The lower flange of the core support barrel supports, secures and positions the lower support structure and is attached to the lower support structure by means of a welded flexural type connection. The lower support structure provides support for the core by means of a core support plate supported by columns mounted on support beams which transmit the load to the core support barrel lower flange. The core support plate provides support and orientation for the lower ends of the fuel assemblies. The core shroud, which provides a flow path for the coolant and lateral support for the fuel assemblies, is also supported and positioned by the core support plate. The lower end of the core support barrel is restricted from excessive radial and torsional movement by six snubbers which interface with the pressure vessel wall.

A. Core Support Barrel

The core support barrel is a right circular cylinder including a heavy ring flange at the top end and an internal ring flange at the lower end. The core barrel is supported from a ledge on the pressure vessel. The core support barrel, in turn, supports the lower support structure upon which the fuel assemblies rest. Press-fitted into the flange of the core support barrel are four alignment keys located 90 degrees apart. The reactor vessel, closure head and upper guide structure assembly flange are slotted in locations corresponding to the alignment key locations to provide proper alignment between these components in the vessel flange region.

The upper section of the barrel contains two outlet nozzles which interface with internal projections on the vessel nozzles to minimize leakage of coolant from inlet to outlet.

Since the weight of the core support barrel is supported at its upper end, it is possible that coolant flow could induce vibrations in the structure. Therefore, amplitude limiting devices, or snubbers, are installed on the outside of the core support barrel near the bottom end. The snubbers consist of six equally spaced lugs around the circumference of the barrel and act as a tongue-and-groove assembly with the mating lugs on the pressure vessel. Minimizing the clearance between the two mating pieces limits the amplitude of vibration. During assembly, as the internals are lowered into the pressure vessel, the pressure vessel lugs engage the core support barrel lugs in an axial direction. Radial and axial expansion of the core support barrel are accommodated, but lateral movement of the core support barrel is restricted. The pressure vessel lugs have bolted, captured, Inconel X shims and the core support barrel lug mating surfaces are hardfaced with Stellite to minimize wear. The shims are machined during initial installation to provide minimum clearance. The snubber assembly is shown in Figure 4.2-10.

B. Core Support Plate and Lower Support Structure

The core support plate is a Type 304 stainless steel plate into which the necessary flow distributor holes for the fuel assemblies have been machined. Fuel assembly locating pins are inserted into this plate.

The fuel assemblies and core shroud are positioned on the core support plate. This plate is welded to the top of a cylindrical structure at the base of which is welded a bottom plate. This structure seats on the lower flange of the core support barrel and transmits the lower support structure loads to the core support barrel. The core support plate is supported by an arrangement of columns welded at the base to support beams. The bottoms of the beams are welded to a bottom plate which contains flow holes for primary coolant flow. The ends of the beams are welded to the lower cylinder. The cylinder guides the main coolant flow and provides core shroud bypass flow by means of holes in the cylinder.

4.2.2.2.1.2 Core Shroud

The core shroud provides an envelope for the core and limits the amounts of coolant bypass flow. The shroud consists of two Type 304 stainless steel ring sections welded to each other and to the core support plate.

A small gap is provided between the core shroud outer perimeter and the core support barrel in order to provide upward coolant flow between the core shroud and the core support barrel, thereby minimizing thermal stresses in the core shroud and eliminating stagnant pockets. The core shroud is shown in Figure 4.2-11. Four equally spaced lugs are furnished on the top of the core shroud to provide alignment of the shroud with the fuel alignment plate.

4.2.2.2.1.3 Flow Skirt

The Inconel flow skirt is a right circular cylinder perforated with flow holes. The flow skirt is used to reduce inequalities in core inlet flow distributions and to prevent formation of large vortices in the lower plenum. The skirt provides a nearly equalized pressure distribution across the bottom of the core support barrel. The skirt is supported by nine equally spaced, machined sections which are welded to the bottom head of the pressure vessel.

4.2.2.2.1.4 Upper Guide Structure Assembly

This assembly consists of the upper guide structure support plate assembly, CEA shrouds and a fuel assembly alignment plate (See Figure 4.2-12). The upper guide structure assembly aligns and laterally supports the upper end of the fuel assemblies, maintains the CEA spacing, holds down the fuel assemblies during operation, prevents fuel assemblies from being lifted out of position during a severe accident condition, protects the CEAs from the effect of coolant crossflow in the upper plenum and supports the in-core instrumentation plate assembly. The upper guide structure assembly is handled as one unit during installation and refueling.

The upper end of the assembly is a structure consisting of a support flange welded to the top of a cylinder. A support plate is welded to the inside of the cylinder approximately in the middle. The support plate is welded to a grid array of deep beams, the ends of which are welded to the cylinder. The support flange contains four accurately machined and located alignment keyways, equally spaced at 90 degree intervals, which engage the core barrel alignment keys. This

system of keys and slots provides an accurate means of aligning the core with the closure head and thereby with the CEA drive mechanisms. The support plate aligns and supports the upper end of the CEA shrouds. The shrouds extend from the fuel assembly alignment plate to an elevation above the upper guide structure support plate. The CEA shroud consists of a cylindrical upper section welded to a base and a flow channel structure shaped to provide flow passage for the coolant through the alignment plate, while isolating the CEAs from crossflow. The shrouds are bolted and lockwelded to the fuel assembly alignment plate. At the upper guide structure support plate, the shrouds are connected to the plate by spanner nuts. The spanner nuts are tightened to proper torque to assure a rigid connection and lockwelded.

The fuel assembly alignment plate is designed to align the upper ends of the fuel assemblies and to support and align the lower ends of the CEA shrouds. Precision machined and located holes in the fuel assembly alignment plate engage machined posts on fuel assembly upper end fittings to provide accurate alignment. The fuel assembly alignment plate also has four equally spaced slots on its outer edge which engage with Stellite hardfaced pins protruding from the core shroud to limit lateral motion of the upper guide structure assembly during operation. The fuel alignment plate bears the upward force of the fuel assembly holddown devices. This force is transmitted from the alignment plate through the CEA shrouds to the upper guide structure support plate. The flange of the upper guide structure support plate is designed to resist axial upward movement of the upper guide structure assembly and to accommodate axial differential thermal expansion between the core barrel flange, upper guide structure and pressure vessel flange support ledge and head flange recess.

4.2.2.2.2 <u>In-Core Instrumentation Support System</u>

The complete in-core neutron flux monitoring system includes self-powered in-core detector assemblies, supporting structures and guide paths, and an amplifier system to process detector signals.

The self-powered in-core detector assemblies and the computer system are described in Chapter 7, Instrumentation and Controls. The instrumentation supporting structures and guide paths are described in this section and are shown in Figures 4.2-14 through 4.2-16.

The support system begins outside the pressure vessel, penetrates the vessel boundary and terminates at the lower end of the fuel assembly. Each instrument is guided over its full length by the external guidance conduit, the instrument plate structure guide tubes and the thimbles that extend downward into selected fuel bundles. The in-core instrumentation guide tubes route the instruments so that the detectors are located and spaced throughout the core. The guide tubes and the in-core thimbles are attached to and supported by the instrument plate assembly shown in Figure 4.2-15.

The instrumentation plate assembly fits within the confines of the reactor vessel head and rests in the recessed section of the upper guide structure assembly. Its weight is supported by four bearing pins. The upper guide structure CEA shrouds extend through the instrumentation plate clearance holes. Above the instrumentation plate, the guide tubes bend and are gathered to form stalks which extend into the reactor vessel head instrumentation nozzles. The instrumentation plate assembly is raised and lowered during refueling to insert or withdraw all instruments and their thimbles simultaneously. The pressure boundaries for the individual instruments are at the instrumentation nozzle flange where the external electrical connections to the in-core instruments are also made.

The supporting structures for the in-core instruments are designed such that the temperature of the coolant surrounding the thermocouples in the in-core instruments is representative of fuel assembly outlet temperatures. The in-core instrument lengths and thimbles are designed to locate individual neutron detectors within a tolerance of ±2 inches. A typical in-core instrument is shown in Figure 4.2-16.

The assemblies have an integral seal plug which forms a seal at the instrument flange and through which the signal cables pass. Carbon packing rings fitted in a recess in the instrument flange are used to seal against operating pressure. The in-core instrument nozzle sealing arrangement is shown in Figure 4.2-14.

4.2.2.3 Design Loading Conditions

4.2.2.3.1 Normal Operating and Upset Conditions

The reactor internals are designed to perform their functions safely under the following combination of design loading:

A. Normal operating temperature differences;

B. Normal operating pressure differences;

C. Flow impingement loads;

D. Weights, reactions and superimposed loads;

E. Vibration loads;

F. Shock loads (including OBE);

G. Anticipated transient loadings not requiring forced shutdown; and,

H. Handling loads (not combined with other loads above).

4.2.2.3.2 Emergency Conditions

The internals are designed to meet the stress limits while experiencing the loadings listed above with the DBE load replacing the OBE load.

4.2.2.3.3 Faulted Conditions

The loadings for these conditions include all the loadings listed for emergency conditions as well as the loadings resulting from postulated branch line pipe breaks. DBE and branch line pipe break loads are combined via SRSS per NUREG-0484, Rev. 1.

4.2.2.4 Design Loading Categories

The loading categories stipulated in Section 4.2.2.3, i.e., normal operating and upset, emergency and faulted, are defined in the March, 1973, draft of Subsection NG of ASME Code, Section III.

The reactor internals structures are designed to meet the stress and deformation limits of Subsection NG which are summarized in Table 4.2-4. To properly perform their functions, the reactor internals structures will also satisfy the deformation limits listed below:

A. Under design loadings plus OBE forces or normal operating loadings plus DBE forces, deflections will be limited so that the CEAs can function and adequate core cooling is preserved;

B. Under normal operating loadings plus SRSS combination of DBE forces and pipe rupture loadings resulting from a break of the largest line connected to the primary system piping, deflections will be limited so that the core will be held in place, adequate core cooling is preserved and all CEAs can be inserted. Those deflections which would influence CEA movement will be limited to less than 80 percent of the deflections required to prevent CEA insertion.

4.2.2.5 Design Criteria Bases

The stress limits summarized in Table 4.2-4 and the deflection limits specified in Section 4.2.2.4 are in accordance with those given in the March, 1973, draft of Subsection NG of the ASME Code, Section III, including Appendix F, "Rules for Evaluation of Faulted Conditions."

4.2.3 REACTIVITY CONTROL SYSTEMS

Reactivity control is accomplished by the adjustment of the boron concentration in the primary coolant, repositioning CEAs and by the presence of fixed burnable neutron absorber rods in the first core. The CVCS is used to adjust the boron concentration. A description of the CVCS is provided in Section 9.3.4. The fixed burnable neutron absorber rods are described in Section 4.2.1. The Control Element Drive Mechanisms (CEDMs) and CEAs are described below. The nuclear characteristics of the reactivity control systems are described in Section 4.3.

4.2.3.1 Design Bases

4.2.3.1.1 Control Element Drive Mechanisms Design Bases

The CEDMs are magnetic jack type drives used to vertically position and indicate the position of the CEAs in the core. Each CEDM is capable of withdrawing, inserting, holding or tripping the CEA from any point within its 150-inch stroke in response to operating signals.

The CEDM is designed to function during and after all normal plant transients. The CEA drop time for 90 percent insertion is 3.2 seconds for the average of all full length CEAs and 3.7 seconds for any individual full length CEA. The drop time is defined as the interval between the time power is removed from the CEDM coils and the time the CEA has reached 90 percent of its fully inserted position. The CEDM has a design life of 40 years. The CEDM is designed to operate without maintenance for a minimum of 1½ years and without replacing components for a minimum of three years. The CEDM is designed to function normally during and after being subjected to the OBE loads. The CEDM will allow scramming and drive-in of the CEA during and after a DBE.

The design and construction of the CEDM pressure housings fulfill the requirements of the ASME Boiler and Pressure Vessel Code, Section III for Class I vessels. The CEDM pressure housings provide a part of the reactor coolant pressure boundary and they are designed to meet stress requirements consistent with those of the vessel. The pressure housings are capable of withstanding, throughout their design life, all normal operating loads including the steady state and transient operating conditions specified for the reactor vessel. Mechanical excitations are also defined and included as a normal operating load. The CEDM pressure housings are service rated at 2,500 psia and 650 °F. The loading combinations and stress limit categories are presented in Table 4.2-5 and are consistent with definitions employed in the ASME Code.

An extension shaft is coupled to the CEA and joins this system to the CEDM. The extension shaft and CEA coupling system are designed to the allowable stress values of the ASME Code, Section III. These components are also designed to function during and after a DBE condition.

The components are designed such that the resonant frequencies are outside pump and fluid flow excitations.

4.2.3.1.2 Control Element Assembly Design Basis

The mechanical design of the CEAs is based on compliance with the following functional requirements and criteria:

A. To provide for or initiate short-term reactivity control under all normal and adverse conditions experienced during reactor startup, normal operation, shutdown and accident conditions;

B. Mechanical clearances of the CEA within the fuel and reactor internals are such that the requirements for CEA positioning and reactor trip are attained under the most adverse accumulation of tolerances; and,

C. Structural material characteristics and mechanical clearances are selected such that radiation induced changes to the CEA materials will not impair the functions of the reactivity control system.

4.2.3.2 Reactivity Control System Description and Drawings

4.2.3.2.1 Control Element Drive Mechanism Design Description

The CEDMs are mounted on nozzles on top of the reactor vessel closure head. The CEDMs consist of the upper and lower CEDM pressure housings, motor assembly, coil stack assembly, reed switch assembly and extension shaft assembly. The CEDM is shown in Figure 4.2-17. The driver power is supplied by the coil stack assembly, which is positioned around the CEDM housing. Two position indicating reed switch assemblies are supported by the upper pressure housing shroud, which encloses the upper pressure housing assembly.

The lifting operation consists of a series of magnetically operated step movements. Two sets of mechanical latches are utilized engaging a notched extension shaft. To prevent excessive latch wear, a means has been provided to unload the latches during the engaging operations. The magnetic force is obtained from large DC magnet coils mounted on the outside of the motor tube. Power for the electromagnets is obtained from two separate supplies. A control programmer actuates the stepping cycle and obtains the correct CEA position by a forward or

reverse stepping sequence. CEDM hold is obtained by energizing one coil at a reduced current while all other coils are de-energized. The CEAs are tripped upon interruption of electrical power to all coils. Each CEDM is connected to the CEAs by an extension shaft. The weight of the CEDMs and CEAs is carried by the pressure vessel head. Installation, removal and maintenance of the CEDM is possible with the reactor vessel head in place; however, the CEDM is inaccessible during operation of the plant.

The axial position of a CEA in the core is indicated by three independent readout systems. One counts the CEDM steps electronically, and the other two consist of magnetically actuated reed switches located at regular intervals along the CEDM upper pressure housing. These systems are designed to indicate CEA position to within ±2½ inches of the true location. This accuracy requirement is based on ensuring that the axial alignment between CEAs is maintained within acceptable limits.

4.2.3.2.1.1 CEDM Pressure Housing

The CEDM pressure housing consists of the motor housing assembly and the upper pressure housing assembly. The motor housing assembly is attached to the reactor vessel head nozzle by means of a threaded joint and seal welded. Once the motor housing assembly is seal welded to the head nozzle, it need not be removed since all servicing of the CEDM is performed from the top of the housing. The upper pressure housing is threaded into the top of the motor housing assembly and seal welded. The upper pressure housing encloses the CEDM extension shaft and contains a vent. The top of the upper pressure housing is closed by means of a threaded cap with a welded Omega seal.

4.2.3.2.1.2 Motor Assembly

The motor assembly is an integral unit which fits into the motor housing and provides the linear motion to the CEA. The motor assembly consists of a latch guide tube, driving latches and holding latches.

