensitization.

4.5.2.3.2 Non-Metallic Thermal Insulation

Non-metallic thermal insulation is not used on the reactor internals.

4.5.2.3.3 Control of Delta Ferrite in Welds

The recommendations of Regulatory Guide 1.31 are followed, as described in paragraph 4.5.1.4.

Furthermore, for submerged arc welding processes, the delta ferrite determination for each fire/flux combination may be made on a production or simulated (qualification) production weld, and the delta ferrite content is controlled to 3FN-23FN.

4.5.2.3.4 Control of Electroslag Weld Properties

The electroslag process, Regulatory Guide 1.34, is not utilized to fabricate reactor internal components.

4.5.2.3.5 Welder Qualification for Areas of Limited Accessibility

The specific recommendations of Regulatory Guide 1.71 were not followed by C-E. However, performance qualifications for personnel welding under conditions of limited accessibility are conducted and maintained in accordance with the requirements of ASME Code, Sections III and IX. A requalification is required when:

a. Any of the essential variables of Section IX is changed.

b. When authorized personnel have reason to question the ability of the welder to satisfactorily perform to the applicable requirements.

Production welding is monitored for compliance with the procedure parameters, and welding qualification requirements are certified in accordance with Sections III and IX. Further assurance of acceptable welds of limited accessibility is afforded by the welding supervisor assigning only the most highly skilled personnel to these tasks. Finally, weld quality, regardless of accessibility, is verified by the performance of the required non-destructive examination.

4.5.2.4 Contamination Protection and Cleaning of Austenitic Stainless

Compliance with the recommendations of Regulatory Guide 1.37, "Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants", is discussed in paragraph 4.5.1.5.

This page intentionally left blank

4.6 FUNCTIONAL DESIGN OF REACTIVITY CONTROL SYSTEMS

PVNGS includes the following reactivity control systems: the control element drive mechanisms (CEDM), the safety injection system (SIS), and the chemical and volume control system (CVCS). The CEDM's are referred to collectively as the control rod drive system (CRDS). The pertinent information, evaluations, and testing of the CRDS are treated in Section 4.6.1, 4.6.2, and 4.6.3 respectively. The combined performance of the CRDS and other reactivity control system is discussed in Section 4.6.4 and 4.6.5.

4.6.1 INFORMATION FOR CRDS

The CRDS consists of the CEDMs. Component diagrams, description, and characteristics of the CEDM's are presented in Section 3.9.4.

4.6.2 EVALUATION OF CRDS

The safety function of the CRDS is to drop CEA'S into the reactor core when the motive power is removed from the CEDM power bus. The active interface between the RPS and the CRDS is at the trip circuit breakers located in the reactor trip switchgear (RTSG).

4.6.2.1 Single Failure

A failure mode and effects analysis of the RPS (including the RTSG) is presented in Section 7.2, which demonstrates compliance with IEEE Standard 279-1971, and shows that no single failure in the RPS can prevent the removal of electrical motive power from the CEDM's. For the trip function, the

CEDM's are essentially passive devices. When power is removed from the CEDM coils, the armature springs automatically cause the latches to be disengaged from the CEDM drive shafts, allowing insertion of the CEA's by gravity. For the execution of the trip function, all the CEDM's are independent of one another. In other words, the failure of one CEDM to trip does not affect the operability of any other CEDM. Sufficient shutdown margin is always maintained to assure that the shutdown capability can be retained in the event of a failure of any CEDM. Therefore, no single failure can prevent the CRDS from providing sufficient scram reactivity to achieve a shutdown.

4.6.2.2 Isolation of the CRDS from other Equipment

The interface between the CEDMs and the CEDM Control System is at the CEDMCS power switches, which provide the isolation of the motive power from the low voltage logic control signal. The interface between the CEDMs and the CEAs involves no non-essential elements. Therefore, no isolation is required.

4.6.2.3 Protection from Common Mode Failure

4.6.2.3.1 Pipe Breaks

Protection of essential systems from the consequences of a postulated pipe rupture shall be by separation via physical plant layout, pipe restraints, protective structures and compartments, watertight rooms, isolation capability or other suitable means, as described in section 3.6.

4.6.3 TESTING AND VERIFICATION OF THE CRDS

The precore and post-core CEDM performance test is described in Chapter 14 which verifies the proper operation and sequencing of the CEDMs.

4.6.4 INFORMATION FOR COMBINED PERFORMANCE OF THE REACTIVITY CONTROL SYSTEMS

Plan and elevation layout drawings of the reactivity control systems are presented in section 1.7.

Table 4.6-1 lists postulated accidents analyzed in Chapter 15 that take credit for two or more reactivity control systems for preventing or mitigating each accident. The related reactivity systems are also tabulated.

4.6.5 EVALUATION OF COMBINED PERFORMANCE

The CRDS, CVCS and SIS are separated and totally diverse in design and operation. In addition, since the CRDS, the SIS, and the CVCS are protected from missiles, pipe breaks and their effects, (as delineated in Section 6.3 and 9.3.4), there are no credible potential common mode failures that could cause the combination of the CRDS, SIS, and CVCS to fail to provide sufficient reactivity insertion to achieve a shutdown under design conditions.

TABLE 4.6-1

POSTULATED ACCIDENTS

Event	CRDS	SIS	CVCS
Feedwater Line Break	A	A	A
Steam Line Break	A	A	A
LOCA	A	A	A
Sample Line or Letdown Line Break	A	A	B
Steam Generator Tube Rupture	A	A	C
CEA Ejection	A	A	C
Boron Dilution	A	C	A
Uncontrolled CEA Withdrawal	A	B	C
CEA Drop	A	B	C
Inadvertent Opening of Atmospheric Dump Valve or Main Steam Safety Valve	A	B	C
Loss of Normal Feedwater Flow	A	B	C
Reactor Coolant Pump Shaft Seizure	A	B	C

A = Use expected, and required

B = Use expected, but not required

C = Use not expected, and not required

5. REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

5.1 SUMMARY DESCRIPTION

The reactor is a pressurized water reactor (PWR) with two coolant loops. The reactor coolant system (RCS) circulates water in a closed cycle, removing heat from the reactor core and internals and transferring it to a secondary (steam generating) system. The steam generators provide the interface between the reactor coolant (primary) system and the main steam (secondary) system. The steam generators are vertical U-tube heat exchangers with an integral economizer in which heat is transferred from the reactor coolant to the main steam system. Reactor coolant is prevented from mixing with the secondary steam by the steam generator tubes and the steam generator tube sheet, making the RCS a closed system thus forming a barrier to the release of radioactive materials from the core of the reactor to the containment building.

The arrangement of the RCS is shown in Figure 4.4-8 and engineering drawing 03-M-RCP-001. The major components of the system are the reactor vessel; two parallel heat transfer loops, each containing one steam generator and two reactor coolant pumps; a pressurizer connected to one of the reactor vessel outlet pipes; and associated piping. All components are located inside the containment building.

Table 4.4-11 shows the principal pressures, temperatures, and flowrates of the RCS under normal steady-state, full-power operating conditions. Instrumentation provided for operation and control of the system is described in Chapter 7.

System pressure is controlled by the pressurizer, where steam and water are maintained in thermal equilibrium. Steam is formed by energizing immersion heaters in the pressurizer, or is condensed by the pressurizer spray to limit pressure variations caused by contraction or expansion of the reactor coolant.

The average temperature of the reactor coolant varies with power level and the fluid expands or contracts, changing the pressurizer water level.

The charging pumps and letdown control valves in the chemical and volume control system (CVCS) are used to maintain a programmed pressurizer water level. A continuous but variable letdown purification flow is maintained to keep the RCS chemistry within prescribed limits. A charging nozzle and a letdown nozzle are provided on the reactor coolant piping for this operation. The charging flow is also used to alter the boron concentration or correct the chemical content of the reactor coolant.

Other reactor coolant loop penetrations are the pressurizer surge line in one reactor vessel outlet pipe; the four safety injection inlet nozzles, one in each reactor vessel inlet pipe; two outlet nozzles to the shutdown cooling system, one in each reactor vessel outlet pipe; two pressurizer spray nozzles; vent and drain connections; and sample and instrument connections.

Overpressure protection for the reactor coolant pressure boundary is provided by four spring-loaded ASME Code safety valves connected to the top of the pressurizer. These valves discharge to the reactor drain tank, where the steam is

released under water to be condensed and cooled. If the steam discharge exceeds the capacity of the reactor drain tank, it is relieved to the containment atmosphere via a rupture disc installed in the tank. The reactor drain tank is part of the Chemical and Volume Control System (Section 9.3.4).

Overpressure protection for the secondary side of the steam generators is provided by spring-loaded ASME Code safety valves located in the main steam system upstream of the steam line isolation valves.

Components and piping in the RCS are insulated with a material compatible with the temperatures involved to reduce heat losses and protect personnel from high temperatures.

Principal parameters of the RCS are listed in Table 4.4-11. Table 5.1-3 lists RCS volumes. Table 5.1-2 contains the principal component material specifications.

Shielding requirements of the surrounding structures are described in Section 12.3. Reactor coolant system shielding permits limited personnel access to the containment building during power operation. The reactor vessel sits in a primary shield well. This and other shielding reduces the dose rate within the containment and outside the shield wall during full power operation to acceptable levels.

Refer to section 18.II.B.1 for a discussion of the reactor coolant gas vent system (RCGVS).

5.1.1 SCHEMATIC FLOW DIAGRAM

The principal pressures, temperatures, and flowrates at major components are listed in Table 5.1-1. These parameters are

referenced to the piping and instrument diagram, by numbered locations.

5.1.2 PIPING AND INSTRUMENT DIAGRAM

Refer to engineering drawings 01, 02, 03-M-RCP-001, -002 and -003 for the reactor coolant system (RCS) piping and instrumentation diagrams applicable to PVNGS. Instrumentation provided for operation and control of the RCS Level is described in Chapter 7. The engineering drawings listed above also show PVNGS tag numbers and vent/drain valves.

5.1.3 ELEVATION DRAWING

Reactor Coolant system plan & elevation drawings are provided as engineering drawing 03-M-RCP-001. Additionally, engineering drawings 13-P-00B-007 and 13-P-00B-008 are elevation drawings that show the principal dimensions of the RCS in relation to the supporting or surrounding concrete structures from which a measure of the protection shielding and missiles afforded by the arrangement and the safety considerations incorporated in the layout can be gained.

5.1.4 CESSAR INTERFACE REQUIREMENTS

The following interface requirements are repeated from CESSAR Section 5.1.4:

Below are detailed the interface requirements that the nuclear steam supply system (NSSS) places on certain aspects of the balance of plant, listed by categories. In addition, applicable General Design Criteria (GDC) and Regulatory Guides, which C-E utilizes in its design of the reactor coolant system

(RCS), are presented. These GDC and Regulatory Guides are listed only to show what C-E considers to be relevant, and are not imposed as interface requirements, unless specifically called out as such in a particular interface requirement

Relevant GDC:	1, 2, 3, 4, 5, 14, 15, 26, 27, 28, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 54, 55, 56, 57.
Relevant Reg. Guides:	1.1, 1.2, 1.4, 1.14, 1.24, 1.26, 1.29, 1.31, 1.34, 1.36, 1.38, 1.42, 1.43, 1.44, 1.45, 1.46, 1.47, 1.48, 1.49, 1.50, 1.51, 1.54, 1.61, 1.64, 1.65, 1.66, 1.67, 1.71, 1.73, 1.74, 1.79, 1.83, 1.84, 1.85.

A. Power

See Chapters 7 and 8 for further power information.

B. Protection from Natural Phenomena

1. The containment shall remain functional for the full range, per GDC 2, of natural phenomena (earthquakes, tornadoes, tornado missiles, flooding conditions, hurricanes, winds, snow, and ice) and external environmental conditions.

2. The steam piping and associated supports from the steam generators up to and including the Main Steam Isolation Valves (MSIVs) and any auxiliary steam supply systems up to the isolation valves which connect upstream of the MSIVs shall be seismic category I and designed to ASME B&PV Code, Section III, Class 2 requirements.

3. The valves, piping, and associated supports of the Feedwater System from and including the Main Feedwater Isolation Valves (MFIVs) to the steam generator feed nozzles shall be Seismic Category I and designed to ASME B&PV Code Section III, Class 2 requirements.

4. All components and piping of the Emergency Feedwater System between the steam generators and the containment isolation valves shall be Seismic Category I and designed to ASME B&PV Code Section III, Class 2 requirements.

5. All components, piping and associated supports in the condensate storage facilities for Emergency Feedwater shall be Seismic Category I and designed in accordance with ASME B&PV Code Section III, Class 3.

6. All components and piping associated with steam generator blowdown between the steam generator and the containment isolation valves shall be Seismic Category I and designed to ASME B&PV Code Section III, Class 2 requirements.

C. Protection from Pipe Failure

1. The following valves shall be protected against internally generated missiles or the effects resulting from a high energy pipe rupture (e.g., pipe whip, jet impingement and steam environment) such that these events will not prevent the valves from performing their requisite safety functions.

a. MSIVs.

b. Secondary Safety Valves.

c. Atmospheric Dump Valves (ADVs).

d. MSIV Bypass Valves.

e. MFIVs.

f. Blowdown Isolation Valves.

2. The MSIVs shall be supported such that the valve body and actuator will not be distorted or displaced as a result of pipe break thrust loadings to such a degree that the valve cannot close.

3. Feedwater piping shall be routed, protected and restrained such that in the case of a rupture of a feedwater line or any other system pipeline, a single failure criteria will not be exceeded with regard to safe shutdown of the plant.

4. A containment shall be provided to limit the release of energy and radioactivity to the environs in the event of a rupture of the RCS and to protect the public health and safety.

5. The containment, including penetrations, shall not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of RCS equipment or piping within the containment.

6. The design pressure and temperature of the containment shall, as a minimum:

a. Be equal to the peak pressure and temperature resulting from either (1) complete blowdown of the reactor coolant through any rupture of the RCS piping, up to and including a postulated double-ended severance of the largest reactor coolant pipe or, (2) a complete blowdown of the unisolated steam system through any rupture of the steam line piping, up to and including a postulated double ended severance of the largest main steam line pipe, assuming a sequence of events for either case which leads to the peak transient accumulation of energy in the building atmosphere. To meet this end, a spectrum of loss-of-coolant accidents (LOCA) and main steam line breaks (MSLB) have been analyzed. They shall be used by the applicant to establish the design pressure and temperature of the containment. (Refer to Sections 6.2.1.3 and 6.2.1.4).

b. Take into account all credible post-blowdown energy additions to the containment atmosphere, such as core residual heat, thin and thick structural metal stored energy, steam generator reverse heat transfer, metal-water reactions and other possible chemical reactions resulting from a loss-of-coolant accident.

7. Compartments within the containment including the reactor vessel cavity shall be designed for the

maximum pressure differential between the compartment and the remainder of the containment based on the maximum RCS pipe break that can occur in the compartment as defined in Section 3.6.

D. Missiles

1. The RCS, which is a potential source of missiles, shall to the extent possible, be either surrounded by barriers or restrained to prevent missiles from reaching other parts of the RCS, the containment lines, the secondary steam and feedwater piping or the engineered safeguards systems. See Section 3.5 for additional discussion of missiles.

2. A containment structure shall be provided to protect the RCS from loss of function due to missiles generated outside the containment, including those resulting from equipment failure, and weather induced forces such as tornadoes and hurricanes.

E. Separation

1. Adequate physical separation shall be maintained between the redundant electrical and instrumentation systems used for emergency control and safe shutdown of the reactor, and between the multiple instrumentation channels in the Plant Protection System.

2. Each MSIV shall have two physically separate and electrically independent closure solenoids in order to provide redundant means of valve operation. A

Main Steam Isolation Signal (MSIS) shall be provided to each solenoid.

3. Redundant feedwater system isolation valves in each feedwater line meeting the single failure criteria shall be provided in piping interconnecting the steam generators to preclude blowdown of both steam generators following a pipe rupture.

F. Independence

1. The provisions of General Design Criteria 54 and 57 for containment isolation valves shall be met.

2. The feedwater system piping, Emergency Feedwater System piping, and main steam piping and all of their associated supports and restraints shall be designed so that a single adverse event, such as a ruptured feedwater line, emergency feedwater line, main steam line inside containment, or a closed isolation valve can occur without:

   a. Initiating a Loss-of-Coolant incident.

   b. Causing failure of the other steam generator's safety class steam and feedwater lines, MSIVs, safety valves, MFIVs blowdown line isolation valves, or ADVs.

   c. Reducing the capability of any of the Engineered Safety Features systems or the Plant Protective System.

   d. Transmitting excessive loads to the containment pressure boundary.

e. Compromising the function of the plant control room.

f. Precluding orderly cooldown of the RCS.

3. An electrical or mechanical malfunction of one solenoid shall not prevent a MSIV from closing.

4. No single failure in the control circuits shall prevent closure of the MSIV bypass valves.

5. The MSIV bypass valve control circuits shall be designed, or precautions shall be taken, such that no single electrical failure would result in the spurious motion of the valves.

6. The ADV control circuits shall be designed or precautions taken, such that no single electrical failure would result in the opening of valves with a total combined capacity greater than 1.9×10^6 lb/hr at 1000 psia.

7. No single failure in the control circuits shall prevent operation of at least one ADV on each steam generator.

8. Each MFIV actuator shall be physically and electrically independent of the other such that failure of one will not cause failure of the other.

9. No single active or passive component failure, single passive or active electrical component failure, or power supply failure shall preclude adequate operation of the Emergency Feedwater System, such as the following events:

a. Loss of normal feedwater with or without a concurrent loss of normal onsite or offsite AC power.

b. Minor secondary system pipe breaks with or without a concurrent loss of normal onsite or offsite AC power.

c. Steam generator tube rupture with or without a concurrent loss of normal onsite or offsite AC power.

d. Major secondary system pipe breaks with or without a concurrent loss of normal onsite or offsite AC power.

e. Small LOCA with or without a concurrent loss of normal onsite or offsite AC power.

10. The ability of the Emergency Feedwater System to perform its design function considering a power supply failure, a single active or passive mechanical component failure, a single active or passive failure of an electrical component, or the effects of a high or moderate energy pipe rupture shall be demonstrated.

11. The Emergency Feedwater System shall provide double isolation from the Main Feedwater System during plant conditions when the Emergency Feedwater System is not required.

12. Blowdown piping exiting containment shall have redundant blowdown line isolation valves which shall

be actuated by an Emergency Feedwater Actuation Signal (EFAS).

G. Thermal Limitations

1. A component cooling system (CCS) shall provide cooling water to each RCP as shown in Figure 5.1.2-2.

2. RCP heat load and flow data presented in Table 5.1.4-1 shall be utilized in the design of the cooling water system.

3. The maximum and minimum temperature of the component cooling water during normal operation shall be 105F and 65F, respectively.

4. Power operated atmospheric dump valves shall be provided in each of the four main steam lines to allow cooldown of the steam generators when the main steam line isolation valves are closed, or when the main condenser is not available as a heat sink. Each ADV shall be capable of holding the plant at hot standby dissipating core decay and reactor coolant pump heat, and allowing controlled cooldown from hot standby to Shutdown Cooling System initiation conditions. Each valve shall be sized to allow a rupture, which renders one steam generator unavailable for heat removal, concurrent with a loss of normal A.C. power and single failure of one of the remaining two ADVs. To accomplish the above, each ADV shall have sufficient capacity to meet the saturated steam flow conditions in Figure 5.1.4-1.

Also no single valve shall have a maximum capacity greater than 1.9 x 10^6 lb/h at 1000 psia.

5. Following the events stated in Section 5.1.4.F.9, the emergency feedwater system shall maintain adequate inventory in the steam generator(s) for residual heat removal and be capable of the following:

   a. Maintaining the NSSS at hot standby with or without normal offsite and normal onsite power available.

   b. Facilitating NSSS cooldown at the maximum administratively controlled rate of 75F/h from hot standby to shutdown cooling initiation with or without normal offsite or onsite power available. (The Shutdown Cooling System becomes available for plant cooldown when the RCS temperature and pressure are reduced to approximately 350F and 400 psia.)

6. The Emergency Feedwater System shall be available to deliver flow to the steam generator(s) automatically upon receipt of an EFAS as follows:

   a. Within 10 seconds when normal offsite or normal onsite power is available.

   b. Within 45 seconds when both normal onsite and normal offsite power are not available.

7. The required emergency feedwater flow, based on residual heat removal requirements is 875 gpm

delivered to the steam generator(s) downcomer feedwater nozzle. Maximum expected steady state steam generator pressure at the downcomer nozzle is approximately 1275 psia.

8. Emergency feedwater temperature shall be at least 40F and no greater than 180F.

9. A minimum of 300,000 gallons of secondary quality makeup water as defined in Section 10.3.4 shall be available to the Emergency Feedwater System for delivery to the intact steam generator(s). This amount ensures sufficient feedwater to allow an orderly plant cooldown to shutdown cooling initiation conditions.

10. Each MSIV leak flow shall not exceed 0.001 percent of nominal flow at 1270 psia in the forward direction and shall not exceed 0.1 percent of nominal flow at 1270 psia in the reverse direction.

11. No single MSIV bypass valve or bypass valve line shall have a capacity greater than 1.9×10^6 lb/hr of saturated steam at 1000 psia.

12. No single turbine bypass valve shall have a capacity greater than 1.9×10^6 lb/hr at 1000 psia.

13. The total reverse leak rate of feedwater check valves to each steam generator shall not exceed 1000 cc/hr.

H. Monitoring

1. Means shall be provided for detection of reactor coolant leakage into the secondary side of the steam generators and cooling water systems associated with components containing reactor coolant.

2. Applicant supplied component designs and RCS construction procedures shall ensure that RCS leakage from known sources will not exceed 10 gpm; from steam generator tubes will not exceed 1.0 gpm; and from unknown sources will not exceed 1 gpm, to minimize in-plant airborne and surface activity levels and activity releases to the environs at system normal operating temperature and pressure.

3. Capability for monitoring each MSIV, MFIV, ADV and blowdown line isolation valve position shall be provided locally and in the control room.

4. The required accuracy of the feedwater temperature measurement devices shall be $\pm$1F for any calorimetric measurement.

I. Operational/Controls

1. A power-operated MSIV capable of establishing shutoff under conditions of design pressure, design temperature, and flow conditions resulting from a break just upstream or downstream shall be provided in each main steam line outside of containment.

2. Capability for controlling MSIV position shall be provided in the control room and the remote shutdown panel.

3. The MSIV and MSIV bypass valve shall be either a fail close valve or a valve that is shown by the applicant to close upon receipt of a MSIS.

4. The full open to close stroke time of each MSIV and MSIV bypass valve shall be 5 seconds or less upon receipt of an MSIS.

5. The ADVs shall be fail close and shall be capable of being remote manually positioned to control the plant cooldown rate.

6. The ADVs shall be provided with manual operators such that the valves may be hand operated from the control room and remote shutdown panel in the event of a loss of normal power supply.

7. In the combined event of either a steam line break or steam generator tube rupture and the loss of power operation of the ADVs, personnel access to the manual operators of the intact valves on the other steam generator shall be possible.

8. A MSIS actuation signal shall close the MSIVs, MSIV bypass valve, MFIVs and the steam generator blowdown valves.

9. Redundant feedwater system isolation valving shall be provided in both the economizer feedlines and the downcomer feedlines such that the following criteria

are met when the effects of single failure criteria are imposed:

a. Complete termination of forward feedwater flow is assumed within 5 seconds after receipt of an MSIS.

b. Abrupt complete termination of reverse feedwater flow with the existence of a reverse flow condition. Check valves are considered to be an acceptable means of achieving the above.

10. The economizer and downcomer feedwater line isolation valves (MFIVs) in each main feedwater line shall be remote-operated and be capable of maintaining leak rate of less than 1000 cc/hr under the main feedwater line pressure, temperature and flow resulting from the transient conditions associated with a pipe break on either side of the valves.

11. The Emergency Feedwater System shall be controllable in a post-accident environment from either the control room or a remote shutdown station.

12. The Emergency Feedwater System shall be controllable such that post accident operation will not result in overfilling the intact steam generator(s).

13. If the Emergency Feedwater System is used as an auxiliary feedwater system, the emergency feedwater pumps shall be designed for operation when steam generator pressure is negligible and not result in damage to the pumps or effect the ability of the

system to deliver the required emergency feedwater flow. Such a condition can exist during startup or shutdown operation subsequent to an EFAS which starts the emergency feedwater pumps and fully opens the system isolation and control valves.

J. Inspection and Testing

1. All ASME B&PV Code, Section III, Class 1 and 2 valves shall be designed, fabricated and installed such that they are capable of being periodically tested in accordance with ASME OM Code.

2. Adequate clearances shall be provided for in-service inspection of the Reactor Coolant Pressure Boundary and the ASME B&PV Code Section III, Class 2 portions of the Main Steam, Main Feed, Emergency Feed, and Blowdown systems' piping, in accordance with the provisions of Section XI of the ASME Boiler and Pressure Vessel Code.

3. Biological shielding and all other insulation, if installed around the Reactor Coolant Pressure Boundary, shall be designed to afford access for inservice inspection as defined by Section XI of the ASME Boiler and Pressure Vessel Code.

4. The pressurizer manway shall be accessible for internal examination of the pressurizer.

K. Chemistry/Sampling

1. A sampling system which provides a means of obtaining remote liquid samples from the RCS for

chemical and radiochemical laboratory analysis shall be provided. The sampling system shall be designed to allow for the following tests: corrosion product activity levels, dissolved gas, fission product activity, chloride concentration, coolant pH, conductivity levels and boron concentration. The pressurizer steam space sample lines shall contain 7/32" x 1" orifice as close to the pressurizer as possible. The sample system shall be as shown on Figure 5.1.2-1.

2. A system or systems shall be provided to maintain the steam generator secondary water chemistry within Section 10.3.4 specifications during plant operation. The system or systems shall incorporate steam generator blowdown, chemical addition, and monitoring.

3. Provisions shall be made to allow sampling of the RCS during Shutdown Cooling System operation.

4. Provisions shall be made to allow sampling of the RCS during startup.

L. <u>Materials</u>

1. The materials used for the containment and its internal structures shall be compatible with both the normal operating environment and the most severe thermal, chemical, and radiation environment expected during post-accident conditions (refer to Section 3.11 for the environmental parameters). Consideration shall be given to compatibility with

spray water chemistry and recirculating water chemistry to ensure that containment materials will withstand this exposure without causing deleterious or undesirable reactions, or significantly altering the existing water chemistry of recirculating ECCS water.

2. The following elements and components shall not come in contact with surfaces which will later be in contact with reactor coolant, at any stage of manufacture, assembly or inspection. These are: (a) lead or lead compounds, (b) mercury or mercury compounds, (c) halogen containing solvents or other halogen compounds.

3. The use of the following materials shall be minimized on surfaces normally in contact with reactor coolant:

   a. sulfonated cutting oils,

   b. zinc metal or zinc compounds,

   c. magnesium metal,

   d. asbestos,

   e. aluminum,

   f. copper acid etchants,

   g. penetrants.

   If the above materials are intended to be used, the use shall first be approved by C-E.

4. The sample lines in contact with the reactor coolant, including welds shall be designed such that the material is compatible with the fluid chemistry described in Section 9.3.4.

5. Construction materials or protective coatings containing low melting point elements, particularly lead, mercury and sulfur, shall not be used if they could come in contact with the secondary systems. This is required to reduce to a minimum the potential for stress corrosion cracking of Inconel material in the steam generators.

6. The secondary system piping shall be designed to allow cleaning for the removal of foreign material and rust prior to operation and to prevent introduction of this material into the steam generator. Chemical cleaning or hand cleaning may be employed. During chemical cleaning, no fluid shall enter the steam generators. Suitable bypass piping shall be provided if required.

7. Non-metallic insulation used on the Reactor Coolant Pressure Boundary shall conform to Regulatory Guide 1.36. The chloride and fluoride content of the non-metallic insulation shall be in the acceptable region as shown in Regulatory Guide 1.36. Tests shall be made on representative samples of the non-metallic thermal insulation shall be demineralized or distilled water.

8. No contaminants, except for cutting oils, shall be left on any RCS component surface except for the time required to perform and evaluate the particular fabrication or inspection operation.

9. Field welding of the RCS piping assemblies and components shall be done in accordance with a welding procedure or procedures by welders qualified to ASME Section IX requirements.

M. System/Component Arrangement

1. The pressurizer and surge line shall be located entirely above the reactor coolant loops.

2. The pressurizer surge line maximum L/D (equivalent) shall be 330 assuming 12-inch Schedule 160 piping. The L/D equivalent (Le/D) excludes entrance and exit losses but includes the height of the pressurizer above the hot leg centerline. The equivalent L/D of the height is found by use of:

$$\frac{Le}{D} = 5Z$$

where:

Z is the height of the pressurizer surge nozzle above the hot leg centerline in feet.

3. The maximum acceptable pressure drop through the pressurizer spray line piping is 19 psi at a total flow rate of 375 gpm and at a water temperature of 565F. This requirement is for the piping only, allowance does not have to be made for elevation

losses, the valves, or for the entrance and exit nozzles.

4. Flooding of the reactor cavity from systems other than the RCS shall be precluded to prevent immersion of the reactor vessel during operation. This is normally accomplished by routing only RCS piping inside the reactor cavity, by minimizing drainage paths to the reactor cavity, and/or providing gravity drainage paths out of the cavity below the bottom head of the vessel. The combined reactor cavity and in-core instrumentation chase may be designed without gravity drainage paths below the hot and/or cold leg pipe penetrations, thereby allowing the reactor cavity to flood in the event of a breach of the reactor coolant pressure boundary inside the cavity.

5. The RCS sample piping shall be designed so that the overall transient time from the loop to the containment wall is approximately 90 seconds to permit the decay of short-lived radionuclides (high energy nuclides such as N-16).

6. The RCS and main steam piping, MSIVs, primary and secondary safety valves and their discharge piping and ADVs shall be arranged and supported such that the limiting loads are not exceeded for normal and relieving conditions.

7. Following a secondary line break, either all steam paths downstream of the MSIVs shall be shown to be

isolated by their respective control systems following a MSIS actuation signal, or the results of a blowdown through a non-isolated path shall be shown to be acceptable. An acceptable maximum steam flow from a non-isolated steam path is 10% of the main steam rate (MSR) (1.9 x 10^6 lb/hr @ 1000 psia saturated steam). It is not required that the control systems for downstream valves nor the downstream valves themselves be designed to IEEE 279 and IEEE 308 or ASME Code, Section III and Seismic Category I criteria respectively.

8. The MSIVs for each steam generator shall be arranged such that a maximum of 2000 cubic feet (total for two steam lines per steam generator) is contained in the piping between each steam generator and its associated MSIVs. This volume shall include all lines off of the main steam line up to their isolation valves.

9. The main steam lines shall be arranged such that a maximum of 14,000 cubic feet is contained between the MSIVs and the turbine stop valves. This volume shall include all lines off to the main steam line up to their isolation valves.

10. The main steam lines shall be headered together prior to the turbine stop valves but not upstream of the MSIVs, and a crossconnect line shall be provided which will maintain steam generator pressure

differences within the following limits for all normal and upset conditions.

a. 0-15% power operation pressure difference to be 1 psi.

b. 15-100% power operation pressure difference to be 3 psi.

11. No automatically actuated valves shall be located upstream of the MSIVs except as required for supply to steam driven emergency feedwater pumps. Provisions shall be made to prevent blowdown of both steam generators through the emergency feedwater supply headers in the event of a steamline break. The maximum allowable flow rate per valve is 1.9×10^6 lb/hr.

12. There shall be no isolation valves in the main steam lines between the steam generators and the secondary relief valves.

13. The main steam safety valves shall be arranged such that any condensate in the line between the safety valves and main steam line drains back to the main steam line.

14. All valves in the main steam line outside of containment up to and including the MSIVs shall be located as close as practical to the containment wall.

15. A 90° or 45° elbow facing downward shall be attached to each feedwater nozzle. Such a pre-caution will aid in the prevention of water hammer.

16. The MFIVs shall be located outside of the containment building as close to the containment wall as possible.

17. The MFIVs for each steam generator shall be arranged such that a maximum of 550 cubic feet of fluid is contained in the piping between each steam generator and its associated isolation valves. This volume shall also include the volumes between the redundant MFIVs. This volume shall include the volumes up to their respective isolation valves of all lines off of the main feedwater lines downstream of the MFIVs for which a mechanism exists for getting the fluid into the main feedwater line (e.g., gravity, flow or flushing).

18. The Emergency Feedwater System connection shall be located in the downcomer feedwater line between the MFIVs and the steam generator down-comer nozzle. Emergency feedwater flow shall be directed to the downcomer nozzle only. A safety Class 2 check valve shall be located in the main feedwater piping upstream of this interface to prevent back flow of emergency feedwater to other portions of the Main Feedwater System.

N. Radiological Waste

1. Actuator-operated valves in the RCS were supplied with double packing with lantern ring and leakoff connection unless they are diaphragm (packless) type. Leakoffs have been capped. During original plant design, an evaluation determined that leakoffs piped to the reactor drain tank present a greater ALARA concern than capping the valve leakoff. The cap has been designed as part of the RCS pressure boundary. The leakoffs for all RCS valves are capped except for the pressurizer spray control (RC-100E and 100F) and bypass (RC-236 and 237) valves.

2. Provisions shall be provided to process the steam generator blowdown water. If separately provided, the radioactive steam generator blowdown processing system shall include filtration and ion exchanger or equivalent processes. With design operating conditions in the steam generator, the blowdown water radio-activity will decrease by 90%.

O. Overpressure Protection

1. Each primary safety valve inlet line shall be designed to pass 125 percent of the minimum required safety valve capacity of 460,000 lb/hr with a maximum pressure drop of 50 psi. This pressure drop of 50 psi is for piping and nozzle losses. (Pressure loss factor for pressurizer nozzle is K = 0.23 based on 6" Schedule 160 pipe.)

2. Each primary safety valve discharge line shall be designed to pass 125 percent of the minimum required safety valve capacity with a maximum valve back pressure of 500 psig at the safety valve discharge during blowdown, assuming the discharge tank is at 132 psig. The minimum required flow rate for each safety valve is 460,000 lb/hr. For the common discharge line, the minimum safety valve flow is 1,840,000 lb/hr (total flow of four valves). Discharge tank design pressure is 130 psig. Maximum pressure of 132 psig is calculated from rupture disk burst pressure of 120 psig plus 10% tolerance.

3. Each main steam line shall be provided with ASME Code, springloaded secondary safety valves between the containment and the isolation valves.

4. The total relieving capacity of the secondary safety valves shall be equally divided between the main steam lines.

5. The total secondary safety valve capacity shall be sufficient to pass 19 x 10^6 lb/hr at the maximum valve set pressure.

6. The maximum steam flow per secondary safety valve shall be no greater than 1.9 x 10^6 lbs/hr at 1000 psia.

7. Secondary safety valve set pressure shall be calculated in accordance with Article NC-7000 of ASME Section III, which requires that the following be considered:

a. A maximum allowable set pressure of 110% steam generator design pressure (1270 psia) which equals 1397 psia.

b. A valve accumulation of 3%

c. A valve set pressure error of ±1%

d. Incorporation of the WP between the steam generator nozzles and the safety valves.

8. The design pressure, temperature, and flow rating of the main steam piping and valves shall be greater than or at least equal to the design pressure, temperature, and flow rating of the steam generator secondary side.

P. <u>Related Service</u>

1. The pressure and thermal transients described in Subsection 3.9.1.1 shall be utilized in the design of those portions of the RCS not within the CESSAR design scope.

2. The systems or portions of reactor coolant pressure boundary outside of the CESSAR design scope shall be Safety Class I unless the conditions of 10CFR50.55A are met.

3. A fire protection system shall be provided to protect the RCS consistent with the requirements of GDC and, shall include as a minimum, the following features:

a. Facilities for fire detection and alarming.

b. Facilities for methods to minimize the probability of fire and its associated effects.

c. Facilities for fire extinguishment.

d. Methods of fire prevention such as use of fire resistant and non-combustible materials whenever practical, and minimizing exposure of combustible materials to fire hazards.

e. Assurance that fire protection systems do not adversely affect the functional and structural integrity of safety related structures, systems, and components.

f. Fire protection systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the capability of safety related structures, systems, and components.

4. Systems shall be provided for the detection of reactor coolant leakage from unidentified sources.

5. If air-operated ADVs are used, a safety related control air system shall be provided to supply air to the ADV actuators should the normal air supply fail to be available.

6. Air for the ADV and MFIV pneumatic valve operator shall be clean, dry and oil-free. The air shall be delivered at the point of use under system full flow conditions at a pressure of 70 psig minimum.

Pneumatic lines and fittings shall have a minimum design pressure of 150 psig.

7. The containment structure shall be designed and sized to accommodate the Reactor Coolant System arrangement shown in Figures 5.1.3-1 and 5.1.3-2.

Q. Environmental

1. For the applicant supplied NSSS components one of the following options shall be followed.

   a. Demonstration of other environmental qualification envelopes for any or all of these buildings not to exceed the qualification envelopes of Section 3.11.

   b. Exclusion of specific components from extreme environmental conditions by suitable physical separations or environmental control system techniques.

   c. Use of the same environmental qualification conditions being employed by C-E supplied NSSS components.

2. The containment pressure and temperature transients resulting from the LOCA shall meet criteria specified in Section 6.2.1.5.

3. A containment ventilation system shall be provided to handle the total RCS heat losses to containment. Table 5.1.4-2 lists the heat loads from NSSS support structures to containment. Table 5.1.4-3 lists typical loads through the NSSS insulation to

containment. These values will be confirmed by each Applicant since the final value depends on system insulation efficiency.

R. Mechanical Interaction Between Components

1. The following components shall be designed to withstand the loads arising from the various normal operating and design basis events.

   a. The main steam piping, supports and restraints.

   b. The steam generator steam and feedwater nozzles.

   c. The MSIVs and the MSIV bypass valves and supports.

   d. Main Steam Safety Valves.

   e. The main feedwater piping, supports and restraints.

   f. MFIVs and supports.

   g. Blowdown piping, supports and restraints.

   h. Blowdown isolation valves.

2. Structures shall be provided to mate with C-E supplied component supports to restrain and support RCS components. The loading conditions specified in Section 3.9.3.1 shall be utilized in the design of the Applicant's supporting structures. C-E will provide to the Applicant the loads at the support/structure interface locations under normal, upset, emergency, faulted, and test conditions,

taking into account the local characteristics of the specific Applicant's structures at the support/structure interfaces.

3. The loadings imposed by connecting system piping on RCS nozzles under normal, upset, emergency, faulted, and test conditions shall be less than the design loads for these nozzles. C-E will confirm using the loads developed by the Applicant that the piping nozzles are within Code allowable stress limits.

5.1.5 CESSAR INTERFACE EVALUATION

The CESSAR interface requirements are met by PVNGS design as follows:

A. Power

See section 8.3.

B. Protection from Natural Phenomena

1. The containment is designed to remain functional for the full range of natural phenomena and external environmental conditions in agreement with General Design Criterion 2. Refer to sections 3.2, 3.3, 3.4, 3.5, 3.7, and 3.8.

2. The steam piping and associated supports from the steam generators up to and including the MSIVs and up to and including the containment isolation valves of any auxiliary steam supply systems which connect upstream of the main steam isolation valves (MSIVs)

are Seismic Category I and designed to ASME Section III, Class 2.

3. The valves, piping, and associated supports and restraints of the feedwater system from and including the main feedwater containment isolation valves to the steam generator feed nozzles are classified Seismic Category I and are designed to ASME Section III, Class 2 requirements, as stated in section 3.2.

4. All components and piping of the auxiliary feed-water system between the steam generators and the containment isolation valves are Seismic Category I and are designed to ASME Section III, Class 2 requirements.

5. All safety-related components, piping, and associated supports in the condensate storage facilities for auxiliary feedwater are Seismic Category I and designed in accordance with ASME B&PV Code Section III, Class 3.

6. All components and piping associated with steam generator blowdown between the steam generator and the containment isolation valves are Seismic Category I and are designed to ASME Section III, Class 2 requirements.

C. Protection from Pipe Failure

1. The MSIVs, secondary safety valves, atmospheric dump valves, main feedwater isolation valves (MFIVs), blowdown isolation valves, and MSIV bypass valves

are environmentally qualified to withstand the pressure and temperature environment resulting from pipe rupture.

2. The MSIVs are supported such that the valve body and actuator will not be distorted or displaced, as a result of pipe break thrust loadings, to such a degree that the valve cannot close.

3. Feedwater piping is routed, protected, and restrained such that in the case of a rupture of a feedwater line or any other system piping, the plant can be brought to safe shutdown with a single active failure.

4. A containment structure is provided to limit the release of energy and radioactivity to the environs in the event of a rupture of the RCS and to protect the public health and safety. Refer to section 6.2.

5. The containment, including penetrations, will not be subject to loss of function from dynamic effects (e.g., missiles, pipe reactions, fluid reaction forces) resulting from failure of RCS equipment or piping within the containment (refer to sections 3.5 and 3.6).

6. The design pressure and temperature of the containment building are discussed in subsection 6.2.1.

7. The design of the containment building compartments for differential pressure as well as the containment pressure design is addressed in subsection 6.2.1.

D. Missiles

1. Section 3.5 describes RCS generated missiles. Protection provided for the RCS and other systems from missiles that could be generated by the RCS is also discussed in section 3.5.

2. Refer to section 3.5 for a discussion of the reactor coolant pressure boundary (RCPB) missile protection design and the protection of the RCS from missiles generated outside of containment.

E. Separation

1. Adequate physical separation is maintained between the redundant electrical and instrumentation systems used for emergency control and safe shutdown of the reactor, and between the multiple instrumentation channels in the plant protection system as discussed in chapter 7.

2. Each MSIV has two physical separate and electrically independent closure solenoids in order to provide redundant means of valve operation. A main steam isolation signal (MSIS) is provided to each solenoid. Refer to paragraph 10.3.2.2.2.

3. Redundant feedwater system isolation valves in each feedwater line meeting the single failure criteria are provided in piping interconnecting the steam generators to preclude blowdown of both steam generators following a pipe rupture. Refer to paragraph 10.4.7.2 for a discussion of main feedwater isolation valves.

F. Independence

1. The provisions for redundancy and independence of containment isolation valves are as discussed in subsection 6.2.4. Table 6.2.4-1 addresses the conformance of each containment isolation valve arrangement to the specific NRC General Design Criteria 54 through 57.

2. Feedwater system piping, auxiliary feedwater piping, and main steam piping and supports are designed so that a single failure, such as a ruptured feedwater line, auxiliary feedwater line, main steam line inside the containment, or a closed isolation valve, can occur without:

    a. Initiating a loss-of-coolant incident.

    b. Causing failure of the other steam generator's steam and feedwater lines, MSIV, safety valves, MFIVs, blowdown isolation valves, or atmospheric dump valves.

    c. Reducing the capability of the engineered safety features (ESF) or the plant protection system (PPS).

    d. Transmitting excessive loads to the containment pressure boundary.

    e. Compromising the function of the plant control room.

    f. Precluding orderly cooldown of the RCS.

Refer to section 3.6 for a discussion of the pipe break analyses.

3. An electrical or mechanical malfunction of one actuator control element will not prevent the MSIV from closing.

4. A single failure of the control circuits will not prevent closure of the MSIV bypass valves. The control circuits were designed to IEEE Standard 279-1971 and IEEE Standard 308-1974.

5. The MSIV bypass valve control circuits are designed such that a single electrical failure will not result in the spurious motion of the valves.

6. The atmospheric dump valves control circuits are designed such that no single electrical failure can result in the spurious opening of the valves.

7. No single failure of the control circuits will prevent operation of at least one atmospheric dump valve on each steam generator. Refer to section 10.3 for the operational description. Refer to paragraph 7.4.1.1 for a description of the control circuits.

8. Each main feedwater isolation valve actuator is physically and electrically independent of the other such that failure of one will not cause failure of the other.

9. No single active or passive component failure, single passive or active electrical component

failure, or power supply failure will preclude adequate operation of the auxiliary feedwater system, such as the following events:

a. Loss of normal feedwater with or without a concurrent loss of normal offsite ac power.

b. Minor secondary system pipe breaks with or without a concurrent loss of normal offsite ac power.

c. Steam generator tube rupture with or without a concurrent loss of normal offsite ac power.

d. Major secondary system pipe breaks with or without a concurrent loss of normal offsite ac power.

e. Small LOCA with or without a concurrent loss of normal offsite ac power.

10. The ability of the auxiliary feedwater system to perform its design function considering a power supply failure, a single active or passive mechanical component failure, a single active or passive failure of an electrical component, or the effects of a high or moderate energy pipe rupture is discussed in subsection 10.4.9.

11. The safety-related portion of the auxiliary feedwater system (AFS) is isolated from the main feedwater system during normal plant operation when the safety-related portion of the AFS is not required, as shown in engineering drawings 01, 02, 03-M-AFP-001 and as described in subsection 7.3.1.

12. Blowdown piping exiting containment has redundant blowdown line isolation valves which are actuated by an auxiliary feedwater actuation signal (AFAS).

G. Thermal Limitations

1. Cooling water is provided for the reactor coolant pumps (RCPs) as presented in subsection 9.2.2.

2. Reactor coolant pump heat load and flow data is used in the design of the cooling water system as provided in subsection 9.2.2 which meets CESSAR requirements.

3. The maximum and minimum temperatures of the nuclear component cooling water during normal operation are 105F and 65F, respectively.

4. One atmospheric dump valve is provided in each of the main steam lines to allow cooldown of the steam generators when the main steam line isolation valves are closed, or when the main condenser is not available as a heat sink. Each valve is sized to hold the plant at hot standby, dissipating core decay and reactor coolant pump heat, and to allow controlled cooldown from hot standby to shutdown cooling initiation temperatures. To meet this requirement, each atmospheric dump valve has a maximum capacity of 1.47×10^6 pounds per hour at 1000 psia.

5. Following the events stated in CESSAR Section 5.1.4.F.9, the auxiliary feedwater system

can maintain adequate inventory in the steam generator(s) for residual heat removal and be capable of the following:

a. Maintaining the NSSS at hot standby with or without normal offsite and normal onsite power available.

b. Facilitating NSSS cooldown at a maximum administratively controlled rate of 75F per hour from hot standby to shutdown cooling initiation with or without normal offsite or onsite power available. (The shutdown cooling system becomes available for plant cooldown when the RCS temperature and pressure are reduced to approximately 350F and 400 psia.)

Refer to section 10.4 for a description of the system design.

6. The AFS will deliver flow to the steam generator(s) automatically upon receipt of an AFAS as follows:

   a. For the motor-driven pump, within 22 seconds when normal offsite or normal onsite power is available. The deviation from the CESSAR requirement of 10 seconds is acceptable to Combustion Engineering as discussed in paragraph 1.9.2.4.10.

   b. For the motor-driven pump, within 45 seconds when normal onsite and normal offsite power are not available.

c. For the steam turbine-driven pump, within 45 seconds regardless of power conditions. The deviation from the CESSAR requirement of 10 seconds is acceptable to Combustion Engineering as discussed in paragraph 1.9.2.4.10.

7. Each of the safety-related auxiliary feedwater pumps is capable of delivering 650 gallons per minute to the intact steam generator downcomer nozzle at 1270 psia or equivalent at the entrance of steam generators. The deviation from the CESSAR requirement of 875 gallons per minute is acceptable to Combustion Engineering as discussed in paragraph 1.9.2.4.10.

8. The auxiliary feedwater temperature will be no less than 40F and no greater than 180F.

9. Refer to subsection 9.2.6 for a discussion of the condensate tank capacity. A minimum of 300,000 gallons will be available for the intact steam generator(s). The quality of the condensate tank water will be equivalent to that of normal main feedwater makeup.

10. Each MSIV leak flow will not exceed 0.001% of nominal flow at 1270 psia in the forward direction and will not exceed 0.1% of nominal flow at 1270 psia in the reverse direction.

NOTE: These valves are excluded from 10CFR50, Appendix J Type C Leakage Testing - NPF-41 Amendment 111, NPF-51 Amendment 103, NPF-74 Amendment 83.

11. Each single MSIV bypass valve or bypass valve line has a capacity not greater than 1.9×10^6 pounds per hour.

12. No single turbine bypass valve has a capacity greater than 1.9×10^6 pounds per hour at 1000 psia.

13. The total reverse leak rate of feedwater check valves to each steam generator does not exceed 1000 cubic centimeters per hour.

H. Monitoring

1. Means are provided for detection of RCS leakage into the secondary side of the steam generators and cooling water systems associated with components containing reactor coolant as discussed in subsections 10.4.2 and 9.2.2.

2. Reactor coolant system component designs and RCS construction procedures ensure that RCS leakage from known sources will not exceed 10 gallons per minute; from steam generator tubes will not exceed 1.0 gallons per minute; and from unknown sources will not exceed 1.0 gallons per minute, to minimize in-plant airborne and surface activity levels and activity releases to the environs at system normal operating temperature and pressure.

3. Capability for monitoring each MSIV, MFIV, ADV, and blowdown line isolation valve position is provided locally and in the control room.

4. The accuracy of the feedwater temperature measurement devices is ±1.5F for any calorimetric measurement. An accuracy of ±1.5F for the feedwater temperature measurement devices is within the uncertainty analysis assumptions for the COLSS secondary calorimetric power calculation.

I. Operational/Controls

1. A power-operated MSIV capable of establishing shutoff under conditions of design pressure, design temperature, and flow conditions resulting from a break upstream or downstream is provided in each main steam line outside of containment. Refer to subsection 10.3.2.

2. Each MSIV position is monitored and controlled locally and in the control room.

3. An MSIS closes the MSIV bypass valves and MSIVs.

4. The full "open to close" stroke time of each MSIV and MSIV bypass valve is 4.6 seconds or less upon receipt of an MSIS.

5. The ADVs fail closed and are capable of being remote manually positioned to control the plant cooldown rate.

6. The ADVs are provided with remote manual controllers such that the valves can be operated from the control room and remote shutdown panel in the event of a loss of offsite power supply.

7. In the combined event of either a steam line break or steam generator tube rupture and the loss of power operation of the atmospheric dump valves, personnel access to the manual operators of the intact valves on the other steam generator is possible.

8. A MSIS actuation signal will close the MSIVs, MSIV bypass valves, MFIVs, and the steam generator blowdown valves.

9. Redundant feedwater system isolation valving is provided in both the economizer feedlines and the downcomer feedlines such that the following criteria are met when the effects of single failure criteria are imposed:

   a. Complete termination of forward feedwater flow is assumed within 9.6 seconds after receipt of an MSIS. The deviation from the CESSAR requirement of 4.6 seconds is acceptable to Combustion Engineering as discussed in paragraph 1.9.2.4.10.

   b. Abrupt complete termination of reverse feedwater flow with the existence of a reverse flow condition. Check valves are considered to be an acceptable means of achieving the above.

10. The economizer and downcomer feedwater line isolation valves (MFIVs) in each main feedwater line are remote-operated and capable of maintaining a leak rate of less than 1000 cubic centimeters per

hour under the main feedwater line pressure, temperature, and flow resulting from the transient conditions associated with a pipe break on either side of the valves.

11. The safety-related AFS can be controlled from either the control room or remote shutdown station as described in subsection 7.3.1.

12. The AFS is controllable such that post-accident operation will not result in overfilling the intact steam generator(s).

13. The auxiliary feedwater pumps of the AFS are designed for operation when steam generator pressure is negligible and will not result in damage to the pumps or affect the ability of the system to deliver the required auxiliary feedwater flow. Such a condition can exist during startup or shutdown operation subsequent to an AFAS which starts the auxiliary feedwater pumps and fully opens the system isolation and control valves.

J. Inspection and Testing

1. All ASME B&PV Code Section III, Class 1 and 2 valves are designed, fabricated, and installed such that they are capable of being periodically tested in accordance with ASME OM Code.

2. Adequate clearances are provided for inservice inspection of the RCPB and the ASME B&PV Code Section III, Class 2 portions of the main steam, main feed, auxiliary feed, and blowdown systems

piping, in accordance with the provisions of Section XI of the ASME B&PV.

3. Biological shielding, where installed around the RCPB, is designed to afford access for inservice inspection as discussed in section 12.1.

4. The pressurizer manway is accessible for internal examination of the pressurizer.

K. Chemistry/Sampling

1. A sampling system which provides a means of obtaining remote liquid samples from the RCS for chemical and radiochemical laboratory analysis is provided. The sampling system is designed to allow for the following tests: corrosion product activity levels, dissolved gas, fission product activity, chloride concentration, coolant pH, conductivity levels, and boron concentration. The pressurizer steam space sample lines contain a 7/32-inch x 1-inch orifice as close to the pressurizer as possible. The sample system is designed as shown in subsection 9.3.2.

2. A system is provided to maintain the steam generator secondary water chemistry within the specifications described in section 10.3.5.1. The system incorporates steam generator blowdown, chemical addition and monitoring, and condensate purification. Refer to subsection 10.4.6.

3. Provisions are made to allow sampling of the RCS during shutdown cooling system operation.

4. Provisions are made to allow sampling of the RCS during startup.

L. Materials

1. The materials used for the containment and its internal structures are compatible with both the normal operating environment and the most severe thermal, chemical, and radiation expected during post-accident conditions (refer to section 3.11). Section 6.1 additionally describes material compatibility.

2. Precautions will be taken to prevent the following elements from being in contact with system surfaces in contact with reactor coolant:

   a. Lead or lead compounds

   b. Mercury or mercury compounds

   c. Halogens or compounds and solvents containing halogens

3. The use of the following materials will be minimized on surfaces normally in contact with reactor coolant:

   a. Sulfonated cutting oils

   b. Zinc metal or zinc compounds

   c. Magnesium metal

   d. Asbestos

   e. Aluminum

g. Copper acid etchants

h. Penetrants

4. The sample lines in contact with the reactor coolant, including welds, are designed such that the material is compatible with the fluid chemistry described in section 9.3.4.3.

5. The use of construction materials or protective coatings containing low melting point elements, particularly lead, mercury, and sulphur, where they could come in contact with the secondary systems is avoided.

6. The secondary system piping is designed to allow cleaning for the removal of foreign material and rust prior to operation and to prevent introduction of this material into the steam generator. Fluids other than demineralized water meeting steam generator chemistry requirements or materials used in cleaning operations in the secondary system piping will not be allowed to enter the steam generators.

7. Care will be taken to limit the amount of leachable halogens in insulation used on austenitic stainless steel in the RCS. Conformance to Regulatory Guides 1.36 and 1.37 is discussed in section 1.8.

8. No contaminants, except for cutting oils, will be left on any RCS component surface except for the time required to perform and evaluate the particular fabrication or inspection operation.

9. Field welding of the RCS piping assemblies and components will be done in accordance with a welding procedure or procedures by welders qualified to ASME Section IX requirements. Additionally, the control of sensitized stainless steel will utilize the guidance stated in Regulatory Guides 1.31 and 1.44 as stated in section 1.8.

M. System/Component Arrangement

1. The pressurizer and surge line is located entirely above the reactor coolant loops.

2. The pressurizer surge line equivalent L/D is less than 330.

3. The maximum pressure drop through the pressurizer spray line piping is less than 19 psi at a total flowrate of 375 gallons per minute and at a water temperature of 565F.

4. Flooding of the reactor cavity from systems other than the RCS is precluded by routing only RCS piping inside the reactor cavity and by providing gravity drainage of the cavity to the incore instrumentation sump.

5. The sample piping is designed to ensure a total transit time from the RCS of approximately 90 seconds.

6. The reactor coolant and secondary safety valve discharge piping are arranged and supported such

that the limiting loads are not exceeded for normal and relieving conditions.

7. Following a secondary line break, all steam paths downstream of the MSIVs can be isolated by their respective control systems following a MSIS actuation signal.

8. The MSIVs for each steam generator are arranged such that a maximum of 1534 cubic feet (total for two steam lines per steam generator) is contained in the piping between each steam generator and its associated MSIVs. This volume includes all lines off the main steam line up to their isolation valves.

9. The main steam lines are arranged such that a maximum of 3390 cubic feet is contained between the MSIVs and the turbine stop valves. This volume includes all lines off of the main steam line up to their isolation valves.

10. The main steam lines are headered together prior to the turbine stop valves but not upstream of the MSIVs, and a cross-connect line is provided which will maintain steam generator pressure differences within the following limits for all normal and upset conditions:

    a. 0 to 15% power operation pressure difference to be 1 psi.

    b. 15 to 100% power operation pressure difference to be 3 psi.

11. No automatically actuated valves are located upstream of the MSIVs except as required for supply to the steam-driven auxiliary feedwater pump. Provisions are made to prevent blowdown of both steam generators through the auxiliary feedwater supply headers in the event of a steam line break. The maximum flowrate per valve is 1.9×10^6 pounds per hour.

12. There are no isolation valves in the main steam lines between the steam generators and the secondary relief valves.

13. The main steam safety valves are arranged such that any condensate in the line between the safety valves and main steam line drains back to the main steam line.

14. All valves in the main steam line outside of the containment up to and including the MSIV are located as close to the containment wall as is practical (refer to section 10.3).

15. A 45° elbow facing downward is attached to each feedwater nozzle, to aid in the prevention of water hammer.

16. The main feedwater isolation valves are located outside of the containment as close to the containment wall as possible as required by NRC General Design Criterion 57, Closed System Isolation Valves.

17. The MFIVs for each steam generator are arranged such that a maximum of 527 cubic feet of fluid is contained in the piping between each steam generator and its associated isolation valves. This volume also includes the volumes between the redundant MFIVs. This volume includes the volumes of all lines off of the main feedwater lines downstream of the MFIVs up to their respective isolation valves, for which a mechanism exists for getting the fluid into the main feedwater line (e.g., gravity, flow, or flushing).

18. The auxiliary feedwater interface with the main feedwater system is located between the main feedwater isolation valves and the steam generator nozzles in the feedwater line to the downcomer:

    a. Auxiliary feedwater flow is directed to both downcomer nozzles.

    b. A Safety Class 2 check valve is located upstream of the interface to prevent backflow of auxiliary feedwater to the main feedwater system.

N. Radiological Waste

1. Actuator-operated valves in the RCS were supplied with double packing with lantern ring and leakoff connection unless they are diaphragm (packless) type. During original plant design, an evaluation determined that leakoffs piped to the reactor drain tank present a greater ALARA concern than capping

the valve leakoff. The cap has been designed as part of the RCS pressure boundary. The leakoffs for all RCS valves are capped except for the pressurizer spray control (RC-100E and 100F) and bypass (RC-236 and 237) valves. The pressurizer spray control and bypass valve leakoffs are piped to the reactor drain tank.

2. Provisions have been provided to process the steam generator blowdown water to radioactivity levels equivalent to that found in the condenser hotwell. Refer to subsection 10.4.6.

O. Overpressure Protection

1. Each primary safety valve inlet line was designed to pass 125% of the original minimum required safety valve capacity of 460,000 pounds per hour with a maximum pressure drop of 50 psi. This pressure drop of 50 psi is for piping and nozzle losses. (Pressure loss factor for pressurizer nozzle is K = 0.23 based on 6-inch Schedule 160 pipe.)

   For each Pressurizer Safety Valve a flow rate of 473,000 lb/hr of saturated steam at a setpoint of 2475 psia plus 3% accumulation ensures the current safety analysis requirements are met.

2. Each primary safety valve discharge line was designed to pass 125% of the original minimum required safety valve capacity with a maximum valve back pressure of 500 psig at the safety valve discharge during blowdown, assuming the discharge

tank is at 132 psig. The original minimum flowrate for each safety valve was 460,000 pounds per hour. For the common discharge line, the minimum safety valve flow was 1,840,000 pounds per hour (total flow of four valves). For each pressurizer safety valve a flow rate of 473,000 lb/hr of saturated steam at the setpoint of 2475 psia plus 3% accumulation ensures the current safety analysis requirements are met. Discharge tank design pressure is 130 psig. Maximum pressure of 132 psig is calculated from rupture disk burst pressure of 120 psig plus 10% tolerance.

3. Each main steam line is provided with ASME Code spring-loaded safety valves between the containment, and the isolation valves (refer to engineering drawings 01, 02, 03-M-SGP-002, -001). The total relieving capacity of these valves is equally divided between the main steam lines (refer to subsection 10.3.2).

4. The total relieving capacity of these valves is equally divided between the main steam lines (refer to subsection 10.3.2).

TABLE 5.1-4

(Sheet 1 of 9)

SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
1.	LPSI Pump Suction Isolation Valves SI-683 SI-692	a) Fails open	Elect. Malf., Mech. binding	Inability to double isolate pump suction from the RWT during shutdown cooling	Position indication in control room, Periodic testing	Redundant SCS flow path.	
		b) Fails closed	Elect. Malf., Mech. binding	None	Same as 1a	None required	Valve is required to be closed during shutdown cooling
2.	LPSI Pumps No. 1 or No. 2	Fails to pump	Elect. Malf., Bearing failure	No flow through one LPSI rain to RCS cold leg	No flow indication from F-307 or F-306. Periodic testing, Pump "Run" light	Redundant LPSI pump and containment spray pump will permit shutdown cooling although the cooling time will be extended	Shutdown cooling with one pump out of service will be extended from 24 hours to approxi-mately 56 hours.
3.	LPSI Pump Discharge Isolation Valves SI-435 SI-447	a) Fails open	Mech. binding	None	Periodic testing	None required	
		b) Fails closed	Mech. binding	Same as 2	Same as 2	Redundant SCS train	Valve is normally locked open at valve.
4.	SCS pumps re-circulation Isolation valves SI-664 SI-665 SI-668 SI-669	a) Fails open	Elect. Malf., Mech. binding	Possible diversion of flow, during shutdown cooling, to RWT	Position indication in control room, Periodic testing	Redundant series mini-flow isolation valves (SI-659, SI-660) prevent flow to RWT during shutdown cooling operation	These valves are closed during shutdown cooling operation
		b) Fails closed	Elect. Malf., Mech. binding	Loss of min-flow protection against operating one pump dead headed during refueling operation	Same as 4a	Redundant SCS train will not be affected	Valve is normally locked open in control room

TABLE 5.1-4
(Sheet 2 of 9)
SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
5.	Mini-flow Isolation Valves SI-659, SI-660	a) Fails open	Mech. binding, Contamination	None	Position indicator in control room, Periodic testing		SCS pumps recirculation valves (SI-664, SI-665, SI-668, SI-669) isolate SCS from RWT
		b) Fails closed	Mech. binding, Contamination	Loss of minimum-flow protection against operating one LPSI pump and one CS pump dead headed during refueling operation.	Same as 5a	Redundant SCS train will not be affected	Valve is normally locked open in control room
6.	CS Pump Suction Valves SI-184, SI-185	a) Fails open	Mech. binding	No effect on shutdown cooling	Periodic testing	None required	Valve is normally locked closed at valve
		b) Fails closed	Mech. binding	Unable to use one CS pump for shutdown cooling. See item 8.	No flow indication from F-348 or F-338, Periodic testing	The associated LPSI pump and redundant SCS train will not be affected.	
7.	CS pump Isolation Valves SI-104, SI-105	a) Fails open	Mech. binding	Inability to double isolate pump suction from the RWT during shutdown cooling	Periodic testing	Redundant SCS subsystem	Valve is normally locked open at valve
		b) Fails closed	Mech. binding	None during shutdown cooling	Same as 7a	None required during shutdown cooling. Redundant train will not be affected.	
8.	CS Pump No. 1 or No. 2	Fails to pump	Elect. Malf., Bearing failure	No flow from one CS pump through SCS	No flow indication from F-348 or F-338, Pump "Run" light, Periodic testing	Tandem LPSI pump and redundant SDC train assure shutdown cooling although cooling time will be extended.	See item 2
9.	CS Pump Discharge to SDCHX Valves SI-684, SI-689	a) Fails open	Elect. Malf., Mech. binding	None during normal shutdown cooling. During post LOCA shutdown cooling, inability to isolate one SCS flow path from one containment spray flow path.	Position indication in control room, Periodic testing	Redundant SCS and containment spray flow paths.	Valve is normally locked open in the control room.

TABLE 5.1-4
(Sheet 3 of 9)
SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
		b) Fails closed	Elect. Malf., Mech. binding	Same as 8	Low flow indication from F-306, F-307. Periodic testing, Position indication in control room.	Same as 9a	
10.	SDCHX Flow Regulator Valve SI-678, SI-679	a) Fails open	Elect. Malf., Mech. binding	During shutdown cooling, inability to operate CS pump in parallel with the LPSI pump	Position indicator in control room, Periodic testing	Redundant SCS train assures shutdown cooling	
		b) Fails closed	Elect. Malf., Mech. binding	Loss of flow from one CS pump during shutdown cooling	Same as 10a	LPSI pump and redundant SCS train assure shutdown cooling	Valve is normally locked open in the control room.
11.	CS Pump Bypass Valves SI-688, SI-693	a) Fails open	Elect. Malf., Mech. binding	None during shutdown cooling	Position indication in control room, Periodic testing	Redundant series isolation valves SI-671, SI-672 (normally closed during plant oper.) and SI-687, SI-695 (normally closed during shutdown cooling operation)	Valve is normally locked closed at control room.
		b) Fails closed	Elect. Malf., Mech. binding	None during normal shutdown cooling. During post LOCA shutdown cooling inability to align one CS subsystem to bypass SDCHX	Position indication in control room, Periodic testing	Redundant Containment Spray and shutdown cooling subsystems.	Valve is required to be closed during latter stages of shutdown cooling operation.
12.	Crossover Valves between LPSI Pump Discharge and SDCHX SI-685, SI-694	a) Fails open	Elect. Malf., Mech. binding	None	Position indication in control room, Periodic testing	None required	Valve is normally locked closed in control room
		b) Fails closed	Elect. Malf., Mech. binding	Inability to align one shutdown cooling train	Position indication in control room, High temperature indication from T-351 or T-352, Periodic testing	Redundant shutdown cooling train will not be affected.	

TABLE 5.1-4
(Sheet 4 of 9)
SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
13.	Shutdown Cooling HX No. 1 or No. 2	a) Loss of Cooling Water	Insufficient Cooling Water	Diminished ability of one subsystem to provide RCS temperature reduction	High temperature indication from T-303Y or T-303X, Periodic testing	Redundant heat exchanger	
		b) Cross Leakage	Corrosion	Leakage from SCS system to the Component Cooling System (CCS)	Radiation and/or level indication in CCS.	Leaking heat exchanger can be isolated. Redundant shutdown cooling subsystem will be unaffected.	
14.	SCS Bypass Flow Control Valves SI-306, SI-307	a) Fails open	Mech. binding, Elect. Malf.	Reduced reactor coolant flow through one shutdown cooling HX	Abnormal temperature indication from T-351 or T-352, Valve position indication, Periodic testing	Redundant SCS subsystem will assure shutdown cooling although cooling time will be extended.	
		b) Fails closed	Elect. Malf., Mech. binding	During initial stage of shutdown cooling, one SDC subsystem would pump excessively cooled water to the reactor core. Reduction in shutdown margin.	Same as 14a. Also, low temperature indication from T-351 or T-352	Operator can turn off the SCS subsystem. The RCS is pre-borated to provide sufficient shutdown margin.	The valve is normally locked open at control room
15	LPSI pump Throttle Valves SI-657, SI-658	a) Fails open	Elect. Malf., Mech. binding	Inability to regulate and maintain cooldown rate. See 14b.	Position indications in control room, Abnormal temperature from T-352 or T-351	Same as 14b	Valve is normally locked closed at control room
		b) Fails closed	Elect. Malf., Mech. binding	No flow through one shutdown cooling HX. Reduced cooling capability	Position Indications in control room, No Delta temperature across SDCHX as indicated by T-351 or T-352	Redundant shutdown cooling subsystem.	Three piece seal ring assembly in valve was replaced with one piece modified retaining ring. Valve does not isolate flow when closed.
16.	Shutdown Purification Valves SI-418, SI-419, SI-420, SI-421	a) Fails open	Corrosion, Mech. binding	None during shutdown cooling	Periodic testing	None required	Valve is normally locked closed at valve

TABLE 5.1-4
(Sheet 5 of 9)
SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
		b) Fails closed	Corrosion Mech. binding	Inability to remove contaminants from one SCS flow path during long-term cooling	Same as 16a. The failure to purify would be detected by periodic sampling	Redundant purification connections to other SCS subsystem	
17.	RWT Return Line Isolation Valves SI-460, SI-464	a) Fails open	Mech. binding	None	Periodic testing	Valves in series prevent inadvertent refilling of the RWT	
		b) Fails closed	Mech. binding	No effect on shutdown cooling. Inability to return water to the RWT until a repair is made.	Same as 17a	Redundant flow path exists to return refueling pool water to RWT prior to startup	Valve is normally locked closed at valve
18.	SDCHX Discharge Valves to LP Headers SI-686, SI-696	a) Fails open	Elect. Malf., Mech. binding	None	Position indication in control room, Periodic testing	None required	Valve is normally locked closed in control room
		b)Fails closed	Elect. Malf., Mech. binding	Isolation of one shutdown cooling HX.	High temperature indication from T-351 or T-352. Also same as 18a.	Redundant shutdown cooling subsystem will not be affected	
19.	Spray Header Isolation Valves for SDCHX SI-687, SI-695	a) Fails open	Elect. Malf., Mech. binding	Inability to align one shut down cooling subsystem to provide entry into shutdown cooling while allowing for simultaneous operation of one containment spray subsystem.	Position indication in control room	Redundant containment spray subsystem and shutdown cooling subsystem will not be affected. Shutdown cooling operation in faulted train not affected.	Valve is normally locked open in control room
		b) Fails closed	Elect. Malf., Mech. binding	No effect on shutdown cooling or refueling operations	Position indication in control room	None required	During shutdown cooling operations these isolation valves are closed. Redundant containment spray subsystem assures adequate containment spray capability.

TABLE 5.1-4
(Sheet 6 of 9)
SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
20.	Containment Spray Valves SI-671, SI-672	a) Fails open	Elect. Malf., Mech. binding	No effect on shutdown cooling or refueling operations	Position indication in control room, Periodic testing	The header isolation valves (SI-687 and SI-695) prevent coolant from being blown through CS nozzles.	Valve is opened by CSAS
		b) Fails closed	Elect. Malf., Mech. binding	Same as 20a	Same as 20a	None required	Valve is normally locked closed in control room and is required to be closed during shutdown cooling operation. Redundant containment spray subsystem assures adequate containment spray capability.
21	LPSI Valves SI-615, SI-625, SI-635, SI-645	a) Fails open	Elect, Malf., Mech. Binding	Inability to gradually warm up the shutdown cooling lines during the shutdown cooling alignment procedure.	Position indication in control room, Periodic testing	Redundant shutdown cooling subsystem will not be affected.	The safety injection piping and nozzles are designed for a limited number of thermal cycles such as could result from operating the Shutdown Cooling subsystem without prior warm up.
		b) Fails closed	Elect. Malf., Mech. binding	Inability to inject cooled coolant into one of the RCS cold legs.	Position indications in control room, Periodic testing	Redundant SCS train	
22.	SCS Return Crossover Valves SI-690, SI-691	a) Fails open	Elect. Malf., Mech. binding	Diversion of flow from discharge leg to suction leg of SCS without passing through the reactor core during shutdown cooling operations.	Position indication in control room, Periodic testing	Redundant shutdown cooling subsystem will not be affected	These valves are gradually closed once warmup and flow rate stability have been reached.
		b) Fails closed	Elect. Malf., Mech. binding	See 21a	Position indication in control room, Periodic testing	Same as 21a	See 21a

TABLE 5.1-4

(Sheet 7 of 9)

SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
23.	SCS Stop Valves for Suction Line SI-651, SI-652, SI-653, SI-654	a) Fails open	Elect. Malf., Mech. binding	None	Position indication in control room, Periodic testing	The redundant series valve ensures that SCS is protected from normal RCS pressure during power operation	Interlocks associated with the valves prevent overpressurization. These interlocks prevent the valves in the suction line of the SCS from being opened if RCS pressure exceeds 400 pisa. These valves automatically close if RCS pressure should rise above the accumulation pressure of the SCS suction line relief valves. This pressure is 700 psia
		b) Fails closed	Elect. Malf., Mech. binding	Prevention of decay heat removal from core via one SCS subsystem during normal shutdown cooling or long term cooling following a small LOCA	Position indication in control room, Periodic testing	Redundant shutdown cooling subsystem assures adequate cooling although cooling time will be extended.	
24.	SI Tank Isolation Valves SI-614, SI-624, SI-634, SI-644	a) Fails open	Elect. Malf., Mech. binding	Unable to isolate one SI tank from the RCS.	Position indication in control room, Periodic testing	None required	During shutdown cooling these valves are closed. However, if a LOCA occurs a SIAS will automatically open these valves. SCS interlock prevents initiation of shutdown cooling unless SIT pressure is reduced to a safe level. SIT pressure can be lowered by bleeding off nitrogen

TABLE 5.1-4
(Sheet 8 of 9)

SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
		b) Fails closed	Elect. Malf., Mech. binding	No effect during shutdown cooling	Valve position indications in control room, Periodic testing	None required	
25.	Shutdown Cooling Line Isolation Valves SI-655, SI-656	a) Fails open	Elect. Malf., Mech, binding	No effect on shutdown cooling	Valve position indication in control room, Periodic testing	None required during shutdown cooling operations	Valve is normally locked closed in control room
		b) Fails closed	Elect. Malf., Mech. binding	Inability to align one shutdown cooling subsystem for shutdown cooling	Valve position indication in control room, Periodic testing	Redundant shutdown cooling subsystem	
26.	PCPS Crossover Valves to SCS SI-256, SI-442, SI-455, SI-458	a) Fails open	Mech. binding	None	Periodic testing	Adjacent valve (SI-204, SI-443, SI-450, SI-454) provides back-up isolation.	Valve is normally locked closed
		b) Fails closed	Mech. binding	None during shutdown cooling. Isolation of the spent fuel pool cooling system from one train of the SCS prevents use of one SDCHX to assist in cooling the spent fuel pool when it contains 1-1/3 cores.	Periodic testing	PCPS connection with redundant SDCHX	One of the shutdown cooling HX may be aligned to the PCPS when no longer needed to maintain reactor coolant at refueling temperature
27.	Shutdown Cooling Line	a) One line clogs	Contaminants	Effective loss of one shutdown cooling subsystem	Low flow indications from F-307 or F-306, Periodic testing	Redundant shutdown cooling subsystem	Periodic sampling will monitor buildup of contaminants
		b) Limited Leakage in one train	Seal failure	Release of coolant and radioactivity outside of containment.	Local leak detection.	The leak can be isolated without affecting the redundant subsystem	
28.	Flow Indicator F-306, F-307 F-338, F-348	False indication	Elect. Malf.	Inability to control cooldown rate in affected train.	Comparison with redundant indicator, with all other process instrumentation and valve position indications consistent.	Redundant indicator	

TABLE 5.1-4

SHUTDOWN COOLING SYSTEM FMEA (CESSAR TABLE 5.4.7-3)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection*	Inherent Compensating Provision	Remarks and Other Effects
29.	Pressure Indicator P-307, P-306, P-303X, P-303Y	False indication	Elect. Malf	None	Periodic testing. Comparison with redundant indicator.	Redundant indicator	
30.	Temperature Indicator T-351, T-352, T-303X, T-303Y	False indication	Elect. Malf.	Inability to control cooldown rate in affected train.	Comparison with redundant indicators, with all other process instrumentation and valve position indications consistent. Periodic testing.	Redundant SCS train	

* The Method of Detection column is used to show that it is passible to detect the failure during or before Shutdown Cooling System operation.