The driving latches are used to perform the major stepping of the CEA. The holding latches hold the CEA during repositioning of the driving latches and perform a load transfer function to minimize latch and extension shaft wear. Engagement of the extension shaft occurs when the appropriate set of magnetic coils is energized. This moves sliding magnets which cam a 2-bar linkage moving the latches inward. The driving latches move vertically a maximum of 3/4 inch. The holding latches move vertically 1/16 inch to perform the load transfer.

4.2.3.2.1.3 Coil Stack Assembly

The coil stack assembly for the CEDM consists of five large DC magnet coils mounted on the outside of the motor housing assembly. The coils supply magnetic force to actuate mechanical latches for engaging and driving the CEA extension shaft. Power for the magnet coils is supplied from two separate supplies. A magnetic coil power programmer actuates the stepping cycle and obtains the correct CEA position by a forward or reverse stepping sequence. CEDM hold is obtained by energizing one coil at a reduced current while all other coils are de-energized. The CEAs are tripped upon interruption of electrical power to all coils. Electrical pulses from the magnetic coil power programmer provide one of the means for transmitting CEA position indication.

A conduit assembly containing the lead wires for the coil stack assembly is located at the side of the upper pressure housing.

4.2.3.2.1.4 Reed Switch Assembly

Two reed switch assemblies provide separate means for transmitting CEA position indication. Reed switches and voltage divider networks are used to provide two independent output voltage proportional to the CEA position. The reed switch assemblies are positioned so as to utilize the permanent magnet in the top of the extension shaft. The permanent magnet actuates the reed switches as it passes by them. The reed switch assemblies are provided with accessible electrical connectors at the top of the upper pressure housing. Three additional pairs of reed switches on each CEDM provide upper electrical limit, lower electrical limit and dropped rod indications.

4.2.3.2.1.5 Extension Shaft Assembly

The coupling of the CEDM to the CEA is accomplished by the extension shaft assembly. The inner portion of the assembly consists of a magnet, operating rod and plunger. The outer portion of the assembly consists of an extension sleeve, extension shaft, drive shaft and gripper.

The extension shaft assembly is coupled to the CEA through the action of the plunger and gripper. The plunger is spring loaded to remain in the center of the gripper. In this position, the gripper is expanded sufficiently to maintain engagement with the CEA.

The plunger is in turn fastened to the operating rod which runs the entire length of the extension shaft assembly along its centerline. At the top end of the operating rod is a magnet. The magnet is used to activate reed switches for CEA position indication. The spring loading of the plunger is maintained by the spring bearing against the gripper and a ledge on the gripper assembly.

The gripper assembly is threaded to the extension shaft which in turn is threaded to the notched drive shaft and the extension sleeve. In order to engage or disengage a CEA to or from the extension shaft assembly, a special gripper operating tool is attached to the top of the extension shaft assembly when the reactor vessel closure head has been removed. One part of the tool is attached to the extension sleeve to hold this portion of the extension shaft assembly stable. Another part of the tool is attached to the operating rod at the magnet assembly and is used to lift the plunger which in turn allows separation of the extension shaft assembly from the CEA. Insertion of the operating rod lowers the plunger, thereby spreading the fingers, which in turn allows the gripper to hold the CEA.

4.2.3.2.2 Control Element Assembly Design Description

The CEAs are shown in Figure 4.2.18. All CEAs have four control elements arranged in a 4.050-inch square array plus one element at the center of the array. The diameter of 0.816 inch is common to all control elements.

The control elements of a full length CEA consist of an Inconel-625 tube loaded with a stack of cylindrical poison pellets. The poison material consists of 73 percent TD boron carbide (B_4C) pellets, with the exception of the lower portion of the rods, which contain silver-indium-cadmium (Ag-In-Cd) alloy cylinders.

Above the poison column is a plenum volume which provides expansion room for gases generated in the poison. The plenum volume also contains a holddown spring which restrains the poison against longitudinal shifting with respect to the clad while allowing for differential expansion between the poison and the clad.

Each full length control element is sealed by welds which join the tube to an Inconel-625 nose cap at the bottom and an Inconel-625 end fitting at the top. The end fittings, in turn, are threaded and pinned to the spider structure which provides rigid lateral and axial support for the control elements. The spider hub bore is specially machined to provide a point of attachment for the CEA extension shaft.

The CEA pattern is shown in Figure 4.2-19. Each CEA is positioned by a magnetic jack CEDM mounted on the reactor vessel closure head. The extension shaft joins with the CEA spider and connects the CEA to the CEDM. CEAs may be connected to any extension shaft depending on control requirements. Mechanical reactivity control is achieved by positioning groups of CEAs by the CEDMs.

In the outlet plenum region, all CEAs are enclosed in CEA shrouds which provide guidance and protect the CEA and drive shaft from coolant cross flow. Within the core, each poison rod travels in a Zircaloy guide tube. The guide tubes are part of the fuel assembly structure and ensure proper orientation of the poison rods with respect to the fuel rods.

Buffering action of the CEA at the end of its stroke during reactor trip is accomplished by means of the dashpot action of the CEA corner elements within their guide tubes.

The lower ends of the four outer CEA guide tubes are tapered gradually to form a region of reduced diameter which, in conjunction with the outer poison rods on the CEA, constitutes an effective hydraulic buffer for reducing the deceleration loads at the end of a trip stroke. This purely hydraulic damping action is augmented by a spring and piston arrangement on the CEA spider. When a CEA is fully inserted, the spider rests on the central post of the fuel assembly upper end fitting.

4.2.3.3 <u>Reactivity Control System Evaluation</u>

4.2.3.3.1 <u>CEDM Design Evaluation</u>

4.2.3.3.1.1 <u>CEDM Stress Limits</u>

The pressure boundary material stress levels comply with the ASME Code, Section III, including Code Cases 1334 and/or 1337. The motor springs are designed to an 80-year fatigue lifetime (double the 40-year expected life) to ensure operation without failure.

The motor assembly hangs from a single ledge which allows for thermal expansion of the motor relative to the lower pressure housing. Tests at reactor operating conditions show that adequate clearances exist and that stress levels will provide a useful life of 40 years.

The CEDM stress analyses consider the following loads:

A. Reactor coolant pressure and temperature;

B. Reactor operating transient conditions;

C. Dynamic stresses produced by seismic loadings;

D. Dynamic stresses produced by mechanical excitations;

E. Loads produced by the operating and scramming of the mechanism; and,

F. Loads produced by BLPB.

Computer codes used in analysis of the above loads are listed in Table 4.1-1. The methods used to demonstrate that the CEDMs operate properly under seismic conditions is presented in Section 3.7.3.15.

4.2.3.3.1.2 CEDM Material Selection

The selection of materials used in the CEDMs is based on the following considerations.

A. Compliance with the ASME Code, Section III including Code Cases 1334 and 1337.

B. Functional characteristics of the CEDM such as minimizing wear, providing magnetic flux paths, enhancing lifetime, adequate magnetic properties, corrosion resistance and high impact strength.

C. Compatibility with adjacent CEDM materials and with the reactor environment.

D. Capability of withstanding radiation for 40 years.

The materials used in the CEDM are listed below.

A. Motor housing assembly pressure housing - Type 403 stainless steel with end fittings of nickel-chromium-iron alloy to SB 166.

B. Upper pressure housing - Type 316 stainless steel with vent valve seal utilizing a 440 stainless steel ball on a 316 stainless steel seat.

C. Motor latches, links and pins - high cobalt alloy.

D. Motor and extension shaft springs - Inconel-X-750.

E. Motor magnet - Type 410 stainless steel.

F. Motor fasteners - Type 304 stainless steel.

G. Extension shaft - Type 304 stainless steel.

H. Extension shaft magnets - Alnico No. 5.

I. Motor and extension shaft wear surfaces - chromium-plated.

J. Magnet coils - Copper wire insulated with high temperature enamel and vacuum impregnated with a high temperature varnish. After impregnation, coil is wrapped with fiberglass tape and encapsulated with a silicone compound.

K. Coil housings - Nickel-plated carbon steel.

4.2.3.3.1.3 CEDM Functional Considerations

Clearances for thermal growth and for dimensional tolerances were investigated and tests have proven that adequate clearances are provided for proper operation of the CEDM.

The latch locations are set by a master gauge and settings are verified by testing at reactor conditions.

A weldable seal closure, per the ASME Code, Section III is provided for the vent valve in case of leakage.

The motor housing fasteners are mechanically positively captured and all threaded connections are preloaded before capturing.

The coil stack assembly can be installed or removed simply by lowering or lifting the stack relative to the CEDM pressure housing for each coil replacement or maintenance.

4.2.3.3.2 Control Element Assembly Design Evaluation

The CEAs are designed for a 10-year lifetime based on conservative estimates of neutron absorber burnup, allowable plastic strain of the Inconel-625 cladding and the resultant dimensional clearances of the elements within the fuel assembly guide tubes.

4.2.3.3.2.1 Control Element Assembly Stress Limits

Stress intensities in the individual structural components do not exceed the allowable limits for the appropriate material established in the ASME Code, Section III. The exceptions to this criteria are that: (a) the Inconel-625 cladding is permitted to sustain plastic strain up to 1.2 percent due to irradiation-induced expansion of the filler materials, (b) where compressive stress occurs, stress limits are revised to take into account critical buckling, and (c) the allowable stresses for the CEA springs are based on values which have been proven in practice. The CEA stress analyses consider the following loads.

A. Internal pressure buildup due to the effect of irradiation on B_4C (production of helium).

B. External pressure of reactor coolant.

C. Dynamic stresses produced by seismic loading.

D. Dynamic loads produced by stepping motion of the magnetic jack.

E. Mechanical and hydraulic loads produced during reactor trip.

F. Loads produced by differential expansion between clad and filler materials.

G. Loads produced by a BLPB.

The fatigue damage produced by significant cyclic stresses is also determined. The calculated cumulative damage factor for any location must be less than 1.0. The fatigue usage factor calculations are based on the fatigue curves (stress range versus number of cycles) contained in the ASME Code, Section III.

4.2.3.3.2.2 Control Element Assembly Material Selections

The selection of materials used in the CEAs is based on the following considerations.

A. Neutron absorption cross section.

B. Irradiated properties of the material.

C. Dimensional stability under irradiation.

D. Compatibility with other CEA materials and with the reactor environment.

E. Whether the material has been used successfully in similar applications.

The actual materials used in the CEA are listed below:

A. Spider: The spider is made from Grade CF-8 cast and Type 304 wrought stainless steel. Selection of this material is based on its proven acceptability for use in reactor structural applications.

B. Cladding tube, end fitting and end cap: These parts are made from Inconel-625. The selection of this material is based on its high strength (including creep resistance), good corrosion resistance and excellent dimensional stability under irradiation at the temperatures and fluences to which it will be subjected. In addition, tests have shown that the Inconel-625 cladding material will sustain less than 0.001 inch of wear during the design life of the CEA.

C. Holddown spring: The holddown springs are made from Type 302 stainless steel. This selection is based on the proven characteristics of this material for spring applications.

D. Primary poison material: The poison material used in the CEA is boron carbide (B_4C) in the form of cylindrical pellets. This selection is based on the excellent neutron absorption capabilities of B_4C and the proven acceptability of B_4C for reactor control applications. Under irradiation, the B_4C pellets may swell up to 1.5 percent and some boron is transmuted to lithium and helium. The resulting effects on clad strain and rod worth are accounted for in the CEA design.

E. Secondary poison material: The selection of Ag-In-Cd alloy in the bottom of the rods is based on its high neutron absorption cross section and its proven acceptability for reactivity control applications. Moreover, this material has good dimensional stability under irradiation (less than 0.5 percent expansion) which contributes to the proper operation of the hydraulic buffer over the lifetime of the CEA by maintaining the proper diametral clearance.

F. Control Rod Spacer Material: Spacers are fabricated from Type 304 stainless steel. Spacers are located at the top and bottom of poison columns and near tube/end cap welds.

G. Spider mounted spring: The spring contained within the spider is made from Inconel X-750. Selection of this material is based on its excellent strength, corrosion resistance, and its resistance to relaxation under irradiation.

All of the materials listed above have been used successfully in similar CEA application in Combustion Engineering reactors.

The effects of neutron irradiation on the integrity and performance of the CEA can be divided into three categories.

A. Neutron interactions with boron carbide produce helium which causes the poison rod internal pressure to increase. The poison rods contain sufficient plenum volume to prevent the internal pressure from having any adverse effect during the life of the CEA.

B. Neutron irradiation causes volumetric expansion of the B_4C poison material as the boron burnup proceeds. Expansion on the order of one to two percent in length and diameter of the B_4C pellets is anticipated. The CEA design is based on allowing for the maximum expected expansions. For the temperatures and fluences encountered by the CEA, the dimensional changes in materials other than the B_4C are insignificant.

C. Long-term neutron irradiation tends to increase the tensile strength and decrease the ductility of reactor structural materials. The only CEA structural material which receives a significant irradiation (from the standpoint of producing changes in the strength and ductility properties) is the Inconel-625 cladding. For the temperatures and fluences seen by the CEA cladding, the maximum strength increase is approximately 10 percent of the unirradiated value, and the ductility is reduced from approximately 30 percent to about six percent. However, the allowable primary stress limit in the cladding assumes no increase in yield strength and the maximum allowable strain for cladding is established at three percent.

4.2.3.3.2.3 <u>CEA Mechanical Clearances</u>

There are two categories into which the mechanical clearances associated with the CEA can be divided: clearances between the CEA and the guide structures and clearances between internal components of the CEA. The clearances between the CEA and its guide structure, both in the fuel assembly and in the Upper Guide Structure (UGS), have been established to meet the following requirements.

A. Assure adequate coolant flow past the CEA poison rods.

B. Assure sufficient freedom of CEA axial motion to meet reactor trip time requirements under conditions of worst case bowing of fuel assemblies; most adverse alignment between fuel bundles, upper guide structure and CEDMs; adverse locating and dimensional tolerances of poison rod cladding and CEA guide tube; and radial growth of poison rods due to irradiation effects.

C. Assure proper hydraulic damping action to prevent damage to the CEA or related components when the CEA is tripped.

The spacing and clearance gaps between the CEA holddown spring, stainless steel spacers, B_4C pellets, and Ag-In-Cd rods assure adequate heat transfer capability between internal components and CEA cladding tubes and prevent excessive filler/clad interaction.

The selection of specific component clearances is based on experience and testing of similar hardware where applicable, as well as tolerance studies performed to demonstrate that the functional requirements of the CEAs are unimpaired under worst tolerance conditions.

4.2.3.3.2.4 CEA Positioning, Driving and Tripping Requirements

The axial positioning of the CEAs in the core is accomplished by a magnetic jack CEDM which steps the CEA in increments of 0.75 inch maximum.

The selection of the step size is based on a requirement that the positive or negative reactivity insertion produced by a single step not be sufficient to produce effects in the reactor which would cause the original reactor regulating system to signal a step in the opposite direction.

The position of the CEA in the core is known within 2½ inches of its true location by a redundant readout system described in Chapter 7.

The driving requirement for the CEAs is a normal 30 inches/minute.

For all full length CEAs, the CEA drop time at reactor operating conditions for a fully withdrawn position to 90 percent of full insertion does not exceed 3.2 seconds for the average of all full length CEAs and 3.7 seconds for any individual full length CEA, measured from the time power is removed from the CEDM holding coils.

CEA insertion requirements for powered operation have been established on the basis of providing sufficient negative reactivity insertion rates to enable the reactor to follow design power reduction transients without exceeding operational limits

4.2.3.3.2.5 Pressure Forces Tending to Eject CEAs

Under normal operating conditions and during all abnormal and accident conditions, except failures of the reactor coolant pressure boundary, the pressure forces pushing upward on the CEA are much less than the weight (in water) of the CEA and extension shaft. During the period of blowdown following a failure of the reactor coolant pressure boundary (LOCA) the combined weight of the CEA and extension shaft will operate against short-term transient upward forces such that CEA motion is negligible.