5. The total secondary safety valve capacity per steam generator is sufficient to pass 19 x 10^6 pounds per hour steam flow at the valve set pressure (105% of steam generator maximum flow).

6. The maximum steam flow per secondary safety valve is no greater than 1.9 x 10^6 pounds per hour at 1000 psia.

7. Safety valve set pressure will be calculated in accordance with Article NC-7000 of ASME Section III, with the following being considered:

   a. Maximum allowable set pressure such that 110% of steam generator design pressure (1270 psia), which equals 1397 psia, is not exceeded.

   b. Valve accumulation of 3%.

   c. Valve set pressure error of $\pm$1%.

   d. Incorporation of the pressure drop between the steam generator nozzles and the safety valves.

8. The design pressure, temperature, and flow rating of the main steam piping and valves are greater than or equal to the design pressure, temperature, and flow rating of the steam generator secondary side.

P. Related Services

1. The pressure and thermal transients described in CESSAR Section 3.9.1.1 were utilized in the design of those portions of the RCS not within the CESSAR scope of design.

2. The portions of the RCPB outside the CESSAR design scope are either Safety Class 1 or meet the requirements of 10CFR50.55a.

3. The fire protection system provided to protect the RCS is discussed in subsection 9.5.1.

4. Systems have been provided for the detection of reactor coolant leakage from unidentified sources. The intent and guidance of Regulatory Guide 1.45 were utilized as described in paragraph 5.2.5.1.

5. A safety-related nitrogen accumulator system has been provided to supply motive power to the ADV actuators should the normal pneumatic (either air or nitrogen) supply fail to be available.

6. Oil-free Instrument Air will be supplied to the ADV's at a static air pressure of 100 to 125 psig meeting air quality standards (ISA-S7.3) with an approximate dewpoint of -40 degrees F. Full flow conditions will provide Instrument Air at no less than 81 psig. Piping shall be designed to withstand at least 150 psig.

7. The containment structure has been designed and sized to accommodate the RCS arrangement shown in CESSAR Figures 5.1.3-1 and 5.1.3-2.

Q. Environmental

1. For the non-C-E-supplied NSSS components, the demonstration of environmental qualification

envelopes for any or all of these buildings is provided in section 3.11.

2. The containment pressure and temperature transients resulting from the LOCA meets criteria specified in CESSAR Section 6.2.1.5.

3. A containment ventilation system has been provided to handle the RCS heat losses to the containment as described in subsection 9.4.6.

R. Mechanical Interaction Between Components

1. The following components have been designed to withstand the loads arising from the various normal operating and design basis events.

   a. The main steam piping, supports, and restraints

   b. The steam generator steam and feedwater nozzles

   c. The MSIVs and the MSIV bypass valves and supports

   d. Main steam safety valves

   e. The main feedwater piping, supports, and restraints

   f. MFIVs and supports

   g. Blowdown piping, supports, and restraints

   h. Blowdown isolation valves

2. Structures are provided to mate with C-E-supplied component supports to restrain and support RCS components. The loading conditions specified in CESSAR Section 3.9.3.1 are utilized in the design of

the supporting structures. The loads at the support/structure interface locations under normal, upset, emergency, faulted, and test conditions, taking into account the local characteristics of specific structures at the support/structure interfaces, were provided by C-E.

3. The loadings imposed by connecting system piping on RCS nozzles under normal, upset, emergency, faulted, and test conditions are less than the design loads for these nozzles. Combustion-Engineering reviewed the loads developed on the PVNGS and confirmed that the piping nozzles are within code allowable stress limits.

5.2 INTEGRITY OF REACTOR COOLANT PRESSURE BOUNDARY

This section discusses the measures employed to provide and maintain the integrity of the Reactor Coolant Pressure Boundary (RCPB) throughout the facility's design lifetime. The reactor coolant pressure boundary is defined in accordance with ANSI N18.2-1973. Included are all pressure-containing components such as pressure vessels, piping, pumps, and valves which are:

A. Part of the Reactor Coolant System, or

B. Connected to the Reactor Coolant System, up to and including the following:

   1. The outermost containment isolation valve in piping which penetrates the containment;

   2. The second of two valves normally closed during reactor operation in piping which does not penetrate the containment;

5.2.1 COMPLIANCE WITH CODES AND CODE CASES

5.2.1.1 Compliance with 10CFR50.55a

PVNGS RCS pressure boundary components are listed in table 5.2-1. Additionally, those components not in C-E's scope of supply will comply with the ASME Code addenda required by 10CFR50.55a (refer to table 5.2-2). The preservice inspection will be conducted in accordance with 10CFR 50.55a(g). The inserice inspection (ISI) program will be updated to a more recent code during each inspection interval as determined to be practical in accordance with the requirements of 10CFR 50.55a(g)(4).

5.2.1.2 Applicable Code Cases

Reactor Coolant Pressure Boundary components are fabricated in accordance with the ASME code Section III.

Unless otherwise stated, Combustion Engineering, Inc., complied with Regulatory Guides 1.84 and 1.85 in determining suitable ASME Code Cases. Similarly, Ansaldo complied with Regulatory Guides 1.84, 1.85 and 1.147 in determining suitable ASME Code Cases for the steam generators and Doosan complied with Regulatory Guide 1.84 in determining suitable ASME Code cases for analysis of the reactor vessel closure head, CEDMs and RVLMS housings. Code Cases not included in the Regulatory Guides, may be used with specific authorization from the Commission under 10CFR 50.55a. Additionally, refer to section 1.8 for a discussion relative to Regulatory Guides 1.84, 1.85, and 1.147.

Tables 5.2-3 and 5.2-4 indicate code cases applicable to PVNGS.

5.2.2 OVERPRESSURE PROTECTION

5.2.2.1 Design Bases

Appendix 5B presents the design bases for sizing the overpressurization protection system. The loss of load transient which is used to size the primary safety valves is not intended to be used as a design transient for any other NSSS equipment.

5.2.2.2 Design Evaluation

Chapter 15 provides the functional design evaluation of the overpressurization protection system. In this analysis, the adequacy of the overpressure protection system to maintain secondary and primary operating pressures within 110% of design is clearly demonstrated for the loss of load analysis. The analytical model used in the analysis is discussed in Chapter 15, Section 15.2, Loss of External Load.

Table 15.2.3-3 of Chapter 15 lists the assumptions used in the loss of condenser vacuum analysis. These assumptions are chosen so that they tend to maximize the required pressure relieving capacity of the primary and secondary valves. The analysis demonstrates that sufficient relieving capacity has been provided so that when acting in conjunction with the reactor protective system the safety valves will prevent the pressure from exceeding 110% of the design pressure.

Table 5.2-1

REACTOR COOLANT SYSTEM

PRESSURE BOUNDARY CODE REQUIREMENTS

Component	Supplier	ASME Boiler & Pressure Vessel Code, Section III, Nuclear Power Plant Components		
		Class	Edition	Addenda

5.2.2.3 Piping and Instrumentation Diagrams

Engineering drawings 01, 02, 03-M-SGP-002 and -001 show the secondary safety valves, and engineering drawings 01,02, 03-M-RCP-001, -002 and -003 show the primary safety valves. In addition, the piping and instrumentation diagram showing the reactor drain tank is given in 01, 02, 03-M-CHP-001, through -005.

5.2.2.4 Equipment and Component Description

The primary safety valves are direct acting, spring loaded, stainless steel valves with enclosed bonnets. These valves are mounted on the top of the pressurizer. For further description of these valves, refer to Section 5.4.13. A schematic drawing of the primary safety valve is given in Figure 5.4-6. Valve parameters are given in Table 5.4-40.

Primary safety valve operation is characterized by a sharp pop at the set pressure. This sharp opening is produced by two stages of reaction working together to produce a continuous action. The initial lift is produced when the steam pressure under the disc exceeds the spring force. The escaping steam reacts against the upper guide ring and pushes the disc up to a high lift. The reaction of the deflected steam against the underside of the disc lifts it higher on an accumulation of pressure. The valve reaches a lift in excess of full bore lift within an accumulation of 3 percent above the set pressure.

As the system pressure drops, the valve disc settles to a moderate lift, and closes sharply with a blowdown of approximately 5 percent of the set pressure.

5.2.2.4.1 Transients

The primary safety valves are designed to withstand the following transients without failure or malfunction:

A. 650°F to 375°F in 50 seconds and return to 650°F in 2000 seconds for 5 cycles (Loss of secondary pressure)

B. 100°F to 400°F and return to 100°F at a rate of 100°F/hr with concurrent pressure changes from 400 psig to 2250 psig and returning to 400 psig in step changes for 200 cycles. (Plant leak test).

C. ± 10°F step change from 653°F for 1,030,000 cycles. (Plant loading and unloading, ± 10% step load, normal plant variation).

D. 75°F to 653°F and return to 75°F at a rate of 200°F/hr with pressures at saturation levels for 500 cycles. (Plant heat up and cool down).

Note: Heat up and cool down are separate transients, each beginning at steady state conditions.

E. Pressurize to 1.5 times set pressure at 100°F-200°F for 10 cycles plus number of hydros conducted prior to valve shipment. (Hydrostatic test).

F. 480 cycles from closed to full open to closed. (Turbine Trip)

5.2.2.4.2 Environment

The primary safety valves are designed to operate in the following environmental conditions.

5.2.2.4.2.1 Normal Environment

A. 120°F maximum

B. Relative humidity of 20 - 90%

5.2.2.4.2.2 Main Steam Line Break (One occurrence)

350°F maximum Superheated steam/air mixture for 12 minutes followed by saturated steam/air mixture.

5.2.2.4.3 Main Steam Safety Valves

The main steam safety valves are direct acting, spring loaded, carbon steel valves. The valves are mounted on each of the main steam lines upstream of the steam line isolation valves, and outside containment. A schematic drawing of the main steam safety valves is given in Figure 5.4-7. The valve parameters are given in Table 5.4-41. For a description of overpressure protection equipment and components for the main steam system refer to Subsection 10.3.2.

5.2.2.4.3.1 Main Steam Safety Valve Operation. The operation of these valves is similar to the primary safety valves, Section 5.2.2.4.2.

5.2.2.4.3.2 Transients. The main steam safety valves are designed to withstand the following transients without failure or malfunction.

A. 565°F to 75°F in 60 seconds for 5 cycles (loss of secondary pressure).

B. Pressure changes from 0 psig to 1375 psig, at a temperature range of between 100°F to 200°F for 200 cycles (secondary side leak test).

C. ± 10°F step change from 553°F, 10^6 cycles (normal plant variations).

D. 75°F to 565°F and return to 75°F at a rate of 100°F/hr with pressures at saturation levels for 500 cycles (plant heatup and cool down).

Note: Heat up and cool down are separate transients, each beginning at steady state conditions.

E. Pressurize to 1.5 times set pressure at 100°F - 200°F for 10 cycles plus number of hydros conducted prior to valve shipment (hydrostatic test).

F. 480 opening and closing cycles to full stem movement (turbine trip).

5.2.2.4.3.3 Environment. The main steam safety valves are designed to operate in the following environmental conditions:

5.2.2.4.3.3.1 Normal Environment

A. 120°F maximum.

B. Relative humidity 20 – 90%.

5.2.2.4.3.3.2 Main Steam Line Break (One Occurrence)

A. 330°F maximum for 3 minutes.

B. Relative humidity of 100%.

5.2.2.4.4 Safety Injection System Relief Valves SI-169 and SI-469

These relief valves are direct acting, spring loaded, stainless steel valves with enclosed bonnets. The design parameters of these valves are:

set pressure	2485 psig
rated flow	15 gpm
water chemistry	0 - 4 weight percent boric acid
throat area	.023 in^2
design temperature	650°F

5.2.2.4.4.1 Valve Operation. As the set pressure is reached, the disc raises off the nozzle seat. This lift continues until the valve is fully open at 10 percent accumulation. The lift decreases as pressure drops until the

seat and disc contacts and seals closed. The valve is fully closed at a maximum of 10% below set pressure (10% blowdown).

5.2.2.4.4.2 Transients. These relief valves are designed to withstand the following transients without failure or malfunction.

A. 60°F to 400°F in 5 seconds, 400°F to 60°F in 15 minutes for 55 cycles.

B. 60°F to 350°F in 15 minutes, 350°F to 60°F in 2.9 hours for 500 cycles.

C. 120°F to 60°F in 5 seconds, 60°F to 120°F in 15 minutes for 660 cycles.

5.2.2.4.4.3 Environment. These relief valves are designed to operate in the following environmental conditions.

A. 122°F maximum.

B. 95% relative humidity at 60°F to 80°F.

C. Fixed moisture content equivalent to 95% RH at 80°F at temperatures above

5.2.2.4.4.4 Material Specifications. Material specifications for the primary safety valves are given in Table 5.4-40.

Material specifications for the main steam safety valves are given in Table 5.4-41.

5.2.2.5 Mounting of Pressure Relief Devices

5.2.2.5.1 Location of Pressure Relief Devices

The design bases for the assumed loads for the primary and secondary side pressure relief devices of the steam generator are described in paragraph 3.9.3.3. Pressure relief devices for the reactor coolant system comprise the four pressurizer safety valves shown in engineering drawing 13-P-RCF-114. These discharge to the reactor drain tank by common header. Engineering drawings 01-P-SGF-118, -155 and 01, 02, 03-P-SGF-401 provide design installation details for the pressure relief devices mounted on the steam lines which are part of the secondary side of the steam generator.

5.2.2.5.2 Design Bases for Mounting of RCPB Pressure Relief Devices

The RCPB pressure relief devices are mounted and installed as follows:

A. Each discharge pipe is supported as close to the valve as practical to transfer transient discharge load to the adjacent structure.

B. There is no rigid restraint in the vertical directions. Thermal vertical load is transferred to pressurizer shear lugs by pipe stubs. The piping system moves up or down with the pressurizer during heat up or cool down. Weight of the piping system is carried by seven variable and two constant spring supports.

C. The support provided on the discharge piping is as close as possible to each safety and relief valve discharge nozzle so that forces and moments during operating plant conditions (normal, upset, emergency, and faulted) will not jeopardize the integrity of the valves, the inlet lines to the valves, and the nozzles on the pressurizer.

D. Pipe breaks are postulated in the high energy piping at the pressurizer nozzle, long radius elbow, and valve flange point (refer to figure 3.6-12). Pipe breaks are not postulated in the safety relief valve discharge piping (i.e., piping from the valve discharge flange to the reactor drain tank). This piping is not considered to be high energy piping because it operates less than 2% of normal plant operating time. Discharge piping is classified as moderate energy piping as defined in paragraph 3.6.2.1.2. Through-wall cracks are not postulated since this piping is adequately separated from other safety-related active systems subject to impairment by such failures.

Dynamic analysis for seismic and valve discharge loadings have been performed to verify the design of the support configuration.

5.2.2.5.3 Pressurizer Safety and Relief Analysis - Loading Criteria and Methods of Analysis

The pressurizer safety lines and relief line are shown as an isometric projection in engineering drawing 13-P-RCF-114.

5.2.2.5.3.1 Loading Conditions. For loading combinations, see tables 3.9-5 and 3.9-6.

5.2.2.5.3.2 Pressure. Pressure loading is identified as membrane design pressure. The membrane design pressure is used in connection with the longitudinal pressure stress calculations in accordance with the ASME B&PV Code. The design pressure is 2485 psig for Class 1 piping and 550 psig for B31.1 piping.

5.2.2.5.3.3 Weight. A weight analysis is performed by applying a 1.0g load downward on the complete piping system. The piping is assigned a distributed mass or weight as a function of its properties. This method provides a distributed loading to the piping system as a function of the weight of the pipe and contained fluid and insulation during normal operating conditions. Hydrotest conditions are also considered.

5.2.2.5.3.4 Seismic. The structural response due to the OBE loadings is analyzed by normal mode theory using the ME 101 computer program. The lumped parameter multidegree-of-freedom model is used along with the appropriate response spectra input for the computer solution. These spectra are the envelope of the in-structure response spectra at the piping support just

downstream of the valve, combined with the response spectra of the pressurizer nozzle. A response spectrum is applied in the horizontal (x and z) and vertical (y) directions.

5.2.2.5.3.5 Thrust.

5.2.2.5.3.5.1 Hydraulic Forces of Thrust. The pressurizer safety valve discharge piping system is a closed system in which no sustained reaction force from a free discharging jet of fluid can exist. However, transient hydraulic forces are imposed at various points in the piping system from the time a safety valve begins to open until steady flow is completely developed. Since no water loop seal is applied, no transient hydraulic forces can occur due to the liquid being forced through the safety valve and then being accelerated down the piping system.

5.2.2.5.3.5.2 Structural Analysis of Thrust. The dynamic structural solution for the thrust loading is obtained using a modified-predictor-corrector-integration technique and normal mode theory.

Subprogram RVDFT (relief valve discharge flow transients) is used in this analysis and predicts the transient flows resulting from actuation of a safety relief valve under normal operating conditions. It also predicts the resulting piping loads to be used as dynamic forcing functions for structural design of discharge piping and its supporting components. The computation is based on finite difference solutions by the method of effluent characteristics. The computed transient

pressure, velocity, and density are then used to calculate loads on bends and pipe runs.

5.2.2.5.4 Pressurizer Safety and Relief Analysis - Summary of Results

5.2.2.5.4.1 Stress Allowables.

Stainless Steel at 460F:	SA 358 Type 304 (Class 1) SA 376 Type 304 (Class 1)
Type 304 at 700F:	B31.1 Code Allowable = 15,980 psi = S_h
Type 304	Class 1 Code Allowable = 15,900 psi = S_m

5.2.2.5.4.2 Stress Summary of Highest Stress Points. Stresses calculated for the highest stress points are within code allowable values.

5.2.2.5.4.3 Anchor Support Points. See engineering drawing 13-P-RCF-114.

5.2.2.5.5 Main Steam Safety Valve Analysis

Engineering drawings 01-P-SGF-118,-115 and 01, 02, 03-P-SGF-401 provide design and installation details.

5.2.2.5.5.1 Valve Forces and Reactor Load Paths. Two conditions were considered in the stress analyses of the safety valve installations; namely, the dynamic effects of the safety valve opening phase and the steady-state flow condition reached

after the valve has opened and is exhausting into the stack. During the valve opening time, dynamic forces due to the hydraulic transients in the valve are compensated by the reaction forces of the header supports via the header. When the valve has opened, and the steam is exhausting into the stack, the valve forces are balanced due to the tee and piston design, and the discharge thrust is compensated by the reaction forces of the stack support structure.

The force versus rise time curve for the safety valve and the valve natural period resulted in a dynamic load factor of 1.22, which was conservatively increased to 1.25. Each valve has a thrust load of 30,500 pounds for a line pressure of 1318 psi; hence, the header reaction load per valve is 38,125 pounds.

It was conservatively assumed that each valve opened simultaneously, resulting in stresses in the headers and support loads within code allowable values.

5.2.2.5.5.2 Loading Conditions. For design loading conditions, see tables 3.9-5 and 3.9-6.

5.2.2.5.5.3 Stress Summary of Safety Valve Headers. The stresses for the main steam line headers are within code allowable values.

Load Cases:

A. Upset Condition

Weight + longitudinal pressure + seismic inertia (OBE) + safety valve thrust

B. Emergency Condition

Weight + longitudinal pressure + seismic inertia (OBE) + fast valve closure

C. Stress Due to Thermal Plant Condition

Thermal expansion + seismic anchor movement

5.2.2.6 Applicable Codes and Classification

Refer to table 3.2-1 and Section 5.2.1.2 for codes and classifications applicable to PVNGS.

5.2.2.7 Material Specification

Refer to Section 5.4.13. In addition, for material specifications related to the secondary system overpressurization protection refer to subsection 10.3.2.

5.2.2.8 Process Instrumentation

Process instrumentation for the overpressurization protection equipment that is associated with the Reactor Coolant System is shown in engineering drawings 01, 02, 03-M-RCP-001, -002 and -003 and described in Chapter 7. Instrumentation associated with pressurizer relief discharge is described in Section 18.II.D.3. In addition, refer to engineering drawings 01, 02, 03-M-RCP-001, -002 and –003 and 01, 02, 03-M-SGP-002 and -001 for the instrumentation related to primary and secondary system overpressurization protection, respectively.

5.2.2.9 System Reliability

Reliability of the main steam system reliefs is discussed in the interface Section 5.1.4. The primary safety valves are passive, spring actuated mechanisms, and cannot fail closed if setpoint pressure is exceeded. The operational reliability of the primary safety valves is assured by:

- Stringent compliance with ASME III and XI Code for safety valves.
- Conservative design criteria.
- Selection of a vendor with proven experience and expertise.
- Accounting for thermal cycling during valve operation.
- Technical Specifications.

Also, refer to subsections 5.1.5 and 10.3.2 for a discussion of secondary system overpressure protection reliability.

5.2.2.10 Testing and Inspection

Testing and inspection of primary and secondary valves are governed by ASME OM Code. Testing and inspection of the secondary safety valves is discussed in sections 3.9, 14.2, and in the Technical Specifications.

5.2.2.11 Overpressure Protection During Low Temperature Conditions

Overpressure protection of the RCS during low-temperature conditions is provided by the relief valves located in the shutdown cooling system (SCS) suction lines. Section 5.4.7 provides a description of the SCS. The SCS is schematically shown on the Safety Injection System (SIS) engineering drawings 01, 02, 03-M-SIP-001, -002 and -003. The electrical schematic for the SCS isolation valves is provided in the SIS P&ID. The SCS relief valves are shown in the engineering drawings listed above and described in paragraph 5.4.7.3.

Alignment of the SCS relief valve to the RCS is provided via plant procedures to ensure RCS overpressure protection for all temperatures below the pressure-temperature (P-T) operating curve limits corresponding to the metal temperature of at least RT_{NDT} + 90°F at the limiting reactor vessel beltline location.

Overpressure protection is provided by the pressurizer safety valves described in subsection 5.2.2.

5.2.2.11.1 Design Criteria

A discussion follows of the criteria considered in the design of the overpressure mitigating system to provide low temperature overpressure protection (LTOP) for the RCS.

5.2.2.11.1.1 Credit for Operator Action. No credit is taken for operator action for 10 minutes after the operator is made aware that a transient is in progress.

5.2.2.11.1.2 Single Failure. In the LTOP mode, each SCS relief valve is designed to protect the reactor vessel given a single failure in addition to a failure that initiated the pressure transient. The event initiating the pressure transient is considered to result from either an operator error or equipment malfunction. The SCS relief valve system is independent of a loss of offsite power. Each SCS relief valve is a self actuating spring-loaded liquid relief valve which does not require control circuitry. The valve opens when the RCS pressure exceeds its setpoint.

The redundant SCS suction line trains between the RCS and SCS relief valves meet the single failure criteria as described in paragraph 5.4.7 and table 5.1-4. No single failure of an isolation valve or its associated interlock will prevent one relief valve from performing its intended function.

5.2.2.11.1.3 Testability. Periodic testing of the SCS isolation valves is defined in the Technical Specifications.

5.2.2.11.1.4 Seismic Design and IEEE 270 Criteria. The SCS suction line relief valves, isolation valves, associated interlocks, and instrumentation are designed to Seismic Category I requirements as discussed in subsections 3.2.1, paragraph 5.4.7 and table 3.2-1. The interlocks and instrumentation associated with the SCS suction isolation valves satisfy the appropriate portions of IEEE 279 criteria as discussed in paragraphs 5.4.7, 7.6.2.1.1 and 7.6.2.2.1.

5.2.2.11.2 Design and Analysis

In demonstrating that the SCS relief valves meet the criteria listed in paragraph 5.2.2.11.1, the following additional information is provided.

5.2.2.11.2.1 Limiting Transients. Transients during the low temperature operating mode are more severe when the RCS is operated in the water-solid condition. Addition of mass or energy to an isolated water-solid system produces increased system pressure. The severity of the pressure transients depends upon the rate and total quantity of mass or energy addition. The most limiting transients initiated by a single operator error or equipment failure are:

A. An inadvertent safety injection actuation (mass input).

B. A reactor coolant pump start when a positive steam generator to reactor vessel ΔT exists (energy input)

The transients were determined as most limiting by conservative analyses which maximize mass and energy additions to the RCS. In addition, the RCS is assumed to be in a water-solid condition at the time of the transient; such a condition has been noticed to exist infrequently during plant operation since the operator is instructed to avoid water-solid conditions whenever possible.

The limiting LTOP mass addition transient results from the simultaneous operation of two HPSI and three charging pumps, along with the simultaneous addition of energy from decay heat

and the pressurizer heaters. Calculated results from the mass addition transient show a peak pressure, given a core power (including instrument uncertainty) of 4070 Mwt, of less than 499 psia.

The limiting LTOP energy addition transient results from startup of a single reactor coolant pump when the steam generator fluid temperature is 100 degrees F higher than the coolant temperature in the reactor vessel. This temperature difference is the maximum allowed by technical specification during the LTOP mode. In addition to considering the energy addition to the RCS from the steam generator secondary side, energy addition from decay heat, the reactor coolant pump and all pressurizer heaters were also included. In this analysis the steam generators were assumed to be filled to the zero power, normal water level. For conservatism, the secondary water, both around and above the U-tubes, was assumed to be thermally mixed in order to maximize the energy input to the primary side. This assumption is conservative since as a result of the temperature distribution within the steam generator during the transient, the water inventory above the tubes is practically isolated thermally from the heat transfer region. Therefore the heat transfer rate, and thus the primary side pressure, is not sensitive to the secondary side water level as long as the tubes are covered.

On the basis of experience, the ΔT value of 100°F used in the analysis is much larger than any ΔT that might be expected during plant operation. This maximum allowable ΔT of 100°F

will prevent pressurizer pressure from exceeding the minimum P-T limit allowed for the lowest system temperature during the LTOP mode of operation. During RCS cooldown using the shutdown cooling system, coolant circulating with the reactor coolant pumps serves to cool the steam generator to keep the temperature difference between the reactor vessel and the steam generator minimal. Procedures will direct the operator to maintain the ΔT below approximately 20°F.

LTOP transients have not been analyzed for the simultaneous startup of more than one reactor coolant pump (RCP). Such operation is procedurally precluded since the operator starts only one RCP at a time and a second RCP is not started until system pressure is stabilized. Additionally, there is an LTOP transient alarm that should indicate that a pressure transient is occurring. Accordingly, the second RCP would not be started.

Technical Specifications require that the operator not start an RCP if the ΔT exceeds 100°F. However, as mentioned above, administrative procedures will ensure that the ΔT is maintained below approximately 20°F.

The calculated peak reactor coolant system pressure resulting from the limiting LTOP energy addition transient, given a core power (including instrument uncertainty) of 4070 MWt, is less than 505 psia.

The results of the analyses show that the use of either SCS relief valve will provide sufficient pressure relief capacity to mitigate the most limiting LTOP events identified above.

5.2.2.11.2.2 Provision for Overpressure Protection. During heatup, RCS pressure is maintained below the maximum pressure for SCS operation until RCS cold leg temperature exceeds the LTOP enable temperature. If SI-651 and 653 or SI-652 and 654 SCS suction isolation valves are open and RCS pressure exceeds the maximum pressure for SCS operation, an alarm will notify the operator that a pressurization transient is occurring during low temperature conditions. Either SCS relief valve will terminate inadvertent pressure transients occurring during RCS temperature below the LTOP enable temperature. Above the maximum LTOP temperature, overpressure protection is provided by the pressurizer safety valves when the SCS relief valve is isolated from the RCS.

During cooldown whenever RCS cold leg temperature is below the applicable temperature for LTOP, the SCS relief valves provide the necessary protection. If the SCS is not aligned to the RCS before cold leg temperature is decreased to the maximum temperature requiring LTOP, an alarm will notify the operator to open the SCS suction isolation valves (SI-651, 652, 653, 654). The maximum temperature requiring LTOP is based upon the evaluation of the applicable P-T curves. However, the SCS can not be aligned to the RCS until the pressure is below the maximum pressure allowing SCS operation (see paragraph 5.4.7).

These LTOP conditions are within the SCS operating range. Technical Specifications require the SCS suction line isolation valves to be open when operating in the LTOP mode. Also, Technical Specifications ensure that appropriate action is

taken if one or more SCS relief valves are out of service during the LTOP mode of operation.

Either SCS relief valve will provide sufficient relief capacity to prevent any pressure transient from exceeding the isolation interlock setpoint.

5.2.2.11.2.3 Equipment Parameters. The SCS relief valves are spring-loaded liquid relief valves with sufficient capacity to mitigate the most limiting overpressurization event. Pertinent valve parameters are as follows:

Parameter

Nominal Setpoint 467 psig

Accumulation 10%

Capacity 5635 (@ 10% acc) gal/min

Since each SCS relief valve is a self actuating spring-loaded liquid relief valve, control circuitry is not required. The valve will open when RCS pressure exceeds its setpoint.

The SCS relief valves are sized, based on an inadvertent safety injection actuation signal (SIAS) with full pressurizer heaters operating from a water-solid condition. The SIAS assumes simultaneous operation of two HPSI pumps and three charging pumps with letdown isolated. The resulting flow capacity requirement for water is less than 4000 gpm. The analysis in Section 5.2.2.11.2.1 assumed that either SCS relief valve relieved water at this rate. The design relief capacity of each of two SCS relief valves as supplied by the valve

manufacturer meets the minimum required relief capacity which contains sufficient margin in relieving capacity for even the worst transient. The SCS relief valves are Safety Class 2, designed to Section III of the ASME Code.

5.2.2.11.2.4 Administrative Controls. Administrative controls necessary to implement the LTOP provisions are limited to those controls that open the SCS isolation valves. Before entering the low temperature region for which overpressure protection is necessary, RCS pressure is decreased to below the maximum pressure required for SCS operation. Once the SCS is aligned, no further specific administrative procedural controls are needed to ensure proper overpressure protection. The SCS will remain aligned whenever the RCS is at low temperatures and the reactor vessel head is secured. As designated in Table 7.5-1, indication of SCS isolation valve position is provided.

5.2.3 REACTOR COOLANT PRESSURE BOUNDARY MATERIALS

5.2.3.1 Material Specifications

A list of specifications for the principal ferritic materials, austenitic stainless steels, bolting and weld materials, which are part of the reactor coolant pressure boundary is given in Table 5.1-2.

Studies have shown that the irradiation induced mechanical property changes of SA-533B materials can depend significantly upon the amount of residual elements present in the compositions, namely; copper, phosphorous, and vanadium. It

has also been found that residual sulfur affects the initial toughness of SA-533B materials. Specific controls are placed on the residual chemistry of reactor vessel plates and the as-deposited welds used to join these plates to limit the maximum predicted increase in the reference temperature (RT_{NDT}, which is discussed in Section 5.3.1.6) and to limit the extent of the reactor vessel beltline. The beltline is defined by Appendix G of 10CFR50. In addition, for steam generator tubing, RCS piping nozzles and pressurizer heater sleeve plugs, SB-163, SB-166, or Alloy 690 is used at PVNGS.

In addition, pressurizer heater sleeve plugs are also fabricated from SA-479 TP316 material.

For CEDM and RVLMS housings, the pressure housings are manufactured from SA-213TP316, SA-479 Type 316, SA-182, F347, Code Case N-4-11, and SB-166 Alloy 690 materials.

Relief Request 17 allows use of a code alternative for mechanical nozzle seal assemblies (MNSAs). The NRC approved Relief Request 17 in a safety evaluation dated October 01, 2001. The APS submittal (dated April 01, 2001, letter no. 102-04551) requesting Relief Request 17, committed to the following actions for all approved MNSA applications (RCS system hot leg pipe nozzles and RCS pressurizer heater sleeves) should MNSAs need to be used in any of the Palo Verde units:

(1) As required by IWA-4820, a VT-I preservice inspection will be performed on all MNSA installations in accordance with IWB-2200.

(2) During plant startup (Mode 3) after initial MNSA installation and during subsequent plant restarts following outages, the pressurizer heater sleeve MNSAs will be pressure tested and inspected for leakage. To ensure quality of installation and continued operation with the absence of leakage, a pressure test with visual inspection will be performed on each of the installed MNSAs with the insulation removed. The test will be performed as part of plant re-start and will be conducted at normal operating pressure with the test temperature determined in accordance with the PVNGS Pressure and Temperature Limits as stated in PVNGS Technical Specifications. Additionally, VT-3 exams will be performed to verify general structural and mechanical condition of the MNSAs.

(3) This request for alternative is for up to two cycles of operation, unless additional relief is requested and approved. Prior to exceeding two operating cycles, installed MNSAs will be removed and appropriate repair or replacement activities will be implemented.

(4) APS will verify pipe wall thickness prior to machining MNSA bolt holes to further assure that adequate pipe wall reinforcement exists.

5.2.3.2 Compatibility with Reactor Coolant

5.2.3.2.1 Reactor Coolant Chemistry

Controlled water chemistry is maintained within the RCS. Control of the reactor coolant chemistry is the function of the CVCS which is described in section 9.3.4. Water chemistry limits applicable to the RCS are given in section 9.3.4.3.

The possibility of reactor coolant leaking onto the reactor vessel head and causing corrosion of the RCS pressure boundary has been evaluated by Combustion Engineering. Testing has demonstrated that reactor coolant leakage onto surfaces of the RCS pressure boundary will not adversely affect the integrity of the pressure boundary when exposure is limited to short periods of time. The requirements of Generic Letter 88-05 have been implemented to ensure that boric acid corrosion does not lead to degradation of the RCS pressure boundary components. Therefore, the RCS has a very low probability of developing abnormal leakage, rapidly propagating failure or gross rupture.

5.2.3.2.2 Materials of Construction Compatibility with Reactor Coolant

The materials of construction used in the RCPB which are in contact with reactor coolant are designated by an "a" in Table 5.1-2. These materials have been selected to minimize corrosion and have previously demonstrated satisfactory performance in other existing operating reactor plants.

5.2.3.2.3 Compatibility with External Insulation and Environmental Atmosphere

The System 80 NSSS design scope for insulation on the RCS is limited to the major components of the RCS. The insulation provided within the System 80 design scope is of the stainless steel reflective type. This insulation minimizes contamination in the event of chemical solution spillage.

Insulation provided for the steam generators is also of the stainless steel reflective type. Further discussion is provided in section 6.2.2.2.

In addition, tables 6.2.2-1 and 6.2.2-2 present a list of insulation utilized on other piping and equipment inside the containment.