A rod ejection incident is possible only in the event of a failure of the CEDM pressure boundary structure in a manner which causes the CEDM to separate from the closure head. The probability for such an event is considered to be very small. The rod ejection accident is analyzed and discussed in Chapter 15.

4.2.3.3.2.6 Potential for and Consequences of CEA/CEDM Functional Failure

The probability for a functional failure of the CEA or CEDM is considered to be very small. This conclusion is based on the conservatism used in the design, the quality control procedures used during manufacturing, and on testing of similar full size CEA/CEDM combinations under simulated reactor conditions for lengths of travel and numbers of scrams greater than that expected to occur during the Arkansas Nuclear One - Unit 2 design life. The consequences of CEA/CEDM functional failure are discussed in Chapter 15.

Another postulated CEA failure mode is cladding failure. In the event that a poison rod is assumed to partially fill with water under low or zero power conditions, the possibility exists that upon returning to power, the path of the water to the outside could be blocked. The expansion of the entrapped water could cause the poison rod to swell. In tests, specimens of CEA

cladding were filled with a spacer representing the poison material. All but nine percent of the remaining volume was filled with water. The sealed assembly was then subjected to a temperature of 650 °F and an external pressure of 2,250 psi followed by a rapid removal of the external pressure. The resulting diametral increases of the cladding were small and not sufficient to impair axial motion of the CEA. This test result, coupled with the low probability of a poison rod cladding failure leading to a waterlogged rod, demonstrates that the probability for a CEA functional failure from this cause is low.

Other possible consequences of failed poison rod cladding are the release of small quantities of CEA filler materials and helium and lithium (from the neutron boron reactions). However, the amounts which would be released are too small to have significant effects on coolant chemistry or rod worth.

In addition to the failure modes discussed above, a small object carried with the coolant could be swept in the CEA guide tube where it could interfere with normal operation of the CEA. In order to minimize the probability for such an occurrence, the guide tube flow inlet holes are of small diameter and are oriented with their axes perpendicular to the coolant flow direction. However, in the event that an object entered the guide tube and interfered with CEA operation, the most serious consequence would be a stuck rod. The effects of a stuck rod incident are discussed in Chapter 15.

4.2.3.3.2.7 Effect of Violent Fuel Rod Failure on CEA Operation

As discussed in Chapter 15, some postulated accident conditions, e.g., LOCA, rod ejection, may produce rapid failure of the cladding on a small number of fuel rods. Since these fuel rods may be adjacent to the CEA guide tubes, the possible effect of such violent fuel rod failures on CEA operation is considered.

The CEA poison rods travel in individual Zircaloy guide tubes which form a permanent part of the fuel assembly structure. It is not possible for swelled or split fuel elements to interfere with CEA operation unless the swelling or splitting has first caused significant deformation of the guide tubes.

The probability that a rod failure would deform the guide tube sufficiently to prevent normal CEA operation was examined and is considered an unlikely event. This conclusion is based on the following considerations:

A. The minimum clearance between a fuel rod and a guide tube in the fuel bundle is approximately .124 inch. Thus, the fuel rod diameter would have to swell by approximately 65 percent before it contacted the guide tube.

B. The guide tube has much greater (~10 times) resistance to lateral deflection than a fuel rod. The fuel rod, therefore, could not exert a lateral force sufficient to cause a significant deflection of the guide tube except at a support grid location. Furthermore, at a support grid, the fuel rod would first have to overcome the additional restraining effects of the support grid before it contacts the guide tube.

In conclusion, even in the event of violent failure of fuel rods adjacent to CEA guide tubes, the probability that such failures would deform the guide tubes enough to affect CEA operation (either driven operation or trip) is small.

4.2.3.4 Testing and Inspection Plan

4.2.3.4.1 CEDM Testing

4.2.3.4.1.1 Prototype Accelerated Life Tests

This section describes tests performed on a standard Combustion Engineering CEDM magnetic jack design. Arkansas Nuclear One - Unit 2 will use essentially the same basic magnetic jack design with the exception of a longer upper pressure housing on the CEDM to accommodate the 150-inch stroke.

The following describes tests performed on a prototype CEDM of the 138-inch stroke magnetic jack design. The tests described below illustrated the type and magnitude of testing used to demonstrate that the CEDM will meet specified operating requirements for the duration of plant life with normal maintenance. (Since Arkansas Nuclear One - Unit 2 will use essentially the same basic magnetic jack design, testing of the Arkansas Nuclear One - Unit 2 mechanism will consist essentially of verifying the trip characteristics of the mechanism.)

A prototype standard CEDM was subjected to accelerated life tests accumulating approximately 100,000 feet of travel equivalent to a 40-year lifetime. The first phases of the accelerated life test consisted of continuous operation of the mechanism at 40 inches per minute lifting 230 pounds for a total travel of 32,500 feet. This test was performed at simulated reactor operating conditions. Upon completion of the test, the motor bearing surfaces were inspected and measured. A maximum bearing wear of .003 inch was measured. This degree of wear is considered acceptable based on the 40-year design life.

The second phase of the accelerated life test consisted of 200 full height gravity drops and 20,000 reversals at one drive shaft position. This test was also performed at reactor operating temperatures and pressures with 230 pounds lift weight. The additional travel accumulated during this phase of testing was 5,400 feet. The mechanism at this point had accumulated a total travel (hot and cold) of 38,400 feet at 40 inches/minute operation. All drops were completed satisfactorily. Inspection of the drive shaft after this test showed no excessive wear in the area of the reversals.

A third phase of the life test was completed. In this test, the prototype magnetic jack was coupled to a dual CEA and extension shaft assembly (335 pounds dry). The test was conducted under operating conditions of 600 °F and 2,200 psig and the water chemistry adjusted to 1,100 ppm boron. The mechanism was operated lifting the dual CEA and extension shaft assembly at 20 inches per minute for a total of 15,625 feet and 200 full height drops. Post-test inspections again showed that motor bearing wear was negligible. No motor failures were encountered during this test phase. Total accumulated travel at the end of this phase of testing (including operational verification test) was 60,000 feet, or 24 years of design life.

Two inadvertent rod drops occurred during the above test phase. These were encountered during rod drop testing when the mechanism was primarily operated in the withdrawal mode of operation. Driving the mechanism in the insertion mode after each series of 10 drops corrected this condition. It was concluded that crud buildup under the pulldown magnet caused difficulty in resetting the mechanism during withdrawal since the pulldown force on this magnet is less in the withdrawal cycle than in the insertion cycle. It was discovered that by driving in the CEA and extension shaft occasionally, instead of continuously dropping the rods, the crud under the pulldown magnet was displaced and the malfunction eliminated.

A non-tripping control rod drive mechanism (PLCEDM) for the part length CEAs was originally included in the Arkansas Nuclear One - Unit 2 contract. The need for a mechanism of this type no longer exists. However, the following test phase is included in order to present an overall view of the drive mechanism test program.

The prototype CEDM was converted to a PLCEDM by installation of a non-tripping assembly. A sixth coil was added to operate the non-trip device. The remainder of the mechanism was the same as the previous tripping prototype mechanism and was utilized in subsequent testing to accumulate additional travel. The mechanism was installed on a high temperature test facility and coupled to a test CEA having a total weight of 230 pounds dry. Its operating speed was increased to 30 inches/minute. The test loop conditions were set at 600 °F and 2,200 psig, and a fourth accelerated life test was initiated. The object of this accelerated life test was to accumulate an additional 30,000 feet of continuous operation utilizing the prototype mechanism as a part length drive.

After a total of 15,000 feet of operation had been accumulated, the holding latch spring in the motor assembly failed. The total travel accumulated on this particular component to that point was 75,000 feet or an equivalent of 30 years of design life. The holding latch spring was replaced and the life test continued without modification to the other parts.

The spring design was reviewed and an improved spring design was incorporated into the production units with a design life of twice that of the failed spring.

During the latter half of the fourth accelerated life test, the drive shaft was distorted. The cause of this distortion was attributed to the operating rod in the extension shaft assembly having been pinned at its upper end causing a high stress to occur as a result of differential thermal growth between the drive shaft and operating rod. This design was changed for the production units to allow for the differential thermal expansion between the drive shaft and operating rod. Drive shaft bowing has not occurred with the new design. Distortion of the drive shaft caused the mechanism to occasionally fail to complete a step. At no time did the CEA drop due to this distortion. Under these test conditions, an additional 18,000 feet was completed for a total accumulated travel on this prototype mechanism as a part length unit of 33,000 feet. Total travel on the drive shaft and major components of this motor assembly was 93,000 feet. Upon disassembly and inspection, no additional failures were found. Upon completion of the non-tripping accelerated life test, the prototype mechanism was converted back to a tripping CEDM by removal of the non-tripping device.

The reconverted mechanism was again operated in the high temperature test facility at normal reactor temperature and pressure. The driven weight was 230 pounds (dry) including drive shaft and CEA. Limit switches were positioned to give a total stroke of 120 inches over the upper end of the mechanism travel. The remainder of the life test consisted of operating the mechanism for 7,000 feet. Upon completion of this travel, the facility was shut down and the bearing surfaces remeasured. The measurements were recorded and the wear was found to be within acceptable limits.

The fast shutdown capability of the tripping magnetic jack mechanism was verified by dropping the minimum effective weight of 130 pounds (dry) with the prototype mechanism. A curve showing CEA position versus time was generated utilizing the reed switch position transmitter. The facility test conditions were set at 40 psig, ambient temperature and no flow. Six drops were completed. Time deviations between the various drops were less than 0.1 second. A preproduction mechanism was installed on a full flow test facility for drop testing under reactor operating conditions including flow.

Two hundred and six full height trips and 126 partial height trips were completed under reactor operating conditions including flow. Drop times for 90 percent insertion at full flow reactor operating conditions met the required criteria and displacement curve.

4.2.3.4.1.2 First Production Test

A qualification test program was completed on the first production 138-inch stroke Combustion Engineering magnetic jack design CEDM. During the course of this program over 4,000 feet of travel was accumulated and 30 full height gravity drops were made without mechanism malfunction or measurable wear on operating parts. The program included the following:

A. Operation of 40 inches per minute lifting 230 pounds (dry) at ambient temperature and 2,000 psig pressure for 800 feet;

B. Six full height, 230-pound (dry) weight gravity drops at ambient temperature;

C. Operation at simulated reactor operating conditions at 40 inches per minute lifting 230 pounds for 1,700 feet;

D. Six full height gravity drops at simulated reactor operating conditions with 230 pounds weight;

E. An operational test ambient temperature and 2,300 psig pressure lifting 335 pounds at 20 inches per minute for 500 feet;

F. Six full height gravity drops of the 335-pound weight;

G. Operation at simulated reactor conditions for 1,700 feet at 20 inches per minute lifting 335 pounds; and,

H. Operating at ambient temperature and 2,300 psig for 1,100 feet and 20 full height gravity drops with an attached dry weight of 130 pounds.

4.2.3.4.1.3 Production Tests

All CEDM production units will be tested for a minimum of 400 feet of total travel at combinations of pressure and temperature from ambient up to reactor operation conditions. The CEDMs are also tested for six full height gravity drops at simulated reactor operating conditions.

4.2.3.4.1.4 Field Tests

After installation of the CEDMs and prior to power operation, the CEDMs are tested in accordance with procedures developed for the startup test program as outlined in Chapter 14.

4.2.3.4.1.5 Maintenance Tests

Tests to be performed during the design lifetime of the CEDM during normal power operation are described in the Technical Specifications.

4.2.3.4.2 Verification of CEA Characteristics by Inspection and Test

The CEAs are subjected to numerous inspections and tests during manufacturing and after installation in the reactor. In addition, various CEA hardware tests have been conducted or are in progress.

During manufacturing, the following inspections and tests are performed:

A. All materials are produced to rigid specifications. A general product specification covers the fabrication, inspection, assembly, cleaning, packaging and shipping of the CEA;

B. All end caps welds are liquid penetrant examined and helium leak tested. A sampling plan is used to section and examine end cap welds;

C. The loading of each control element is carefully controlled to obtain the proper amounts and types of filler materials for each type of CEA application,

D. Each poison rod has unique external features which distinguish it from other types;

E. Each CEA has unique external characteristics on the spider which distinguish it from others. The CEAs are also serialized. See Figure 4.2-18.

F. Fully assembled CEAs are checked for proper alignment of the neutron absorber elements using a special fixture. The alignment check ensures that the frictional force that could result from adverse tolerances is below the force which could significantly increase trip time.

In addition to the basic measures discussed above, the manufacturing process includes numerous other quality control steps for ensuring that the individual CEA components satisfy design requirements for material quality, detail dimensions and process control.

After installation in the reactor, but prior to criticality, each CEA is traversed through its full stroke and tripped. A similar procedure will also be conducted at refueling intervals.

Hardware tests to date have been performed using CEA components developed primarily for Combustion Engineering's 800 MWe class reactors which use 14 x 14 fuel assemblies.

CEAs used in the Unit 2 reactor are essentially similar in design and construction to the 800 MWe class CEA, with the exception that the CEA spider arms are shorter and the neutron absorber elements are smaller in diameter for compatibility with the 16x16 fuel assembly guide tube diameters and pitches employed in the Unit 2 plant.

The predicted 90 percent insertion time for the lightest CEA in the Unit 2 reactor is 2.75 seconds under worst case conditions as described in Technical Specification 3.1.3.4. The required time is $\leq$ 3.2 seconds for the average of all full length CEAs and $\leq$ 3.7 seconds for any individual full length CEA. The predicted insertion time is determined using the Control Element Assembly Scram Analysis (CEASA) computer program which models the hydraulic forces acting on a CEA during the scram. The CEASA code determines the effects of various parameters, e.g., pressure differential, clearances, weights, friction, etc., on CEA insertion times. After establishing the proper combination of parameters, the CEA design is completed. Verification

of adequacy will be determined by testing in the Combustion Engineering TF-2 flow test facility, which is scheduled for completion in December 1975. This facility contains prototypical Arkansas-type reactor components consisting of a fuel assembly, a CEA shroud, CEDM, and a simulation of surrounding core internal support components. The test conditions simulate the worst possible core pressure differential at reactor temperature and pressure conditions, in addition to adverse control element assembly alignment.

The buffer mechanism has also been evaluated using the CEASA computer program and was found to be adequate. Verification of the buffer performance will be included in the test program described above.

4.2.3.5 Instrumentation

A detailed discussion of the instrumentation and control systems associated with reactivity control is presented in Chapter 7.

4.2.3.6 Neutron Source Assembly

Prior to Cycle 10, the core contained two neutron source assemblies. The function of the neutron source assembly was to provide a base neutron level such that required monitoring of neutron level could be accomplished during fuel loading, refueling and shutdown conditions. The neutron level provided was sufficient to allow continuous monitoring during fuel loading. The neutron level was sufficient to monitor an approach to criticality when the reactor was in a shutdown condition and during refueling operations.

A primary Pu-238/Be source was utilized to monitor the initial core loading, testing and approach to criticality, while a secondary Sb-Be source fulfilled the function during subsequent operations.

Two source assemblies were used; each source assembly contained a primary and a secondary source. The source assembly was installed in an empty guide tube in the fuel assembly. The neutron source assembly was positively restrained within the guide tube by a spring load applied against a recessed surface in the fuel assembly alignment plate. The two neutron source assemblies were located in fuel assemblies that were adjacent to the out-of-core startup neutron detectors.

The Pu-238/Be primary source material was encapsulated in a 304 stainless steel tube with an outer assembly tube serving as a second encapsulation barrier. Within the outer assembly, Sb-Be pellets were positioned to serve as a secondary source material. All outer parts of the neutron source assembly exposed to reactor coolant conditions were fabricated from an age-hardened nickel base alloy for corrosion resistance and high strength. The spring was housed within the outer encapsulation to ensure that it would remain captured in the event of a failure.