5.2.3.3 Fabrication and Processing Ferritic Materials

5.2.3.3.1 Fracture Toughness

5.2.3.3.1.1 Components in the C-E, Ansaldo or Doosan Scope of Supply.

NSSS Components. Fracture toughness requirements for Reactor Coolant Pressure Boundary components are established in accordance with the ASME Boiler and Pressure Vessel Code, Section III. Data from these tests will be available after the required testing has been performed and may be examined upon request at the appropriate manufacturing facility. Fracture toughness testing was performed in accordance with applicable ASME Code and Addenda.

C-E and Ansaldo complied with 10CFR Part 50 Appendix G, "Fracture Toughness Requirements" as enacted July 1973 with the following exceptions:

A. Section II, "Definitions," A. "ASME Code." The applicable Code Edition and Addenda for each System 80 plant will be as specified in 10CFR Part 50.55a, "Codes and Standards"

B. Section III, "Fracture Toughness Tests", B.5 Mill test reports containing fracture toughness test results do not include a certification that the tests have been performed in accordance with the requirements of 10CFR50 Appendix G. However, the test reports are certified to conform with the requirements of the applicable ASME Code Edition and Addenda specified in the component purchase order. Appendix G to 10CFR50 references the ASME Code for fracture toughness testing requirements; therefore, conformance with the applicable Code meets the intent of Section III B.5.a. Conformance with the Code also entails the certification requirements set forth in item III B.5.b., c., and d.

C. Section III, C.2. Excess material for the test specimens representing reactor vessel beltline weldments is not necessarily from the actual production plates, although it is from the same P-number classification. The same heat of filler material and the same production welding conditions

as those used in joining the corresponding shell materials are used. Material prepared for the reactor vessel material surveillance program, however, is from the actual production plate used in the reactor vessel. Details of the materials surveillance program are found in Section 5.3.1.6.

Consideration is given to the effects of irradiation on material toughness properties in the core beltline region of the reactor vessel to assure adequate fracture toughness for the service lifetime of the vessel. Refer to Section 5.3.1.6 for discussion concerning prediction of irradiation effects and the material surveillance program. In addition, C-E complied with the guidance of Regulatory Guide 1.2, "Thermal Shock to Pressure Vessels".

Testing and measuring equipment for fracture toughness tests for the reactor vessel, replacement reactor vessel closure head, steam generators, pressurizer, piping and reactor coolant pumps are calibrated in accordance with Subarticle NB2360 of the ASME Code, Section III.

Fracture toughness data for the reactor coolant pressure boundary components for Palo Verde Unit 1 are presented in tables 5.2-5 through 5.2-31, data for Unit 2 are presented in tables 5.2-5A through 5.2-31A, and data for Unit 3 are presented in tables 5.2-5B through 5.2-31B. A schematic of the reactor vessel beltline region showing weld seam numbers and plate code numbers is shown in figure 5.2-6.

Charpy transition curves (including upper and lower shelf levels for energy absorbed, lateral expansion, and percent cleavage fracture) for the six belt line plate materials, obtained from specimens tested in the weak direction (transverse orientation), are shown in figure 5.2-1 for Unit 1, figure 5.2-2 for Unit 2, and figure 5.2-3 for Unit 3. The personnel performing the Charpy and drop height impact testing were qualified by schooling, training, and many years of experience. Their qualification to perform work was certified by qualified supervisory personnel. Records of the certification of personnel are maintained and available for review at C-E's Chattanooga facility.

Individuals performing inservice fracture toughness tests shall be qualified by training and experience and shall have demonstrated competency to perform the tests in accordance with written procedures and ASME Code, Section III, Subarticle NB-2300, Fracture Toughness Requirements for Materials. The recommendations for qualification of nuclear power plant inspection, examination, and testing personnel that are included in ANSI N45.2.6-1973 are generally acceptable and provide an adequate basis for complying with Paragraph III.B.4 of Appendix G, 10CFR50.

All beltline welds are fabricated using submerged arc and shielded metal arc technique.

a. See Code Case N-4-11, Special Type 403 Modified Forgings or Bars, Section III, Division 1, Class 1 and CS

b. Lowest service temperature per NB-2332, required Cv values per Table 2332(a)-1, nominal wall thickness > 3/4 inch but $\leq$ 1-1/2 inches

c. 6(Six) motor housings supplied as spare loose parts

5.2.3.3.1.2 Components in the Doosan Scope of Supply

NSSS Components. Fracture toughness requirements for Reactor Coolant Pressure Boundary components, replacement Reactor Vessel Closure Heads (RVCH), replacement Control Element Drive Mechanisms (CEDM) and Reactor Vessel Level Monitoring System (RVLMS) pressure housings are established in accordance with the ASME Boiler and Pressure Vessel Code, Section III. Fracture toughness testing was performed in accordance with applicable ASME Code and Addenda.

Post-weld heat treatment of the test welds[a] is as follows:

Stress relief - 1150F ±50F for 40 hours

Furnace cool to 800F.

Plates used to fabricate test welds[a] are SA-533 Grade B, Class 1, quenched and tempered (12-inch thickness) on both sides of the weld. Test welds are made with the same P number classification for both base metals as used for the fabrication of the beltline region. The same type of filler material and welding conditions are also used.

Test specimen for the longitudinal seams are not removed from excess material and welds in the vessel shell course following completion of the longitudinal weld joint. However, the procedure utilized in fabricating these seams are qualified in

---

a. All test welds are performed in accordance with ASME Boiler and Pressure Vessel Code, Section III, Article NB-4330 (General Requirements for Welding Procedure Qualification Tests).

accordance with ASME Boiler and Pressure Vessel Code, Section III, Article NB-4330 (General Requirements for Welding Procedure Qualification Tests). Fracture toughness data from these procedure qualification tests are given in table 5.2-7.

5.2.3.3.1.3 Components Not in the C-E Scope of Supply. All non-NSSS ASME Section III, Code Class 1, valves and piping are of austenitic stainless steel construction, and are, therefore, exempt from impact testing in accordance with Subsection NB-2311(a)(6).

5.2.3.3.2 Control of Welding

5.2.3.3.2.1 Avoidance of Cold Cracking. C-E complied with the recommendations of Regulatory Guide 1.50, Control of Preheat Temperature for Welding of Low Alloy Steel, May 1973, as discussed below.

Paragraph C.1.b implies that the qualification plates are an infinite heat sink that would instantaneously dissipate the heat input from the welding process. The qualification procedure consists of starting the welding at the minimum preheat temperature. Welding is continued until the maximum interpass temperature is reached. At this time, the test plate is permitted to cool to the minimum preheat temperature and the welding is restarted. Preheat temperatures utilized for low alloy steel are in accordance with Section III of the ASME Code. The maximum interpass temperature utilized is 500°F.

The Paragraph C.2 recommendation is considered an unnecessary extension of procedures which apply to low-alloy steel welds, meeting ASME Code Sections III and IX requirements. The recommendations of Regulatory Guide 1.50 are met by complying with Paragraph C.4. The soundness of all welds is verified by ASME Code acceptable examination procedures.

With regard to Regulatory Guide 1.43, major components are fabricated with corrosion resistant cladding on internal surfaces exposed to reactor coolant. The major portion of the material protected by cladding from exposure to reactor coolant is SA-533, Grade B, Class 1 plate which, as discussed in the Regulatory Guide, is immune to underclad cracking. Cladding of SA-508, Class 2 forging material is performed using low-heat-input welding processes controlled to minimize heating of the base metal. Low-heat-input welding processes are not known to induce underclad cracking. This discussion is also applicable to RCPB components not in the C-E scope of supply.

5.2.3.3.2.2 Regulatory Guide 1.34. Regulatory Guide 1.34 recommends controls to be applied during welding using the electroslag process. The electroslag process is not used in the fabrication of any RCPB components. Therefore, the recommendations of this guide are not applicable. This discussion is also applicable to RCPB components not in the C-E scope of supply.

5.2.3.3.2.3 Regulatory Guide 1.71. C-E complied with the recommendations of Regulatory Guide 1.71 except for the differences indicated below.

Performance qualifications for personnel welding under conditions of limited accessibility are conducted and maintained in accordance with the requirements of ASME B&PV Code Sections III and IX. A requalification is required when (1) any of the essential variables of Section IX is changed, or (2) when authorized personnel have reason to question the ability of the welder to satisfactorily comply with the applicable requirements. Production welding is monitored for compliance with the procedure parameters, and welding qualifications are certified in accordance with Sections III and IX. Further assurance of acceptable welds of limited accessibility is afforded by the welding supervisor assigning only the most highly skilled personnel to these tasks. Finally, weld quality, regardless of accessibility, is verified by the performance of the required non-destructive examinations. This discussion is also applicable to RCPB components not in the C-E scope of supply.

5.2.3.3.3 Nondestructive Examination of Tubular Products

5.2.3.3.3.1 Components in the C-E Scope of Supply. C-E complied with the requirements of Regulatory Guide 1.66 for steam generator tubing. The non-destructive examination requirements imposed by C-E for other tubular products are those specified by Section III of the ASME code rather than this guide.

5.2.3.3.3.2 Components Not in the C-E Scope of Supply. Tubular products for non-NSSS components of the RCPB are non-destructively examined in accordance with the requirements of ASME Code, Section III, Division 1, 1974 Edition and Addenda through Summer 1974.

5.2.3.4 Fabrication and Processing of Austenitic Stainless Steel

5.2.3.4.1 Avoidance of Stress Corrosion Cracking

5.2.3.4.1.1 Avoidance of Sensitization.

5.2.3.4.1.1.1 Components in the C-E Scope of Supply

NSSS Components. Fabrication of RCPB components is consistent with the recommendations of Regulatory Guide 1.44 as described in items A through D except for the criterion used to demonstrate freedom from sensitization. The ASTM A 708 Strauss Test is used in lieu of the ASTM A 262 Practice E, Modified Strauss Test, to demonstrate freedom from sensitization in fabricated, unstabilized, stainless steel.

A. Solution Heat Treatment Requirements

   All raw austenitic stainless steel material, both wrought and cast, used in the fabrication of the major NSSS components in the RCPB, is supplied in the annealed condition as specified by the pertinent ASTM or ASME Code; viz., 1900-2050F for 1/2 to 1 hour per inch of thickness and water quenched to below 700F. The time at temperature is determined by the size and type of component.

Solution heat treatment is not performed on completed or partially-fabricated components. Rather, the extent of chromium carbide precipitation is controlled during all stages of fabrication as described below.

B. Material Inspection Program

Extensive testing on stainless steel mockups, fabricated using production techniques, has been conducted to determine the effect of various welding procedures on the susceptibility of unstabilized 300 series stainless steels to sensitization-induced intergranular corrosion. Only those procedures and/or practices demonstrated not to produce a sensitized structure are used in the fabrication of RCPB components. The ASTM standard A 708 (Strauss Test) is the criterion used to determine susceptibility to inter-granular corrosion. This test has shown excellent correlation with a form of localized corrosion peculiar to sensitized stainless steels. As such, ASTM A 708 is utilized as a go/no-go standard for acceptability.

As a result of the above tests, a relationship was established between the carbon content of 304 stainless steel and weld heat input. This relationship is used to avoid weld heat-affected-zone sensitization as described below.

C. Unstabilized Austenitic Stainless Steel

The unstabilized grades of austenitic stainless steels with carbon content of more than 0.03% used for components of the RCPB are 304 and 316. These materials are furnished in the solution annealed condition. Exposure of completed or partially-fabricated components to temperatures ranging from 800F to 1500F is prohibited.

Duplex, austenitic stainless steels containing more than 5 FN delta ferrite (weld metal, cast metal, weld deposit overlay), are not considered unstabilized since these alloys do not sensitize, that is form a continuous network of chromium-iron carbides. Specifically, alloys in this category are:

CFM Cast stainless steel (delta ferrite 5FN to 33FN)

CF8 Cast stainless steel (delta ferrite 5FN to 33FN)

308, 309 Singly and combined stainless steel weld filler metals

312, 316 (delta ferrite controlled to 5FN-23FN depositied)

In duplex, austenitic/ferritic alloys, chromium-iron carbides are precipitated preferentially at the ferrite/austenite interfaces during exposure to temperatures ranging from 800-1500F. This precipate

morphology precludes intergranular penetrations associated with sensitized 300 series stainless steels exposed to oxygenated or fluoride environments.

D. Avoidance of Sensitization

Exposure of unstabilized austenitic 300 series stainless steels to temperatures ranging from 800 to 1500F will result in carbide precipitation. The degree of carbide precipitation, or sensitization, depends on the temperature, the time at that temperature, and also the carbon content. Severe sensitization is defined as a continuous grain boundary chromium-iron carbide network. This condition induces susceptibility to intergranular corrosion in oxygenated aqueous environments, as well as those containing fluorides. Such a metallurgical structure will rapidly fail the Strauss test ASTM A 708. Discontinuous precipitates (i.e., an intermittent grain boundary carbide network) are not susceptible to intergranular corrosion in a PWR environment.

Weld heat affected zone sensitized austenitic stainless steels (which will fail the Strauss Test, ASTM A 708) are avoided by careful control of:

- Weld heat input to less than 60 kJ/in
- Interpass temperature to 350F maximum
- Carbon content

Homogeneous or localized heat treatment in the temperature range 800-1500F is prohibited for unstabilized austenitic stainless steel with a carbon content greater than 0.03% used in components of the RCPB. When stainless steel safe ends are required on component nozzles, fabrication techniques and sequencing require that the stainless steel piece be welded to the component after final stress relief. This is accomplished by welding an Inconel overlay on the end of the nozzle. Following final stress relief of the component, the stainless steel safe end is welded to the Inconel overlay, using Inconel weld filler metal.

5.2.3.4.1.1.2 Components Not in the C-E Scope of Supply. Regulatory Guide 1.44 is discussed in section 1.8.

5.2.3.4.1.2 Avoidance of Contaminants Causing Stress Corrosion Cracking.

5.2.3.4.1.2.1 Components in C-E Scope of Supply.

NSSS Components. Specific requirements for cleanliness and contamination protection are included in the equipment specifications for components fabricated with austenitic stainless steel. The provisions described below indicate the type of procedures utilized for NSSS components to provide contamination control during fabrication, shipment, and storage as required by Regulatory Guide 1.37.

Contamination of austenitic stainless steels of the 300 type by compounds which can alter the physical or metallurgical structure and/or properties of the material is avoided during all stages of fabrication. Painting of 300 series stainless steels is prohibited. Grinding is accomplished with resin or rubber-bounded aluminum oxide or silicon carbide wheels which were not previously used on materials other than austenitic alloys. Outside storage of partially-fabricated components is avoided and in most cases prohibited. Exceptions are made for certain components provided they are dry, completely covered with a waterproof material, and kept above ground.

Internal surfaces of completed components are cleaned to produce an item which is clean to the extent that grit, scale, corrosion products, grease, oil, wax, gum, adhered or embedded dust or extraneous materials are not visible to the unaided eye. Cleaning is effected by either solvents (acetone or isopropyl alcohol) or inhibited water (hydrazine). Water will conform to the following requirements:

Halides	
Chloride (ppm)	<0.60
Fluoride (ppm)	<0.40
Conductivity (mmhos/cm)	<5.0
pH	6.0-8.0
Visual clarity	No turbidity, oil, or sediment

To prevent halide-induced intergranular corrosion which could occur in aqueous environment with significant quantities of

dissolved oxygen, flushing water is inhibited via additions of hydrazine. Results of tests have proven these inhibitors to be completely effective. Operational chemistry specifications restrict concentrations of halide and oxygen both prerequisites of intergranular attacks (Refer to Section 9.3.4).

5.2.3.4.1.2.2 Components Not in the C-E Scope of Supply. Requirements for cleanliness and contamination protection are included in the equipment specifications for components fabricated with austenitic stainless steel. Additionally, detailed vendor procedures are reviewed for acceptability of cleaning materials, cleaning equipment and procedures, and quality assurance provisions. The provisions described below indicate the type of criteria utilized for non-NSSS components to provide contamination control during fabrication, shipment, storage, and installation.

Contamination of austenitic stainless steels of the 300 type by compounds that can alter the physical or metallurgical structure and/or properties of the material was avoided during fabrication, shipment, storage, construction, testing, and operation. Grinding was accomplished with aluminum oxide or silicon-carbide grinding wheels that had not previously been used on ferritic materials.

Restrictions are placed on lubricants, marking materials, tapes, penetrants, water, solvents, and other materials used in the fabrication, marking, cleaning, examination, and testing.

Internal surfaces of completed components were cleaned to produce a clean item to the extent that grit, scale, corrosion

products, grease, oil, wax, gum, adhered or embedded dust, or extraneous materials were not visible to the unaided eye. Cleaning was effected by either solvents or water. Acetone, alcohol, or other organic solvents were specified to contain less than 200 ppm by weight of inorganic halogens and not more than 1% total halogens (organic and inorganic by weight). Water conformed to the following requirements:

pH at 25C	5.5 to 8.0
Inorganic halogen (ppm)	≤1
Sulfide (ppm)	≤1
Conductivity (μmho/cm)	≤3
Total dissolved solids (ppm)	≤5

Prior to shipment, RCPB components were packaged in such a manner that they were protected from the weather, dirt, wind, water spray, and any other extraneous conditions expected to be encountered during shipment and subsequent site storage. The environment within the package and/or component was maintained clean and dry. In some instances, dessicants were utilized.

Site-related activities for storage, construction, cleaning, and testing were governed by ANSI N45.2.1-1973 as interpreted by Regulatory Guide 1.37 and ANSI N45.2.2-1972 as interpreted by Regulatory Guide 1.38. Refer to section 1.8 for a discussion of these regulatory guides. Established procedures include:

A. Receiving and storage of materials in accordance with ANSI N45.2.2.

B. Vendor-supplied piping subassemblies and components were shop-cleaned, inspected, and sealed by the vendor per approved cleaning procedures. Source inspection verified and documented that cleaning was done in accordance with the approved cleaning procedure and that the cleanliness was achieved. Onsite quality control procedures monitored the vendor-installed seals up to the point at which the piping subassemblies or components were installed and openings were closed. Care was taken during installation of components and piping subassemblies to preclude introduction of foreign materials into the interiors of the piping subassemblies and components.

C. Field-fabricated austenitic stainless steel piping (2 inches and smaller) was fabricated from vendor-cleaned materials. During fabrication, care was taken to preclude the introduction of foreign materials into the interior of the subassemblies. After fabrication, the subassemblies were precleaned by blowing out with clean, dry, oil-free, compressed air and/or drawing clean, white, lint-free cloth through the interior of the subassembly. This precleaning was performed to minimize the flushing time required during the preoperational proof flush.

D. After erection completion, piping and components were pressure-tested as required by the code. Austenitic stainless steel systems were hydrostatically tested

with demineralized water as defined in ANSI N45.2.1. Specific water requirements are:

pH at 25C (corrected for N_2H_4 and CO_2)	5.5 to 8
Chloride (ppm)	<1
Fluoride (ppm)	<1
Sulfide (ppm)	<1
Conductivity at 25C (μmho/cm) (corrected for dissolved CO_2, NH_3, and N_2H_4)	<3
Silica (ppm)	<0.05
Turbidity (Jackson Turbidity Unit/Formazin Turbidity Unit)	<1

In addition, the water should be inhibited with 30-50 ppm hydrazine (N_2H_4) if testing is anticipated to take an extended period (>5 days) of time.

E. Preoperational proof flushes and final proof flushes were conducted in accordance with ANSI N45.2.1. Water quality for flushing is identical to that listed for pressure testing in listing D above.

F. Following proof flushes and hydrostatic testing, components were drained and placed in wet layup using water meeting the following requirements prior to hot functional testing:

Halides	
Chloride (ppm)	<0.15
Fluoride (ppm)	<0.10
Conductivity (μmho/cm) (corrected for dissolved CO_2, NH_3, and N_2H_4)	<2.00
pH (corrected for CO_2 and N_2H_4)	6.9-8.0
Visual Clarity	No turbidity, oil, or sediment

In addition, the water is inhibited with 30-50 ppm hydrazine (N_2H_4).

Leachable chlorides and fluorides in nonmetallic insulation materials in contact with stainless steel were controlled by inclusion of Regulatory Guide 1.36 requirements in the purchase specifications.

Operational chemical specifications restrict concentrations of halide and oxygen, both of which contribute to intergranular corrosion attacks (refer to subsection 10.3.5).

5.2.3.4.1.3 Characteristics and Mechanical Properties of Cold-Worked Austenitic Stainless Steels for RCPB Components. Cold-worked austenitic stainless steel is not utilized for components of the RCPB.

5.2.3.4.2 Control of Welding

5.2.3.4.2.1 Avoidance of Hot Cracking.

A. Components in C-E Scope of Supply

NSSS Components

1. Regulatory Guide 1.31

In order to preclude microfissuring in austenitic stainless steel welds, RCPB components are consistent with the recommendations of Regulatory Guide 1.31 as follows:

The delta ferrite content of A-No. 8 (Table QW-442 of the ASME Code, Section IX) austenitic stainless steel welding materials, except Type 16-8-2 and welding materials for weld metal overlay cladding, used in the fabrication of components of the reactor coolant system, is controlled to 5FN-23FN. The delta ferrite determination is carried out using a calibrated magnetic measuring instrument and undiluted weld deposits produced in accordance with the American Welding Society Specification AWSA.5.4 or another comparable procedure for other than coated electrodes. The ferrite requirement is met for each heat, lot or heat/lot combination of weld filler material. For submerged arc welding processes, the delta ferrite determination for each wire/flux combination may

be made on a production or simulated (qualification) production weld, and the delta ferrite content is controlled to 3FN-23FN.

"Delta ferrite contents of consumable inserts, rod or wire filler metal used with the gas tungsten and welding process, and deposits made with the plasma arc welding process may be determined from their chemical compositions using a constitutional diagram for austenitic stainless steel welding material."

As an alternative the delta ferrite determination may be carried out on production welds by magnetic measurement methods. The average delta ferrite content must be 3FN or more with no single reading less than 1FN when measured at four equally spaced positions. Each production weld greater than 1 inch in thickness is examined while welds of thicknesses 1 inch and less are tested in accordance with a sampling plan.

2. Regulatory Guide 1.34

   Regulatory Guide 1.34 is discussed in Section 5.2.3.3.2.2.

3. Regulatory Guide 1.71

   Regulatory Guide 1.71 is discussed in Paragraph 5.2.3.3.2.3.

B. Components Not in C-E Scope of Supply

In order to preclude microfissuring in austenitic stainless steel, PVNGS design is consistent with the recommendations of Regulatory Guide 1.31 except as noted in section 1.8.

5.2.4 INSERVICE INSPECTION AND TESTING OF REACTOR COOLANT PRESSURE BOUNDARY

Details of the inservice inspection program are included in the Technical Specifications.

Class I components and supports are designed to meet the access requirements of Section XI of the ASME Boiler and Pressure Vessel Code.

In the case of the reactor vessel, all internals except the flow baffle are removable. Their removal makes the entire inner surface of the vessel, as well as the weld zones of the internal load-carrying structural attachments, available for the surface and volumetric inspections. The closure head is available for inspection whenever it is removed, and its removal also makes available the vessel closure flange, closure stud holes and ligaments, and the closure studs and nuts. Each control element drive mechanism is removable as a unit through a closure at the top of its housing.

For interim inspections of the reactor vessel primary coolant nozzle to shell welds and inner radii, the two outlet nozzles are accessible from inside the reactor vessel without removal of the vessel internals. The outlet nozzles are accessible

either from outside the vessel or from inside after removal of the vessel internals.

Manways are provided for those inspections which must be made internally on the steam generators and pressurizer. Access holes are provided in the support skirt of the steam generators to allow examination of the tube sheet support stay cylinder welds. The steam generators are capable of being examined in accordance with the guidance of Regulatory Guide 1.83.

The reactor coolant pumps may be disassembled, if necessary, for inspection.

5.2.5 REACTOR COOLANT PRESSURE BOUNDARY LEAKAGE DETECTION SYSTEMS

The reactor coolant system is constructed such that no leakage is expected to occur through the principal boundary members such as the pressure vessel walls, coolant piping walls, reactor coolant pump bowls, and valve bodies. However, a certain amount of coolant loss is expected through other pressure boundary components that cannot practically be made completely leak tight. The latter would include valve packing and stems, isolation valve seats, pump and valve seals as well as the steam generator tubes and tubesheet. To the extent practical, these potential leak pathways have been identified and routed to collection tanks or sumps so as not to obscure the presence of unanticipated reactor coolant pressure boundary leakage.

As required by 10CFR50, Appendix A, General Design Criterion 30, means have been provided for the detection of reactor coolant leakage from the reactor coolant system. The purpose of the reactor coolant leakage detection equipment is to alert operators to the existence of leakage above acceptable limits so that corrective actions, including reactor shutdown if necessary, may be taken to prevent further degradation of the boundary. Except as noted in this section, the leakage detection systems meet the criteria of Regulatory Guide 1.45.

The appropriate CESSAR and CESSAR SER commitments relative to RCS leakage detection equipment and methods have been incorporated into the following discussion. Therefore, the following description of the RCS leakage detection systems is the safety analysis report of record and supersedes any CESSAR text related to this topic.

5.2.5.1 Limits for Reactor Coolant Leakage

The terms pressure boundary leakage, unidentified leakage, identified leakage, and RCS pressure isolation valve leakage are all formally defined in the Technical Specifications. The Technical Specifications contain operational limits for these various types of leakage including separate limitations on steam generator tube leakage and pressure isolation valve leakage. These limits and bases are consistent with the positions of Regulatory Guide 1.45 as well as the assumptions used in the safety analyses and the interface requirements for RCS design and fabrication given in UFSAR 5.1.4.H.

Operability and testing requirements for equipment used to detect pressure boundary leakage and unidentified leakage shall also be provided in the Technical Specifications. The operability of leakage detection equipment and the associated surveillance requirements for RCS leakage provide reasonable assurance that the reactor can be shut down and depressurized before substantial degradation of the reactor pressure boundary occurs.

The surveillance requirements established in the Technical Specifications for operational leakage are commensurate with the safety significance of the leakage and comply with the applicable portions of the ASME Boiler and Pressure Vessel Code.

5.2.5.2 Identified Leakage

The amount of identified leakage from the Reactor Coolant System can be determined by adding up the individual contributions from the paths described below. Indicators and alarms associated with all of the identified leakage pathways are provided in the control room.

5.2.5.2.1 Pressurizer Safety Relief Valves

The relief from the primary safety valves located on the pressurizer is routed to the reactor drain tank. A temperature sensor with indication and alarm capability in the main control room is provided on each relief discharge line downstream of the valve. Safety valve leakage would be indicated by a pronounced temperature increase downstream of the leaking valve

accompanied by less severe increases in the other temperature indicators. Indirect indication of leakage may be evidenced by increased pressure, temperature and level in the reactor drain tank. Each relief discharge line also contains an acoustic monitor to provide indication of safety relief valve position as described in Section 18.II.D.3.

5.2.5.2.2 Reactor Coolant Pump Seals

As described in Section 5.4.1.2, the reactor coolant pumps are equipped with hydrodynamic seals containing three stages, each capable of retaining full RCS pressure. During normal operation, the reactor coolant system operating pressure is nominally decreased through the first two seals to within 330 psid of the pressure in CVCS volume control tank. The third seal, also known as the vapor seal or the backup seal, prevents leakage to the containment atmosphere and maintains sufficient pressure to direct the controlled seal bleed-off flow to the volume control tank. Leakage past the vapor seal would produce an increase in seal face leak-off into containment which is collected and routed to the reactor drain tank. Such leakage would be detected by a decrease in the second stage seal outlet pressure and an increased level in the reactor drain tank. Both parameters are indicated and alarmed in the control room.

Reactor coolant pump seal controlled-bleed off which returns to the volume control tank is not considered reactor coolant leakage. Loss of reactor coolant into the nuclear cooling water system via the high-pressure seal injection coolers is

classified as intersystem leakage and is discussed below in Section 5.2.5.4.

5.2.5.2.3 Component Vents and Drains

In addition to the pressurizer relief valve discharge and reactor coolant pump seal face leak-off described above, leakage of reactor coolant and connected systems is also possible from the following sources:

- Safety injection piping safety relief valve discharges
- RCP seal high-pressure filter drains
- Regenerative heat exchanger drain
- Pressurizer spray control and bypass valve drains
- Reactor coolant loop drains
- Auxiliary pressurizer spray valve drains
- Reactor vessel head seal leakage
- Reactor head and pressurizer vent valve discharge or leakage

The pressurizer relief is routed directly to the reactor drain tank and enters the tank via a submerged sparging nozzle. The rest of the identified leakages described above are collected in a header which goes to the reactor drain tank as well. Both the pressurizer relief sparger and the drain collection header enter the reactor drain tank below the normal water level in order to faciliatate condensate of two-phase fluids. Leakage of the component vents and drains would then be indicated by an

increase in reactor drain tank temperature, pressure, and level.

5.2.5.2.4 Leakage Through Steam Generator Tubes or Tubesheet

The increase in secondary side radioactivity concentrations produced by reactor coolant leakage through steam generator tubes/tubesheet would be indicated by radiation monitors located in the condenser air removal system, the steam generator blowdown, and the main steam system. Routine radiochemical analysis of steam generator water samples would also indicate leakage of reactor coolant into the secondary system. See Section 11.5 for radiation monitoring system details such as monitor range, sensitivity, communications, remote indication/control, and alarms. The magnitude of the identified leak rate through the steam generators is determined by calculation.

5.2.5.3 Detection of Unidentified Leakage

This section describes the four principal methods for detecting and quantifying unidentified leakage and pressure boundary leakage.

5.2.5.3.1 Inventory Method

The Reactor Coolant System (RCS) and the Chemical and Volume Control System (CVCS) together constitute a semi-closed system. Under roughly steady state power conditions, the net inventory of coolant contained in the RCS and the letdown and charging portions of the CVCS will be constant providing that:

- Reactor coolant pump seal controlled bleed-off flow is lined up to the volume control tank
- No makeup from the RWT/RMWT is added to the volume control tank or charging pump suction
- Letdown is not diverted to the CVCS Holdup Tank
- No RCS chemistry sampling is in progress.

In this configuration, coolant leakage will be seen as a deflection of level in the pressurizer and volume control tank. If this semi-closed RCS configuration is maintained for a sufficiently long period of time, nominally 2 hours, the sensitivity of the pressure and volume control tank level instrumentation will permit determination of reactor coolant leakage at rates much lower than 1 gpm. While the system is “isolated” as described above, transient changes in letdown flow rate or reactor coolant inventory can normally be accommodated by the capacitance in the pressurizer and volume control tank. The test will be discontinued if pressure or inventory control is jeopardized during its performance.

5.2.5.3.2 Sump Level Method

As described in section 9.3.3, leakage of liquid water and condensed liquid from steam leakage in the containment are collected and routed to the containment east and west radwaste sumps and to the reactor cavity sump. The levels of these three sumps in the reactor drain system are monitored continuously in the control room. A control room alarm will be generated on high level or if the rate of level increase

corresponds to a sump inflow greater than 1 gpm for one hour. Alarms may also result from other abnormal sump activity such as excessive sump pump run time. This sump level and flow monitoring equipment is qualified to perform its intended function following seismic events that do not require plant shutdown.

5.2.5.3.3 Containment Atmosphere Radiation Monitor Particulate Channel

Located in the auxiliary building, radiation monitor RU-1 provides the third and fourth methods of detecting unidentified pressure boundary leakage. This process monitor continuously draws a containment atmosphere sample into a closed loop that returns the sample back to containment. The sample flow passes through a particulate filter, an I-131 sampler (charcoal), and gaseous sample chamber in order to measure particulate, iodine, and gaseous radioactivity levels. The particulate and gaseous channels in particular are used to monitor RCS leakage. Section 11.5.2 provides a detailed description of the monitor including sampling assembly design, principle of detection, signal processing, communications, alarms, range, sensitivity, and accuracy. Both instrument channels are qualified to remain functional when subjected to a Safe Shutdown Earthquake (SSE).

In the event of reactor coolant leakage into the containment atmosphere, dissolved or otherwise entrained noble gases in the coolant will evolve out of solution. The particulate daughter products from these nuclides will be collected on the RU-1 filter paper, and the associated detector will use the increase

in count rate to indicate the activity concentration. The sensitivity of the particulate channel for reactor coolant leak rate detection depends on the magnitude of the normal baseline leakage into the containment and reactor coolant activity. Shortly after startup and also during steady operation with low levels of defect fuel, the concentration of radioactivity in the reactor coolant may not be sufficient to permit detection of a 1 gpm leak within 1 hour. Therefore, position C.5 of Regulatory Guide 1.45 has been exempted for this method of reactor coolant leak detection. The particulate setpoint given in Technical Specifications is established so that, in an isolated containment atmosphere at equilibrium concentration with an existing 1 gpm leak and 0.1% defect fuel, a 1 gpm increase in leak rate would roughly provide a 10% increase in indicated concentration within one hour. This method is further limited by the fact that large uncertainties are possible when determining the associated leak rate by calculation. Therefore, in the event of a high alarm or increasing trend on this channel, station procedures shall direct the operator to perform a water inventory balance within 1 hour in order to determine the equivalent RCS leak rate.

5.2.5.3.4 Containment Atmosphere Radiation Monitor Gas Channel

In radiation monitor RU-1 discussed above in the previous section, containment atmosphere is directed to the gaseous sampler assembly after the particulate matter and volatile halogens have been collected out of the stream by the particulate and I-131 samplers, respectively. The sample

stream is constantly mixed in a fixed, shielded volume where it is viewed by a beta scintillation detector located in a completely enclosed housing.

The gas channel setpoint given in Technical Specifications is established so that, in an isolated containment atmosphere at equilibrium concentration with an existing 0.5 gpm leak and 0.1% defect fuel, a 1 gpm increase in leak rate would roughly provide a 10% increase in indicated concentration within 9 hours. Because the noble gas channel has less sensitivity for detecting RCS leakage than the particulate channel, Regulatory Guide 1.45 position C.5 has also been exempted for this method of reactor coolant leak detection. The compensatory administrative controls described above apply for this method as well.

5.2.5.4 Intersystem Leakage

Intersystem leakage is loss of reactor coolant system inventory into an interfacing system through degradation of an engineering barrier such as heat exchanger tubes or closed reactor coolant isolation valves. Leakage from the reactor coolant system may occur into the following interfacing or auxiliary systems: safety injection system, nuclear cooling water system, essential cooling water system, nuclear sampling system, and chemical and volume control system. Leakage across the steam generator tubesheet or tubes is a special case of intersystem leakage which is discussed above.

Since intersystem leakage usually does not go to the containment atmosphere, it is not normally detected through

monitoring of the "identified" or "unidentified" leakage as described above. Instead, leakage into a particular system can be detected through various process instruments. Unless otherwise specified, the instruments described have indication and alarms in the main control room. The sensitivity of these indicators depends on a number of factors, and they are not required by Regulatory Guide 1.45 to be able to detect a 1gpm increase in leakage within 1 hour. If the instrumentation does not permit quantification of the intersystem leak rate, a water inventory material balance will be commenced within 1 hour to determine the extent of the leakage. Radiochemical analysis of grab samples taken from the system may be used to locate and quantify the leak.

Leakage of reactor coolant into the safety injection system via the cold leg injection lines is detected by pressure transmitters on the low pressure side of the first isolation check valves (SI-V217, V227, V237, V247). Pressure transmitters on the HPSI and LPSI pump discharge can detect leakage into those subsystems. Leakage of reactor coolant through the safety injection tank check valves is detected by monitoring the tank water level and pressure. Leakage past the hot leg injection check valves (SI-V522 and V532) can be detected by pressure transmitters on the low-pressure side of those valves.

Loss of reactor coolant to the shutdown cooling system may occur by leakage through two isolation valves arranged in series: SI-651 and SI-653 on the A train and SI-652 and SI-654 on the B train. The pressure relief valve positioned between

each pair of isolation valves is provided to prevent over-pressurization of that line segment due to thermal expansion resulting from heat conducted across the first (most inboard) valve. Since the nominal setpoint of the valve is 2485 psig, it should not lift in the event of leakage across the first valve. The pressure relief valve discharge is piped to the reactor drain tank. Should the first isolation valve and the relief valve both leak, the inflow to the reactor drain tank will be detected by increased tank pressure, temperature, and level. Leakage past both isolation valves in either train would pressurize the downstream portion of shutdown cooling line up to the outboard containment isolation valve (SI-655 or SI-656). When the line pressure exceeds the setpoint of the low temperature over-pressure (LTOP) relief valves, the valves will lift and discharge to the containment recirculation sumps. This leakage would eventually register on the containment atmosphere process radiation monitor RU-1 particulate and gas channels. A temperature sensor located on the wall of each recirculation sump may detect large leakage rates through the LTOPs.