At the end of Cycle 9, the neutron source assemblies were discharged from the core. The function provided by the neutron source assemblies, however, continues to be provided by the irradiated fuel in the core, with neutrons from spontaneous fission and radioactive decay.

4.3 NUCLEAR DESIGN

4.3.1 DESIGN BASES

The bases for the nuclear design of the fuel and reactivity control systems are discussed in the following sections.

4.3.1.1 Excess Reactivity and Fuel Burnup

The excess reactivity provided for each cycle is based on the depletion characteristics of the fuel and burnable poison and on the desired burnup for each cycle. The desired burnup is based on an economic analysis of both the fuel cost and the projected operating load cycle for the plant. The average burnup is chosen so as to ensure that the peak burnup is within limits discussed in Section 4.2.1. This design basis, along with the design basis in Section 4.3.1.7, satisfies General Design Criterion 10.

4.3.1.2 Core Design Lifetime and Fuel Replacement Program

The core design lifetime and fuel replacement program are based on an 18-month (approximately) refueling cycle with about one-half of the fuel assemblies replaced at each refueling. A multi-batch fuel management program is employed which may use zoned fuel assemblies and poison rods.

4.3.1.3 Negative Reactivity Feedback and Reactivity Coefficients

In the power operating range, the inherent combined response of the reactivity feedback characteristics (fuel temperature coefficient, moderator temperature coefficient, and moderator pressure coefficient) to an increase in reactor thermal power will be a decrease in the reactivity. The negative reactivity feedback provided by the design satisfies General Design Criterion 11.

4.3.1.4 Burnable Poison Requirements

The burnable poison reactivity worth provided in the design is sufficient to ensure that moderator coefficients of reactivity have values consistent with the requirements for negative reactivity feedback and acceptable consequences in the event of postulated accidents or anticipated operational occurrences, viewed in conjunction with the characteristics of the Reactor Protective System (RPS).

4.3.1.5 Stability Criteria

The design of the reactor and the instrumentation and control systems is based on meeting the requirements of General Criterion 12, with respect to spatial xenon oscillations and stability. Sufficient Control Element Assembly (CEA) worth is available to suppress xenon-induced spatial oscillations.

4.3.1.6 Maximum Controlled Reactivity Insertion Rates

The maximum reactivity addition rates are limited by core, CEA, and boron charging system design based on preventing increases in reactivity which would result in the violation of specified acceptable fuel design limits, damage to the reactor coolant pressure boundary, or disruption of the core or other internals sufficient to impair the effectiveness of emergency core cooling. This design basis, along with the design basis in Section 4.3.1.10, satisfies General Design Criteria 25 and 28.

4.3.1.7 Power Distribution Control

The power distribution is controlled such that, in conjunction with other core parameters, limiting conditions for operation are not violated. Limiting conditions for operation are chosen to substantiate the accident analyses in Chapter 15. Limiting conditions for operation and limiting safety system settings are determined such that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences, and such that predicted acceptable consequences are not exceeded for other postulated accidents. This design basis satisfies General Design Criterion 10.

4.3.1.8 Shutdown Margins and Stuck Rod Criteria

The amount of reactivity available from insertion of withdrawn CEAs under all power operating conditions, even when the highest worth CEA fails to insert, will provide for the following:

A. At least one percent shutdown margin after cooldown to hot zero power; and,

B. Any additional shutdown reactivity requirements assumed in the safety analyses.

This design basis, along with the design basis in Section 4.3.1.9 satisfies General Design Criterion 26.

4.3.1.9 Chemical Shim Control

The Chemical and Volume Control System (CVCS) (Section 9.3.4) is used to adjust dissolved boron concentration in the moderator. After a reactor shutdown, this system is able to compensate for the reactivity changes associated with xenon decay and reactor coolant temperature decreases to ambient temperature, and it provides adequate shutdown margin during refueling. This system also has the capability of controlling long-term reactivity changes due to fuel burnup, and reactivity changes during xenon transients resulting from changes in reactor load independently of the CEAs. In particular, any xenon burnout transient may be accommodated at any time in the fuel cycle. The maximum reactivity addition rate for which the CVCS will be required to compensate is given in Table 4.3-1. The maximum value occurs at the end-of-cycle when the moderator temperature coefficient is most negative and the soluble boron worth is a minimum. This design basis, along with the design basis in Section 4.3.1.8, satisfies General Design Criterion 26.

4.3.1.10 Maximum CEA Speeds

Maximum CEA speeds are consistent with the accident analyses requirements discussed in Chapter 15 and with Section 4.3.1.6. Maximum CEA speeds are also discussed in Section 4.2.

4.3.2 DESCRIPTION

4.3.2.1 Nuclear Design Description

This section summarizes the nuclear characteristics of the ANO-2 reactor core and discusses the design parameters that are of significance to the performance of the core parameters in steady state and normal transient operation, as presented in Tables 4.3-1 and 4.3-2, and Figures 4.3-1A through 4.3-1E. Figure 4.3-1 shows the fuel management scheme. The core consists of those assembly types and numbers listed in Figure 4.3-1D.

Limiting values for relevant parameters are discussed in the appropriate sections.

Fuel enrichment and burnable poison distributions are shown in Figures 4.3-1A through 4.3-1C. The other three quadrants of the core have rotational symmetry to the quadrant shown in Figure 4.3-1E. Physical features of the lattice and fuel assemblies are described in Section 4.2.

Typical reload critical soluble boron concentrations and worths, delayed neutron fractions and neutron lifetime are shown in Table 4.3-1. These values vary slightly with core and fuel batch design as noted in Table 4.3-1. Also, typical K_{eff} reactivity and reactivity defect data associated with the cold zero power, hot standby, and hot full power equilibrium xenon and samarium conditions are shown in Table 4.3-2. Soluble boron insertion rates as discussed in Section 9.3.4 are sufficient to compensate for the maximum reactivity addition due to xenon burnout and normal plant cooldown.

4.3.2.2 Power Distribution

4.3.2.2.1 General

The power distribution is one of many items that affect the margin between the actual core conditions at a given instant of time and either the operating limits, or the specified acceptable fuel design limits for the reactor. The acceptability of a given power distribution is therefore, dependent on the power level and coolant conditions.

At all times during operation, it is intended that the power distribution and coolant conditions be controlled so that the peak linear heat rate and the minimum Departure from Nucleate Boiling Ratio (DNBR) are maintained within operating limits supported by the safety analyses (Chapter 15) with due regard for the correlations between measured quantities, the power distribution and uncertainties in the determination of power distribution. Methods of controlling the power distribution include the use of CEAs to alter the axial power distribution; decreasing CEA insertion by boration, thereby improving the radial power distribution; and correcting off-optimum conditions which cause margin degradations, e.g., CEA mis-operation.

The Core Operating Limit Supervisory System (COLSS) has the capability to indicate continuously to the operator how far the core is from the operating limits and give an audible alarm should an operating limit be exceeded. Such a condition signifies reduction of the capability of the plant to withstand an anticipated transient, but does not necessarily imply a substantial reduction of margin to fuel design limits. If the margin to fuel design limits continues to decrease, the Reactor Protection System (RPS) assures that the specified acceptable fuel design conditions are not exceeded, by initiating a trip.

The COLSS monitoring system, described in Section 7.7 and Reference 14, generates continually an assessment of the margin to linear heat rate and DNBR operating limits. The data required for these assessments include measured in-core neutron flux data, CEA positions, and coolant inlet temperature, pressure and flow. In the event of an alarm indicating that a limit has been exceeded, power must be reduced unless the alarm can be cleared by improving the power distribution or another process parameter.

In addition to the monitoring performed by COLSS, the RPS receives primary coolant data, signals from ex-core neutron flux detectors each containing three axially stacked elements, and from redundant reed switch assemblies for CEA position indication. These signals are processed to obtain the core power distribution and thermal margin. In the event the power

distributions or other parameters are perturbed as the result of an anticipated operational occurrence, the high local power density or low DNBR trips will initiate a reactor trip if required to prevent the respective fuel design limits from being exceeded.

4.3.2.2.2 Nuclear Design Limits on the Power Distribution

The design limits on the power distribution stated here were employed during the design process as initial conditions for accident analyses described in Chapters 6 and 15. However, the acceptability of the consequences of the accident analyses for the completed design are factored into a final determination of the operating limits. These are not stated separately on the power distributions, but in terms of peak linear heat generation rate and required minimum DNBR overpower, as noted below.

The design limits on power distribution are as follows:

A. The limiting three-dimensional heat flux peaking factor, F_q^n was established for full power conditions at 2.28. F_q^n is defined in Section 4.4.2.3.4.C, and is termed the nuclear heat flux factor or the total nuclear peaking factor.

   An F_q^n of 2.28 in combination with uncertainties and allowances on heat flux which give the peak linear heat rate initially assumed in the safety analyses constituted one limiting combination of parameters for full power operation. Other combinations giving acceptable accident analysis consequences are equally acceptable. Implementation in the Technical Specification is via an operating limit on the monitored peak linear heat generation.

B. The margin to the Technical Specification DNBR Safety Limit that is available to accommodate anticipated operational occurrences will be as acceptable as the margin calculated with the following combination of:

   1. The coolant conditions;

   2. The axial power distribution; and,

   3. The integrated radial peaking factor, F_r^n, where F_r^n is the rod radial nuclear factor or the rod radial peaking factor and is defined in Section 4.4.2.3.4.A.

   An F_r^n of 1.55, the set of axial shapes displayed in Figure 4.4-2, and the coolant conditions assumed in the safety analyses constitute one limiting combination of parameters for full power operation. Other combinations giving acceptable accident analysis consequences are equally acceptable. Implementation in the Technical Specification is via an operating limit on allowed minimum monitored DNBR overpower versus axial shape index.

   It will be shown below that operation within these limits is achievable.

4.3.2.2.3 Comparison Between Expected Core Conditions and Operating Limits

In comparing the expected power distributions and implied Peak Linear Heat Generation Rate (PLHGR) produced by analysis with the anticipated limiting PLHGR operating limit stated in Technical Specification 3/4.2.1, consideration must be given to the uncertainty and allowances associated with monitoring by CECOR, which is discussed in Reference 22.

Figures 4.3-2 through 4.3-10 and 4.3-14 through 4.3-18 show typical planar radial and unrodded core average axial power distributions. They illustrate conditions expected at full power at various times in the fuel cycle as specified on the figures. It is expected that the normal operation of the reactor will be with limited CEA insertion so that those distributions represent the expected power distribution during most of the cycle.

The one-pin planar radial power peaks presented in these figures represent the maximum that could be expected between about 20 and 80 percent of core height. Power peaks outside this axial region were examined and found not to be limiting at any time during the cycle.

The radial power distribution described in this section is calculated data which do not include any uncertainties or allowances. The calculations performed to determine these radial power peaks explicitly account for augmented power peaking which is characteristic of fuel rods adjacent to the water holes.

The three-dimensional peaking factor, F_q^n, expected during steady state operation is then just the product of the unrodded planar radial peak and the axial peak. The maximum value of this product can be seen from the figures to give a maximum F_q^n well below the allowed F_q^n.

This difference between limiting and expected F_q^n represents margin that is available for maneuvering. Reductions in the limiting PLHGR result in reductions in the maximum F_q^n allowed at full power, and are reflected as reductions in the margin available for maneuvering. Reductions below the limits of Technical Specification 3/4.2.1 could lead to restrictions on maneuvering in the form of reduced rates of return to full power or reduced flexibility to initiate maneuvers from non-equilibrium conditions.

For discussion purposes, the typical power distributions occurring during typical load following transients indicate that the power distribution and PLHGR limits can be met. These power distributions consider the effects of the time and spatial variations of xenon and iodine concentration, CEA position, thermal and moderator density feedback mechanisms as well as the effect of the burnup distribution near end-of-cycle.

Figure 4.3-20D shows typical F_q^n, F_r^n, and relative power level for an EOC maneuver. Also, Figures 4.3-21 and 4.3-21A show the calculated F_q^n and relative power level throughout the transient for both early and late in cycle transient calculations. Both step and ramp power changes are illustrated in these figures. The CEA programming used in these calculations is discussed in Section 4.3.2.4. As may be seen from these figures, the limiting value of F_q^n is met with margin.

The values of F_q^n and F_r^n are obtained by synthesis of the three-dimensional power distributions from two-dimensional (planar) MC and one-dimensional (axial) QUIX calculations for Cycles 1 through 3, for Cycles 4 through 17 with the ROCS computer code, and for subsequent cycles, beginning with Cycle 18, with the ANC computer code. Axial-dependent depletion effects are included in the end of cycle synthesized values of F_q^n by using the end of cycle axial nuclide distribution computed from three-dimensional ROCS or ANC depletion calculations.

The ROCS or ANC model calculates values of radial peaking factors for each type of CEA bank insertion (unrodded, Bank 6 inserted, etc.). These radial peaking factors are evaluated for the appropriate core average burnup condition shown in Figures 4.3-20D through 4.3-21A, and are applied over that region of the core having the specified CEA bank configuration, e.g. unrodded, Bank 6 inserted, etc. These radial peaking factors are then used to augment the power

distribution in the rodded axial regions to obtain the pseudo-hot channel power for a given rodded core segment. The magnitude of the radial peaking factor is determined primarily by the number and location of the inserted CEAs; it is evaluated at the full power condition and taken to be independent of power level.

Figures 4.3-22 and 4.3-22a show a conservative estimate of the integrated radial peaking factor F_r^n during the load following transients described above. These are shown because they correspond roughly to changes in thermal margin during the maneuvers. As may be seen from the figures, the value of F_r^n remains below a value of 1.55 throughout the full power portion of the maneuvers.

Throughout the calculations of the power distributions during the transient described above, it was assumed that the CEAs were available to be moved to control the axial power distribution. Section 4.3.2.5 discussed the methods of control to be used. However, in the event that the CEAs were not moved properly, the power distribution could have become unacceptable. In this case, the monitoring system would have indicated if insufficient margin were available and would have provided an audible alarm to indicate that action had to be taken to improve the core power distribution, to improve the coolant conditions, or to reduce core power.

The radial peaking factor used in the calculation of required initial margin to DNB for a particular axial shape and set of thermal hydraulic conditions is that peaking factor which produces minimum hot channel DNBR equal to the Technical Specification DNBR Safety Limit during a calculated 4-pump loss of flow transient.

Care is taken in the fuel management design to ensure in effect that no flatter power distribution occurs in assemblies that are limiting or near-limiting with respect to DNB. Section 4.3.3.1.2 discusses the accuracy of the calculation of power distribution within a fuel assembly.

4.3.2.3 Reactivity Coefficients

Reactivity coefficients relate changes in core reactivity to variations in fuel or moderator conditions.

The data identified here illustrate the range of values of the various reactivity coefficients anticipated for a variety of expected conditions. Section 4.3.3 presents a comparison of calculated and measured moderator temperature coefficients and power coefficients for operating reactors. The good agreement provides confidence that the data presented in this section adequately characterize this reactor. The values used in the accident analyses are chosen in a conservative manner for each analysis, and these values may fall outside the ranges of the data presented in this section whenever appropriate to allow for uncertainties in calculated values. Table 4.3-3 presents a comparison of the reactivity coefficients calculated for this core with those actually used in the safety analysis. As may be seen from this table the safety analyses used suitably conservative values of reactivity coefficients, even allowing for uncertainties as discussed in Section 4.3.3.1.2. A more extensive listing of typical reload core predicted reactivity coefficients is given in Table 4.3-4.

4.3.2.3.1 Fuel Temperature Coefficient

The fuel temperature coefficient is the change in reactivity per unit change in fuel temperature. A change in fuel temperature affects not only the thermal expansion of the fuel pellet but, in addition, the reaction rates in both the thermal and epithermal neutron energy regimes.

Epithermally, the principal contributor to the change in reaction rate with fuel temperature is the Doppler effect arising from the increase in absorption widths of the resonances with an increase in fuel temperature. The ensuing increase in absorption rate with fuel temperature causes a negative fuel temperature coefficient. In the thermal energy regime, a change in reaction rate with fuel temperature arises from the effect of temperature dependent scattering properties of the fuel matrix on the thermal neutron spectrum. In typical PWR fuels containing strong resonance absorbers such as U-238 and Pu-240, the magnitude of the component of the fuel temperature coefficient arising from the Doppler effect is more than a factor of 10 larger than the magnitude of the thermal energy component.

Figure 4.3-24 shows typical dependence of the calculated fuel temperature coefficient on average fuel temperature, both at the beginning and the end of cycle.

4.3.2.3.2 Moderator Temperature Coefficient

The moderator temperature coefficient relates changes in reactivity to uniform changes in moderator temperature, including the effects of moderator density changes with changes in moderator temperature. Typically, an increase in the moderator temperature causes a decrease in the core moderator density and therefore a reduction in the number of neutrons that are slowed to thermal energy and a reduction in the core reactivity.

However, in the presence of soluble boron, a reduction in moderator density causes a reduction in the content of soluble boron in the core, thus producing a positive contribution to the moderator temperature coefficient. One objective of the core design is to limit the moderator temperature coefficient to values that are acceptable from the standpoint of all accident situations treated in Chapter 15. Burnable poison rods (shims) are provided in the form of cylindrical pellets of alumina with uniformly dispersed boron carbide particles, gadolinia dispersed uniformly in UO_2 pellets, erbia dispersed uniformly in UO_2 pellets, or a thin UO_2 pellet coating of zirconium diboride in order to limit the dissolved boron concentration, thereby making the moderator temperature coefficient more negative. The number of poison rods typically used in a reload core design is given in Table 4.3-1, and their distribution in the core is shown for one quadrant in Figures 4.3-1A through 4.3-1F. As indicated in Table 4.3-1, the specific numbers vary with core and fuel batch design. The distribution is identical for the other three quadrants. The reactivity control provided by the poison rods makes possible a reduction in the dissolved boron concentration relative to the values given in Table 4.3-1.

The calculated moderator temperature coefficient for a typical reload core at various core conditions is given in Table 4.3-4. The CEAs, when inserted into the core, provide a negative contribution to the moderator temperature coefficient. The moderator temperature coefficient becomes more negative with burnup, due mainly to the reduction in the dissolved boron content of the coolant with burnup. The contribution to this negative trend of the neutron spectral effect of plutonium and fission products is small. The net effect of the buildup of equilibrium xenon is a negative contribution to the moderator temperature coefficient due mainly to the contribution of the concomitant reduction in soluble boron content.

The moderator temperature coefficients generated at normal operating temperatures would not be adequate for the conditions that exist during an ATWS. A detailed discussion of the methods used in the ATWS analysis is given in Reference 8.

4.3.2.3.3 Moderator Density Coefficient

The moderator density coefficient is the change in reactivity per unit change in the average core moderator density at constant moderator temperature. The density coefficient is opposite in sign to the moderator temperature coefficient since an increase in moderator temperature means a decrease in moderator density. The density coefficient is always positive in the operating range but the magnitude is reduced in the presence of dissolved boron because an increase in water density (a positive reactivity effect) is accompanied by an increase in the soluble boron content of the core (a negative reactivity effect).

The density coefficients explicitly used in the accident analyses are based upon core conditions with the most limiting temperature coefficients allowed by the Technical Specifications.

Table 4.3-3 shows a comparison of the expected values of core reactivity coefficients with those actually used in the accident analyses.

4.3.2.3.4 Moderator Pressure Coefficient

The moderator pressure coefficient is the change in reactivity per unit change in Reactor Coolant System (RCS) pressure. Since an increase in pressure increases the water density, the pressure coefficient is opposite in sign to the temperature coefficient. The reactivity effect of increasing the pressure is reduced in the presence of dissolved boron because an increase in water density adds boron to the core.

4.3.2.3.5 Moderator Void Coefficient

During full power operation, local subcooled boiling results in a predicted average steam (void) volume fraction in the moderator of substantially less than one percent. Changes in reactivity are associated with the appearance of these voids in the moderator and are reflected in the void coefficient of reactivity. The presence of boron provides a positive contribution to the coefficient since an increase in voids results in a reduction in the boron content of the core.

4.3.2.3.6 Power Coefficient

The power coefficient is the change in reactivity per unit change in core power level. All of the previously mentioned coefficients contribute to the power coefficient, but only the moderator temperature coefficient and the fuel temperature coefficient contributions are significant. The contributions of the pressure and void coefficients are negligible due to their small magnitude and the small changes in pressure and void fraction per unit change in power level. The effect of moderator density changes is included in the moderator temperature coefficient contribution.

In order to determine the change in reactivity with power, it is necessary to know the changes in the average fuel and moderator temperatures with power. The average moderator (coolant) temperature is controlled to be a linear function of power. The current model used to compute effective fuel temperature employs an empirical function based on power coefficients that have been determined experimentally for operating cores. The following functional relationship is used throughout the burnup cycle.

$$T_{FUEL} = T_{MOD} + \left(\sum_{0}^{2} B_i MD^i \right) P + \left(\sum_{0}^{3} C_i MD^i \right) P^2$$

where MD is the nodal burnup - (MWD/TEM)
P is the nodal power density (KWT/FT)

B_i and C_i coefficients are derived from a fuel temperature and fuel rod power correlation.

The total power coefficient at a given core power can be determined by evaluating, for the conditions associated with the given power level, the following expression:

$$\frac{d\rho}{dP} = \frac{\partial\rho}{\partial T_f}\frac{\partial T_f}{\partial P} + \frac{\partial\rho}{\partial T_m}\frac{\partial T_m}{\partial P}$$

Since the factors $\partial\rho/\partial T_f$ and $\partial\rho/\partial T_m$ are functions of one or more independent variables, e.g., burnup, temperature, soluble boron content, xenon worth, and CEA insertion, the total power coefficient, $d\rho/dP$, also depends on these variables.

The power coefficient tends to become more negative with burnup due to the more negative moderator temperature coefficient. The insertion of CEAs into the core at constant power makes the power coefficient more negative due to a reduction in the soluble boron concentration as well as the spectral effects of the control rods.

4.3.2.4 CEA Patterns and Reactivity Worths

CEAs designated as regulating rods and CEAs designated as shutdown rods are divided into groups, where all members of a group are withdrawn or inserted quasi-simultaneously and groups are moved in a specified sequence. Figure 4.3-28 shows the CEA group identification. The order of insertion of the regulating banks, a typical degree of overlap of successive banks of regulating rods, and maximum insertion as a function of power level throughout the cycle are illustrated in the COLR PDIL figure. Shutdown banks are inserted after the regulating banks are inserted and are withdrawn before the regulating banks are withdrawn. The reactivity worths of individual CEA groups at BOC and end of cycle are shown in Table 4.3-5. Compliance with the limiting relationship between power level and CEA insertion limit, a typical example of which is shown in the COLR PDIL figure, ensures that shutdown margin requirements are met and that the core conditions are not more severe than the initial conditions assumed in the accident analyses described in Chapter 15.

The reactor is expected to be operated in an essentially unrodded mode for steady state operation at full power, with only limited insertion of regulating banks (refer to Section 4.3.2.5.4) in order to compensate for minor variations in moderator temperature and boron concentration.

The maximum reactivity worth of any individual CEA and the associated change in power distribution which would result in the event that a CEA was ejected from the core is presented in Section 15.1.20. The reactivity decrease and associated change in power distribution in the event of a dropped CEA is discussed in Section 15.1.3, and the CEA withdrawal accident is discussed in Sections 15.1.1 and 15.1.2. The uncertainties associated with these calculated reactivity worths is eight percent. The reactivity worth uncertainties used in the analyses described in these subsections is 10 percent. The allowable rod misalignment from any bank is specified in the Technical Specifications. Experimental verification of the calculated rod worths used in the accident analyses will be accomplished during startup testing of the reactor. Negative reactivity insertion as a function of time after scram signal is discussed in Chapter 15. Adherence to the rod misalignment limit discussed in the Technical Specifications will ensure that the monitoring and the protective system accurately reflects the power distribution so that no degradation of core margins will occur due to an abnormal power distribution caused by rod misalignment.

4.3.2.5 Control Requirements

Core reactivity data, including reactivity changes associated with core temperature and power changes, the reactivity worth of equilibrium xenon and samarium, and the reactivity available to compensate for burnup and fission product poisoning, are shown in Table 4.3-2. Soluble boron concentrations required for criticality at various core conditions are shown in Table 4.3-1. Burnable poison rods are provided as described in Section 4.3.1.4 to ensure that the moderator temperature coefficient has the required magnitude and algebraic sign. The reactivity controlled by these burnable poison rods is given in Table 4.3-1. At end of cycle, the reactivity worth of the residual burnable poison is small (typically one percent or less), and the soluble boron concentration is near zero.

Soluble boron is used to compensate for slow reactivity changes, for example, reactivity effects due to burnup, changes in xenon worth, etc. Furthermore soluble boron is used as a mechanism to maintain shutdown reactivity at cold conditions. The regulating CEA groups are used to compensate for the changes in reactivity associated with routine power level changes. In addition, the CEAs may be used to compensate for minor variations in moderator temperature and boron concentrations at operating condition. The reactivity worth requirements for the full complement of CEAs (regulating plus shutdown CEAs) are shown in Table 4.3-6 and are discussed below. The total worth of all CEAs, including shutdown CEAs, covers these requirements and provides adequate shutdown capability with the most reactive CEA stuck in the fully withdrawn position as shown in Table 4.3-7, at any time in the cycle.

4.3.2.5.1 Fuel Temperature Variation

The increase in reactivity that occurs when the fuel temperature decreases from a full power value to a zero power value is due primarily to the Doppler effect in U-238.

4.3.2.5.2 Moderator Temperature Variation

An increase in reactivity occurs when the moderator temperature decreases from the full power value to the zero power value. This reactivity increase, which is due to the negative moderator temperature coefficient, is largest at end of cycle when the soluble boron concentration is near zero and the moderator coefficient is strongly negative. At BOC, when the moderator temperature coefficient is less negative, the reactivity increase is smaller. The CEA reactivity allowance for moderator temperature variation given in Table 4.3-6 includes an allowance for this effect plus allowances for the reduction in CEA worth due to increased moderator density in going from full power to zero power and for the effect of the axial flux redistribution that occurs in going from hot full power to hot zero power. The latter effect is included as part of the moderator temperature allowance since it occurs as a result of the change in the axial moderator temperature profile between hot full power and hot zero power in conjunction with the asymmetric burnup distribution resulting from the negative moderator temperature coefficient of reactivity.

4.3.2.5.3 Moderator Voids

In going from full power to zero power, an increase in reactivity results from the collapsing of steam bubbles caused by local boiling at full power. The amount of void reactivity in the core is small and is estimated to be substantially less than one percent at full power. As with the moderator temperature effect, the maximum increase in reactivity from full to zero power occurs at end of cycle, when the least amount of dissolved boron is present. The reactivity effect is small, and the allowance for this effect is shown in Table 4.3-6.

4.3.2.5.4 CEA Bite

The CEA bite is the amount of reactivity worth in CEAs that can be inserted in the core at full power to initiate ramp changes in reactivity associated with load changes, and to compensate for minor variations in moderator temperature, boron concentration, xenon concentration, and power levels. The reactivity allowance for this effect is shown in Table 4.3-6.

4.3.2.5.5 Shutdown Margin and Accident Analysis Allowance

The allowance shown in Table 4.3-6 for shutdown margin is consistent with that assumed under various postulated accident conditions addressed in Chapter 15, which result in predicted acceptable consequences.

4.3.2.5.6 Available Reactivity Worth

Table 4.3-7 shows the reactivity worths of the full complement of CEAs, and the highest reactivity worth of a single CEA in the fully withdrawn position, at beginning and end of cycle. This table also compares the available net shutdown worth (including the effects of the stuck CEA) to the reactivity worth requirements from Table 4.3-6.

The uncertainty in total CEA reactivity worth is nine percent. Even allowing for the maximum calculated errors for CEA worth in the adverse direction, sufficient shutdown margin is available.

4.3.2.6 Control and Monitoring of the Power Distribution

Methods of reactor control include manual regulating CEA motion or dissolved boron concentration changes to change power level or to improve the axial and radial power distribution; and correcting off-optimum conditions which cause margin degradation, e.g., CEA misalignments. In using these methods of control, at any power level and any time in life the following are required.

A. There is sufficient reactivity worth in withdrawn CEAs to meet shutdown margin requirements.

B. The amount of CEA insertion and individual CEA worth be such that the core conditions are not more severe than the initial conditions assumed in the accident analyses described in Chapter 15.

C. Limiting conditions for operation, including required DNBR and kW/ft margins be satisfied.

The first two of these restrictions are met by maintaining the CEAs above the allowable position shown on the Power Dependent Insertion Limit (PDIL) curve typified in the COLR PDIL figure. The zero power PDIL limits the CEA insertion allowed at criticality. The third restriction requires that during normal operation, the combination of power distribution and other variables, e.g., CEA positions, power level, and coolant conditions, be maintained so that the limiting conditions for operation are not violated. The PDIL restricts the maximum amount of inserted CEA reactivity at full power. This allowance is limited to the CEA bite allowance given in Table 4.3-6 and discussed in Section 4.3.2.5.4.

Reactor operation within the limiting conditions for operation is verified by COLSS. COLSS is used to:

A. Monitor Nuclear Steam Supply System (NSSS) parameters affecting operating limits (such as CEA positions and overlaps, azimuthal tilt, and axial power distributions); and,

B. Process this information to provide the capability to indicate the margin available to operating limits on linear heat rate, DNBR, and core average power.

From this information provided by COLSS, it is determined whether CEA movement is necessary to improve the power distribution, or whether a reduction in core power is necessary to maintain sufficient core margins. The radial power distribution may be improved by withdrawing full length CEAs, and substituting soluble boron for the concurrent reactivity change. As may be seen in Figures 4.3-2 through 4.3-10, the radial power distribution with no CEAs inserted is more favorable than the radial power distribution with CEAs inserted. Table 4.3-6a summarizes the effects of CEA insertion on the radial power distribution. The CEAs are also used to control the effects of axial xenon oscillations. Partial insertion of the regulating CEA banks during those times when the xenon concentration is increasing in the bottom regions of the core provides an effective means of quickly damping such oscillations.

4.3.2.7 <u>Criticality of Fuel Assemblies</u>

The maximum K_{eff} value of a single fuel assembly, when moderated and completely reflected by unborated water at room temperature, is 0.92 based on an enrichment of 5.0 wt percent U-235 and the fuel parameters shown in Table 9.1-7. Two such assemblies with optimum spacing in water could be supercritical. Note however, that in practical situations ideal reflection is extremely improbable. Under dry conditions, the K_{eff} of a very large array of assemblies is estimated to be less than 0.7. Fuel assembly average U-235 loadings and burnup limits which provide adequate margin to criticality for fuel storage in the spent fuel pool are contained in Technical Specifications.

4.3.2.8 <u>Stability</u>

4.3.2.8.1 <u>General</u>

PWRs with a negative power coefficient are inherently stable to total core power oscillations. Design Basis 4.3.1.3 insures that a negative power coefficient will exist for this core at all times during the cycle. Therefore, the discussion on reactor stability will be limited to a discussion of xenon induced spatial power oscillations. Xenon induced spatial oscillations in large PWRs fall into three classes or modes. These are referred to as axial oscillations, azimuthal oscillations and radial oscillations. An axial oscillation is one in which the axial power distribution periodically shifts upward and downward in the core. An azimuthal oscillation is one in which the X-Y power distribution periodically shifts from one side of the reactor to the other (See Figure 4.3-31). A radial oscillation is one in which the X-Y power distribution shifts inward and outward from the center of the core to the periphery (See Figure 4.3-32).