When shutdown cooling is in service, reactor coolant may enter the essential cooling water (EW) system through material flaws in the shutdown cooling heat exchangers. The resulting influx of radioactivity and inventory will be detected by process radiation monitors RU-2 or RU-3 as well as the high level switches on the EW surge tank levels.

Reactor coolant leakage into the nuclear cooling water system through tube leaks in the letdown heat exchanger or the reactor

coolant pump high pressure seal coolers can be detected by process radiation monitor RU-6 and high level switches on the nuclear cooling water surge tank. Seal cooler leakage may also produce elevated seal temperatures.

Although chemistry sampling from the reactor coolant system and connected systems does represent a loss of inventory, the removal of sample aliquots and the associated purge volumes does not constitute coolant leakage because it involves no degradation of the boundary materials. When the sample line isolation valves are closed, flow past the isolation valve seats would result in intersystem leakage of reactor coolant into the nuclear sampling system. Such leakage can be detected by increased temperatures and pressures in the sampling system. These instrument readings are indicated on a local panel located in the Chemistry Hot Lab.

As design inputs of reactor coolant to the connecting chemical and volume control system (CVCS), letdown and controlled bleed-off from the reactor coolant pump seals are not considered to be reactor coolant leakage. When letdown is isolated, coolant leakage may be detected in a number of ways depending on the system configuration. Examples include increased equipment drain tank level from lifts of relief valve CH-PSV-345 when the downstream piping is isolated, indicated flow in the failed fuel monitor sample loop, or increasing volume control tank level. Depending on how controlled bleed-off is isolated, leakage through the isolation valves may be detected by level increases in the volume control tank or reactor drain tank.

5.2.5.5 Evaluation of Reactor Coolant Leakage Indication

Primary control room indication of reactor coolant leakage into the containment is provided by (1) abnormally high particulate and radioactive gas levels in the containment atmosphere and (2) high flow alarms if flow to any of the reactor drain (RD) system sumps increases to 1 gpm for 1 hour. Upon actuation of a high activity alarm or indication of an increasing activity trend on the containment atmosphere radioactive gas and particulate channels, the operator will commence a water inventory balance to determine coolant leakage rate within 1 hour. Upon actuation of the excessive sump leakage alarm in the control room, the operator will begin periodically recording sump levels. Based on the sump level increase during the intervals, the operator can determine the leak rate for comparison with the leakage limits.

Other indirect control room indications of significant reactor coolant leakage to the containment would include changes in pressurizer level; increased containment pressure, temperature, and humidity; increasing trends of containment area radiation monitor readings; and an increase in borated and dilute makeup water based on flow totalizer readings. Process instruments can also provide indirect indication of intersystem leakage as described above. Once potential reactor coolant leakage to the containment or to another system has been detected by process instruments, the operator will attempt to quantify the leak rate by direct measurement or by calculation. If this is not practical, then a water inventory balance should be conducted to determine the leak rate in common leakage equivalent units

(gpm evaluated at reactor standard operating temperature and pressure) in order to facilitate comparison with the Technical Specification limits.

For the purpose of leak detection, Regulatory Guide 1.45 and PVNGS Technical Specifications limit the definition of the “reactor coolant pressure boundary” to those portions of the reactor coolant system which are constructed so that no leakage is expected to occur. This refers to the principal boundary members such as the pressure vessel wall, coolant piping walls, reactor coolant pump bowls, and isolation valve bodies. Since leakage of the pressure boundary as defined in the Technical Specifications is a possible precursor to gross failure of the boundary, the reactor must shutdown and depressurized in a timely fashion if any “pressure boundary leakage” is detected.

Identified and unidentified leakage is expected through other pressure retaining components that cannot practically be made completely leak tight: isolation valve packing and stems, isolation valve seats, pump and valve seals as well as the steam generator tubes and tubesheet. The Technical Specifications limit identified leakage in order to prevent it from obscuring unidentified leakage. Due to inherent limitations of the containment leak detection systems, unidentified leakage is limited by the Technical Specifications because it is possibly “pressure boundary leakage.”

The water inventory balance determines the total reactor coolant leak rate. Leakage detected by this method is presumed to be unidentified until the source is determined and the leak

rate has been quantified. The overall identified leak rate shall be determined by summing all of the identified leak rate contributions together. By design, the RCS inputs to the reactor drain tank are identified, and therefore the leak rate for each input need not be identified individually. Inventory entering the reactor drain tank which did not originate from the reactor coolant or a connecting system may be subtracted from the identified leak rate if it can be quantified. Unidentified leakage is calculated as the difference between the total coolant leakage and the sum of all the identified leakages.

Planned flow of reactor coolant into a connecting system through open isolation valves for the purpose of reactor coolant process control or assessment is not leakage. In addition, inventory losses out of connecting systems through boundary degradation need not be considered reactor coolant leakage provided that the location is known, the leak rate can be quantified, and the leakage is known not to interfere with the leak detection methods described in the Technical Specifications. In this case, the leak rate out of the connecting system may be subtracted from the total leakage prior to calculating the identified and unidentified leak rates. Known leakage from a connecting system that interferes with or otherwise obscures the detection of unidentified leakage, however, must be considered identified leakage. Examples would include connecting system leakage into the containment atmosphere or containment sumps, or those connecting system leaks quantified with uncertainties that are

large in comparison with the unidentified leakage limit. If reactor coolant leakage out of a degraded connecting system exceeds limits in the Technical Specifications, then the isolation valves must be closed, or the reactor must be placed in a condition where the limit does not apply.

The Technical Specifications apply leak rate limits to RCS pressure isolation valves individually as added assurance against over-pressurization of low-pressure connecting systems due to valve failure. This requirement is normally surveilled on the refueling interval using in-service testing techniques. In operational modes 1-4, leakage through both RCS pressure isolation valves in series which is located and quantified shall be applied to the identified leak rate limit.

5.3 REACTOR VESSEL

5.3.1 REACTOR VESSEL MATERIALS

5.3.1.1 Material Specifications

The principle ferritic materials used in the reactor vessel are listed in Table 5.1-2. These materials are in accordance with the ASME Boiler and Pressure Vessel Code, Section III.

5.3.1.2 Special Process Used for Manufacturing and Fabrication

The reactor vessel is fabricated in accordance with the ASME Boiler and Pressure Vessel Code, Section III. No special manufacturing methods that could compromise the integrity of the vessel are used.

The reactor vessel is a vertically mounted cylindrical vessel with a hemispherical lower head welded to the vessel and a removable hemispherical upper closure head. The construction of the vessel is basically that of formed plates welded into cylinders and hemispherical heads. The closure head, including the flange is a single forging having machined nozzles. The internal surfaces that are in contact with the reactor coolant are clad with austenitic stainless steel.

The reactor vessel consists basically of a vessel flange, three shell sections (upper, intermediate and lower) and a bottom head. The vessel flange is a forged ring with a machined ledge on the inside surface to support the core support barrel, which in turn supports the reactor internals and the core. The flange is drilled and tapped to receive the closure studs and is machined to provide a mating surface for the reactor vessel

closure seals. Each shell section consists of three 120°, or four 90° segments formed from plate material and welded together to form a cylindrical shell. The bottom head is constructed of two spherical sections formed from plate material and welded together to form a hemispherical head. These sections are joined together by welding, along with four inlet nozzles and two outlet nozzles, to form a complete vessel assembly.

The closure head is fabricated separately since it is joined to the reactor vessel by bolting. The flange is drilled to match the vessel flange stud hole locations, and the lower surface of the flange is machined to provide a mating surface for the vessel closure seals. The control element drive mechanism (CEDM) nozzles are welded into the head to complete the assembly.

The reactor vessel closure heads were purchased from Doosan Heavy Industries and Construction Company Limited, of South Korea. In a letter from the NRC to APS, dated January 3, 2007, the NRC specified that by accepting this equipment, installing it, and utilizing it at the plant, Arizona Public Service (APS) accepted responsibility for complying with certain peaceful use commitments undertaken on behalf of APS by the United States (U.S.) Government. The U.S. has agreed that this equipment will not be used for any purpose that would result in any nuclear explosive device. For example, this would preclude use of the Palo Verde reactors to produce tritium for the weapons program. Second, the U.S. Government has agreed that if this equipment is ever to be exported from PVNGS to a country other than Japan, the U.S. Government will obtain similar peaceful

use assurances from the proposed recipient country prior to approving its export. APS would be required to submit an application to the Nuclear Regulatory Commission for a license to export this equipment and these assurances would be obtained in the context of that review.

5.3.1.3 Special Methods for Nondestructive Examination

Prior to, during, and after fabrication of the reactor vessel, nondestructive tests based upon Section III of the ASME Boiler and Pressure Vessel Code are performed on all welds, forgings, and plates as indicated. The nondestructive examination requirements including calibration methods, instrumentation, sensitivity, reproducibility of data, and acceptance standards are in accordance with requirements of the ASME B&PV Code, Section III. (See Table 5.2-1). Strict quality control is maintained in critical areas such as calibration of test instruments.

All full-penetration, pressure-containing welds are 100% radiographed to the standards of Section III of the ASME Boiler and Pressure Vessel Code, Weld preparation areas, back-chip areas, and final weld surfaces are magnetic-particle or dye-penetrant examined. Other pressure-containing welds, such as used for the attachments of nonferrous nickel-chromium-iron mechanism housings, vents, and instrument housings to the reactor vessel and head, are inspected by liquid-penetrant tests of the root pass, the lesser of one-half of the thickness or each 1/2-inch of weld deposit, and the final surface. Additionally, the base metal weld preparation area is magnetic-

particle examined prior to overlay with nickel-chromium-iron weld metal.

All forgings are inspected by ultrasonic testing, using longitudinal beam techniques. In addition, ring forgings are tested using shear wave techniques.

All carbon-steel and low alloy forgings and ferritic welds are also subjected to magnetic-particle examination after stress relief.

Plates are subjected to ultrasonic examination using straight beam techniques.

All vessel bolting material receives ultrasonic and magnetic-particle examination during the manufacturing process.

The bolting material receives a straight-beam, radial-scan, ultrasonic examination with a search unit not exceeding 1 square-inch area. All hollow material receives a second ultrasonic examination using angle-beam, radial scan with a search unit not exceeding 1 square inch in area. A reference specimen of the same composition and thickness containing a notch (located on the inside surface) 1 inch in length and a depth of 3% of nominal section thickness, or 3/8-inch, whichever is less, is used for calibration. Use of these techniques ensures that no materials that have unacceptable flaws, observable cracks, or sharply defined linear defects are used.

The magnetic-particle inspection is performed both before and after threading of the studs.

Upon completion of all postweld heat treatments, the reactor vessel is hydrostatically tested, and all accessible ferritic weld surfaces, including those of welds used to repair material, are magnetic-particle inspected in accordance with Section III of the ASME Boiler and Pressure Vessel Code.

5.3.1.4 Special Controls for Ferritic and Austenitic Stainless Steels

are as follows:

Regulatory Guide 1.31, Control of Stainless Steel Welding, is addressed in Section 5.2.3.4.

- Regulatory Guide 1.34, Control of Electroslag Weld Properties is addressed in Paragraph 5.2.3.3.
- Regulatory Guide 1.43, Control of Stainless Steel Weld Cladding of Low-Alloy Steel Components, is addressed in Paragraph 5.2.3.3.
- Regulatory Guide 1.44, Control of the Use of Sensitized Stainless Steel, is addressed in Paragraph 5.2.3.4.
- Regulatory Guide, 1.50, Control of Preheat Temperature for Welding of Low-Alloy Steel, is addressed in Paragraph 5.2.3.3
- Regulatory Guide 1.71, Welder Qualification for Areas of Limited Accessibility, is addressed in Paragraph 5.2.3.3.

5.3.1.5 Fracture Toughness

In accordance with 10 CFR 50 Appendix G, Paragraph IV B, the reactor vessel beltline materials have minimum upper-shelf energy, as determined from Charpy V-notch tests on unirradiated

specimens in accordance with Paragraphs NB-2322.2 (a) of ASME Code, of 75 ft-lbs. Charpy impact tests were performed on transversely (weak direction) oriented specimens from the beltline plate materials to establish RT_{NDT} as required by 10CFR50, Appendix G.

Data from fracture toughness tests of base metal, weld metal, and heat affected zone (HAZ) material for Palo Verde Unit 1, Unit 2, and Unit 3 are presented in the tables of section 5.2.

Chemical analyses for the beltline plates and weld metal for Palo Verde Unit 1 are presented in tables 5.3-1 and 5.3-2, for Unit 2 in tables 5.3-3 and 5.3-4, and for Unit 3 in tables 5.3-5 and 5.3-6, respectively.

5.3.1.6 Reactor Vessel Material Surveillance Program

The surveillance program monitors the radiation induced changes in the strength and toughness properties of the reactor vessel beltline materials. These changes are determined by comparison of pre- and post-irradiation test results using uniaxial tension specimens, standard and precracked Charpy impact specimens, and compact tension specimens.

This surveillance program was established using the criteria presented in ASTM E185-79 for Unit 1 and ASTM E185-82 for Unit 2 & 3, Standard Practice for Conducting Surveillance Tests for Light-Water Cooled Nuclear Power Reactor Vessel. It also conforms to the requirements of 10CFR50, Appendix H (October 26, 1979), entitled, Reactor Vessel Material Surveillance Program Requirements. The material toughness requirements are determined in accordance with 10CFR50,

Appendix G, and ASME Boiler and Pressure Vessel Code (B&PV), Section III, Article NB-2300.

5.3.1.6.1 Test Material Selection

Three metallurgically different materials, representative of the reactor vessel, are investigated. These are base metal, weld metal, and heat-affected zone material. Base metal specimens for Unit 1 are fabricated from sections of two plates in the beltline region of the vessel which become the limiting plates with respect to reactor operation during its lifetime.

Selection was based on an evaluation of initial toughness (characterized by the reference temperature, RT_{NDT}), predicted effect of chemical composition (residual copper and phosphorus), and neutron fluence on the toughness (RT_{NDT} shift) during reactor operation. For Unit 1, a plate from the lower shell course had the highest predicted RT_{NDT} shift. A plate from the intermediate shell (nozzle) course had the highest adjusted RT_{NDT} (initial RT_{NDT} plus RT_{NDT} shift). Thus, for Unit 1, two plates were selected as base metal test material.

For Units 2 and 3, base metal test material was manufactured from one plate for each unit selected from the reactor vessel beltline. This plate from the lower shell course was predicted to have the highest predicted RT_{NDT} shift and the highest adjusted RT_{NDT}, and, therefore, was selected as the base metal test material.

Weld region test material was produced by welding together sections of lower shell course plates from the beltline of the

reactor vessel. The HAZ test material is manufactured from a section of the same plate used for lower shell course base metal surveillance test material. The weld metal test material is produced from the same heat of weld wire or rod and lot of flux used in the beltline of the reactor vessel. Welding parameters duplicated those used for the beltline welds.

Representative stock (archive material) to provide two additional sets of test specimens for each material was provided, with full documentation and identification.

In addition, material is included from a standard heat of ASTM A533, Grade B, Class 1, manganese-molybdenum-nickel steel made available by the USNRC-sponsored Heavy Section Steel Technology (HSST) Program. This standard reference material (SRM) was used as a monitor for Charpy impact tests, permitting comparisons among the irradiation data from operating power reactors and experimental reactors. Compilation of data generated from post-irradiation tests of these correlation monitors was carried out by the HSST program.

5.3.1.6.2 Test Specimens

5.3.1.6.2.1 Type and Quantity. The total quantity of specimens furnished in this program for baseline (unirradiated) and post-irradiation testing is presented in table 5.3-7 for Unit 1 and in table 5.3-8 for Units 2 and 3. The types of specimens are drop weight, tension, standard Charpy impact, pre-cracked Charpy, and compact tension for baseline testing; and tension, standard Charpy impact, precracked Charpy, and compact tension for post-irradiation testing.

Table 5.3-7

	Total	339	237	108	69	753

a. All specimens from lower shell, as noted in paragraph 5.3.1.6.1

b. Standard reference material characterized by Heavy Section Steel Technology Program.

5.3.1.6.2.2 Baseline Specimens. The type and quantity of test specimens provided for establishing the properties of the baseline (unirradiated) reactor vessel materials are presented in table 5.3-9 for Unit 1 and in table 5.3-10 for Units 2 and 3. The data from tests of these specimens provide the basis for determining the radiation-induced property changes of the reactor vessel materials.

Drop weight test specimens were provided to establish the nil-ductility transition temperatures (T_{NDT}) of the unirradiated lower shell course base metal (transverse orientation), weld metal, and HAZ material. Standard Charpy impact test specimens from the lower and intermediate shell (Unit 1) are provided to establish the initial Charpy impact energy transition curve and reference temperature (RT_{NDT}) of the base metals (longitudinal and transverse orientation), weld metal, and HAZ material. Uniaxial tension test specimens are provided to define the initial strength versus temperature relationship for the surveillance materials. For intermediate shell course base metal from Unit 1, no drop weight or longitudinal tension specimens are provided. Reactor vessel material qualification test results will be used instead.

Precracked Charpy impact and compact tension (1t and 1/2t) specimens from the base metals and weld metal are provided to determine the fracture toughness properties over the range extending from linear elastic to elastic-plastic fracture.

a. All specimens from lower shell, as noted in paragraph 5.3.1.6.1

b. Standard reference material.

5.3.1.6.2.3 Irradiated Specimens. The type and quantity of test specimens for monitoring the properties of the irradiated materials over the lifetime of the reactor vessel are presented in table 5.3-11 for Unit 1 and in table 5.3-12 for Units 2 and 3. Standard Charpy impact, precracked Charpy, 1/2t compact tension, and uniaxial tension specimens are used to measure changes in the strength and toughness of the surveillance materials.

Charpy impact test specimens are provided to establish the impact energy transition curve after irradiation for the base metals, weld metal, and HAZ material. Tension test specimens are provided to measure the strength and ductility of the base metals and weld metal following irradiation. The precracked Charpy and compact tension specimens are provided to measure the fracture toughness after irradiation.

5.3.1.6.3 Surveillance Capsules

The surveillance test specimens are placed in corrosion-resistant capsule assemblies for protection from the primary coolant during irradiation. The capsules also serve to physically locate the test specimens in selected positions within the reactor vessel and to facilitate the removal of a desired quantity of test specimens when a specified radiation exposure has been attained. Six surveillance capsule assemblies are provided for the reactor vessel. A summary of specimen type, origin, and quantity contained in each capsule assembly is presented in table 5.3-13 for Unit 1, in table 5.3-14 for Unit 2, and in table 5.3-15 for Unit 3.

A typical capsule assembly, illustrated in figure 5.3-1, consists of a series of three specimen compartments, connected by wedge couplings, and a lock assembly. Each compartment enclosure of the capsule assembly is internally supported by the surveillance specimens and is externally pressure tested to 3125 pounds per square inch during final fabrication. The wedge couplings also serve as end caps for the specimen compartments and position the compartments which are housed within the capsule holders attached to the reactor cladding. The lock assemblies fix the locations of the capsules within the holders by exerting axial forces on the wedge coupling assemblies which in turn cause these wedges to exert horizontal forces against the sides of the holders preventing relative motion. The lock assemblies also serve as a point of attachment for the tooling used to remove the capsules from the reactor.

Each capsule assembly consists of three compartments. Each compartment consists of two sections attached by a connecting spacer. Each capsule compartment section is assigned a unique identification so that a complete record of test specimen locations within each compartment section can be maintained.

Each Palo Verde Unit will have six surveillance capsule assemblies. For Unit 1 with two different base metal materials, there will be two precracked Charpy assemblies and one compact tension assembly for lower shell specimens and two precracked Charpy assemblies and one compact tension assembly for intermediate shell specimens. For Units 2 and 3, there will be three precracked Charpy assemblies and three compact tension assemblies. The types of specimens contained in each

unit are given in tables 5.3-13, 5.3-14, and 5.3-15. In addition, each of the six capsules contains one set of nine flux monitors, two sets of five flux monitors, and one set of temperature monitors.

5.3.1.6.3.1 Precracked Charpy Capsule Assembly. The four Unit 1 and three Unit 2 precracked Charpy capsule assemblies consist of three capsule compartments, two Charpy and flux compartments, and one temperature, flux, tension, and Charpy compartment. The contents of each compartment are described below:

A. Charpy and Flux Compartment Assembly

   This assembly (figure 5.3-2) contains 15 base metal (transverse) impact test specimens and a set of five flux spectrum monitors in the top section. The bottom section contains nine precracked Charpy test specimens each of base metal (longitudinal and transverse). The Charpy test specimens are arranged vertically in 1 by 3 arrays and are oriented with the notch toward the reactor core. The temperature differential between the specimens and the reactor coolant is minimized by using spacers between the specimens and the compartment and by sealing both sections of the assembly in an atmosphere of helium.

B. Temperature, Flux, Tension, and Charpy Compartment Assembly

   This assembly (figure 5.3-3) contains three base metal (transverse) tension test specimens and 12 HAZ impact

test specimens in the top section. The tension specimens are placed in a housing machined to fit the compartment. Split spacers are placed around the gauge length of the specimens to minimize the temperature differential between the specimen gauge length and the coolant. The impact specimens are arranged vertically in 1 by 3 arrays and are oriented with the notch toward the reactor core. Spacers are utilized between the test specimens and the compartment. The bottom section contains a set of nine flux spectrum monitors, a set of temperature monitors, nine SRM impact test specimens, and three weld metal tension test specimens. Both compartment sections are sealed within an atmosphere of helium.

C. Charpy and Flux Compartment Assembly

This assembly (figure 5.3-2) contains 15 weld metal impact test specimens and a set of five flux spectrum monitors in the top section. The bottom section contains nine precracked weld metal and nine base metal (longitudinal) impact test specimens. The test specimens are arranged vertically in 1 by 3 arrays and are oriented with the notch toward the reactor core. The temperature differential between the specimens and the reactor coolant is minimized by using spacers between the specimens and the compartment and by sealing both sections of the assembly in an atmosphere of helium.

5.3.1.6.3.2 Compact Tension Capsule Assemblies. The two Unit 1 and three Unit 2 compact tension (CT) capsule assemblies consist of three capsule compartments; two Charpy, flux, and compact tension compartments, and one temperature, flux, tension, and Charpy compartment. The contents of each compartment are described below:

A. Charpy, Flux, and Compact Tension Compartment Assembly

   This assembly (figure 5.3-3A) contains 15 base metal (transverse) impact test specimens and set of five flux spectrum monitors in the top section. The bottom section contains 10 base metal (transverse) 1/2t compact tension test specimens. The 1/2t compact tension specimens are oriented so that opening of the crack starter notch is facing the top of the compartment. This orientation will result in a neutron flux gradient parallel to the crack front. The temperature differential between the specimens and the reactor coolant is minimized by using spacers between the specimens and the compartment and by sealing both sections of the assembly in an atmosphere of helium.

B. Temperature, Flux, Tension, and Charpy Compartment Assembly

   This assembly (figure 5.3-3) is the same as that in the precracked Charpy capsule.

C. Charpy, Flux, and Compact Tension Compartment Assembly

   This assembly (figure 5.3-3A) contains 15 weld metal impact test specimens and a set of five flux monitors in the top section. The bottom section contains ten weld

metal 1/2t compact tension test specimens. The Charpy and compact tension specimens are arranged in the same manner as in listing A and are surrounded by spacers to minimize temperature differentials between the specimens and the reactor coolant.

5.3.1.6.4 Neutron Irradiation and Temperature Exposure

Predicted changes in the properties of the reactor vessel materials are based on data from specimens irradiated to various fluence levels and in different neutron energy spectra. In order to permit accurate evaluations of the radiation-induced changes in the surveillance materials, complete information on the neutron flux, neutron energy spectra, and the irradiation temperature of the encapsulated specimens must be available.

5.3.1.6.4.1 Flux Measurements. Fast neutron flux measurements are obtained by insertion of threshold detectors into each of the six irradiation capsules. Such detectors are particularly suited for the proposed application, because their effective threshold energies lie in the range of interest (0.5 to 15 MeV).

These neutron threshold detectors and the thermal neutron detectors, presented in table 5.3-16, can be used to monitor the thermal and fast neutron spectra incident on the test specimens. These detectors possess reasonably long half-lives and activation cross-sections covering the desired neutron energy range. These neutron threshold detectors exceed the number required in ASTM E482.

Table 5.3-16

PVNGS UNITS 1, 2, AND 3 CANDIDATE MATERIALS FOR NEUTRON THRESHOLD DETECTORS

Material	Reaction	Threshold Energy (MeV)	Half-Life
Uranium	U^{238} (n,f) Cs^{137}	0.7	30.2 years
Sulfur	S^{32} (n,p) P^{32}	2.9	14.3 days
Iron	Fe^{54} (n,p) Mn^{54}	4.0	314 days
Nickel	Ni^{58} (n,p) Co^{58}	5.0	71 days
Copper	Cu^{63} (n,α) Co^{60}	7.0	5.3 years
Titanium	Ti^{46} (n,p) Sc^{46}	8.0	84 days
Cobalt	Co^{59} (n,γ) Co^{60}	Thermal	5.3 years

One set of nine flux spectrum monitors and two sets of five flux spectrum monitors are included in each surveillance capsule. Each detector is placed inside a sheath which identifies the material and facilitates handling. Cadmium covers are used for those materials (e.g., uranium, nickel, copper, and cobalt) which have competing neutron capture activities. The neutron threshold detectors are placed in holes drilled in stainless steel housings (figure 5.3-3).

In addition to these detectors, the program also includes correlation monitors (Charpy impact test specimens made from a reference heat of ASTM A533-B, Class 1, manganese-molybdenum-nickel steel) which are irradiated along with the specimens made from reactor vessel materials. The changes in impact

properties of the reference material provide a cross-check on the dosimetry in any given surveillance program. These changes also provide data for correlating the results from this surveillance program with the results from experimental irradiations and other reactor surveillance programs using specimens of the same reference material.

5.3.1.6.4.2 Temperature Estimates. Because the changes in mechanical and impact properties of irradiated specimens are highly dependent on the irradiation temperature, it is necessary to have knowledge of the specimen temperature as well as that of the pressure vessel. During irradiation, instrumented capsules are not practical for a surveillance program extending over the design lifetime of a power reactor. Thus, the maximum temperature of the irradiated specimens can be estimated with reasonable accuracy by including in the capsule assemblies small pieces of low melting point alloys or pure metals. The compositions of candidate materials with melting points in the operating range of power reactors are listed in table 5.3-17. The monitors are selected to bracket the operating temperature of the reactor vessel.

The temperature monitors consist of a helix of low melting alloy wire inside a sealed quartz tube. A stainless steel weight is provided to destroy the integrity of the wire when the melting point of the alloy is reached. The compositions and, therefore, the melting temperatures of the temperature monitors are differentiated by the physical lengths of the quartz tubes which contain the alloy wires.

A set of temperature monitors is included in each surveillance capsule. The temperature monitors are placed in holes drilled in stainless steel housings as shown in figure 5.3-3.

5.3.1.6.5 Irradiation Locations

The test specimens are enclosed within six capsule assemblies, the axial positions of which are bisected by the midplane of the active core. The capsules are positioned near the inside wall of the reactor vessel so that the irradiation conditions (fluence, flux spectrum, temperature) of the test specimens resemble as closely as possible the irradiation conditions of the reactor vessel. The neutron fluence of the test specimens is expected to be within 50% of that seen by the adjacent vessel wall, so the measured changes in properties of the surveillance materials will closely approximate the radiation-induced changes in the reactor vessel beltline materials.

Table 5.3-17

PVNGS UNITS 1, 2, AND 3 COMPOSITION AND MELTING POINTS OF CANDIDATE MATERIALS FOR TEMPERATURE MONITORS

Composition (wt%)	Melting Temperature (F)
80.0 Au, 20.0 Sn	536
90.0 Pb, 5.0 Sn, 5.0 Ag	558
97.5 Pb, 2.5 Ag	580
97.5 Pb, 0.75 Sn, 1.75 Ag	590

The capsule assemblies are placed in capsule holders positioned circumferentially about the core at locations which include the regions of maximum flux. Figure 5.3-4 presents the exposure locations for the capsule assemblies.

Capsule assemblies are inserted into their respective capsule holders during the final reactor assembly operation.

5.3.1.6.6 Withdrawal Schedule

The capsule assemblies remain within their capsule holders until the test specimens contained therein have been exposed to predetermined levels of fast neutron fluence. At that time, the capsule assembly is removed and the surveillance materials are evaluated. Detailed instructions for the removal of capsule assemblies are provided for each plant. The capsule assembly removal schedule for Unit 1 is presented in table 5.3-18 and for Units 2 and 3 is provided in table 5.3-19. Removal time is in terms of effective full power years (EFPYs). The capsule withdrawal schedule has been designed to periodically monitor the effects of neutron irradiation on the reactor vessel based on the magnitude of the predicted RT_{NDT} shift and the decrease in upper shelf energy. Sufficient standby capsules have been provided to enable monitoring the effects of any major core change, measure changes resulting from reactor vessel annealing or evaluating a flaw in the beltline materials. For Unit 1, four capsules are scheduled for withdrawal during the design lifetime of the reactor vessel. For Units 2 and 3, three capsules are scheduled for withdrawal during the design lifetime of the reactor vessels. The two remaining Unit 1 capsules and the three remaining

Units 2 and 3 capsules are designated as standby capsules. The schedule was established in accordance with 10CFR50, Appendix H, monitoring requirements for the base metal, weld, and HAZ materials.

Withdrawal schedules may be modified to coincide with those refueling outages or plant shutdowns most closely approaching the withdrawal schedule.

Changes to the reactor vessel surveillance specimen withdrawal schedule that meet the applicable ASTM standard must be submitted to the NRC with technical justification for approval prior to implementation (the NRC must verify compliance with the ASTM standard), in accordance with 10CFR50, Appendix H, paragraph III.B.3. Changes to the withdrawal schedule that do not meet the applicable ASTM standard must be submitted to the NRC for approval as a license amendment with information required by 10CFR50.91 and 50.92 (see NRC Administrative Letter 97-04 date September 30, 1997).

5.3.1.6.7 Irradiation Effects Prediction Basis

The design curve used to predict the radiation induced increase in transition temperature is shown in figure 5.3-5. Predicted changes in the transition temperature are used to select the surveillance materials (paragraph 5.3.1.6.1) and to formulate the initial heatup and cooldown limit curves for plant operation. Once actual post-irradiation surveillance data become available, these data will be used to adjust plant operating limit curves.

Figure 5.3-5 was conservatively drawn using the data given in table 5.3-20 including SA533B, Class 1, plate and weld zone material typical of that used in the fabrication of the Palo Verde reactor vessel beltline materials. The curve is applicable for materials with copper contents of 0.10 w/o or less, consistent with Palo Verde beltline material specifications, irradiated at 550F ±25F.

5.3.1.7 Reactor Vessel Fasteners

The bolting material for the reactor vessel closure head is fabricated from SA-540, B23 or B24, Class III material. This material conforms to the requirements of 10CFR50, Appendix G and Regulatory Guide 1.65, "Materials and Inspections for Reactor Vessel Closure Studs."

The reactor vessel vendor provided lubrication specifications for threads of studs, nuts and washers to improve the antigalling properties and resistance to corrosion of these components. These lubrication specifications are delineated in the vendor technical manual for the reactor vessel. Laboratory testing and field experience have determined that there is no evidence of deleterious breakdown of the specified lubricants when they are applied in accordance with the applicable instructions.

Fracture toughness and tensile test data for reactor vessel closure head bolting are presented for Palo Verde Unit 1 in Table 5.3-21, for Unit 2 in Tables 5.3-24 and 5.3-25, and for Unit 3 in Tables 5.3-33 and 5.3-34.

Fracture toughness and tensile test data for all other fasteners used in the reactor coolant pressure boundary (RCPB) for Palo Verde Unit 1 are presented in Tables 5.3-22 and 5.3-23, for Unit 2 in Tables 5.3-26 through 5.3-32, and Unit 3 in Tables 5.3-35 through 5.3-41.

5.3.2 PRESSURE-TEMPERATURE LIMITS

All components in the reactor coolant system are designed to withstand the effects of cyclic loads due to reactor coolant system temperature and pressure changes. These cyclic loads are introduced by normal unit load transients, reactor trips and startup and shutdown operation.

During unit startup and shutdown, the rates of temperature and pressure changes are limited. The design number of cycles for heatup and cooldown is based upon a rate of 100F/h.

The maximum allowable reactor coolant system pressure at any temperature is based upon the stress limitations for brittle fracture considerations. These limitations are derived by using the rules contained in Section XI of the ASME Code, including Appendix G, Protection Against Nonductile Failure, and the rules contained in 10CFR50, Appendix G, Fracture Toughness Requirements. Compliance with the criteria in 10CFR50, Appendix H is discussed in Section 5.3.1.6.

5.3.2.1 Limit Curves

Limitations on pressurization are determined using material property test data, for Reactor Coolant Pressure Boundary material, as required by Appendix G to Section XI of the ASME Code. An initial RT_{NDT} of +40°F is assumed for the reactor vessel beltline material, as required by the reactor vessel equipment specifications. For the remaining pressure boundary materials in the reactor coolant system, a limiting RT_{NDT} of +60°F is assumed.

As a result of fast neutron irradiation in the region of the core, RT_{NDT} will increase with operation. The techniques used to analytically and experimentally predict the integrated fast neutron (E>1 MeV) fluxes of the reactor vessel are described in Section 5.3.1.6.

Since the neutron spectra and flux measured at the samples and reactor vessel inside radius should be nearly identical, the measured reference transition temperature shift for a sample can be applied to the adjacent section of the reactor vessel for later stages in plant life equivalent to the difference in

calculated flux magnitude. The maximum exposure of the reactor vessel will be obtained from the measured sample exposure by application of the calculated azimuthal neutron flux variation. The actual shift in RT_{NDT} will be established periodically during plant operation by testing of reactor vessel material samples which are irradiated cumulatively by securing them near the inside wall of the reactor vessel as described in Section 5.3.1.6 and shown in Figure 5.3-4. To compensate for any increase in the RT_{NDT} caused by irradiation, limits on the pressure-temperature relationship are periodically changed to stay within the stress limits during heatup and cooldown.

The limit lines identified are based on the following:

A. Heatup and Cooldown Curves (from Section XI of the ASME Code Appendix G-2215)

K_{IC} = $2\ K_{IM} + K_{IT}$

K_{IC} = Reference stress intensity factor as a function of coolant temperature.

K_{IM} = Membrane stress intensity factor due to pressure. (A safety factor of 2 is applied to membrane stress).

K_{IT} = Stress intensity factor for radial thermal gradient.

The above equation is applied to the reactor vessel beltline.

For plant heatup, the thermal stress at the vessel beltline I.D. is opposite in sign from the pressure

induced stress, thus tending to cancel each other out. These same stresses however, are similar in sign, and hence additive at the vessel O.D. This stress level variation across the wall, in conjunction with the fact that the neutron fluence (and hence RT_{NDT} shift) is higher at the inside wall, necessitates the investigation of crack locations on both the O.D. and I.D. surfaces.

For conservatism, therefore, the following areas are specifically analyzed:

1. An "isothermal" heatup (i.e., $K_{IT} = 0$) transient with a T/4 crack on the inside surface of the beltline
2. A conventional rate dependent heatup transient with a T/4 crack on the outside surface of the beltline.

For plant cooldown thermal and pressure stress are additive. The design cooldown rate of 100F/hr is used for calculation.

Thermal stress intensity factor is obtained through a detailed thermal analysis of the beltline wall using a computer code. A finite element heat transfer model is used to determine varying wall temperature as a function of radius, time, and thermal rate. Since a varying temperature profile is obtained, an alternate method for calculating K_{IT} was employed as suggested by Article G-2214.3 of ASME III. The alternate method uses a polynomial fit of the temperature profile and super position using influence coefficients to calculate K_{IT}.

K_{IC} is then varied as a function of temperature from Figure G-2110-1 of ASME XI and the allowable pressure calculated. Instrumentation errors are considered when plotting the curves. Whenever the core is critical, an additional 40F is added to these curves as required by 10CFR50, Appendix G.

B. System Hydrostatic Test

The system hydrostatic test curve is developed in the same manner as in A above, with the exception that a safety factor of 1.5 is used as allowed by ASME XI in lieu of 2.

C. Lowest Service Temperature

As indicated previously, an RT_{NDT} for all material with the exception of the reactor vessel beltline was +60F.

ASME III, Article NB-2332 (b) requires a lowest service temperature of RT_{NDT} + 100F for piping, pumps and valves. Below this temperature, a pressure of 20% of the system hydrostatic test pressure cannot be exceeded.

D. Maximum Pressure for Shutdown Cooling

This pressure is established by considering the design pressure of the shutdown cooling system, shutoff head of the low pressure safety injection (LPSI) pumps, elevation head from the pressurizer to the LPSI pumps, instrument and interlock tolerances, and the design temperature of the shutdown cooling system.

The pressure-temperature limitation curves are predicted for 60-year life. During plant life the surveillance capsules (refer to Section 5.3.3.7) will be removed from

their location in the reactor vessel for testing. The data obtained will be compared to that used to develop the pressure – temperature limit curves discussed in the Technical Specifications. If this information indicates anomolies to the existing predictions, the curves will be redrawn as previously indicated to reflect actual data.

5.3.2.2 Operating Procedures

Pressure-temperature limitations and additional information are discussed in the Technical Specifications and provided in the TRM. The pressure-temperature limit curves are prepared in accordance with Appendix G, ASME Code Section XI.

Maintenance of reactor coolant system (RCS) pressure and temperature within these prescribed limits ensures that the integrity of the reactor coolant pressure boundary (RCPB) is maintained.

5.3.3 REACTOR VESSEL INTEGRITY

C-E designs and fabricates the reactor vessels for System 80. C-E has been involved in reactor vessel design and fabrication since the late 1950's, and this proven expertise is reflected in the System 80 reactor vessels and the satisfactory performance of large numbers of reactor vessels in operating plants.

Vessel integrity is ensured because proven fabrication techniques are employed and because well characterized steels, which exhibit uniform properties and consistent behavior, are used. The characterization of these materials was established

through industrial and governmental studies which examined the prefabrication material properties through to irradiated service operation. Inservice inspection and material surveillance programs are also conducted during the service life of the vessel, which further ensures that vessel integrity is maintained.

5.3.3.1 Design

Applicable design codes are found in Table 5.2-1. A schematic of the reactor vessel is shown in Figure 4.1-1. Additional information on design may be found in Section 5.3.1.2.

The design permits all required inspections to be performed, and does not preclude access to areas requiring inservice inspection.

5.3.3.2 Materials of Construction

The materials used in the construction of the reactor vessel, as listed in Table 5.1-2, are in accordance with Section III of the ASME Boiler and Pressure Vessel Code.

5.3.3.3 Fabrication Methods

Fabrication of the reactor vessel is described in Section 5.3.1.2. Fabrication processes used in construction of the reactor vessel comply with Sections III and IX of the ASME B&PV Code.

5.3.3.4 Inspection Requirements

Inspection requirements of ASME Code, Section III are discussed in Section 5.3.1.3.

PVNGS UNIT 1

COMPONENT: REACTOR COOLANT PUMP
PRODUCT FORM: FASTENERS INCLUDING STUDS, NUTS, AND WASHERS (Sheet 1 of 2)

Reference Number	Material Code Number	ASME Material Specification	Location In Component	Preload Temp (°F)[a]
Reactor coolant pump No. 1				
78173-S/N1109-2A	V112	SA540-GRB24-CL3	RCP Nuts	70
78173-S/N1109-2A	V113	SA540-GRB24-CL3	RCP Nuts	70
78173-S/N1109-2A	V41	SA540-GRB24-CL3	RCP Studs	70
78173-S/N1109-2A	V42	SA540-GRB24-CL3	RCP Nuts	70
78173-S/N1109-2A	86293[b]	SA540-GRB24-CL3	RCP Nuts	70
Reactor coolant pump No. 2				
78173-S/N1109-18	V110	SA540-GRB24-CL3	RCP Nuts	70
78173-S/N1109-1B	V111	SA540-GRB24-CL3	RCP Nuts	70
78173-S/N1109-1B	V52	SA540-GRB24-CL3	RCP Studs	70

a. Determined per applicable ASME B&PV Code and Addenda, Section III, Subsection NB, Article NB233-A (diameter over 4 inches)

b. Heat Number

5.3.3.5 Shipment and Installation

The requirements of Regulatory Guide 1.38 were followed in the packaging and shipment of the reactor vessel. Regulatory Guide 1.37 and 1.39 address requirements during the construction phase.

The reactor vessels are prepared to be shipped by barge or rail to the site, while mounted on the shipping skid used for installation. The vessels are protected by closing all openings (including the top of the vessel) with wooden shipping covers. The closure heads are shipped with separate skids and covers. Vessel surfaces and covers are sprayed with a strippable coating for protection against corrosion during shipping and installation. Prior to the welding of interconnecting piping, and installation of insulation; the temporary protective coating is removed by peeling. For a discussion of compliance with Regulatory Guides 1.37 and 1.39 during installation, refer to section 1.8.

The replacement closure head and CEDMs were shipped to the site in accordance with the requirements of the Regulatory Guides 1.37, 1.38 and 1.39.

5.3.3.6 Operating Conditions

Refer to sections 3.9 and 4.4 for information on design transients and operating conditions, respectively.

5.3.3.7 Inservice Surveillance

The reactor vessel surveillance program is described in detail in Section 5.3.1.6. It is designed on the basis of 10CFR50,

Appendix H and ASTM E185-79 for Unit 1 and ASTM E185-82 for Unit 2 & 3. Standard reference material to corroborate the post-irradiation surveillance data and precracked Charpy impact specimens to enable determination of fracture toughness properties before and after irradiation are included in the program. Standard Charpy specimens in excess of the number required by E185-82 are included for key materials to increase the accuracy in defining post-irradiation index temperatures. When combined with the use of highly radiation resistant materials in the beltline of the reactor vessel, this surveillance program provides maximum assurance, consistent with commercial requirements, of the integrity of the reactor pressure vessel in terms of strength and fracture resistance.

For a discussion of the inservice inspection program, see subsection 5.2.4 and section 6.6, and the Technical Specifications.

5.4 COMPONENT AND SUBSYSTEM DESIGN

5.4.1 REACTOR COOLANT PUMPS

The reactor coolant pumps provide sufficient forced circulation flow through the reactor coolant system to assure adequate heat removal from the reactor core during power operation. A low limit on reactor coolant pump flow rate (i.e., design flow) is established to assure that specified acceptable fuel design limits are not exceeded. Design flow is derived on the basis of the thermal-hydraulic considerations presented in Section 5.2.

The reactor coolant pump and motor assembly in conjunction with the flywheel, provide sufficient coastdown flow following loss of power to the pumps to assure adequate core cooling.

The reactor coolant pump pressure boundary is designed for the transients given in Section 3.9 so that the ASME Code Section III allowable stress limits are not exceeded for the specified number of cycles. Stress criteria concerning earthquake and pipe rupture conditions are presented in Section 3.9.3.

The design overspeed of the reactor coolant pump is 125 percent of normal speed.

5.4.1.1 Pump Flywheel Integrity

A. The material used to manufacture the flywheel of the reactor coolant pump motor will be produced by a commercially acceptable process that minimizes flaws, such as the vacuum melt and degassing process. This

provides adequate fracture toughness properties under reactor operating conditions. The acceptance criteria for flywheel design will be compatible with the safety philosophy of the PVRC primary coolant pressure boundary criteria as appropriate considering the inherent design and functional requirement differences between the pressure boundary and the flywheel.

1. The reference nil-ductility temperature (RT_{NDT}) of the material, as obtained from the drop-weight tests (DWT) performed in accordance with specification ASTM-E-208 will be no greater than 10F.

2. The Charpy V-notch (Cv) upper shelf energy level, in the "weak" (Wr) direction, as obtained per ASTM-A-370 will be no less than 50 ft-lb. A minimum of three Cv specimens will be tested from each plate or forging.

3. The minimum fracture toughness of the material at the normal operating temperature of the flywheel will be equivalent to a dynamic stress intensity factor (K_{IC} dynamic) of at least 100 ksi-in$^{1/2}$. Compliance will be demonstrated by either of the following:

   a. Testing of the actual material of the flywheel to establish the K_{IC} (dynamic) value at the normal operating temperature, or

b. Use of a lower bound fracture toughness curve obtained from tests on the same type of material. The curve will be translated along the temperature coordinate until the KIC (dynamic) value of 45 ksi-in$^{1/2}$ is indicated at the NDT of the material, as obtained from drop-weight tests.

4. Each finished flywheel will be subjected to a 100 percent volumetric ultrasonic inspection from the flat surface per ASME BPVC Section III.

   This inspection will be performed on the flywheel after final machining and overspeed test.

5. If the flywheel is flame cut, at least 1/2 inch of stock will be left on the outer and bore radii, for machining to final dimensions.

6. The flywheel will be subjected to a magnetic particle or liquid-penetrant examination per "Section III" before final assembly. The inspection will be performed on finished machined bores, keyways, and on both flat surfaces to a radial distance of 8 inches minimum beyond the final largest machined bore diameter but not including small drilled holes. There will be no stress concentrations such as stamp marks, center punch marks, or drilled or tapped holes within 8 inches of the edge of the largest flywheel bore.

B. The flywheels will be designed to withstand normal operating conditions, anticipated transients, and the largest mechanistic LOCA break size defined in CENPD-168 (Revision 1) combined with the Safe Shutdown Earthquake.

The following criteria will be satisfied:

1. The combined stress, both centrifugal and interference, at normal operating speed will not exceed one-third of the minimum specified yield strength for the material selected in the direction of maximum stress;

2. The design speed of the flywheel will be 125 percent of normal operating speed.

   The lowest of the critical speeds of the flywheel will be at least 10% above the highest anticipated overspeed of the pump. The highest anticipated overspeed is predicted for a discharge leg break of the largest break size defined in CENPD-168 (Revision 1).

3. The combined centrifugal and interference stresses at the design speed will be limited to two-thirds of the minimum specified yield strength. Design speed is defined as 125 percent of normal operating speed.

4. The motor and pump shaft or bearings and coupling will withstand any combination of normal operating loads or anticipated transients, and the design basis Loss-of-Coolant

Accident combined with the Safe Earthquake Shutdown.

Each flywheel will be tested at design speed, 125 percent of normal operating speed, as defined in Step B.2, above.

The flywheel will be accessible for 100 percent in-place volumetric ultrasonic inspection. The flywheel-motor assembly is designed to allow such inspection with a minimum of motor disassembly.

5.4.1.2 Description

Table 5.4-42 lists the principal parameters of the reactor coolant pumps and Figure 5.4-9 depicts the arrangement of the pump and motor. Reactor coolant pump supports are discussed in Section 5.4.14. The pump piping and instrument diagram is given in engineering drawings 01, 02, 03-M-RCP-001, -002 and -003.

The four reactor coolant pumps are vertical, single stage bottom suction, horizontal discharge, motor-driven centrifugal pumps. The pump impeller is keyed and locked to its shaft. Pump shaft alignment is maintained by a water lubricated radial bearing within the pump and by radial and thrust bearings located in the motor stand. The pump and motor shafts are directly connected by a coupling.

The shaft seal assembly consists of two face-type, mechanical seals in series, with controlled leakage bypass to provide the same pressure differential across each seal. The seal assembly is designed for 2500 psi differential and to reduce the leakage

pressure from Reactor Coolant System pressure to the volume control tank pressure. A third, face-type, low-pressure vapor seal at the top is designed to withstand system operating pressure when the pumps are not operating. The leakage past the second pressure seal and the controlled leakage is piped to the volume control tank in the Chemical and Volume Control System. Leakage past the low-pressure vapor seal is collected and piped to the reactor drain tank.

The temperature of the water in the seal assembly is maintained within acceptable limits by a watercooled heat exchanger. Water is also injected into the seal area from an external seal injection system. The performance of the shaft seal system is monitored by pressure and temperature sensing devices in the seal system. The seal assembly can be replaced without draining the pump casing or removing the shaft.

Nominal values for controlled bypass flow are given below. It is noted that actual RCP controlled bleed-off (CBO) flow may be different from these values and vary slightly from pump to pump and Unit to Unit. In addition, actual CBO flow may change for any given RCP over time as the pump seals wear. Bounding values for CBO flow are used in the accident analyses as described in UFSAR Chapter 15:

Controlled bypass flow, per pump:

(Normal) (All seals functioning)	3.0 +/- 1.0 gpm;
Alarm Setpoint (Hi)	6.0 gpm.

The motor is sized for continuous operation at the flows resulting from four-pump or one-pump operation with 1.0 to 0.74 specific gravity water. The motors are designed to start and

accelerate to speed under full load with a drop to 80 percent of normal rated voltage at the motor terminals.

Each motor is provided with an anti-reverse rotation device. The device is designed to prevent impeller rotation in the reverse direction due to each of the following conditions: motor starting torque, if the motor was incorrectly wired for reverse rotation; reactor coolant flow through the pump in the reverse direction due to a pump suction line LOCA.

5.4.1.3 Evaluation

The reactor coolant pumps are sized to deliver flow that equals or exceeds the design flow rate utilized in the thermal hydraulic analysis of the Reactor Coolant System. Analysis of steady-state and anticipated transients is performed assuming the minimum design flow rate. Tests are performed to evaluate reactor coolant pump performance during the post core load hot functional testing to verify adequate flow. Leakage from the pump via the pump shaft is controlled by the shaft seal assembly. Reactor coolant entering the seal chambers is cooled and collected in closed systems to prevent reactor coolant leakage to containment. Instrumentation is provided to monitor seal operation.

The design speed of the flywheel is 125 percent of normal speed. An overspeed test of each flywheel at the design speed is performed prior to assembly. Refer to pump flywheel integrity Section 5.4.1.1.

In the event of a break in the reactor coolant pump suction piping, the anti-reverse rotation device prevents impeller

rotation in the reverse direction. In the event of a discharge pipe break, increased flow through the pump tends to accelerate the pump impeller. The highest anticipated overspeed is predicted for a discharge leg break of the largest break size defined in CENPD-168. The highest predicted LOCA overspeed is less than the lowest critical speed of the flywheel.

The pump and motor oil lubricated bearings are lubricated by internal oil systems. Each bearing assembly has its own internal oil system consisting of either an oil bath type or force-feed type system. During normal operation, no external pumps will be required because pumping action is accomplished by internal pumping devices. Lubricating oil is cooled by cooling coils submerged in the oil sumps. Both sumps and cooling coils are internal to the motor structural frame and are designed for Seismic Category I operation, and use the intent of the ASME Boiler and Pressure Vessel Code, Section III, Class 3 as a guide for design and construction. This is established within the Combustion Engineering Topical Report, CENPD-201, which demonstrates the reactor coolant pump performance during a loss of component cooling water incident. Although the pump-motor assembly operation is not considered necessary for plant safety, this design minimizes the direct effects of seismic events on the reactor coolant pump and motor assembly oil lubricating systems so that adequate coast down characteristics are not detrimentally affected.

Bearing metal temperatures, oil flow and/or pressure oil levels, cooling water flow and/or pressure are continuously monitored and alarmed in the control room.

In the unlikely event that component cooling water to the reactor coolant pump and motor oil lubricating systems is not available or that an oil leak occurs during operation, the operator is alerted as soon as cooling water to the oil system is lost and has a time period of at least 30 minutes in which to reduce power, if necessary, isolate cooling water and shutdown the reactor coolant pump motor assembly to prevent bearing seizure. This time limit is established in the Topical Report CENPD-201. Combustion Engineering has performed a test to verify the analysis in Appendix A. The component cooling water was secured to the pump lubrication oil sumps and data taken so as to demonstrate the heat up rate of the oil sump up to a maximum sump temperature of 300°F. A test securing cooling water to the pump seals has been performed to demonstrate the seals operability. In the remote possibility of a simultaneous loss of component cooling water to all reactor coolant pump motor assemblies, 30 minutes is adequate to secure the plant and maintain the normal coast down capabilities of the reactor coolant pump motor assemblies.

During a loss of component cooling water event, it is unlikely that a shaft seizure due to bearing failure will occur for the following reasons:

A. The design is such that the heat generated in the bearing normally carried away by the cooling water, is transferred by alternate paths. The lube oil sump baths surrounding the bearings, the stagnant cooling water remaining in the heat exchanger coils, and the bearing and sump assembly metal masses, all act as heat sinks.

Also conduction down the pump shaft and outer sump shell radiation help to reduce the temperature rise.

B. The rotation of the bearing assemblies insures adequate oil flow and mixing of heated oil to insure the heat transfer as described in A.

C. In the event that the oil temperature rises such that the viscosity degrades significantly, the design of the thrust bearing continues to produce a hydrodynamic film so as to preclude metal to metal contact.

D. Operation and test experience has demonstrated that the reactor coolant pump motor assembly will operate without cooling water to the lubricating oil system for at least the calculated 30 minute time period.

Should an oil leak occur, redundant instrumentation will alert the operator to shut down the reactor coolant pump motor assembly and thereby avoid bearing damage.

In the event of an oil leak, the separation of lubrication systems would limit the problem to a single reactor coolant pump.

The loss of the oil in the bearing oil reservoir would not result in bearing seizure for the following reasons:

A. Temperature and oil level monitors will provide appropriate indication of an abnormal condition.

B. The vibration monitoring device furnished on the pump will respond to bearing degradation and allow the operator to shutdown the pump.

C. If the above protective measures fail, the high torque produced by the motor will cause a slow breakdown of the bearings and not a rapid shaft seizure. Industry experience indicates that the babbitt bearing surfaces wear away and the bearing pads and sleeves will be badly worn but the shaft will continue to rotate.

If the extremely remote possibility of bearing seizure occurs while the reactor coolant pump motor assembly is in operation, adequate flow to the core is available from the other reactor coolant pump motor assemblies as demonstrated by the one pump loss of flow study.

Engineering drawings 01, 02, 03-M-RCP-001, -002 and -003 show a separate oil lift system which is required for start-up of the pump assembly. The oil lift system furnishes high pressure oil to the pump assembly thrust bearings, thereby lifting the rotor and reducing bearing friction during pump start-up. Interlocking devices are furnished which prevent pump start-up until oil lift flow is established. The oil lift system is automatically shutdown when the pump reaches full speed. Since oil lift is not required during normal operation, an oil leak in this system will not cause a bearing failure.

5.4.1.4 Tests and Inspections

The reactor coolant pump pressure boundary is nondestructively inspected as required by ASME Section III for Class 1 components. The pump casing inspections include complete radiography and liquid penetrant or ultrasonic testing. The pump receives a hydrostatic pressure test in the vendor's shop

and with the Reactor Coolant System. Inservice inspection of the pump pressure boundary will be performed during plant life in accordance with ASME Section XI.

The pump assembly is performance tested in the vendor's shop over at least the normal operating range in accordance with the Standards of the Hydraulic Institute. The tests also demonstrate ability of the pumps to function under the various operating conditions specified. Tests commonly performed are hot and cold performance and stop-start cycling. Special testing will also be performed on one pump. Such testing will include loss of cooling and/or seal injection water. Vibrations are monitored at several places on the pump during shop testing.

In addition to meeting an absolute criterion for vibration amplitude, the test results are examined for evidence of critical speed problems.

The pump motors undergo a "routine" test in accordance with NEMA MG-1. This test also confirms that the motors are within their vibration limits. At least one motor is tested by being used as the driver for the pump assemblies, during the pump manufacturer's shop testing.

The following testing may also be performed where significant seal experience is lacking to develop confidence in the sealing system.

Seal materials testing for suitability in reactor coolant environment.

Long term testing of an entire seal assembly.

To the greatest extent practicable, all conditions of operation within the reactor coolant pump will be duplicated.

Reactor coolant pump flywheel inspections and testing are described in Section 5.4.1.1.

The reactor coolant pump anti-reverse rotation device is tested in the motor vendor's shop by reversing the power leads to the motor and applying power at rated voltage. This test subjects the anti-reverse rotation device to maximum motor starting torque and duplicates what would occur if the power leads were accidentally reversed in the plant.

In response to an RCP shaft cracking issue, the original shafts have been replaced. A vibration monitoring system has been installed such that the RCPs are continuously monitored using a Programmable Logic Controller (PLC) type with solid state I/O modules for vibration monitoring system. The system monitors the critical vibration related to parameters, such as overall vibration, synchronous 1XRPM and 2XRPM amplitude, and phase angle.

The PLC have setpoints, which sound an alarm and flash an alarm window in the control room. In addition to the alarm, a computer system is installed which provides the Man-Machine-Interface (MMI) and performs the data acquisition and trending for further vibration analysis and evaluation.

5.4.2 STEAM GENERATORS

5.4.2.1 Design Bases

The steam generators are designed to transfer 4013 MWt from the RCS to the secondary system, producing approximately 18.0 x 10^6

lb/h of 1030 psia saturated steam, when provided with 450F feedwater. Moisture content of the steam for steam generators is limited to less 0.1%. The steam generator design parameters are listed in Table 5.4.2-1. The steam generators, including the tubes, are designed for the RCS transients listed in Section 3.9.1 so that the code allowable stress limits are not exceeded for the specified number of cycles. All transients have been established based on conservative assumptions of operating conditions in consideration of supportive system design capabilities. The steam generators are capable of sustaining the following additional design transients without exceeding code allowable stress limits:

A. Ten secondary side hydrostatic tests with secondary side pressurized to 1-1/4 times the design pressure and the primary side pressurized so that the tube differential pressure does not exceed 820 psid (test condition);

B. Two hundred secondary side leak tests with the secondary side pressurized from 820 psia to design pressure, with the primary side pressurized so that tube differential pressure (secondary to primary) does not exceed 820 psid (test condition);

C. Fifteen thousand cycles of adding 40F feedwater at 875 gpm to the steam generator through the downcomer feedwater nozzle when at hot standby conditions (normal condition);

D. Five hundred cycles of adding 40F feedwater at 875 gpm to the steam generator through the downcomer feedwater nozzle during loading conditions (normal condition);

E. Five hundred cycles of adding 100F feedwater at 875 gpm to the steam generator through the downcomer feedwater nozzle during loading conditions (normal condition);

F. Seven cycles of adding 40F feedwater at 1750 gpm to the steam generator through the downcomer feedwater nozzles during a steam line break. This provides for one steam line break incident with the auxiliary feedwater cycled to a maximum of seven times (faulted condition);

G. Two hundred and eighty cycles of adding 40F feedwater at 1750 gpm to the steam generator through the downcomer feedwater nozzles with the flow initiated 30 seconds after a loss of normal feedwater. This provides for 40 loss of normal feedwater incidents with the auxiliary feedwater cycled at a maximum of seven times (upset condition);

H. Four thousand pressure transients of 85 psi across the primary divider plate in either direction caused by starting and stopping reactor coolant pumps (normal condition).

The steam generator are designed to ensure that critical vibration frequencies are well out of the range expected during normal operation and during abnormal conditions. The tubing and tubing supports are designed and fabricated with considerations given to both secondary side flow induced vibration and reactor coolant pump induced vibrations. In addition, the steam generator assemblies are designed to withstand the blowdown forces resulting from the severance of a steam nozzle. The steam generator assemblies are also designed to withstand the severance of any one of the feedwater nozzles. The two accidents are not considered simultaneously.

The steam generator tubes are ¾” OD with 0.042-inch nominal wall thickness and are constructed of thermally treated Inconel 690 alloy.

A steam generator tube rupture incident is a penetration of the barrier between the reactor coolant system and the main steam system. The integrity of this barrier is significant from the standpoint of radiological safety in that a leaking steam generator tube allows the transfer of reactor coolant into the main steam system. Radioactivity contained in the reactor coolant would mix with water in the shell side of the affected steam generator. This radioactivity would be transported by steam to the turbine and then to the condenser, or directly to the condenser via the Turbine Bypass System. Noncondensable radioactive gases in the condenser are removed by the main condenser's evacuation system and discharged to the plant ventilation system.

Experience with nuclear steam generators indicates that the probability of complete severance of a tube is remote. A double-ended rupture has never occurred in a steam generator of this design. The more probable modes of failure, which result in smaller penetrations, are those involving the occurrence of pinholes or small cracks in the tubes, and of cracks in the seal welds between the tubes and tube sheet. Detection and control of steam generator tube leakage is described in Section 5.2.

The concentration of radioactivity in the secondary side of the steam generators is dependent upon the concentration of the radionuclides in the reactor coolant, the primary-to-secondary

leak rate, and the rate of steam generator blowdown. The expected specific activities in the secondary side of the steam generators during periods of normal operation are given in Section 11.2.

The recirculation water within the steam generators will contain volatile additives necessary for proper chemistry control. These and other chemistry considerations of the main steam system are discussed in Section 10.3.5.

5.4.2.2 Description

The steam generators are illustrated in Figure 5.4-8. Moisture-separating equipment in the shell side of the steam generators limits moisture content of the exit steam. Manways and handholes are provided for access to the steam generator internals. Reactor coolant enters at the bottom of each steam generator through the single inlet nozzle, flows through the U-tubes, and leaves through the two outlet nozzles. A vertical divider plate separates the inlet and outlet plenums in the lower head. The steam generator with integral economizer is in most respects similar to earlier U-tube recirculating steam generators. The basic difference is that instead of introducing feedwater only through a sparger ring to mix with the recirculating water flow in the downcomer channel, feedwater is also introduced into a separate, but integral section of the steam generator. A semi-cylindrical section of the tube bundle, at the cold leg or exit end of the U-tubes, is separated from the remainder of the tube bundle by vertical divider plates. Feedwater is introduced directly into this section and pre-heated before discharge into the evaporator section.

The lower portion of the evaporator section and the downcomer channel occupy only one-half of the steam generator cross-section. The effect of this non-symmetry is considered in calculation of recirculation ratio, internal flow considerations, and in design of tube support structures.

The steam-water mixture leaving the vertical U-tube heat transfer surface enters the separators which impart a

centrifugal motion to the mixture and separate the water particles from the steam. The water exits from the perforated separator housing and recirculates through the downcomer channel to repeat the cycle. Final drying of the steam is accomplished by passage of the steam through Peerless Hook-vane type dryers.

The pressure drop from the steam generator feedwater nozzles to the steam outlet nozzle including the economizer is approximately 41 psi. The steam generators include design enhancement features to improve blowdown system performance. A six inch nozzle is provided in the hot side downcomer region. This makes it possible to take recirculating water not only at the tubesheet level, but also from the downcomer.

Features to enhance wet layup recirculation chemistry control during outages are also provided. A nozzle is provided in the upper shell and is connected to a distribution ring located inside the shroud above the tube bundle.

The steam generator supports are described in Section 5.4.14.

5.4.2.3 Economizer Integrity

The economizer section is designed in full consideration of operating transients, startup and standby operation, and accident conditions such as loss of feedwater flow and feedwater line break. The structural design of the various parts is adequate to withstand the thermal and pressure loadings from these various conditions, consistent with the appropriate load classifications and design rules in the ASME Code, Section III, see Appendix G.

The components of the steam generator economizer section have been designed for the primary stresses which occur due to the blowdown associated with a feedline break. The divider plates, which separate the economizer region from the evaporator region of the secondary side, are supported from the vessel shell and the central cylindrical support welded to the tubesheet. This divider cylinder becomes an extension of the primary tubesheet stay cylinder, though less massive, and extends the full height of the economizer. The tube support/flow baffle plates are supported from the vessel shell, the divider cylinder and the tubesheet via an array of support rods. The support rods, which also serve as support plate spacers are solid and designed for either tensile or buckling loads. An effort has been made to avoid the use of thin plates which may collapse when subjected to differential pressure.

5.4.2.4 Steam Generator Materials

The pressure boundary materials used in the construction of the steam generator are listed in the Fracture Toughness tables. These materials are in accordance with the ASME Boiler and Pressure Vessel Code, Section III. Code cases used in the fabrication of the steam generator are discussed in Section 5.2.1.

The Class 1 components of the steam generator will meet the fracture toughness requirements of the ASME code. An additional discussion of fracture toughness testing is included in Section 5.2.3.

Discussion of the techniques used to maintain cleanliness during final assembly and shipment are discussed in Section 5.2.3.

5.4.2.4.1 Steam Generator Tubes

The method of fastening tubes to the tube sheet conforms with the requirements of Section III and IX of the ASME Code. Tube expansion into the tube sheet is total with no voids or crevices occurring along the length of the tube in the tube sheet.

Localized corrosion of tubing material has led to steam generator tube leakage in some operating reactor plants. Examination of tube defects that have resulted in leakage has shown that two mechanisms are primarily responsible. These localized corrosion mechanisms are referred to as (1) stress assisted caustic cracking, and (2) wastage or beavering. Both of these types of corrosion have been related to steam generators that have operated on phosphate chemistry. The caustic stress corrosion type of failure is precluded by controlling bulk water chemistry to the specification limits shown in Section 10.3.5. Removal of solids from the secondary side of the steam generator is discussed in Section 10.4.8.

Localized wastage or beavering has been eliminated by removing phosphates from the chemistry control program.

Volatile chemistry (discussed in Section 10.3.5) has been successfully used in all C-E steam generators that have gone into operation since 1972.

Fracture toughness data for the primary side of steam generators 1 and 2 for Palo Verde Units 1, 2, and 3 are presented in paragraph 5.2.3.3.1.

Fracture toughness data for the secondary side of steam generators 1 and 2 are presented for Palo Verde Unit 1 in tables 5.4-1 to 5.4-12, for Unit 2 in tables 5.4-13 to 5.4-24, and for Unit 3 in tables 5.4-25 to 5.4-36.

Onsite cleaning and cleanliness control for the steam generators is in accordance with the recommendations of ANSI Standard N45.2.1-1973, Cleaning of Fluid Systems and Associated Components During Construction Phase of Nuclear Power Plants, and Regulatory Guide 1.37 as discussed in section 1.8.

5.4.2.5 Tests and Inspections

Prior to, during and after fabrication of the steam generator, nondestructive tests based upon Section III of the ASME Code are performed.

Initial hydrostatic tests of the primary and secondary sides of the steam generator were conducted in accordance with ASME Code, Section III. Following satisfactory performance of the hydrostatic tests, magnetic-particle inspections are made on all accessible welds.

Inservice inspection of the steam generator is described in Section 5.2.4.

43-4	PV-DWD-15-ABB081	-	SA-194 Gr. B7	Nut	10

a. Preload temperature (diameter less than 4 inches) per ASME B&PV Code, Section III, Article NB 2333.

b. Includes studs, nuts, and washers.

c. For Unit 2, cycle 12 only, SA-540 material may be replaced by SA-194, Gr 7 material for the secondary manway nuts (MEE 03689).

43-4	PV-DWD-15-ABB081	-	SA-194 Gr. B7	Nut	10

a. Preload temperature (diameter 1-4 inches) per ASME B&PV Code, Section III, Article NB-2333

b. Includes studs, nuts, and washers.

c. For Unit 2, cycle 12 only, SA-540 material may be replaced by SA-194, Gr 7 material for the secondary manway nuts (MEE 03689).

5.4.3 REACTOR COOLANT PIPING

5.4.3.1 Design Basis

Applicable design codes are found in Table 5.2-1. The reactor coolant loop piping is designed and analyzed for all transients specified in Section 3.9.1. In addition, certain nozzles are subjected to local transients which are included in the design and analysis of the areas affected. Thermal sleeves are installed in the charging nozzle to accommodate these additional transients.

In addition to being specified as Seismic Category I, the piping is designed to ensure that critical vibration frequencies are well out of the range expected during normal operation and during abnormal conditions. Additional presentations relating to seismic and dynamic analysis and criteria for the reactor coolant piping is contained in Sections 3.7.2 and 3.9.2, respectively.

5.4.3.2 Description

Each of the two heat transfer loops contains five sections of pipe: one 42-in. internal diameter pipe between the reactor vessel outlet nozzle and steam generator inlet nozzle, two 30-in. internal diameter pipes from the steam generator's two outlet nozzles to the reactor coolant pumps suction nozzle, and two 30-in. internal diameter pipes from the pumps discharge nozzle to the reactor vessel inlet nozzles. These pipes are referred to as the hot leg, the suction legs, and the cold legs, respectively. The other major pieces of reactor coolant piping are the surge line, a 12-in. pipe between the

pressurizer and the hot leg, and the spray line, a 4-inch pipe at the pressurizer end reduced to a 3-inch pipe and connected to two (2) cold legs.

The 42-in. and 30-in. pipe diameter are selected to obtain coolant velocities which provide a reasonable balance between erosion-corrosion, pressure drop, and system volume. The surge line is sized to limit the frictional pressure loss through it during the maximum in-surge so that the pressure differential between the pressurizer and the heat transfer loops is no more than 5 percent of the system design pressure. The spray line sizing is discussed in Section 5.4.10.

To reduce the amount of field welding during plant fabrication, the 42-in. and 30-in. pipes are supplied in major pieces, complete with shop-installed instrumentation nozzles and connecting nozzles to the auxiliary systems. Where required, the nozzles are supplied with safe ends to facilitate field welding of the connecting piping.

Flow restricting orifices (7/32" dia. x 1" long) are provided in the nozzles for the RCS instrumentation and sampling lines to limit flow in the event of a break downstream of a nozzle.

The flow restricting orifice in the reactor head vent line limits flow in the event of a downstream pipe break. This orifice is 1/4" dia. x 1.25" long and is functionally equivalent to the 7/32" dia. x 1" long orifices serving the RCS instrument and sample lines.

5.4.3.3 Materials

The materials used in the fabrication of the piping are listed in Table 5.2-2. These materials are in accordance with the ASME Code, Section III. The provisions taken to control those factors that contribute to stress corrosion cracking are discussed in Section 5.2.3.

Fracture toughness of the reactor coolant piping is discussed in Section 5.2.3.

5.4.3.4 Tests and Inspections

Prior to, during and after fabrication of the reactor coolant piping, nondestructive tests based upon Section III of the ASME Code were performed. In addition, the fully assembled reactor coolant system is hydrostatically tested in accordance with the Code.

Inservice inspection of the reactor coolant system piping is discussed in Section 5.2.4.

5.4.4 MAIN STEAM LINE FLOW RESTRICTIONS

The steam generator outlet nozzles are one piece forgings with an integral venturi type flow restrictor. The venturi section of the nozzle is designed to reduce the flow area by 70%.

5.4.5 MAIN STEAM LINE ISOLATION SYSTEM

The main steam line isolation system is composed of portions of the main steam system and the engineered safety features actuation system. Discussed here are those portions of these systems that respond to a Main Steam Isolation Signal, as

defined in Section 7.3. A discussion of radiological considerations is provided in Section 12.3.

In addition, the main steam system valves and arrangement are described in subsection 10.3.2. Main steam line isolation system operability is discussed in section 3.9.

5.4.5.1 Design Bases

A. The main steam line isolation valves are designed to isolate the steam generators and the main steam lines in the event of a main steam line rupture.

B. The main steam line isolation valves are designed to perform containment isolation functions for the main steam lines in the event of a design basis accident, as discussed in Section 6.2.4. In the event of a steam line break outside the containment, the isolation function serves to reduce the potential leakage of radioactivity to the environment.

C. The main steam isolation valves are designed to isolate the main steam lines and the steam generators as required for maintenance.

   C-E interface requirements for the main steam isolation valves are listed in Subsection 5.1.4.

5.4.5.2 System Design

5.4.5.2.1 General Description

Each of the four main steam lines is provided with a power-actuated main steam isolation valve designed to stop flow from either direction when it is tripped closed. Each valve is

located outside containment and is provided with means of actuation from the engineered safety features actuation system, meeting the requirements of IEEE Standard 279.

The logic circuitry required to isolate the main steam lines is discussed in Section 7.3. The main steam system valves and arrangement are discussed in Section 10.3.2.2.2.

5.4.5.2.2 Component Description

The main steam isolation system consists of the main steam isolation valves and their associated controls and instrumentation. The main steam isolation valves are remotely operated valves designed to either fail closed or be guaranteed to close upon receipt of Main Steam Isolation Signal. The main steam isolation valves can be monitored and controlled locally and in the control room.

5.4.5.2.3 System Operation

The main steam isolation valves are designed to isolate the main steam lines and the steam generators as required during operation and under accident conditions.

A steam line break inside containment would result in a pressure rise in the containment. Reverse flow protection is also achieved through the main steam isolation valves. To achieve reverse flow protection in the case of the main steam pipe rupture, the valve is fully closed within 5 seconds from receipt of the initiating signal.

The main steam line isolation system components are qualified to serve in the environment specified in Section 3.11.

5.4.5.3 Design Evaluation

Design evaluations are listed to correspond with the design bases listing.

A. The main steam isolation valves are capable of isolating the steam generators within 4.6 seconds after receiving a signal from the engineered safety features actuation system. In the event of a steam line break, this action prevents continuous uncontrolled steam release from more than one steam generator. Protection is offered for breaks inside or outside the containment.

B. The main steam isolation valves, their operators, and associated circuitry are Seismic Category I, and are protected against missiles and the effect of high-energy line breaks.

   All main steam isolation valves are designed, fabricated, tested, and installed in accordance with the codes and standards identified in the interface requirements described in Section 5.1.4. Assurance of operability is discussed in Section 3.9.3.