Stability of a reactor to a particular mode of oscillation is characterized by a damping factor. When the damping factor is positive, the reactor is unstable to that mode of oscillation. This means that when the power distribution is perturbed, i.e. altered in any manner, the magnitude of the oscillation will increase with time in the absence of control intervention. When the damping factor is negative, the reactor is stable and the magnitude of the oscillation decreases with time.

A linear stability criterion, employing only the fundamental and first harmonic modes, has been used to judge the stability of the reactor to xenon induced spatial oscillations. This criterion has been shown to be adequate (Reference 131) when either of the following exist.

A. The reactor is stable to xenon induced oscillations, since the second harmonic modes contribute little to either the periods or the decay constants of the first harmonic mode oscillations.

B. The reactor is unstable to xenon induced oscillations, since the first harmonic modes excite the second harmonic modes without affecting the periods of the first harmonic modes.

A discussion of the methods used to calculate the damping factor is given in Section 4.3.3.2.

Xenon oscillation studies lead to the following general conclusions.

A. The damping factor for an oscillatory mode depends primarily upon the power coefficient and the time in the burnup cycle.

B. The time scale on which any oscillations occur is long, the period of oscillation being generally between 25 and 30 hours.

C. As long as the initial power peaking associated with an oscillation inducing perturbation is within limiting conditions for operation, specified acceptable fuel design limits will not be approached for a period of hours if the reactor is unstable to oscillations. If the reactor is stable to xenon oscillations, specified acceptable fuel design limits will not be approached.

D. The reactor is predicted to be stable to both radial and azimuthal mode xenon oscillations at all times in the burnup cycle. Figure 4.3-33 shows the predicted damping factor for azimuthal xenon oscillations as a function of the core moderator temperature coefficient for a typical eigenvalue separation. The least negative moderator temperature coefficient that is predicted to occur with equilibrium xenon present is $-0.4 \times 10^{-4}\ \Delta\rho/°F$. As may be seen from the figure, even with an uncertainty in the moderator coefficient of $\pm 0.3 \times 10^{-4}\ \Delta\rho/°F$, the reactor is predicted to be stable to azimuthal xenon oscillations.

E. The reactor is expected to be naturally unstable to axial mode oscillations before the end of the cycle.

F. All possible modes of un-damped oscillations can be detected by either out-of-core or in-core instrumentation.

4.3.2.8.2 Detection of Oscillation

The power range (safety channel) out-of-core neutron detectors are used to monitor the symmetry of power distributions by means of parameters derived from the relative responses of detectors located at distinct azimuthal and axial positions.

In addition, the COLSS will be used to detect axial and azimuthal oscillations, as described in Section 7.2.

4.3.2.8.3 Special Features Required by Xenon Instability

The RPS described in Section 7.2.2 is designed to prevent exceeding acceptable fuel design limits and to limit the consequences of postulated accidents. In addition a means is provided to assure that under all allowed operating modes the state of the reactor is confined to conditions not more severe than the initial conditions assumed in the design and analysis of the protective system.

Since the reactor is predicted to be stable with respect to azimuthal xenon oscillations, no special protective system features are needed to accommodate azimuthal mode oscillations. Nevertheless, a maximum quadrant tilt is prescribed in the Technical Specifications along with prescribed operating restrictions in the event that the tilt is exceeded. The quadrant power tilt is determined by COLSS and included in the COLSS determination of core margin. The quadrant power tilt limit is accounted for in the RPS.

In the unlikely event that the core is observed to be unstable to azimuthal xenon oscillations, measures will be taken that will sufficiently increase the natural stability of the core. For instance, CEAs can be inserted to make the power coefficient more negative or to shape the radial power distribution to make the core more stable. Measurements of xenon spatial stability in cores larger than this core have been made. These measurements provide added confidence in the methods that are used to predict the azimuthal stability of this core.

The features provided for azimuthal xenon effects are as follows:

A. Administrative limits on azimuthal power tilt;

B. Monitoring and indicating the azimuthal power tilt in COLSS as well as accounting for this tilt in the COLSS determination of core margin; and,

C. Accounting for azimuthal power tilt limit in the RPS.

The features provided for axial xenon effects and power distribution effect and control are as follows:

A. CEAs for control of the axial power distribution, if required;

B. Monitoring and accounting for changes in the axial power distribution in COLSS; and,

C. Monitoring and accounting for the axial power distribution in the RPS.

4.3.2.9 Vessel Irradiation

The maximum fast neutron fluxes greater than 1 MeV used in the determination of vessel fluence incident on the vessel ID and shroud ID are as shown in Table 4.3-8. Fluence aspects, in regards to the reactor vessel, are discussed in Section 4.3.3.3 and Section 5.2.4. The fluxes are based on a time averaged equilibrium cycle radial power distribution and an axial power distribution with a peak to average of 1.20.

4.3.3 ANALYTICAL METHODS

4.3.3.1 Reactivity and Power Distribution

4.3.3.1.1 Methods of Analysis

The following discussion includes historical information that describes the evolution of the analytical neutronics modeling. Starting with Cycle 18, the Westinghouse neutronics code system consisting of the ANC and PARAGON codes replaces the ROCS/DIT computer codes.

The nuclear design analysis for low enrichment PWR cores is based on the two-dimensional integral transport code DIT, which provide cross sections appropriately averaged over a few broad energy groups for the whole assembly or individual cells, and few group one-, two-, and three-dimensional diffusion theory calculations of integral and differential reactivity effects and power distributions. The ROCS/DIT code system is documented in Reference 159.

The reactor physics model derived from the Arkansas Nuclear One - Units 1 and 2 benchmarking effort, together with the methodology used to determine calculational uncertainties, and the resultant reliability factors associated with the model, are presented in the report, MSS-NA1-P, Reference 30, and MSS-NA3-P, Reference 163. Beginning in Cycle 12, the methods, calculational uncertainties, and reliability factors from ENEAD-01-P-A, Reference 174, and ENEAD-02-NP-A, Reference 175, were employed. Beginning in Cycle 20, the methods, calculational uncertainties, and reliability factors from ENEAD-01-P-A (Reference 174) and ENEAD-02-NP-A (Reference 175), or CENPD-153-P Rev. 1 P-A (Reference 22) are employed. Application of this model and calculation techniques commences with Arkansas Nuclear One - Unit 2, Cycle 2, and includes application to reactor operations, safety evaluations, updates to the core monitoring programs (CECOR, COLSS, CPCs, CEACs) and the safety evaluation of reload designs.

Comparisons between calculated and measured data which validate the design procedures are presented in Section 4.3.3.1.2. As improvements in analytical procedures are developed, and improved nuclear data become available, they will be added to the design procedures, but only after validation by comparison with related experimental data.

The function of the DIT lattice code is to prepare few-group averaged cross sections for coarse-mesh and fine-mesh diffusion theory codes. These cross sections are used in ROCS (coarse-mesh) and in the MC module of ROCS (fine-mesh).

Spatial averages of microscopic and macroscopic cross sections are performed for editing purposes and are passed on to ROCS, and MC. Few-group cross sections are prepared in the HARMONY format for ROCS. Cross sections are input directly to MC without intermediate processing.

Static and depletion dependent reactivities and nuclide concentration, flux, and power distributions in two- and three-dimensional representations of the core are determined by diffusion depletion programs, ROCS-MC. The ROCS code is designed to perform two- or three-dimensional coarse-mesh reactor core calculations with full-, half- or quarter-core symmetric geometries.

Cross section information used in the ROCS system is derived from microscopic cross sections supplied by DIT for each nuclide in two energy groups. This information is supplied in table form.

The depletion equations are solved using the flux and microscopic cross section values based on the neutronics and thermal-hydraulic feedback calculations preceding the depletion time step. The initial flux and cross sections are assumed constant over the depletion time step.

Static and time dependent reactivities and power distributions in a one-dimensional (axial) representation of the core are determined by the diffusion theory program QUIX. This program solves the neutron flux and associated eigenvalue for problems containing up to 140 distinct regions or compositions with variable mesh intervals. In addition to the eigenvalue problem, QUIX will perform four types of search calculations to attain a specified eigenvalue, viz., a poison search, buckling search, CEA region boundary search, and a moderator density dependent poison search. The effects of moderator and fuel temperature feedback on the power distribution can be treated.

Analyses have been performed in the same manner and with similar methodologies to those used for previous analyses. However, several method improvements were implemented for Cycle 10. Those improvements include the use of anisotropic scattering within pin cells and anisotripic neutron currents at pin cell interfaces in the DIT code.

Improvements were also made in the ROCS code via the application of the Nodal Expansion Method (NEM), which is based upon a fourth order solution, and by the implementation of assembly discontinuity factors. The improved methodology is discussed in approved topical reports with the exception of the application of assembly discontinuity factors which is, today, a widely accepted and used procedure in the industry.

The new DIT/ROCS methodology was implemented primarily to improve core power distribution predictions. This improvement is obtained via the calculation of more accurate global radial power and local fuel pin power distributions. The global radial power distribution is particularly enhanced through the better modeling of the power sharing between neighboring assemblies. The local pin power distribution is improved via the better modeling of both intra and inter pin phenomena.

In addition to improved power distribution predictions, the new methodology improves upon the calculation of control rod worths. The remaining impact of the improved methodology on the reload analyses performed for Cycle 10 was essentially limited to the application of a revised set of biases and uncertainties determined specifically for use with the improved methodology.

The effect of the new uncertainty values pertaining to scram worth/shutdown margin calculations can be demonstrated as follows. The combined bias and uncertainty used for Cycle 9 was 15.40%. The combined bias and uncertainty that was applied to the Cycle 10 calculated data was 6.28%.

Nuclear design calculations were performed using the coarse mesh code ROCS and the fine mesh code MC. The coarse mesh code ROCS was used in 3-dimensional geometry to calculate all core wide parameters and assembly relative power densities. The fine mesh code MC was used to calculate pin peaking data.

All cross sections for both the coarse (ROCS) and fine mesh calculations (MC) were generated using the DIT assembly spectrum code. The MC calculations intrinsically account for the increased peaking that is characteristic of fuel pins adjacent to water holes in the assembly lattice.

The FLAIR code used for the uncertainty analysis (see Section 7.7), also has the capability of simulating ex-core detector responses expected during operation. The calculated normalized core average power distribution is first corrected by the application of CEA shadowing factors to simulate the peripheral fuel assembly power distribution. Shape annealing factors are then applied to the peripheral axial power distribution to simulate the integrated response of the sub-channels of the three element ex-core detectors.

CEA shadowing is the change in ex-core detector response in going from an unrodded configuration to a core configuration with CEAs inserted while maintaining constant power operation. Although CEA shadowing is a function of azimuthal location, its affect is minimized by placing the ex-core detectors at azimuthal locations where minimum CEA shadowing occurs.

CEA shadowing factors can be determined using FLAIR code with assembly weighing factors and shape annealing functions from SHADRAC and DOT codes. SHADRAC (see Reference 137) calculates fast neutron and gamma ray spectra, heating, and dose rates in a three-dimensional system utilizing a moments method solution of the transport equation. The core, vessel internals, vessel and ex-core detector location are treated explicitly in the calculation.

Normalized CEA shadowing factors are relatively constant with burnup.

Figure 4.3-46 shows the typical behavior of the CEA shadowing factor during a CEA insertion and withdrawal sequence. Simulated factors and experimentally measured CEA shadowing factors during this transient situation are shown to have quite good agreement over a significant range of CEA insertions.

Shadowing factors account for the radial effects and annealing accounts for the axial effects on the ex-core detector responses. Due to neutron scattering in the large air gap between the vessel and the biological shield, the ex-core detector subchannels respond to neutrons from the entire length of the core and not just from the section immediately opposite the subchannel. This effect is independent of the axial power shape and the azimuthal CEA shadowing factors. Typical axial annealing functions, given as fractional response per percent of core height for a three subchannel systems, are shown in Figure 4.3-47.

This annealing is determined utilizing a fixed source DOT calculation. DOT (see Reference 139) is a two-dimensional discrete ordinates transport code. The RZ geometry option is used for the annealing calculation with representation of the core, vessel, vessel internals, air gap, and biological shield. The actual detector walls are not represented in the DOT calculation.

However, the self-shielding effect of the walls on the detector response is small and uniform along the length of the detector and as a result will not change the normalized annealing. The DOT calculation uses an S_{12} angular quadrature and a 13-group neutron cross section set with P_3 scattering as determined by GGC-341 and CEPAK. The fixed source is distributed over 20 uniform axial segments of the active core height. Figure 4.3-48 illustrates the radial regions represented in the DOT calculation as well as one of the axial fixed source segments. The total pointwise subchannel response from that axial fixed source segment is:

$$\sum_{E=1}^{13} \sum\nolimits_{f}^{U-235} (\mathrm{E}) \theta (\mathrm{E})$$

where

$\sum_f^{U-235}(\mathrm{E})$ is a macroscopic fission cross section taken from GGC-3 and CEPAK results, and

$\theta(\mathrm{E})$ is the neutron flux along the fission chamber centerline

By integrating the total pointwise response along the length of the subchannel, one can determine the subchannel response for each axial fixed source segment. Utilizing this same technique for all 20 axial segments of the core and normalizing to the total ex-core detector response, annealing curves similar to Figure 4.3-47 are determined.

As the annealing is determined using a flat axial shape, the resulting annealing factors (S(z)) must be multiplied by the appropriate peripheral axial shape to obtain total detector response.

$$D_{Lower} = \Sigma_z P(z)\, S(z) \qquad \text{Lower}$$

$$D_{Middle} = \Sigma_z P(z)\, S(z) \qquad \text{Middle}$$

$$D_{Upper} = \Sigma_z P(z)\, S(z) \qquad \text{Upper}$$

The shape annealing factors are purely geometric correction factors applied to the peripheral axial power distribution. As such, the effects of time in fuel cycle, transient xenon redistribution and rod insertion, although affecting the peripheral bundle power shape, do not effect the geometric shape annealing correction factors. Figure 4.3-49 compares the peripheral axial shape index with the external shape index during a rod and PLR motion test for the Palisades reactor. Shown are the results of simulations of the test as well as experimental data taken during the test. From this curve we can conclude that even though the axial power distribution in the core and on the core periphery was changing during this transient, the relationship between the ex-core response and the peripheral response was not. These results justify not only the separability of CEA shadowing and shape annealing as summed in the calculation but also demonstrate that shape annealing is purely a geometric effect, independent of the peripheral axial power distribution.

The ex-core detector temperature decalibration effect is the relative change in detector response as a function of reactor water inlet temperature. The temperature decalibration effect is calculated utilizing SHADRAC with explicit representation of core, vessel internals, vessel and detector location for various reactor inlet temperatures. Typical detector temperature decalibration effect as a function of inlet temperature normalized to an inlet temperature of 525 °F is as shown in Figure 4.3-50.

Beginning with Cycle 18, the Advanced Nodal Code (ANC) (References 188, 189, and 190) was implemented in the reload design analysis. ANC is an advanced nodal analysis theory code capable of two- or three-dimensional calculations. Also beginning with Cycle 18, PARAGON, (Reference 191) computer code was implemented in the reload design analysis. PARAGON is a two-dimensional transport theory based code that calculates lattice physics constants. These are the same methods and models that have been used in other Westinghouse reload cycle designs. These codes are replacements for the ROCS/DIT computer codes.

The primary purpose of PARAGON is to provide input data for use in three dimensional core simulator codes. This includes macroscopic cross sections, microscopic cross sections for feedback adjustments to the macroscopic cross sections, pin factors for pin power reconstruction calculations, and discontinuity factors for a nodal method solution. PARAGON can be used as a standalone or as a direct replacement for all the previously licensed Westinghouse PWR lattice codes, such as PHOENIX-P, as approved by the NRC in Reference 191.