5.4.6 REACTOR CORE ISOLATION COOLING SYSTEM

This system is not applicable to a pressurized water reactor.

5.4.7 RESIDUAL HEAT REMOVAL SYSTEM

5.4.7.1 Design Bases

5.4.7.1.1 Summary Description

The Shutdown Cooling System (SCS) is used in conjunction with the Main Steam and Main or Emergency Feedwater Systems (see Sections 10.1 and 10.4.7) to reduce the temperature of the Reactor Coolant System (RCS) in post shutdown periods from normal operating temperature to the refueling temperature. The initial phase of the cooldown is accomplished by heat rejection from the steam generators (SG) to the condenser or atmosphere. After the reactor coolant temperature and pressure have been reduced to approximately 350°F and 400 psia, the SCS is put into operation to reduce the reactor coolant temperature to the refueling temperature and to maintain this temperature during refueling.

The Shutdown Cooling Heat Exchangers (SDCHX) are also used during the recirculation mode following a Loss-Of-Coolant Accident (LOCA) or Main Steam Line Break (MSLB) for containment spray purposes as described in Section 6.3.

The SCS is used in addition to the S.G. atmospheric steam release capability and the Auxiliary Feedwater System to cooldown the RCS following a small break LOCA (see Section 6.3). The SCS would also be used subsequent to steam and feedline breaks, steam generator tube ruptures, and is used to maintain flow through the core during plant startup.

5.4.7.1.2 Functional Design Bases

The following functional design bases apply to the Shutdown Cooling System:

A. No single active failure prevents at least one complete train of the SCS from being brought on line from the control room, whether this is during normal plant cooldown or following a Design Basis Event.

B. The functional requirements defined in Paragraph 5.4.7.1.1 are met assuming the failure of a single active component during shutdown cooling or a single active or limited leakage passive failure of a component during the recirculation mode following a Design Basis Event.

C. No single failure allows the SCS to be overpressurized by the RCS. Shutdown Cooling System components whose design pressure is less than the Reactor Coolant System design pressure are provided with overpressure protection by use of interlocks, valve arrangement, and relief valves.

D. The PVNGS Shutdown Cooling System was originally designed and sized to provide sufficient cooling capacity to cool the RCS from 350°F to a refueling temperature of 125°F in less than 27.5 hours following reactor shutdown using two trains of SCS. Note that, although the PVNGS SCS was designed based on a final refueling temperature of 125°F, PVNGS has established the refueling temperature at 135°F. Two trains of shutdown cooling are capable of attaining refueling temperature in less than 27.5 hours following reactor shutdown.

A single train of SCS provides sufficient cooling capacity to cool and maintain the RCS temperature below 200°F in less than 36 hours after reactor shutdown. The PVNGS SCS cooling capacity is based on a component cooling water temperature of 105°F and the decay heat associated with a 4000 MWth APR Core.

Typical cooldown curves are shown in Figures 5.4-10 and 5.4-11.

E. The components of the shutdown cooling system are designed in accordance with Section 5.4.7.3.4.

F. Materials are selected to preclude system performance degradation due to the effects of short and long term corrosion.

G. Deleted

H. Pressure and temperature of the reactor coolant system (RCS) vary from 410 psia and 350F at initiation of shutdown cooling to atmospheric pressure and 135F at refueling conditions.

I. Each train of the SCS may be initiated and operated with one injection nozzle isolated as long as SCS flow through a nozzle does not exceed 6000 gpm.

J. Shutdown cooling system suction line relief valves have a set pressure of 467 psig with a capacity of 5635(@ 10% accumulation) gallons per minute each.

K. Shutdown cooling system heat exchanger relief valves have a set pressure of 650 psig with a capacity of 120 gallons per minute each.

L. Shutdown cooling system thermal relief valves have a set pressure of 650 psig with a capacity of 10 gallons per minute per valve, except for relief valves SI-141/150 which have a set point of 485 psig and a capacity of 10 gallons per minute (as described in paragraph 6.3.2.2.5.a.9) and valves SI-194/191 which have a set point of 650 psig and a capacity of 120 gallons per minute (as described in paragraph 5.4.7.1.2.K, above.

M. When the RCS temperature is below 200F and pressurizer pressure less than 250 psia, the containment spray pumps may be realigned and started to provide additional flow through the heat exchangers.

N. Interlocks associated with the shutdown cooling suction isolation valves prevent the valves from being opened if RCS pressure exceeds 410 psia. Visual and audible alarms are provided in the main control room to inform the operator that the shutdown cooling suction isolation valves are not fully closed when RCS pressure is above the shutdown cooling system operating pressure. These alarms are tested at each refueling outage. An interlock for automatic closure of the isolation valves is not provided. The instrumentation and controls which implement this are discussed in section 7.6.

O. Shutdown cooling isolation valves UV-653 (train A) and UV-654 (train B) are deenergized during plant operation. These valves are deenergized due to findings from the 10CFR50, Appendix R, spurious actuation analysis.

P. Interlocks supplied by independent power supplies are provided to isolate the low-pressure portion of the shutdown cooling system.

Q. When RCS pressure is less than 430 psia, the safety injection tank isolation valves may be closed.

In addition pressure, temperature, flow indication, and SDC isolation valve position (SI-UV-651 through UV-656) are provided in the control room.

5.4.7.2 CESSAR Interface Requirements

Provided below are interface requirements repeated from CESSAR Section 5.4.7.1.3.

Below are detailed the interface requirements that the Shutdown Cooling System (SCS) places on certain aspects of the BOP, listed by categories. In addition, applicable GDC and Regulatory Guides which C-E utilizes in its design of the SCS are presented. These GDC and Regulatory Guides are listed only to show what C-E considers to be relevant, and are not imposed as interface requirements unless specifically called out as such in a particular interface requirement.

Relevant GDC-	1, 2, 3, 4, 10, 34, 35, 36, 37, 38, 39, 40, 50, 54, 56, 57
Relevant -	1.1, 1.4, 1.26, 1.28, 1.29, 1.31, 1.34, 1.36,
Reg. Guides	1.44, 1.46, 1.37, 1.48, 1.50, 1.51, 1.61, 1.64, 1.68, 1.73, 1.74, 1.75, 1.79, 1.84, 1.85, 8.8.

A. Power

1. Electrical power requirements for the motor-operated valves in the Shutdown Cooling System as contained in CESSAR Table 8.3.1-1 are met in the PVNGS design as discussed in Section 8.3.

2. The electrical supplies for Shutdown Cooling System pumps, valves and instruments shall be as follows:

    a. The Shutdown Cooling System pumps and valves shall be capable of being powered from the plant's normal and emergency power sources. Power connections shall be through independent power trains so that in the event of a LOCA, in conjunction with the loss of normal power and a single failure in the emergency electrical supply, the capability of initiating shutdown cooling with a minimum of one subsystem exists.

    b. An independent electrical bus shall supply one LPSI pump and the valves in the associated heat exchanger train.

    c. The shutdown cooling suction line isolation valves (SI-651 through SI-656 on engineering drawing 01, 02, 03-M-SIP-002) shall receive electrical power such that no fault to a single power supply could open the valves to connect the RCS and Shutdown Cooling System inadvertently, nor could a fault to a single power supply prevent opening all the valves of

at least one suction line during initiation of shutdown cooling.

The power supply to the shutdown cooling isolation valves is shown below. The numbers adjacent to valves indicate the source of power.

	Valve	Source of Power[a]
Train A	UV655	1
	UV653	3
	UV651	1
Train B	UV656	2
	UV654	4
	UV652	2

a. Sources of Power

(1) Fed from Class 1E MCC E-PHA-M35

(2) Fed from Class 1E MCC E-PHB-M36

(3) Fed from Class 1E, Channel C, battery through Class 1E inverter E-PKC-N43

(4) Fed from Class 1E, Channel D, battery through Class 1E inverter E-PKD-N44

d. Two independent instrument power supplies shall be provided for the Shutdown Cooling System Instrumentation.

B. Protection From the Effects of Natural Phenomena

1. The location, arrangement, and installation of the Shutdown Cooling System components shall be such that floods (and tsunami and seiches for applicable sites) or the effects thereof, per the requirements of General Design Criteria (GDC) 2 of 10CFR50, will not prevent them from performing their safety functions.

2. The location, arrangement, and installation of the SCS components shall be such that winds and tornadoes or the effects thereof, per the requirements of GDC 2 of 10CFR50, will not prevent them from performing their safety functions.

3. The location, arrangement, and installation of the SCS components shall be such that they will withstand the effects of earthquakes, per the requirements of GDC 2 of 10CFR50, without loss of the capability to perform their safety functions.

   Failure of nonseismic systems and structures shall not cause loss of either SCS train.

C. Protection From Pipe Failure

1. Pipe Break Considerations

   The Shutdown Cooling System both inside and outside containment shall be protected from the

effects of postulated high and moderate energy pipe rupture.

2. Pipe Leakage Considerations

No limited leakage passive failure or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, or loss of NPSH) in a connecting system (e.g., Safety Injection System or Containment Spray System) shall preclude the availability of minimum acceptable shutdown cooling capability. Minimum acceptable shutdown cooling capability is defined as that provided by one LPSI pump and its associated heat exchanger train.

All SCS instruments and associated instrument lines, root valves, and isolation valves, shall be designed to maintain pressure boundary integrity following a seismic event.

3. Design Requirements for Protection from Pipe Break

For all parts of the SCS appropriate design procedures shall be employed to ensure that a postulated pipe failure does not result in a loss of function of the SCS.

a. Protection of the SCS from the consequences of a postulated pipe failure shall be by (1) separation via physical plant layout, (2) pipe restraints, (3) protective

structures, (4) watertight rooms, (5) isolation capability, or (6) other suitable means.

b. Isolation valves (system and/or containment) used to contain leakage shall be protected from the adverse effects of a pipe failure which might preclude their operation when required.

D. Missiles

1. For the portion of the SCS located inside containment, appropriate missile barrier design procedures shall be used to insure that the impact of any potential missile will not lead to a Loss-Of-Coolant Accident (LOCA) or preclude the system from carrying out its specified safety functions.

2. For the portion of the SCS located outside containment, appropriate design procedures (e.g., proper turbine orientation, physical separation, or missile barriers) shall be used to insure that the impact of any potential missile does not prevent the system or equipment from carrying out its specified safety functions.

3. Appropriate design procedures shall be used to insure that the impact of any potential missile does not prevent the conduct of a safe plant

shutdown, or prevent the plant from remaining in a safe shutdown condition.

E. Separation

1. Concrete compartments within containment shall serve as protection for that portion of the SCS which is inside the containment and thus could be subjected to credible dynamic effects originating within the containment under the conditions of accidents the SCS is required to mitigate. Separation via physical plant layout, pipe restraints, isolation capability, or other suitable means shall be provided as necessary to guard against damage to the components of the SCS inside the containment from these dynamic effects.

2. Containment isolation valves, operators, and associated power and control systems located outside the containment that are part of the SCS shall be protected from dynamic effects and loss of function resulting from equipment failures and pipe ruptures originating in adjacent areas. Protection from such failure and rupture effects shall be by separation, enclosure, restraint, water-tight rooms or other suitable means.

3. Adequate physical separation shall be maintained between the redundant piping paths and containment penetrations of the Shutdown Cooling System such that the Shutdown Cooling System

will meet its functional requirements even with a single active failure or a limited leakage passive failure.

F. Independence

1. Electrical - See Section 5.4.7.1.3 (A.2.b.)

2. Environmental - See Section 5.4.7.1.3 (Q)

3. Mechanical - See Section 5.4.7.1.3 (C, D, E)

G. Thermal Limitations

1. Component Cooling Water - See Section 5.4.7.1.3 (P)

2. Environmental - See Section 5.4.7.1.3 (Q)

H. Monitoring

1. The safety related instrumentation of the SCS is identified in Table 7.5-2.

I. Operational/Controls

1. The SCS components shall be powered such that the operational and control requirements of Section 5.4.7.1.3 (A) are met.

2. The SCS shall meet the operation and control requirements of Section 5.4.7.1.2.

J. Inspection and Testing

1. All SCS ASME, Section III components shall be arranged to provide adequate clearances to permit inservice inspection.

2. Manually operated valves which contain reactor coolant or other potentially radioactive liquids during normal plant operations shall be provided with handwheel extensions and shielding, to allow periodic actuation.

3. SCS components which contain reactor coolant or other potentially radioactive liquids during normal plant operations, and which require access for periodic pressure tests and nondestructive examination, shall be capable of being flushed prior to testing. The low pressure safety injection pumps shall provide the driving head for flushing.

4. System components not designed to ASME, Section III, should be located such that the access for periodic visual inspection for leakage, structural distress, and corrosion is possible.

5. System and component arrangement shall allow adequate clearances for performance of inspections identified in the Technical Specifications.

K. Chemistry/Sampling

1. The component cooling water shall contain corrosion inhibitors. The water shall not contain scale-forming compounds. The cooling water chemistry control program is the same as that described in Section 9.2.2.1.4.

2. The Sampling System shall provide a means of obtaining remote liquid samples from the Shutdown Cooling System for chemical and radiochemical laboratory analysis.

3. The sample lines in contact with reactor coolant shall be austenitic stainless steel that is compatible with the fluid chemistry.

4. The sample lines shall be sized such that the fluid velocity allows a representative sample and the purge flowrate is high enough to remove crud from the sample lines.

L. Materials

1. Piping and all metallic parts in contact with the system fluid, with the exception of some component internals as required, shall be of austenitic stainless steel.

   Selection shall be on the basis of compatibility with design pressure and temperature stress considerations and with the chemistry of the system fluid.

   Valve packing, gaskets, and diaphragm materials forpackless valves shall also be compatible with the radiation dose and the chemistry of the system fluid.

2. Fabrication and erection of system materials shall be consistent with the quality standards

of General Design Criteria 1 of 10CFR50, Appendix A.

3. Care shall be taken to prevent sensitization and to control the delta ferrite content of (1) the welds which join any system fabricated of austenitic stainless steel to the SCS, and (2) the field welds of the SCS.

4. Controls shall be exercised during system construction to assure that contaminants do not significantly contribute to stress corrosion of stainless steel.

M. System/Component Arrangement

1. The first isolation valve on the shutdown cooling suction lines shall be located as close to the Reactor Coolant System as practical. The volume of the shutdown cooling suction piping between the RCS and the first isolation valve shall be as small as possible. This requirement minimizes the amount of piping exposed to normal RCS pressure.

2. The maximum allowable distance of the low pressure safety injection pump suctions below the pressurizer upper pressure sensor nozzle shall be 115 feet. This ensures that the SCS design pressures will not be exceeded.

3. The low pressure safety injection pumps shall be located as close as practical to the containment.

a. The elevation of these pumps shall be low enough such that adequate NPSH is available during shutdown cooling when the pumps take a suction on the RCS. The required NPSH during shutdown cooling is 20 feet.

b. The elevation of these pumps shall be low enough such that adequate NPSH is available during the recirculation mode of safety injection when the pumps take a suction on the containment sump.

4. The Shutdown Cooling System piping and components shall be arranged such that straight piping runs upstream and downstream of the flow measurement device orifices are provides of sufficient length to comply with: ASME Fluid Meters; their theory and application, Parts 1 & 2.

5. The SCS suction lines shall be arranged such that no portion is physically above the lowest point of the RCS hot leg piping.

6. If the shutdown cooling suction line overpressure relief valves are located at a higher elevation than the LPSIP suction centerline, their set pressure shall be reduced to adequately compensate. An elevation difference greater than 50 feet will invalidate the valve setpoint.

7. Physical identification for safety related RCS equipment shall be provided to allow recognition of safety status by plant personnel.

8. The elevation difference from the bottom discharge nozzle of the SIT's to the centerline of the LPSI pump suctions shall not exceed 85 feet. This ensures that the SCS design pressure will not be exceeded.

9. In the event of a limited leakage passive failure in one SCS train during long term cooling, personnel access to the intact train shall be possible.

10. Protection shall be provided from internally generated flooding that could prevent performance of safety-related functions.

N. Radiological Waste

1. The containment sump shall be designed to accept relief valve discharge from the shutdown cooling suction line overpressure relief valves at temperatures up to 400F and at flows up to 4000 gal/min.

O. Overpressure Protection

1. Thermal relief valves shall be provided in isolated sections of piping in the system to prevent over-pressurization due to thermal transients.

P. Related Service

1. A fire protection system shall be provided to protect the SCS and shall include, as a minimum, the following features:

   a. Facilities for fire detection and alarming;

   b. Facilities or methods to minimize the probability of fire and its associated effects;

   c. Facilities for fire extinguishment;

   d. Methods of fire prevention such as use of fire resistant and non-combustible materials whenever practical, and minimizing exposure of combustible materials to fire hazards;

   e. Assurance that fire protection systems do not diversely affect the functional and structural integrity of safety related structures, systems, and components;

   f. Assurance that fire protection systems are designed to assure that their rupture or inadvertent operation does not significantly impair the capability of safety related structures, systems, and components;

   g. The fire protection system piping design and arrangement shall be such as to assure that the functional and structural

integrity of the Shutdown Cooling System is adequately protected against the effects of pipe whip, jet impingement, and environmental effects resulting from postulated piping ruptures in the fire protection system.

2. Cooling Water System Requirements

   a. The cooling water system design shall be such that cooling water consistent with the requirements of b. below is available to supply the shutdown cooling heat exchangers when an irradiated core is present in the reactor vessel or the spent fuel pool.

   b. Cooling water shall be supplied at the following temperatures and be able to remove the heat loads listed for the given conditions.

SHUTDOWN COOLING HEAT EXCHANGERS

Situation	Cooling Water Inlet Temperature	Design Heat Load (Million Btu/ hour) (includes both heat exchangers)
Post-LOCA	65 - 120F	290
Shutdown Cooling:		
3-1/2 hours after Shutdown	65 - 120F	247
27-1/2 hours after Shutdown	65 - 105F	87.6

c. For all conditions, cooling water shall be supplied as follows:

Parameter	Required Value Per Heat Exchanger
Normal Allowable Delivery Pressure	100 psig
Maximum Allowable Delivery Pressure	150 psig
Required Flowrate	11,000 gal/min
Maximum Allowable Flowrate	13,000 gal/min

d. Cooling water piping supplying the shutdown cooling heat exchangers shall be designed and fabricated in accordance with ASME B&PVC, Section III, Class 3, as a minimum, and shall be designed as Seismic Category I, Safety Class 3, as a minimum.

e. The cooling water system which services the SCS shall be designed with sufficient redundancy and diversity such that one SCS heat exchanger train will always be supplied cooling water.

f. The cooling water system which services the SCS shall be designed consistent with the cooling water chemistry.

3. Containment Spray System (CSS)

a. The CSS shall be designed to allow use of the containment spray pumps can augment the SCS during the later stage of plant cooldown when plant temperature is less

than 200F. The spray system shall provide 4000 gal/min per train at a head which can be set between 250-300 feet.

b. The CSS shall be designed such that the containment spray pumps can be aligned for automatic spray initiation concurrent with shutdown cooling operation of the LPSI pumps. When shutdown cooling is in operation and the containment spray pumps are aligned for automatic initiation, the containment spray alignment shall bypass the shutdown cooling heat exchangers.

Q. Environmental

1. The proper operating environmental conditions for the equipment of one train of the SCS shall be maintained independently of the environment of the other train of the SCS, e.g., failure or isolation of the ventilation capability to one train of the SCS shall not cause the environmental limits of the other SCS train to be exceeded.

2. The auxiliary building ventilation system shall control ambient air conditions in the proximity of all C-E supplied motor driven or diaphragm operated equipment in the SCS in accordance with the requirements of Section 3.11.

5.4.7.3 CESSAR Interface Evaluation

The CESSAR interface requirements listed in paragraph 5.4.7.1 are met by the PVNGS design as follows:

A. Power

1. Electrical power requirements for the motor-operated valves in the SCS as contained in CESSAR Table 8.3.1-1 are met in the PVNGS design as discussed in section 8.3.

2. The electrical supplies for Shutdown Cooling System pumps, valves, and instruments are as follows:

   a. The SCS pumps and valves are capable of being powered from the plant's normal and emergency power sources. Power connections are through independent power trains so that in the event of a LOCA, in conjunction with the loss of normal power and a single failure in the emergency electrical supply, the capability of initiating shutdown cooling with a minimum of one subsystem exists. Refer to section 8.3 for a detailed description of the electrical supply system.

   b. An independent train-oriented power supply to each LPSI pump and valves in the associated heat exchanger train is provided.

c. The shutdown cooling suction line isolation valves (SI-651 through SI-656 on CESSAR Figure 6.3-1B) receive electrical power such that no fault to a single power supply can open the valves to connect the RCS and SCS inadvertently, nor can a fault to a single power supply prevent opening all the valves of at least one suction line during initiation of shutdown cooling.

The power supplies to the shutdown cooling isolation valves are given below. Valve arrangement is shown in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003.

Train A:	UV-655	(Note 1)
	UV-653	(Note 3)
	UV-651	(Note 1)
Train B:	UV-656	(Note 2)
	UV-654	(Note 4)
	UV-652	(Note 2)

NOTES:

1. Fed from train A Class 1E MCC E-PHA-M35
2. Fed from train B Class 1E MCC E-PHB-M36
3. Fed from Class 1E, Channel C, battery through Class 1E inverter E-PKC-N43
4. Fed from Class 1E, Channel D, battery through Class 1E inverter E-PKD-N44

The power supplies indicated provide power to the valve operator (motor). Train A valves are completely independent from train B valves, each train providing a redundant parallel shutdown cooling path. Each train consists of three valves in series powered from two separate channels. Therefore, no single or common failure can result in loss of shutdown cooling capability, either due to failure of a valve to open or failure of a valve to close. Thus, PVNGS meets the single failure criterion.

d. Two independent instrument power supplies are provided for the shutdown cooling system Instrumentation.

B. Protection From the Effects of Natural Phenomena

1. Design provisions for maintaining functional capability of the safety-related systems during a flood, earthquake, a tornado, or high winds as defined in GDC 2 are discussed in subsection 3.1.2. The SCS is located inside Seismic Category I structures. The protection of Seismic Category I structures against natural phenomena is presented in sections 3.3 and 3.4.

2. See paragraph 5.4.7.2, listing B.1.

3. Design provisions for maintaining functional capability of the safety-related systems during

an earthquake or other natural phenomena as defined in GDC 2 are discussed in subsection 3.1.2. All components of the SCS are located in Seismic Category I structures in accordance with Regulatory Guides 1.29 and 1.48. Assessment of the geologic and seismic characteristics of the site was accomplished in accordance with 10CFR100, Appendix A.

Failure of nonseismic systems and structures will not cause loss of either SCS train.

C. Protection from Pipe Failure

1. Pipe Break Considerations

The SCS, both inside and outside containment, is protected from the effects of postulated high and moderate energy pipe rupture (See Subsection C.3 below). During SCS operation, the piping system is considered a moderate energy system per Branch Technical Position MEB 3-1 because it operates in the high-energy range for less than 2% of system operation. In accordance with MEB 3-1, the largest crack is based on a circular opening whose area is equal to a rectangle one-half pipe diameter in length and one-half pipe wall thickness in width.

Maximum expected leakage from a moderate energy pipe rupture postulated in the SCS is defined by the methods of Subsection 3.6.2. At the NRC’s request, a line break is postulated downstream

of the Shutdown Cooling System (SCS) heat exchanger while in the shutdown cooling mode. The purposes of evaluating this break are to ensure that (1) the RCS piping system can sustain the resulting loss of inventory while maintaining core cooling (i.e., the core remains covered) and (2) at least one SCS train remains operable. This postulated break will flood the heat exchanger compartment. Flooding from this line break is enveloped by the worst case (design bases) flood scenario (See Subsection C.3 below).

The maximum discharge rate during SCS operation is approximately 990 gallons per minute based on the upper limits of 275 psig and 200°F for a moderate energy system. The rate is calculated using a 2.5-square inch crack in the shutdown cooling heat exchanger (SDCHX) discharge line since this line is a 20-inch line. The crack location is in the SDCHX room on the 70-foot level of the auxiliary building. Assuming no operator action for 30 minutes, the total loss of RCS inventory is approximately 30,000 gallons. This loss of RCS inventory will not adversely affect core cooling as the redundant train can provide full heat removal capability, and sufficient RCS inventory remains to provide core cooling. The water level will be well above the midpoint of the RCS hot leg

when the operator isolates the break and places the redundant train into service.

Alarms are provided in the control room on low-low pressurizer level (25%). In addition to these alarms, control room indication of room level alarms is provided to alert the operator of a leak and to assist the operator in locating the affected train which then can be isolated. Room sump level instrumentation is provided in each ECCS pump room, pipe chase room, SDCHX room, valve gallery area, and piping penetration room for both train A and train B piping which is separated from each other. The above mentioned rooms are also separated so that a leak in one train is specifically identified with that train. Sump volumes are relatively small so that a leak of 990 gallons per minute would be alarmed very quickly (high level alarm corresponds to approximately 3.5 gallons). The room sump level alarms and instrumentation for the ECCS pump rooms are Class 1E.

2. Pipe Leakage Considerations

No limited leakage passive failure or the effects thereof (such as flooding, spray impingement, steam, temperature, pressure, radiation, or loss of NPSH) in a connecting system (e.g., safety injection system or containment spray system) precludes the

availability of minimum acceptable shutdown cooling capability. Minimum acceptable shutdown cooling capability is defined as that provided by one LPSI pump and its associated heat exchanger train.

All SCS instruments and associated instrument lines, root valves, and isolation valves are designed to maintain pressure boundary integrity following a seismic event.

3. Design Requirements for Protection from Pipe Break

   The SCS, both inside and outside containment, is protected from the effects of postulated high and moderate energy pipe rupture. Appropriate design procedures are employed to ensure that postulated failures do not result in a loss of SCS function. The SCS design includes the following features:

   a. Protection from the consequences of a postulated pipe failure by: (1) separation via physical plant layout, (2) pipe restraints, (3) protective structures, (4) isolation capability, or (5) other suitable means (see UFSAR Table 3.6-3);

   b. Isolation valves (system and/or containment) used to contain leakage are protected from the adverse effects of a

pipe failure which might preclude their operation when required.

These design features protect the redundant SCS train and other plant equipment from the effects of a pipe break (pressurization, pipe whip, impingement, and flooding). The design basis flood for specific rooms and compartments is based on the line break with the largest spillage per Section 3.6.2.1.

Flood protection for the ECCS pumps is provided by train separation and drainage system design. Each HPSI, LPSI, and CS pump is located in a separate compartment. The compartment walls serve as flood barriers so that flooding within or outside of the ESF pump room of one train will not jeopardize the operation of the pump of the redundant train. Water in the ECCS compartments is routed to the Radioactive Waste Drain System, which includes two ESF drain subsystems, one serving Train A equipment and the other serving Train B equipment. A drain header from each ECCS pump room is routed directly to the appropriate ESF sump and is equipped with a check valve to prevent backflow. These check valves are included in the ISI/IST Program. The two ESF drain subsystems are

included in the Maintenance Rule, and the two ESF drain subsystems are physically separate from drains serving the non-ESF equipment rooms (reference engineering drawings 01, 02, 03-M-RDP-002). Thus, the worst case (design basis) flooding of one ESF pump room, will not affect the operation of redundant safety-related equipment that is required to perform protective actions to mitigate the consequences of the postulated break or place the plant in a safe shutdown condition.

D. Missiles

1. Design provisions for protecting the SCS from missiles inside the containment are discussed in subsection 3.5.2.

2. Design provisions for protecting the SCS from missiles outside the containment are discussed in subsection 3.5.2.

3. Appropriate design procedures which ensure that the impact of any potential missile does not prevent the conduct or maintenance of a safe plant shutdown are discussed in section 3.5.

E. Separation

1. Protection of redundant safety systems inside containment is discussed in section 3.6.

2. Protection of redundant safety systems outside containment is discussed in section 3.6.

3. Adequate physical separation is maintained between the redundant piping paths and containment penetrations of the SCS such that the shutdown cooling system will meet its functional requirements even with a single active failure or a limited leakage passive failure.

F. Independence

1. Electrical - See paragraph 5.4.7.2, sublisting A.2.b.

2. Environmental - See paragraph 5.4.7.2, listing Q.

3. Mechanical - See paragraph 5.4.7.2, listings C, D, and E.

G. Thermal Limitations

1. Essential cooling water - See paragraph 5.4.7.2, listing P.

2. Environmental - See paragraph 5.4.7.2, listing Q.

H. Monitoring

Instrumentation used for monitoring of SCS performance is provided as discussed in section 7.5.

I. Operational/Controls

1. The SCS components are powered such that the operational and control requirements of CESSAR interface requirements stated in paragraph 5.4.7.1, listing A, are met.

2. The SCS is designed to meet the operation and control requirements of CESSAR Section 5.4.7.1.2.

J. Inspection and Testing

1. All SCS ASME, Section III, components are arranged to provide adequate clearances to permit inservice inspection. Refer to subsection 5.2.4 and section 6.6.

2. Manually-operated valves which contain reactor coolant or other potentially radioactive liquids during normal plant operations are provided with handwheel extensions or shielding, to allow periodic actuation, unless they are operated less frequently than once a year. Refer to paragraph 12.3.1.1.

3. Shutdown cooling system components that contain reactor coolant or other potentially radioactive liquids during normal plant operations, and that require access for periodic pressure tests and nondestructive examination, are capable of being flushed prior to testing. The low-pressure safety injection pumps can provide the driving head for flushing.

4. System components not designed to ASME, Section III, are located such that the access for periodic visual inspection for leakage, structural distress, and corrosion is possible.

5. System and component arrangement allows adequate clearances for performance of inspections identified in CESSAR Technical Specification 16.4.0.5.

K. Chemistry/Sampling

1. The essential cooling water makeup conductivity will be 2.0 micromhos/cm or less. The cooling water will not contain scale-forming compounds. The cooling water chemistry control program is described in Section 9.2.2.1.4.

2. The sampling system provides a means of obtaining remote liquid samples from the shutdown cooling system for chemical and radiochemical laboratory analysis. Refer to subsection 9.3.2.

3. The sample lines in contact with reactor coolant are of austenitic stainless steel.

4. The sample lines are sized such that the fluid velocity allows a representative sample and the purge flowrate is high enough to remove crud from the sample lines. Refer to subsection 9.3.2.

L. Materials

1. Piping and metallic parts in contact with the system fluid, with the exception of some component internals as required, are of austenitic stainless steel.

   Selection is made on the basis of compatibility with design pressure and temperature stress considerations and with the chemistry of the system fluid.

   Valve packing, gaskets, and diaphragm materials for packless valves are also compatible with the radiation dose and the chemistry of the system fluid.

2. Fabrication and erection of system materials were consistent with the quality standards of GDC 1 and Regulatory Guide 1.26. Refer to subsection 3.1.1 and section 1.8.

3. Methods used to avoid severe sensitization of unstabilized austenitic stainless steels as the result of welding are listed in section 5.2. Regulatory Guides 1.31 and 1.44 are used as discussed in section 1.8.

4. Controls will be exercised to assure that contaminants do not significantly contribute to stress corrosion of stainless steel. Refer to section 5.2. Regulatory Guides 1.36 and 1.37 are used as discussed in section 1.8.

M. System Component Arrangement

It is noted that some of the Interface Requirements described in this section were provided for original piping and component design/selection to ensure that the as-built system would support required design functions. For the operating plant, the adequacy of the design to support required design functions is maintained and demonstrated by current design basis calculations and surveillance tests that evaluate the as-built systems, and the values specified by the original interface requirements are no longer relevant. The specific interface requirements in this section for which this applies and that provide historical information are: M.2, M.8.

1. The first isolation valve on the shutdown cooling suction lines is located as close as practical to the RCS. The volume of water in the pipe between the first isolation valve and the RCS is less than 16 cubic feet for A train for all three units and less than 44 cubic feet for B train for all three units.

2. The distance between the pressurizer upper pressure sensor nozzle and the LPSI pump suction piping is less than 112 feet. This interface requirement describes an aspect of the plant's physical configuration upon which the system design limits were originally established and is historical.

3. The LPSI pumps are located as close as practical to the containment. In addition, the LPSI pumps' NPSH requirements are satisfied as follows:

   a. The available NPSH during shutdown cooling, when both the LPSI and CS pumps take suction from the RCS, is greater than 25 feet. The CESSAR Interface Requirement for required NPSH is 20 feet. The actual required NPSH based on the specific PVNGS design requirements is 22 feet. The available NPSH exceeds the CESSAR Interface Requirement and the PVNGS specific required NPSH.

   b. The available NPSH during the recirculation mode of safety injection, when the pumps take a suction on the containment emergency recirculation sumps, is greater than 25 feet, which is adequate.

4. The SCS flow measuring orifices are installed in compliance with ASME Publication, ASME Fluid Meters; Their Theory and Application, Parts 1 and 2.

5. The SCS suction lines are arranged such that no portion is physically above the lowest point of the RCS hot leg piping.

6. The setpoint for the Shutdown Cooling suction relief valves is compensated for elevation

differences from the LPSI/CS pump centerline. This setpoint is 467 psig. The original CE requirement established a 50 ft. maximum elevation difference based on a relief valve setpoint of 435 psig. However, the relief valve setpoint was subsequently increased to 467 psig at PVNGS and, therefore, the original CE interface requirement no longer applies. This requirement was changed by CE for PVNGS to simply state that the setpoint for the Shutdown Cooling suction relief valves is compensated for elevation differences from the LPSI/CS pump centerline, and the setpoint is 467 psig.

7. RCS components are provided with equipment tags which include a designator, A, B, C, D, or E, for safety-related components, or N for nonsafety-related components.

8. The elevation difference between the bottom discharge nozzles of the SITs and the centerline of the LPSI pump suctions is less than 70 feet. This interface requirement describes an aspect of the plant's physical configuration upon which the system design limits were originally established and is historical.

9. In the event of a limited leakage passive failure in one SCS train during long-term cooling, personnel access to the intact train will not be prevented by flooding. However,

access will be limited by the dose rate at the intact train.

10. Protection is provided from internally generated flooding that could prevent performance of safety-related functions. Also refer to section 3.6 and subsection 9.3.3.

N. Radiological Waste

1. The containment emergency recirculation sump is designed to accept relief valve discharge from the shutdown cooling suction line overpressure relief valves at temperatures up to 400F and at flows up to 4000 gallons per minute.

O. Overpressure Protection

1. Thermal relief valves and overpressure protection is provided in isolated sections of piping and valves (in accordance with responses to Generic Letter 96-07) in the system to prevent overpressurization due to thermal transients.

P. Related Services

1. The fire protection system provided to protect the SCS is discussed in subsection 9.5.1.

2. Cooling Water System Requirements

   a. The cooling water system is designed as shown in the listing below, to supply cooling water to the shutdown cooling heat exchangers when an irradiated core is

present in the reactor vessel or the spent fuel pool.

b. Cooling water will be supplied at the following temperatures and will be able to remove the heat loads listed for the given conditions.

SHUTDOWN COOLING HEAT EXCHANGERS

Situation	Cooling Water Inlet Temperature °F	Design Heat Load (Million Btu/hour) (includes both heat exchangers)
Post-LOCA & Forced Shutdown	65 - 135	*
Normal Shutdown Cooling:		
3-1/2 hours after Shutdown	65 - 120	245.1
27-1/2 hours after Shutdown	65 - 105	86.56

* Heat load is variable and discussed in Section 6.2.1

c. For all conditions, cooling water will be supplied as follows:

Parameter	Nominal Value Per Heat Exchanger
Normal delivery pressure	96 psig
Maximum delivery pressure	116 psig
Minimum flow range	12,000 - 12,600 gal/min

d. Cooling water a piping supplying the shutdown cooling heat exchangers is designed and fabricated in accordance with

ASME B&PV Code, Section III, Class 3, and is designed as Seismic Category I, Safety Class 3.

e. The cooling water system which services the SCS is designed with sufficient redundancy and diversity such that one SCS heat exchanger train will always be supplied with cooling water.

f. The cooling water system which services the SCS is designed consistent with the cooling water chemistry control program described in Section 9.2.2.1.4.

3. Containment Spray System (CSS)

a. The CSS is designed to allow the containment spray pumps to augment the SCS during the later stages of plant cooldown when plant temperature is less than 200F. The spray system will provide approximately 4000 gallons per minute per train at a head which can be set between 250 and 300 feet.

b. The CSS is designed to allow the containment spray pumps to be aligned for automatic spray initiation concurrent with shutdown cooling operation of the LPSI pumps. This can be achieved by aligning the containment spray pumps discharge path to bypass the shutdown cooling heat exchangers.

Q. Environmental

1. The proper operating environmental conditions for the equipment of one train of the SCS will be maintained independently of the environment of the other train of the SCS, e.g., failure or isolation of the ventilation capability to one train of the SCS: will not cause the environmental limits of the other SCS train to be exceeded.