PARAGON is a two-dimensional multi-group neutron (and gamma) transport code. The PARAGON flux solution calculation uses Collision Probability theory within the interface current method to solve the integral transport equation. Throughout the whole calculation, PARAGON uses the exact heterogeneous geometry of the assembly and the same energy groups as in the cross-section library to compute the multi-group fluxes for each micro-region location of the assembly.

In order to generate the multi-group data that will be used by a core simulator code PARAGON goes through four steps of calculations: resonance self-shielding, flux solution, homogenization and burnup calculation.

ANC is the three-dimensional core simulator code in the Westinghouse nuclear design code system. The ANC nodal flux solution is based on a set of two-group diffusion theory nodal balance equations that are solved using a solution method based on the nodal expansion method (NEM). This method and the specific approximations made in the ANC implementation provide an accurate representation of the core nodal neutronics. ANC is used to calculate core reactivity, reactivity coefficients, critical boron, rod worths, and core, assembly, and rod power distributions for normal and off-normal conditions for use in design and safety analyses. The ANC computer code is also used in the uncertainty analysis, as a replacement for the ROCS code, which in turn was a replacement for the FLAIR computer code.

4.3.3.1.2 <u>Comparison with Experiments</u>

The nuclear analytical design methods in use for Arkansas Nuclear One, Unit 2 have been checked against a variety of critical experiments and operating power reactors. Reactivity and reaction rate calculations are performed which lead to information concerning the validity of the basic fuel cell calculations.

The accuracy of the calculational system in its entirety can only be assessed through the analysis of experimental data collected on operating power reactors. The data under investigation consists of critical conditions, reactivity coefficients, and rod worths measured during the startup period, and of critical conditions, power distributions, and reactivity coefficients measured throughout the various cycles. The details of these studies have been previously presented in Reference 159.

The accuracy of the power distribution predictions cannot be disassociated from the accuracy of the instrumentation which is used to measure these power distributions. The instrumentation in C-E reactors consists of fixed self-powered rhodium detectors, whose signals are fed into the computer code system CECOR (Reference 22) which unfolds a full core power distribution with the help of precalculated coupling coefficients. The uncertainties associated with each step of this process, and the differences observed between calculated and measured three-dimensional power distributions, are documented in detail in References 22 and 159.

The benchmarking of the Westinghouse neutronics computer codes, ANC, PHOENIX, and PARAGON, is documented in detail in References 188 through 191.

4.3.3.2 Spatial Stability

4.3.3.2.1 Methods of Analysis

An analysis of xenon induced spatial oscillations may be done by two classes of methods: time dependent spatial calculations and linear mode analysis. The first method is based on computer simulation of the space, energy, and the time dependence of neutron flux and power density distributions. The second method calculates the damping factor based on steady state calculations of flux, importance (adjoint flux), xenon and iodine concentrations, and other relevant variables.

The time dependent calculations are indispensable for studies of the effects of CEA, core margin, out-of-core and in-core detector responses, etc., and are performed in one, two, and three dimensions with few group diffusion theory using tested computer codes and realistic modeling of the reactor core.

The linear modal analysis methods are used to calculate the effect on the damping factors of changes in fuel zoning, enrichment, CEA patterns, operating temperature, and power levels. These methods, using information at a single point in time, are particularly suited to survey type calculations. Methods are based on the work of Randall and St. John (Reference 127) as extended by Stacey (Reference 140). These methods have been verified by comparison with time dependent calculations.

4.3.3.2.2 Radial Xenon Oscillations

To confirm that the radial oscillation mode is extremely stable, a space-time calculation was run for a reflected, zoned core 11 feet in diameter without including the damping effects of the negative power coefficient. The initial perturbation was a poison worth of 0.4 percent in reactivity placed in the central 20 percent of the core for one hour. Following removal of the perturbation, the resulting oscillation was followed in 4-hour time steps for a period of 80 hours. As shown on Figure 4.3-32 the resulting oscillation died out very rapidly with a damping factor of about -0.06 per hour. When this damping factor is corrected for a finite time mesh by the formula in Reference 124, it is more negative and indicates a more strongly convergent oscillation. On this basis, it is concluded that a radial oscillation instability will not occur.

4.3.3.2.3 Azimuthal Xenon Oscillations

Two-dimensional modal analysis techniques have been used to calculate the damping factor for azimuthal oscillations, and have included both the fuel temperature and moderator temperature components of the total power coefficient. These calculational techniques have been used to predict the results of azimuthal oscillation tests at Maine Yankee at 75 percent power. The predicted damping factor of -0.045 hr^{-1} for azimuthal oscillations was found to agree well with the measured value of -0.47 ± .005 hr^{-1}.

4.3.3.2.4 Axial Xenon Oscillations

To check and confirm the predictions of the linear modal analysis approach, numerical space-time calculations have been performed for both beginning and end of cycle. The fuel and poison burnup distributions were obtained by depletion with soluble boron control so that the

power distribution was strongly flattened. Spatial Doppler feedback was included in these calculations. In Figure 4.3-41, the time variation of the power distribution along the core axis is shown near end of cycle with reduced Doppler feedback. The initial perturbation used to excite the oscillations was a 50 percent insertion into the top of the core of a 1.5 percent reactivity CEA bank for one hour. The damping factor for this case was calculated to be about 0.02 per hour; however, when corrected for finite time mesh intervals by the methods of Reference 124, the damping factor is increased to approximately +0.04. When this damping factor is plotted on Figure 4.3-42 at the appropriate eigenvalue separation for this mode at end of cycle, it is apparent that good agreement is obtained with the modified Randall-St. John prediction. This good agreement is a result of the generally antisymmetric distribution of the moderator coefficient about the core midplane, and its consequent flux and adjoint weighted integrals of approximately zero. Calculations performed with both Doppler and moderator reactivity feedback have resulted in damping factors which are essentially the same as those obtained with Doppler feedback alone. In addition, one-dimensional linear modal analysis calculations have been performed to predict the results of axial oscillation tests at Maine Yankee at 75 percent power. The measured damping factor of $-0.05 \pm .01$ hr^{-1} was more negative than the calculated value of -0.036 hr^{-1}, illustrating that the calculation is conservative and that the core is somewhat more stable with respect to axial oscillations than predicted by present calculational techniques.

The QUIX code is used to calculate the axial power distributions, shape indices, integrated radial peaking factors, and scram reactivity curves for conditions occurring during a free xenon oscillation which produces large numbers of different iodine and xenon axial distributions. The xenon distributions studied cover a wider range of situations than normal operation including axial xenon redistributions one could observe during maneuvering and transient situations. The calculations are repeated for several different CEA insertions allowed by the power dependent insertion limits. The analyses are repeated for selected times in life.

Thermal margin analyses are performed to determine the sensitivity of the hot channel minimum DNBR to changes of core flow for each of the shapes generated in the above physics calculation which are within a defined range of axial shape indices. The radial peaking factors used in the calculations include values which are greater than the maximum value associated with the power dependent CEA insertion limits given in the COLR PDIL figure. The methods used for these thermal margin calculations are standard CE analysis methods described in Section 4.4. These analyses establish which combinations of conditions produce the nearest approach to the Technical Specification DNBR Safety Limit during a loss of flow transient.

4.3.3.3 Reactor Vessel Fluence Calculation Model

The vessel fluence was calculated based on the methods described in Reference 180. These methods use the two dimensional discrete ordinates transport theory code, DORT along with cross-sections, geometry definition and other modeling techniques consistent with the requirements of Regulatory Guide 1.190 (March 2001). DORT is used to calculate the neutron flux distribution, radially and azimuthally along the core mid-plane. A separate axial flux distribution is determined as a function of radial position from the center of the core. These two distributions are combined to produce a synthesized three-dimensional flux distribution for the vessel. The fluence is determined by integrating the actual operating history using the flux distribution applicable to each reload core through the end of Cycle 14. Integration to beyond Cycle 14 is performed based on conservatively extrapolated 18 month core designs. The integration assumes full power operation of 2815 MWt for Cycles 1-15 with a power increase to 3026 MWt occurring at the beginning of Cycle 16. The results of the vessel fluence calculations are discussed in Section 5.2.4.

The calculated fluence uncertainty (95/95) has been established in Reference 180 to be well within the 20 % defined by Regulatory Guide 1.190. A dosimetry capsule was removed from inside the ANO-2 vessel at the end of Cycle 14. Comparisons of the dosimetry measurements to those predicted by the fluence analysis were consistent with the uncertainties reported in Reference 180, confirming method's applicability to ANO-2 (Reference 181).

4.3.3.4 Local Axial Power Peaking Augmentation

An analysis performed by C-E for EPRI, (Reference 160), demonstrated that the increased power peaking associated with the small interpellet gaps found in C-E's modern fuel rods (non-densifying fuel in pre-pressurized tubes) is insignificant compared to the uncertainties in the safety analyses. The report concluded that augmentation factors can be eliminated from the reload analyses of any reactor loaded exclusively with this type of fuel. This discussion of the elimination of the augmentation factors was used by BG&E in Reference 161 and accepted by the NRC in Reference 162. Since the manufacturing process of C-E's modern fuel is the same for both BG&E and AP&L/Entergy Arkansas, Inc., and the fuel differs only in dimensions, it is concluded that the peaking factor penalty due to fuel densification is insignificant compared to the uncertainties incorporated into COLSS and CPC and thus the augmentation factors have been eliminated.

4.3.4 CHANGES

A significant amount of core operating data has been incorporated into the nuclear design methods used for the design of this reactor. Operating reactor power distributions, critical boron concentrations, reactivity coefficients and control rod worths have been measured on the Maine Yankee reactor. The excellent agreement between these measured values and those predicted by the analytic methods used in Combustion Engineering as described in Section 4.3.3 lends confidence to the methods used to design this reactor.

Arkansas Nuclear One - Unit 2 will use continuous, on-line measurement of the core power distribution by in-core detectors in order to monitor the core power distribution. COLSS will continuously evaluate the core margins based on the measured in-core power distribution.

4.4 THERMAL AND HYDRAULIC DESIGN

This section presents a description of the thermal and hydraulic analysis of the reactor core, analytical methods utilized, and experimental work supporting the analytical techniques. The prime objective of the thermal and hydraulic design of the reactor is the assurance that the core can meet normal steady state and transient performance requirements without exceeding the design bases.

4.4.1 DESIGN BASES

4.4.1.1 Thermal Design

Avoidance of thermally induced fuel damage during normal steady state operation and during anticipated operational occurrences is the principal thermal hydraulic design basis. The following design limits are established, but violation of these will not necessarily result in fuel damage. The Reactor Protective System (RPS) will provide for automatic reactor trip or other corrective action before these design limits are reached:

A. A minimum allowable limit of 1.23 (see Section 4.4.2.3.2) is set on the Departure from Nucleate Boiling Ratio (DNBR) during normal operation and any anticipated operational occurrence.

B. The peak temperature of the fuel will be less than the melting point (2,805 °C unirradiated and reduced by 32 °C per 10,000 MWD/MTU) during normal operation and any anticipated operational occurrences. A discussion of the maximum fuel and clad temperatures under overpower conditions is presented in Section 4.4.2.2.

The analyses described in Section 4.4 were developed using the W-3 Correlation which yielded a minimum DNBR of 1.30, and the COSMO and INTHERMIC computer codes applicable to Cycle 1 operation. Subsequent cycles utilize either the CE-1, ABB-NV, or WSSV-T Correlation, and the TORC and CETOP-D computer codes. The DNBR safety limit is maintained at a WSSV-T / ABB-NV value of 1.23 as described in Section 4.4.2.3.2. TORC and CETOP-D are described in Section 4.4.3.4.2.

4.4.1.2 Coolant Flow Rate and Distribution

A lower limit on the total primary pump flow rate, called "design" flow, is utilized for all core thermal margin analyses to assure that the core is adequately cooled when uncertainties in system resistance, pump head, and core bypass flow are taken in the adverse direction. (Refer to Chapter 5 for pump design.) The design of the reactor internals ensures that this flow is distributed to the core such that the core is adequately cooled during normal operation and any anticipated operational occurrence. No specific inlet orificing configuration is used.

The hydraulic loads for the design of the internals are based on the upper limit of the flow. The upper limit on flow is obtained when the uncertainties in system resistance, pump head, and core bypass flow are taken in the direction to maximize the flow.

4.4.1.3 Fuel Design Bases

The fuel design bases to assure fuel clad integrity and fuel assembly integrity are given in Section 4.2.1. Thermal and hydraulic parameters which influence the fuel integrity include maximum linear heat rate, core coolant velocity, coolant temperature, clad temperature, fuel-to-

clad gap conductance, fuel burnup, and UO_2 temperature. There are no thermal limits applied directly to these parameters other than those in Section 4.4.1.1, but the values of these parameters given in the following sections are consistent with those used in Section 4.2.1 to show that the fuel design bases are satisfied.

4.4.2 DESCRIPTION

4.4.2.1 Summary Comparison

The thermal and hydraulic parameters for the reactor are listed in Table 4.4-1 for Cycle 1 and Table 4.4-2 for a representative recent cycle. A comparison of these parameters with those of the San Onofre Units 2 and 3 (Unit 2 Docket Number 50-361, Unit 3 Docket Number 50-362) is given in Table 4.4-1. The San Onofre parameters given in the table have been extracted from the San Onofre PSAR up to and including Amendment 17.

The obvious differences include decreases in the power, flow rate, and number of fuel assemblies. Within the reactor vessel, the internals design is basically the same except smaller for those components affected by the fewer fuel assemblies.

The Arkansas Nuclear One - Unit 2 fuel assemblies incorporate a 16 x 16 fuel rod array. Compared to the 14 x 14 fuel rod array described in the San Onofre PSAR (through Amendment 17) and in Table 4.4-1, the 16 x 16 fuel assembly contains a greater number of fuel rods of smaller diameter and pitch. The 16 x 16 fuel assembly has greater heat transfer surface area and fuel rod linear footage, thereby reducing the peak heat flux and linear heat rate. These reductions provide an increased thermal margin relative to a 14 x 14 fuel assembly at a given core power density.

4.4.2.2 Fuel and Cladding Temperatures

This section describes the correlations used and the method of analysis for determining the fuel cladding temperatures and the fuel pellet temperature.

4.4.2.2.1 Fuel Cladding Temperatures

The surface temperature of the cladding is dependent on the axial and radial power distributions, the temperature of the ambient coolant, and the surface heat transfer coefficient. Cladding temperatures are obtained for a typical radial power distribution such as that shown in Figure 4.3-23. The standard thermal-hydraulic codes used to obtain subchannel conditions are utilized with this radial distribution and with typical axial power distributions such as shown in Figure 4.4-2. Use of the resulting temperatures in the calculation of mechanical interactions in the fuel assembly is discussed in Section 4.4.3.7, including effects of differential thermal expansion, transients and growth throughout the fuel lifetime.

The surface heat transfer coefficient for non-boiling forced convection is obtained from the Dittus-Boelter correlation (Reference 69) where fluid properties are evaluated at the bulk condition.

$$h_{db} = \left(\frac{0.023k}{D_e}\right) (N_{Re})^{0.8} (N_{Pr})^{0.4}$$

where:

h_{db} = Heat transfer coefficient, Btu/hr-ft^2-°F

K = Thermal conductivity, Btu/hr-ft - °F

De = Equivalent diameter, ft $= \frac{4A}{P_w}$

N_{Re} = Reynolds number, based on the equivalent diameter and coolant properties evaluated at the local bulk coolant temperature.

N_{Pr} = Prandtl number, based on coolant properties evaluated at the local bulk coolant temperature.

A = Cross-sectional area of flow channel, ft^2

P_w = Wetted perimeter of flow channel, ft

No specific allowance is made or considered necessary for the uncertainties associated with the Dittus-Boelter correlation. That is because the Dittus-Boelter correlation is not used directly in computing thermal margin, but rather plays a part in determining pressure drop and cladding temperature. The validity of the overall scheme for predicting pressure drop is shown by the excellent agreement between predicted and experimental values obtained during the DNB test program and described in Section 4.4.3.1.2. The uncertainty associated with the cladding temperatures calculated for single-phase heat transfer is not a major concern because the limiting fuel and cladding temperatures occur where the cladding-to-coolant heat transfer is by nucleate boiling.