2. The auxiliary building ventilation system described in subsection 9.4.2 will control ambient air conditions in the proximity of C-E-supplied motor-driven or diaphragm-operated equipment in the SCS to between 50 and 104F under normal operating conditions.

   Following a LOCA, including the subsequent recirculation mode of operation, auxiliary building ambient air conditions are controlled in accordance with the requirements of section 3.11.

5.4.7.4 System Design

5.4.7.4.1 System Schematic

The SCS is shown on the RCS engineering drawing 01, 02, 03-M-RCP-001, -002 and -003 and on the SIS engineering drawing 01, 02, 03-M-SIP-001, -002 and -003. Figures 6.3-2G through 6.3-2J show flow rates at various locations during system operation. The pressure and temperature of the RCS system vary

from 410 psia and 350°F at initiation of shutdown cooling to atmospheric pressure and 135°F at refueling conditions. SCS design parameters are given in Table 5.4-43. The SCS suction side pressure and temperature follow RCS conditions. The discharge side pressure is higher by an amount equal to the pump head and the temperature is lower at the shutdown cooling heat exchanger outlet.

The SCS contains two shutdown cooling heat exchangers and employs the two low pressure safety injection pumps throughout shutdown cooling. The applicant may utilize the flow of the containment spray pumps through the shutdown cooling heat exchangers to achieve an increased cooldown rate during the latter stages of shutdown cooling. During initial shutdown cooling, a portion of the reactor coolant flows out the shutdown cooling nozzles located on the reactor vessel outlet (hot leg) pipes and is circulated through the shutdown cooling heat exchangers by the LPSI pumps. The return to the RCS is through the four LPSI lines.

The SCS suction line isolation valves are interlocked to prevent overpressurization of the SCS by the RCS. These interlocks are described in Sections 5.4.7.3.3 and 7.6.

Shutdown cooling and LPSI flow are measured by orifice meters installed in each LPSI header. The information provided by these flow elements is used by the operator for flow control during shutdown cooling operation.

The cooldown rate is controlled by adjusting flow through the heat exchangers with throttle valves on the discharge of each heat exchanger. The operator maintains a constant total

shutdown cooling flow to the core by adjusting the heat exchanger bypass flow to compensate for changes in flow through the heat exchangers.

5.4.7.4.2 Component Description

A. Shutdown Cooling Heat Exchangers

The shutdown cooling heat exchangers are used to remove decay, sensible and safeguards pump heat during cooldown, and decay and pump heat during cold shutdown. The units are sized to maintain a refueling water temperature of 125°F with the design component cooling water temperature 105°F at 27-1/2 hours after shutdown following an assumed reactor core average burnup of two years. A conservative fouling resistance is assumed, resulting in an additional area margin for the heat exchangers.

Shutdown cooling heat exchanger characteristics are given in Tables 5.4-43 and 5.4-44.

The design pressure of the heat exchanger is based on the suction line design pressure plus the shutoff head of the LPSI pump.

The design temperature is based upon the temperature of the reactor coolant at the initiation of shutdown cooling plus a design tolerance.

B. Instrumentation

The operation of the SCS is controlled and monitored through the use of installed instrumentation. The

instrumentation provides the capability to determine heat removal, cooldown rate, shutdown cooling flow, and the capability to detect degradation in flow or heat removal capacity. The instrumentation provided for the SCS is discussed in Section 6.3.5.

C. Piping

All SCS piping is austenitic stainless steel. All piping joints and connections are welded, except for a minimum number of flanged connections that are used to facilitate equipment maintenance or accommodate component design.

D. Valves

The location of valves, along with the type and size, type of operator, position (during the normal operating mode of the plant), type of position indication, and failure position is shown in engineering drawing 01, 02, 03-M-SIP-001, -002 and -003. Pressure design rating and code design classification are also shown.

Throttle valves (SI-306, 657, 307, 658) are provided for remote control of the heat exchanger tube side and bypass flow.

1. Relief Valves

Protection against overpressure of components within the SCS is provided by conservative design of the system piping, appropriate valving between high pressure sources and low pressure

piping, and by relief valves. The shutdown cooling suction lines up to and including SI-653 and SI-654 are designed for full RCS pressure. Relief valves are provided as required by the applicable codes. All relief valves are of the totally enclosed, pressure tight type, with suitable provisions for gagging. A tabulation of relief valves is provided below:

a. SI-169 and 469

   Shutdown cooling suction isolation valve thermal relief valves. These valves are sized to protect the piping between the shutdown cooling isolation valves of each shutdown cooling suction line from the pressure developed due to a temperature increase. The valves are located inside the containment and discharge into the reactor drain tank. The set pressure is 2485 psig with a capacity of 15 gpm each.

b. SI-179 and 189

   Shutdown cooling suction line relief valves. These valves are sized to protect the SCS from operation of the pressurizer heaters, operation of the HPSI pumps, and operation of the charging pumps during shutdown cooling. The valves are located inside the containment and discharge into the containment sump. The set pressure is

467 psig with a capacity of 5635 (@ 10% accumulation) gpm each.

c. SI-191 and 194

Shutdown cooling heat exchanger reliefs. These valves are sized to protect an isolated heat exchanger from the pressure developed due to a component cooling water temperature increase. The valves discharge into the equipment drain tank. The set pressure is 650 psig with a capacity of 120 gpm each.

d. SI-161 and 193

Thermal relief valves. These valves are sized to protect the isolated piping from the pressure developed due to a temperature increase. The valves discharge to the equipment drain tank. The set pressure is 650 psig with a capacity of 10 gpm each.

2. Actuator Operated Throttling and Stop Valves

The failure position of each valve on loss of actuating signal or power supply is selected to ensure safe operation. System redundancy is considered when defining the failure position of any given valve. Valve position indication is provided at the main control panel, as indicated in engineering drawings 01, 02, 03-M-SIP-001, -002 and -003. A locking type control switch on the main control panel and/or manual override

handwheel is provided where necessary for efficient and safe plant operation. All actuator operated valves were supplied with a double packing with a lantern ring leakoff connection. During original plant design, an evalution determined that leakoffs piped to the equipment drain tank present a greater ALARA concern than capping the valve leakoff. The cap has been designed as part of the SIS pressure boundary.

E. Pumps Used During Shutdown Cooling

The LPSI pumps are used as part of the SCS. During shutdown cooling, these pumps take suction from the reactor hot leg pipes and discharge through the shutdown cooling heat exchangers. The flow is then returned to the RCS through the LPSI header to the four cold legs. One LPSI pump is aligned to each shutdown cooling heat exchanger. At the start of shutdown cooling, both of the LPSI pumps are in service. When the RCS temperature is below 200°F, the containment spray pumps may be realigned and started to provide additional flow through the heat exchangers. The LPSI pumps are described in Section 6.3.2.2.2.

5.4.7.4.3 Overpressure Prevention

A. Overpressurization of the SCS by the RCS is prevented in the following ways:

1. The shutdown cooling suction isolation valves (SI-651, 652, 653, and 654) are powered by four independent power supplies such that a fault in one power supply or valve will neither line up the RCS to either of the two SCS trains inadvertently nor prevent the initiation of shutdown cooling with at least one train when pressure permits.

2. Interlocks associated with the shutdown cooling suction isolation valves prevent the valves from being opened if RCS pressure exceeds 410 psia. The instrumentation and controls which implement this are discussed in Section 7.6.

3. The SCS suction valves inside the containment are designed for full RCS pressure with the second valve forming the pressure boundary and class change.

4. Alarms on SI-651, 652, 653 and 654 annunciate when the shutdown cooling system suction isolation valves are not fully closed. Also, if SI-651 and 653 or SI-652 and 654 valves are open and RCS pressure exceeds the maximum pressure for SCS operation, an alarm will notify the operator that a pressurization transient is occurring during low temperature conditions.

5. Relief valves are provided as discussed in Section 5.4.7.4.2.

   The effects of inadvertent operation are discussed in Table 5.1-4.

5.4.7.4.4 Applicable Codes and Classifications

A. The SCS is a Safety Class 2 System, except for that portion discussed in B. below, which is Safety Class 1.

B. The piping and valves from the RCS up to and including SI-653 and 654 are designed to ASME B&PVC Section III, Class 1.

C. The piping, valves, and components of the SCS, with the exception of those in Section 5.4.7.4.4 B. are designed to ASME B&PVC Section III, Class 2.

D. The component cooling water side of the shutdown cooling heat exchanger is designed to ASME B&PVC Section III, Class 3.

E. The power operated valves are designed to the applicable IEEE Standards.

F. The SCS is a Seismic Category 1 System.

5.4.7.4.5 System Reliability Considerations

The SCS is designed to perform its design function assuming a single failure, as described in Section 5.4.7.1.2.

To assure availability of the SCS when required, redundant components and power supplies are utilized. The RCS can be

brought to refueling temperature utilizing one of the two redundant SCS trains. However, with the design heat load, the cooldown would be considerably longer than the specified 27-1/2 hour time period.

A loss of instrument air to the shutdown cooling system will not result in a loss of cooling ability.

Inadvertent overpressurization of the SCS is precluded by the use of pressure relief valves and interlocks installed on the shutdown cooling suction line isolation valves and safety injection tank isolation valves (see Section 7.6 and 5.4.7.4.3).

The instrumentation, control, and electric equipment pertaining to the SCS was designed to applicable portions of IEEE Standards 279 and 308.

In addition to normal offsite power sources, physically and electrically separated and redundant emergency power supply systems are provided to power safety-related components. See Chapter 8 for further discussion.

Since the SCS is essential for a safe shutdown of the reactor, it is a Seismic Category I system and designed to remain functional in the event of a design basis earthquake.

For long-term performance of the SCS without degradation due to corrosion, only materials compatible with the pumped fluid are used.

Environmental conditions are specified for system components to ensure acceptable performance in normal and applicable accident environments (see Section 3.11).

In the event of a limited leakage passive failure in one train of the SCS, continued core cooling is assured by the two independent train design of the SCS. Make-up of the leakage is provided by the manual alignment of the SIS to the refueling water tank or by opening the Safety Injection Tank isolation valves. The affected SCS train can then be isolated and core cooling continued with the other train.

A limited leakage passive failure is defined as the failure of a pump seal or valve packing, whichever is greater. The maximum leakage is expected to be from a failed LPSI pump seal.

This leakage to the pump compartment will normally drain to the room sump. From there it is pumped to the water management system. The sump pumps in each room will handle expected amounts of leakage. If leakages are greater than the sump pump capacity, the room will be isolated.

5.4.7.4.6 Manual Actions

A. Plant Cooldown

   Plant cooldown is the series of manual operations which bring the reactor from hot shutdown to cold shutdown. Cooldown to approximately 350°F is accomplished by releasing steam from the secondary side of the steam generators. When the RCS pressure falls below 2150 psia, the Safety Injection Actuation Signal (SIAS) setpoint can be manually decreased as discussed in Section 7.2.1.1.1.6. When RCS pressure reaches 750 psia, the safety injection tank pressure is reduced to 300 psig. When RCS pressure is between 380 and

400 psia, the safety injection tank isolation valves are closed.

When RCS temperature and pressure decrease below 350°F and the maximum pressure for SCS operation, the SCS may be used. If the SCS is not aligned to the RCS before cold leg temperature is reduced to below the maximum RCS cold leg temperature requiring LTOP, an alarm will notify the operator to open the SCS isolation valves (SI-651, 652, 653, 654). The maximum temperature requiring LTOP is based upon the evaluation of the applicable P-T curves. This operator action requires that the RCS be depressurized to below the maximum pressure for SCS operation, in order to clear the permissive SCS interlock (see paragraph 5.4.7.4.3, item A.2). Interlocks associated with the six valves on the two SCS suction lines prevent overpressurization of the SCS. See Section 7.6 and 5.4.7.4.3 for details. Also, if SI-651 and 653 or SI-652 and 654 SCS suction isolation valves are open and RCS pressure exceeds the maximum pressure for SCS operation, an alarm will notify the operator that a pressurization transient is occurring during low temperature conditions.

Shutdown cooling is initiated using only the LPSI pumps (LPSIP), with the CSS lined up for automatic initiation of spray, bypassing the shutdown cooling heat exchanger. The SCS is warmed up and placed in operation as follows (refer to engineering drawings 01, 02, 03-M-SIP-001, -002 and -003):

1. The containment spray isolation valves for the shutdown cooling heat exchangers (SI-684*, 687*, 689, 695) are shut.
2. The containment spray valves bypassing the shutdown heat exchangers (SI-688*, 693) are opened.
3. The LPSI pump minimum flow recirculation isolation valves (SI-668, 669*) are shut.
4. The LPSI pump suction valves (SI-683*, 692) from the RWT and containment sump are shut.
5. The shutdown cooling suction line isolation valves (SI-651*, 652, 653*, 654, 655*, 656) in the two suction lines are opened.
6. The crossover valves between the LPSI pump discharge and the shutdown cooling heat exchangers (SI-685*, 694) are opened.
7. The SDCHX Discharge valves between the shutdown cooling heat exchanger outlet and the LPSI header (SI-686*, 696) are opened and the shutdown cooling throttle valves (SI-657*, 658) are cracked open.
8. The SCS warmup line isolation valves (SI-690, 691*) are opened and the LPSI pumps are started to induce recirculation flow through the SCS (flow is limited to 5000 gpm per pump).
9. Once flow has been induced in the SCS, the LPSI isolation valves (SI-615, 625, 635*, 645*) are

cracked open to allow a small amount of flow from the RCS to heat up SCS valves and piping.

10. The LPSI header isolation valves (SI-615, 625, 635*, 645*) are then gradually opened, while the warmup line isolation valves (SI-690, 691*) are gradually closed to maintain a constant flow of 5000 gpm per pump. When the LPSI header isolation valves (SI-615, 625, 635*, 645*) are open to their preset positions and the SCS warmup line isolation valves (SI-690, 691*) are closed, the SCS is aligned in its operating mode.

11. The shutdown cooling throttle valves (SI-657*, 658) and the SCS bypass flow control valves (SI-306*, 307) are adjusted as necessary to maintain the RCS cooldown rate at 75°F/hour or less, at a SCS flow of 5000 gpm through each heat exchanger.

When reactor coolant temperature decreases below 200°F (typically 170°F), the containment spray pumps are aligned to provide additional shutdown cooling flow. The SCS is realigned to the following line-up (refer to engineering drawings 01, 02, 03-M-SIP-001, -002 and -003):

1. The containment spray pump suction valves (SI-104, 105*) from the RWT and containment sump are closed.

2. The containment spray pump minimum flow recirculation line isolation valves (SI-664*, 665) are shut.

3. The containment spray bypass around the shutdown cooling heat exchanger valves (SI-688*, 693) are shut.

4. The containment spray pump suction valves (SI-184*, 185) from shutdown cooling suction lines are opened.

5. The containment spray pump discharge to the shutdown cooling heat exchanger valves (SI-684*, 689) are opened.

6. The containment spray pump discharge valves (SI-678*, 679) are opened to the position determined by preoperational testing.

7. The CSS pumps are started, and the shutdown cooling throttle valves (SI-657*, 658) are opened to give a total shutdown cooling flow of 9000 gpm per train.

Shutdown cooling is then continued using the containment spray pumps in parallel with the LPSI pumps until the refueling temperature of 135°F is attained.

A maximum rate of cooldown (not to exceed 75°F/hour) is maintained by adjusting the flowrate of reactor coolant through the shutdown cooling heat exchangers with the throttle valves on the discharge of the heat

exchangers. With the shutdown cooling flow indicators, the operator maintains a total shutdown cooling flowrate by adjusting the amount of coolant which bypasses the shutdown cooling heat exchangers.

When the system is first put into operation, the temperature difference for heat transfer is large and only a portion of the total flow from the LPSIP's is diverted through the heat exchangers. As cooldown proceeds, the temperature differential decreases and the flowrate through the heat exchangers is increased to maintain the cooldown rate.

The flow to the shutdown cooling heat exchangers is increased periodically until full LPSIP flow through the heat exchangers is reached, at which time the rate of cooldown begins a decline, which continues until the RCS is below 200°F (typically 170°F). At this point, the containment spray pumps (CSP) are realigned to provide additional shutdown cooling flow. With the combined flow of the LPSIP's and CSP's, the cooldown rate will rise. As cooldown proceeds, the rate will again go into a decline lasting until the RCS reaches refueling temperature at about 27-1/2 hours after shutdown.

A graph of RCS temp. vs. time after shutdown for a typical cooldown is presented in Figure 5.4-10 and 5.4-11.

Shutdown cooling is continued throughout the entire period of plant shutdown to maintain a refueling

water temperature of 135°F or less. Whenever shutdown cooling is in operation, shutdown purification flow may be initiated to purify the circulating coolant in the CVCS.

B. Plant Heatup

Plant heatup is a series of manual operations which bring the RCS from cold shutdown to hot standby. The SCS is used during cold shutdown to control reactor coolant temperature. Prior to plant heatup above 200°F, the CSS is aligned for automatic initiation. The SCS heat exchangers are bypassed to maintain flow through the core without the heat removal effect of the heat exchangers. Flow can be initiated to the heat exchangers if necessary to control the heatup rate. When the reactor coolant pumps can be run and prior to reaching 350°F or 400 psia, the LPSI pumps are stopped and the shutdown cooling heat exchangers are aligned for their containment spray function.

C. Abnormal Operation

1. The shutdown cooling heat exchangers may be used to supplement the spent fuel pool cooling heat exchangers when more than one-third of a spent core is stored in the spent fuel pool. Normally this would be done during refueling when both shutdown cooling heat exchangers are no longer needed to maintain reactor coolant at the refueling temperature. The SCS would be aligned with one heat exchanger train lined up to the

spent fuel pool cooling system and the other shutdown cooling heat exchanger train lined up for shutdown cooling of the RCS. The SCS heat exchanger train aligned to the spent fuel pool would be in a normal shutdown cooling lineup for use of either the LPSI or CS pump, except the pump takes suction on the spent fuel pool vice the RCS, and the discharge of the shutdown cooling heat exchanger goes to the spent fuel pool, vice the RCS.

2. Initiation of shutdown cooling with the most limiting single failure (loss of one shutdown cooling train) can be accomplished using the procedure under plant cooldown for the operable train (i.e., operating the valves with (*) for train number 1 or the valves without (*) for train number 2).

3. Following a loss of offsite power, natural circulation provides the primary method of core heat removal during hot standby and the subsequent cooldown to shutdown cooling entry conditions. As described in the natural circulation cooldown analysis, shutdown cooling is initiated to continue the cooldown and stabilize the plant in cold shutdown. A summary of the analysis is included at the end of this chapter as Appendix 5C.

D. Design Bases Event Operations

Following Design Bases Events, Shutdown Cooling may be initiated in the same manner as a normal shutdown as described in Paragraph A of Section 5.4.7.4.6.

5.4.8 REACTOR COOLANT CLEANUP SYSTEM

One function of the Chemical and Volume Control System (CVCS) is to provide radiological and chemical cleanup of the Reactor Coolant System. A description of the CVCS is given in Section 9.3.4. Radiological considerations are described in Chapters 11 and 12.

5.4.9 MAIN STEAM LINE AND FEEDWATER PIPING

The main steam line is described in section 10.3. The feedwater piping is described in subsection 10.4.7.

5.4.10 PRESSURIZER

5.4.10.1 Design Basis

The pressurizer is designed to:

A. Maintain RCS operating pressure such that the minimum pressure observed during operating transients is above the setpoint for the Safety Injection Actuation Signal and that the maximum pressure is below the high pressure reactor trip.

B. Meet the design transients specified in Section 3.9.1 except that the maximum allowable rate of change in pressurizer temperature during plant heatup and cooldown is 200°F/hr.

C. Provide sufficient water volume to prevent draining the pressurizer as a result of a reactor trip.

D. Provide sufficient water volume to prevent pressurizer heaters from being uncovered by the outsurge following a step load decrease of 10% from 25% to 15% or a 5% per minute ramp decrease from 100% to 15%.

E. Provide sufficient steam volume to yield an acceptable pressure response to normal system volume changes, during all design load change transients.

F. Provide sufficient steam volume to allow acceptance of the insurge resulting from load reduction from any load to any load without the vessel water level reaching the primary safety valve nozzles.

G. Minimize the total reactor coolant mass change and associated charging and letdown flow rates in order to reduce the quantity of wastes generated by load follow operations.

H. Provide sufficient pressurizer heater capacity to heat up the pressurizer, filled with water at the zero power level, at a rate that ensures a pressurizer temperature (and thus pressure) which will maintain an adequate degree of subcooling of the water in the reactor coolant loop as it is heated by core decay heat and/or pump work from the reactor coolant pumps.

I. Contain a total water volume that does not adversely affect the total mass and energy released to the containment during the maximum hypothetical accident.

J. Ensure that, in addition to being specified as Seismic Category I, the pressurizer vessel, including heaters, baffles, and supports shall be designed such that no damage to the equipment is caused by the frequency ranges of 19-20 cps and 95-100 cps. The lower frequency is defined as for the reactor vessel. The design basis for the higher frequency consists of a pressure pulse of 5 psi which diminishes internally within the vessel.

5.4.10.2 Description

The pressurizer, as shown in Figure 5.4-5, is a vertically mounted, bottom supported, cylindrical pressure vessel. Replaceable direct immersion electric heaters are vertically mounted in the bottom head. The pressurizer is furnished with nozzles for spray, surge, safety, and pressure and level instrumentation. A manway is provided in the top head for access for inspection of the pressurizer internals. The pressurizer surge line is connected to one of the reactor coolant hot legs and the spray lines are connected to two of the cold legs at the reactor coolant pump discharge. The pressurizer spray and surge nozzles are furnished with a thermal sleeve to withstand specified plant transients during the design life. Heaters are supported inside the pressurizer to preclude damage from vibration and seismic loadings. Principal design parameters are listed in Table 5.4-37.

The pressurizer is designed and fabricated in accordance with the ASME Code listed in Table 5.2-1. The interior surface is clad with weld deposited stainless steel.

The total volume of the pressurizer is established by consideration of the factors given in Section 5.4.10.1. To account for these factors and to provide adequate margin at all power levels, the water level in the pressurizer is programmed as a function of average coolant temperature as shown in Figure 5.4-2, in conjunction with Figure 5.4-3. High or low water level error signals result in the control actions shown in Figure 5.4-4. The pressurizer surge line is sized to accommodate the flow rates associated with the RCS expansion and contraction due to the transients specified in Section 3.9.1.

The pressurizer maintains Reactor Coolant System operating pressure and, in conjunction with the Chemical and Volume Control System (CVCS), Section 9.3.4, compensates for changes in reactor coolant volume during load changes, heatup, and cooldown. During full-power operation, the pressurizer is about one-half full of saturated steam. Reactor Coolant System pressure may be controlled automatically or manually by maintaining the temperature of the pressurizer fluid at the saturation temperature corresponding to the desired system pressure. A small continuous spray flow is maintained to the pressurizer to avoid stratification of pressurizer boron concentration and to maintain the temperature in the surge and spray lines, thereby reducing thermal shock as the spray control valves open. An auxiliary spray line is provided from the charging pumps to permit pressurizer spray during plant heatup, or to allow cooling if the reactor coolant pumps are shut down. The pressurizer spray nozzle usage factor is calculated and limited as described in Table 5.4-38.

During load changes, the pressurizer limits pressure variations caused by expansion or contraction of the reactor coolant. The average reactor coolant temperature is programmed to vary as a function of load as shown in Figure 5.4-3. A reduction in load is followed by a decrease in the average reactor coolant temperature to the programmed value for the lower power level. The resulting contraction of the coolant lowers the pressurizer water level, causing the reactor system pressure to decrease. This pressure reduction is partially compensated by flashing of pressurizer water into steam. All pressurizer heaters are automatically energized on low system pressure, generating steam and further limiting pressure decrease. Should the water level in the pressurizer drop sufficiently below its setpoint, the letdown control valves close to a minimum value, and additional charging pumps in the chemical and volume control system are automatically started to add coolant to the system and restore pressurizer level.

When steam demand is increased, the average reactor coolant temperature is raised in accordance with the coolant temperature program. The expanding coolant from the reactor coolant piping hot leg enters the bottom of the pressurizer through the surge line, compressing the steam and raising system pressure. The increase in pressure is moderated by the condensation of steam during compression and by the decrease in bulk temperature in the liquid phase. Should the pressure increase be large enough, the pressurizer spray valves open, spraying coolant from the reactor coolant pump discharge (cold leg) into the pressurizer steam space. The relatively cold spray water condenses some of the steam in the steam space,

limiting the system pressure increase. The programmed pressurizer water level is a temperature dependent function. A high level error signal, produced by an in-surge, causes the letdown control valves to open, releasing coolant to the chemical and volume control system and restoring the pressurizer to the programmed level. Small pressure and primary coolant volume variations are accommodated by the steam volume that absorbs flow into the pressurizer and by the water volume that allows flow out of the pressurizer.

The pressurizer heaters are single unit, direct immersion heaters that protrude vertically into the pressurizer through sleeves welded in the lower head. Each heater is internally restrained from high amplitude vibrations and can be individually removed for maintenance during plant shutdown. There are 35 pressurizer heaters in Unit 1 (1 abandoned in place), 34 pressurizer heaters in Unit 2 (2 abandoned in place), and 36 pressurizer heaters in Unit 3.

A number of the heaters are connected to proportional controllers, which adjust the heat input to account for steady-state losses and to maintain the desired steam pressure in the pressurizer. The remaining heaters are connected to on-off controllers. These heaters are normally deenergized except those required to compensate for main spray bypass flow. The backup heaters are automatically turned on by a low pressurizer pressure signal or a high level error signal. This latter feature is provided since load increases result in an in-surge of relatively cold coolant into the pressurizer, thereby decreasing the bulk water temperature. The CVCS acts to restore level, resulting in a transient pressure below normal

operating pressure. To minimize the extent of this transient, the backup heaters are energized, contributing more heat to the water. Backup heaters are deenergized in the event of concurrent high-level error and high-pressurizer pressure signals. A low-low pressurizer water level signal deenergizes all heaters before they are uncovered to prevent heater damage. The pressure control program is shown in Figure 5.4.-1.

5.4.10.3 Evaluation

It is demonstrated by analysis in accordance with requirements for ASME Code, Section III, Class 1 vessels that the pressurizer is adequate for all normal operating and transient conditions expected during the life of the facility. Following completion of fabrication, the pressurizer is subjected to the required ASME Code, Section III hydrostatic test and post-hydrostatic test non-destructive testing.

During hot functional testing, the transient performance of the pressurizer is checked by determining its normal heat losses and maximum pressurization and depressurization rates. This information is used in setting the pressure controllers.

Further assurance of the structural integrity of the pressurizer during plant life will be obtained from the inservice inspections performed in accordance with ASME Code, Section XI, and described in Section 5.2.

Overpressure protection of the Reactor Coolant System is provided by four ASME Code spring-loaded safety valves. Refer to Section 5.4.12 and 5.4.13.

5.4.10.4 Tests and Inspections

Prior to and during fabrication of the pressurizer, non-destructive testing is performed in accordance with the requirements of Section III of the ASME Boiler and Pressure Vessel Code. Table 5.4-39 summarizes the pressurizer inspection program, which also includes tests not required by the Code. Refer to Section 5.2.1 for inservice inspections of the pressurizer.

5.4.11 PRESSURIZER RELIEF DISCHARGE SYSTEM

The reactor drain tank is used as the pressurizer relief tank. The design and description of this tank are given in Section 9.3.4.

5.4.12 VALVES

5.4.12.1 Design Basis

The safety related functions of valves within the RCS pressure boundary are to act as pressure retaining vessels and leak-tight barriers during normal operation, accidents and seismic events.

The valves are designed and fabricated in accordance with ASME B&PV Code, Section III, Class I requirements. These valves must withstand the affects of system design transients (Section 3.9.1) and any other transients associated with the individual valve's location or service requirements. The valves are designed to meet Seismic Category I requirements. Backseats are specified on manual and motor operated gate and globe valves to minimize valve stem leakage.

TABLE 5.4-37
PRESSURIZER PARAMETERS

Property	Parameter
Design pressure, psia	2500
Design temperature, °F	700
Normal operating pressure, psia	2250
Normal operating temperature, °F	652.7
Internal free volume, ft^3	1800
Normal (full power) operating water volume, ft^3	900
Normal (full power) steam volume, ft^3	900
Installed heater capacity, KW	1800[(1)(4)]
Heater type	Immersion
Spray flow, maximum, gal/min	525[(2)]
Spray flow, continuous, gal/min	~1[(3)]
Nozzles	
Surge, in. (nominal)	12, schedule 160
Spray, in. (nominal)	4, schedule 160
Safety valves, in. (nominal)	6, schedule 160
Instrument	
Level, in. (nominal)	3/4, schedule 160
Temperature, in. (nominal)	1, schedule 160
Pressure, in. (nominal)	3/4, schedule 160
Heater, O.D., in.	1-1/4

(1) Unit 2 has 1700 KW of installed heater capacity. This difference is due to the failure of two heaters, which have been abandoned in place.

(2) The nominal main pressurizer spray flow rate is approximately 475 gpm including the bypass flow assuming that both main spray valves are full open under typical RCS conditions (core ΔP = 70 psid and average spray fluid temperature = 565°F). The table value includes a 10% margin to account for method and process uncertainties.

(3) The table value represents the estimated flow rate through each bypass valve at nominal RCS conditions. Individual bypass valve positions have been adjusted so that each valve provides sufficient flow to maintain the fluid temperature difference between the cold legs and the spray nozzle inlet piping less than 70°F.

(4) Unit 1 has 1750 KW of installed capacity. This difference is due to the failure of one heater which has been abandoned in place.

Table 5.4-38
PRESSURIZER SPRAY NOZZLE USAGE FACTOR
(Sheet 1 of 2)

The pressurizer spray nozzle usage factor is calculated as shown below for conditions when the main spray (less than four RCPs operating ΔT_m[(a)] >200F, and/or auxiliary spray ΔT_a[(b)] >200 F.

Main Spray				Auxiliary Spray			
ΔT_m	N_A	N	N/N_A	ΔT_a	N_A	N	N/N_A
201-250	33,400			201-250	26,900		
251-300	13,100			251-300	10,800		
301-350	6,700			301-350	5,200		
351-400	4,100			351-400	2,900		
401-450	2,900			401-450	1,800		
451-500	2,400			451-500	1,200		
501-550	2,100			501-550	890		
				551-600	680		
				601-650	540		
		$\Sigma N/N_A$ = ______	________			$\Sigma N/N_A$ =	____________

Cumulative Usage Factor

$\Sigma N/N_A$(Main Spray) ____________

$\Sigma N/N_A$(Aux. Spray) ____________

Total ____________ = Cumulative Usage Factor

Where:

$\Delta T_a = (T_{101} - T_{229}) + 60$

$\Delta T_m = (T_{103*} \text{ or } _{104*}) + 70$

N_A = Allowable number of spray cycles

N = Number of cycles in ΔT range indicated

Table 5.4-38
Pressurizer Spray Nozzle Usage Factor
(Sheet 2 of 2)

Calculational Method:

1. The spray cycle is defined as any initiation and termination of main or auxiliary spray flow throughout the pressurizer spray nozzle.

2. If the difference between pressurizer water temperature and the spray water temperature exceeds 200F each spray cycle and the corresponding temperature difference is logged. These are the controlling pressurizer spray transients. The non-controlling pressurizer spray transients include plant heatup/cooldown, system hydrostatic/leak test, and spray cycle events where ΔTm or ΔTa less than 200°F. The non-controlling cumulative usage factor is accounted for in the 0.65 limit.

3. The spray nozzle usage factor shall be calculated as follows:

   A. Fill in Column "N" above

   B. Calculate "N/N_A" (Divide N by N_A)

   C. Add column "N/N_A" to find Σ N/N_A

   Σ N/N_A is the cumulative spray nozzle usage factor. If the cumulative usage factor is equal to or less than 0.65 no further action is required.

4. If the cumulative usage factor exceeds 0.65, subsequent pressurizer spray operation shall continue to be monitored and an engineering evaluation of nozzle fatigue shall be performed within 90 days. The evaluation shall determine that the nozzle remains acceptable for additional service beyond the 90 day period or subsequent spray operation shall be restricted so that the difference between the pressurizer water temperature and the spray water temperature shall be limited to less than or equal to 200F when spray is operated.

*Use lower temperatures

----

a. ΔT_m = The difference in temperature between the pressurizer and main spray water as adjusted by the instrument correction factor.

b. ΔT_a = The difference in temperature between the pressurizer and auxiliary spray water as adjusted by the instrument correction factor.

Control of valve stem leakage for valves used in the RCS pressure boundary is accomplished through several different methods depending on the design of the individual valve. All valves use valve packing. Some valves have a conventional packing design. Other valves may have double packing with a leak-off connection at the lantern ring. The leak-off connection provides a method of collecting any leakage that may occur around the valve stem.

During original plant design, an evaluation determined that leakoffs piped to the reactor drain tank present a greater ALARA concern than capping the valve leakoff. The cap has been designed as part of the RCS pressure boundary. The leakoffs for all RCS valves are capped except for the pressurizer spray control (RC-100E and 100F) and bypass (RC-236 and 237) valves.

Manual globe valves with a bellows seal are also utilized as RCS pressure boundary valves. These valves are designed and fabricated in accordance with ASME B&PV Code, Section III, Division I, Class NB requirements. The bellows seal valves also employ a packing set as a backup to the bellows to prevent leakage.

5.4.12.2 Design Description

All valves in the RCS are constructed primarily of stainless steel. Other materials in contact with the reactor coolant, such as hard facing and packing, are fabricated from materials that are compatible with the RCS and reactor coolant. Yoke and other miscellaneous fasteners and packing gland assemblies are constructed of stainless steel to eliminate corrosion concerns.

5.4.12.3 Design Evaluation

Stress analyses that take into consideration cyclic loadings have been performed for all valves within the RCS pressure boundary. These analyses are performed in accordance with ASME B&PV Code, Section III, Class I requirements.

5.4.12.4 Tests and Inspections

The valves are hydrostatic and leak tested in accordance with ASME B&PV Code as specified in Table 5.2-1. The leak tests include testing for leakage across the valve seats and across the valve packing.

5.4.13 SAFETY AND RELIEF VALVES

5.4.13.1 Design Basis

The safety valves on the pressurizer are designed to protect the system, as required by the ASME B&PV Code, Section III.

The design basis for establishing the relieving capacity of the pressurizer safety valves is presented in Appendix 5B. For the postulated transients presented in Chapter 15, the results indicate that relieving capacity of the safety valves is sufficient to provide overpressure protection in accordance with Section III of the ASME Code.

Safety valves on the steam side of each steam generator are designed to protect the steam system, as required by the ASME Code, Section III. They are conservatively sized to pass a steady flow equivalent to the maximum expected power level at the design pressure of the steam system.

5.4.13.2 Description

The RCS has four safety valves to provide overpressure protection. A typical safety valve is illustrated in Figure 5.4-6. The design parameters are given in Table 5.4-40. These valves are connected by piping to the top of the pressurizer. They are direct acting, spring-loaded safety valves meeting ASME Code requirements. They have an enclosed bonnet and have a balanced bellows to compensate for back pressure. The safety valves pass sufficient pressurizer steam to limit the reactor coolant system pressure to 110% of design pressure (2750 psig) following a complete loss of turbine generator load without simultaneous reactor trip. A delayed reactor trip is assumed on a high-pressurizer pressure signal. To determine maximum steam flow through the pressurizer safety valves, the main steam safety valves are assumed to be operational. Values for the system parameters, delay times, and core moderator coefficient are given in Chapter 15.

Overpressure protection for the shell side of the steam generators and the main steam line up to the inlet of the turbine stop valves is provided by the secondary safety valves. A typical main steam safety valve is illustrated in Figure 5.4-7.

These valves (20 total) are sized to a minimum steam flow capacity of $19x10^6$ lb/hr at accumulation pressure (see Table 5.4-41). This limits steam generator pressure to less than 110% of steam generator design pressure during worst case transients. The secondary safety valves consist of 10 valves per steam generator (5 valves per steam line) with staggered

set pressures. The valves are spring-loaded safety valves procured in accordance with ASME Boiler and Pressure Vessel Code, Section III (see Table 5.2-1). Parameters for the secondary safety valves are given in Table 5.4-41.

5.4.13.3 Evaluation

Overpressure protection is discussed in Section 5.2.2. The ASME Code report on Overpressure Protection is provided in Appendix 5B.

5.4.13.4 Tests and Inspections

The safety valves are inspected during fabrication in accordance with ASME B&PV Code, Section III, requirements.

5.4.13.4.1 Pressurizer Safety Valves