The temperature drop across the surface film is calculated from:

$$\Delta t_{film} = q/h_{db}$$

where:

q" = surface heat flux, Btu/hr-ft^2

The maximum heat flux is the product of the core average heat flux and the total heat flux factor. (Refer to Table 4.4-1 and Section 4.4.2.3.4.) At the location of maximum heat flux, nucleate boiling may occur on the clad surface. In the nucleate boiling regime, the surface temperature of the cladding is determined from the Jens and Lottes correlation (Reference 91):

$$T_{wall} = T_{sat} + 60\ (q'' \times 10^{-6})^{0.25}\ [\exp\ (-P/900)]$$

where:

P = Pressure, psia

q" = Defined above

T_{sat} = Saturation temperature, °F

Nucleate boiling is assumed to exist if T_{wall} is less than the sum of $T_{coolant}$ plus ΔT_{film}.

The cladding surface temperatures are calculated by either summing the temperature of the coolant at the particular location and the temperature drop across the surface film, or directly from the Jens and Lottes correlation, depending on whether nucleate boiling is occurring.

The steady state radial temperature difference through the cladding, assuming uniform internal volumetric heat generation and temperature dependent thermal conductivity, is calculated from the one-dimensional heat conduction equation.

The thermal conductivity of Zircaloy-4 clad material in the range of 100 °F to 1,000 °F is determined from Reference 11.

The axial profile of the average clad temperature over the active fuel length for an average and a hot fuel rod is shown on Figure 4.4-1 for the typical axial power shape used for DNB calculations (Figure 4.4-2). The difference between these rods is that the hot rod experiences design values for the rod radial peak and engineering heat flux factor while the average rod experiences values of unity for these factors. The local coolant temperature surrounding these rods depends on the axial distance along the rod from the channel inlet.

4.4.2.2.2 Fuel Thermal Performance

Steady state fuel temperatures are determined by the FATES computer program. The calculational procedure considers the effect of linear heat rate, fuel relocation, fuel swelling, densification, thermal expansion, fission gas release, and clad deformations. The model for predicting fuel thermal performance is discussed in detail in Reference 10.

The thermal performance of the various types of fuel assemblies were evaluated using the FATES fuel evaluation model (Reference 10). The analysis was performed using power history data that enveloped the power and burnup levels of the various types of fuel assemblies for rod average burnups up to 60 MWD/kg U (References 176 and 177).

Significant parameters such as cold pellet and clad diameters, gas pressure and composition, burnup and void volumes are calculated and used as initial conditions for subsequent calculations for stored energy during the Emergency Core Cooling System (ECCS) analysis. The coupling mechanism between FATES calculations and the ECCS analysis is described in detail in Reference 35.

4.4.2.3 Critical Heat Flux Ratio (Departure from Nucleate Boiling)

4.4.2.3.1 Departure from Nucleate Boiling (Cycle 1)

The margin to Departure from Nucleate Boiling (DNB) at any point in the core is expressed in terms of the Departure from Nucleate Boiling Ratio (DNBR). The DNBR is defined as the ratio of the heat flux required to produce departure from nucleate boiling at the calculated local coolant conditions to the actual local heat flux. At some point in the core, the DNBR is a minimum and it is at this point that the margin to DNB is evaluated.

The W-3 correlation (Reference 151) was used for determination of DNB in Cycle 1. The design basis value of 1.30 for the minimum DNBR was chosen on the basis of evaluation of the W-3 correlation and its source data. That evaluation indicated that a minimum DNBR of 1.30 provides a 95 percent probability with 95 percent confidence that DNB will not occur in a subchannel having that minimum DNBR during normal operation and any anticipated operational occurrence.

To support this thermal hydraulic design basis, calculations for steady state conditions and for selected limiting transients were performed using the CE-1 CHF correlation. A comparison of the results for the steady state analyses over a wide range of core conditions and for the selected limiting transients shows that the W-3 correlation has conservatively accounted for DNB relative to the CE-1 CHF correlation.

The statistics from the data base were used in CENPD-162-P to establish the minimum DNBR which provides 95 percent probability at the 95 percent confidence level of not having DNB on a rod with that minimum DNBR. For CE-1 that evaluation yielded a minimum DNBR of 1.13.

During the steady state operation, many combinations of power, pressure and coolant inlet temperature may occur. Table 4.4-6a presents a comparison of the DNBR from CE-1 with that from W-3 for a range of these parameters and for constant power distribution. For each combination of pressure and inlet temperature, the reactor power is calculated which gives a W-3 DNBR of 1.30. Then, the CE-1 DNBR is calculated at the same power.

The results in Table 4.4-6a show that the CE-1 DNBR is greater than the W-3 DNBR for normal operating temperatures and pressures. For the low pressure trip limit of 1,750 psi the value of the CE-1 DNBR is less than the W-3 DNBR, but the CE-1 DNBR is greater than the required value of 1.13.

In the development of the CE-1 correlation, the local coolant conditions for the source data were calculated using the TORC computer code. Therefore, the TORC code is used here for the hot bundle subchannel analysis.

The mass velocity into the subchannel array which represents the hot assembly in TORC is set equal to the mass velocity in the hot assembly, which is calculated by COSMO, except that it is first divided by 1.05 to account for inlet plenum flow maldistributions.

The CE-1 DNBR is calculated for all of the subchannels in the array representing the hot assembly. Figure 4.3-23 shows the local normalized radial power distribution for the subchannel array used in TORC. The design hot channel engineering factors given in Table 4.4-1 are applied to the matrix subchannel adjacent to the guide tube as shown on the figure. The location of minimum DNBR is either in this matrix subchannel or in one of the cold wall subchannels adjacent to the guide tube. When a minimum DNBR is quoted for the CE-1 correlation, it is the lowest value in the array of subchannels.

The CE-1 correlation with a DNBR of 1.13 provides the same assurance of not having DNB as previously assumed for a W-3 DNBR of 1.30. Therefore, the CE-1 correlation and its data base provide significantly greater assurance of not having DNB for the same transient conditions. Further discussion of the limiting transients, their effect on DNBR, and their relative magnitudes for W-3 and CE-1 analyses is contained in Chapter 15 and in the CE report, "Application of the CE-1 Correlation for C-E Fuel Assemblies with C-E Standard Spacer Grids and a Nonuniform Axial Power Distribution."

Table 4.4-1 gives the DNBR for 100 percent power.

4.4.2.3.2 Departure from Nucleate Boiling (Cycle 2 and on)

NRC evaluation of the uniform axial power distribution CHF test data for CE's 16 x 16 fuel design results in their concluding that the CE-1 critical heat flux correlation, when coupled with the TORC code, provides an acceptable correlation of uniform axial CHF data and that the minimum acceptable DNBR is 1.19 (Reference 166). Starting with Cycle 2, Statistical Combination of Uncertainties (SCU) methods were used to statistically combine the uncertainties of the thermal hydraulic code input parameters (system parameters) as described in Reference 164. Using this SCU methodology, the following uncertainties were statistically combined with CE-1 CHF correlation statistics at 95/95 confidence/probability level to yield a 1.24 DNBR limit for Cycle 2:

a) uncertainty in the inlet flow distribution

b) systematic variation on fuel rod pitch

c) systematic variation on fuel clad O.D.

d) engineering enthalpy rise factor

e) engineering heat flux factor

f) penalty on minimum DNBR due to fuel rod bowing

g) statistics associated with the NRC approved 1.19 DNBR limit

Also included in this MDNBR limit is the penalty due to the CHF correlation uncertainty and penalties imposed by NRC to account for CHF correlation "prediction uncertainty" and TORC code uncertainty. Starting with Cycle 3, the MDNBR limit was increased by a 0.01 penalty to 1.25 to conservatively address potential NRC concerns regarding the use of HID-1 spacer grids. The 1.25 DNBR limit is used in safety analysis, CPC trip setpoints and COLSS power operating limit calculations in conjunction with a CETOP model based on a nominal geometry.

The SCU methodology divided the uncertainties into two categories. The uncertainties of the two categories are effectively combined in a deterministic manner due to the separate application in the DNBR limit and the overall uncertainty factors.

In Cycle 12, the SCU methodology was replaced with the Modified Statistical Combination of Uncertainties (MSCU). The MSCU methodology statistically combines the uncertainty components which were previously combined deterministically. Also, the statistical treatment of several uncertainty components is modified so that the overall uncertainty factors can be calculated and applied as a function of burnup, axial shape index, and power in the COLSS and CPCs.

In Cycle 19, the ABB-NV CHF correlation described in Reference 193 was applied to the CPC overall uncertainty analysis. Although improved statistics associated with the ABB-NV correlation provided justification for a smaller DNBR limit, the existing limit of 1.25 (based on CE-1) was maintained to simplify the reload anlyses.

In Cycle 20, the WSSV-T correlation described in Reference 196 was applied for NGF assemblies in the mixed core. The DNBR limit for WSSV-T was calculated to be 1.23 using the above uncertainties. However, the existing safety limit of 1.25 (based on CE-1) is maintained for simplicity.

Beginning in Cycle 21, which was comprised of a full core of NGF assemblies, the WSSV-T CHF correlation described in Reference 196 was applied in the mixing vane region of NGF assemblies, and the ABB-NV CHF correlation described in Reference 193 was applied in the non-mixing vane region of NGF assemblies. The SCU DNBR limit of 1.23 derived using the above uncertainties is applicable to both WSSV-T and ABB-NV CHF correlations.

4.4.2.3.3 Distribution of DNB Ratio in the Core

The DNB ratio at a core average rod is much greater than the DNBR at the hottest rod and it would not be meaningful to report this high value to represent the core. However, it is appropriate to present the distribution of the DNBR at a number of high power rods. Figure 4.4-3 shows the number of rods in the reactor at which the DNBR is less than the value indicated on the abscissa when the reactor conditions are such that the W-3 DNBR at the hottest rod in the core is equal to 1.3.

4.4.2.3.4 Application of Hot Channel Factors

The thermal design of the reactor core takes into account the nuclear power distribution, flow distribution, mixing, and manufacturing tolerances. Nuclear power distribution and manufacturing tolerances are expressed as factors which are imposed on the nominal channel in the input to the core analytical model. Flow distribution and mixing are explicitly treated by the core analytical model.

A. Rod Radial Nuclear Factor

The rod radial nuclear or rod radial peaking factor is the ratio of the peak power from a fuel rod relative to the core average fuel rod power. Radial power distributions are dependent upon a variety of parameters (rod insertion, power level, fuel exposure, etc.). A typical cumulative distribution of the fraction of rods above a given rod radial nuclear factor is shown in Figure 4.4-4.

The radial peaking factor used in the calculation of required initial margin to DNB for a particular axial shape and set of thermal hydraulic conditions was that peaking factor which produced a minimum hot channel DNBR equal to the DNB Specified Acceptable Fuel Design Limit (SAFDL) during a calculated 4-pump loss of flow transient. The DNB SAFDL provides at least 95% probability with at least 95% confidence that the hot fuel rod will not experience DNB.

The analyses upon which the Power Dependent Insertion Limits is based employed a limited number of axial shapes and associated scram reactivity curves from Beginning of Cycle (BOC), since BOC conditions were found to be most limiting. The particular axial shapes employed were chosen from the Arkansas Nuclear One - Unit 2 NSSS design data and included the limiting shape used for thermal margin design calculations. These analyses were prepared specifically to illustrate dependence of required initial margin to DNB on axial shape index.

B. Axial Peaking Factor

The axial peaking factor is the ratio of the peak heat flux to the average heat flux in a rod.

The axial power distribution directly affects DNBR. When the axial location of maximum heat flux occurs farther from the core inlet, the DNBR limit may be reached with lower values of peak heat flux. On the other hand, fuel temperature is almost independent of the location of the peak heat flux or linear heat rate. The axial power distribution and the rod radial nuclear factor are continually determined and processed through the Core Operating Limit Supervisory System (COLSS) and the Reactor Protective System (RPS) such that the design basis limits are not exceeded. Section 4.3 describes the power distributions and their control.

C. Nuclear Heat Flux Factor

The nuclear heat flux factor or the total nuclear peaking factor is the ratio of the maximum local heat flux in the core to the core average heat flux. Table 4.4-1 gives the design value for this factor.

D. Engineering Heat Flux Factor

The effect on local heat flux due to deviations from nominal design dimensions and specifications is accounted for by the engineering heat flux factor. Design variables that contribute to this engineering factor are pellet density, fuel enrichment, pellet diameter, and clad outside diameter.

These variables are combined statistically to obtain the engineering heat flux factor. The design value used for the engineering heat flux factor is based on deviations obtained from fuel manufacturing inspection data for the Palisades reactor (Docket No. 50-255) and the Maine Yankee reactor (Docket No. 50-309). Similar tolerances and quality control procedures are used for this reactor, and inspection data is expected to confirm that the factor given in Table 4.4-1 is appropriate. The engineering heat flux factor is applied to the hot rod, and increases the heat flux when calculating DNBR. It does not affect the enthalpy rise in the channel.

Statistical evaluation of the fuel manufacturing inspection data for ANO-2 yields a value of less than 1.025 for the effect on local linear heat rate and heat flux due to variations in fuel density, fuel enrichment, and pellet diameter.

E. Nuclear Enthalpy Rise Factor

The nuclear enthalpy rise factor is the ratio of the average power generated in the four rods that surround the hot channel to the average power generated in all the fuel rods in the core.

F. Engineering Enthalpy Rise Factor

The engineering enthalpy rise factor accounts for the effects of deviation in fuel fabrication from nominal dimensions or specifications on the enthalpy rise in the hot channel. Tolerance deviations (averaged over the length of the fuel rods that enclose the hot channel) for fuel density, enrichment and pellet diameter contribute to this factor. The engineering enthalpy rise factor accounts for the increased heat input resulting from higher than normal U-235 content. The value of the engineering enthalpy rise factor is 1.02.

The engineering enthalpy rise factor is applied by multiplying the rod radial power factor for each of the fuel rods surrounding the limiting subchannel by the factor. This increases the enthalpy rise in the limiting subchannel and, to a lesser extent, also in the surrounding subchannels which are partially bounded by the same fuel rods.

G. Rod Pitch, Bowing and Clad Diameter Factor

The rod pitch, bowing and clad diameter factor accounts for the increased heat input due to the decreased flow rate resulting from a smaller than nominal channel flow area. The rod pitch, bowing and clad diameter factor is 1.05.

The rod pitch, bowing and clad diameter factor is applied by multiplying the incremental heat input in the limiting subchannel by the factor. This increases the heat input in the limiting subchannel in the same manner as does the enthalpy rise factor, but does not directly affect the surrounding subchannel heat input. These increases in subchannel heat input cause higher lateral enthalpy gradients. The net combined

effects of changes in divergent crossflow and in turbulent interchange resulting from the higher heat input and enthalpy rise are computed by the COSMO/INTHERMIC analytic model in Cycle 1 and the TORC model in subsequent cycles (See Reference 37, Appendix D, page D-23 and Appendix E, page E-6), as part of the subchannel analysis for each core condition analyzed.

H. Inlet Flow Distribution (Plenum) Factor

The inlet flow distribution or plenum factor was used with COSMO/INTHERMIC methods in Cycle 1 to account for the effect of nonuniform flow at the core inlet on the hot channel enthalpy rise. Its value is dependent on the number and location of pumps in use. Plenum factors used in Combustion Engineering reactor design are determined from flow model testing as described in Section 4.4.3.1.1.

Taking into consideration the similarities between the Arkansas Nuclear One - Unit 2 reactor and other Combustion Engineering reactors in conjunction with the experimental data from the various flow model programs, the following flow distribution factors for the various pumping configurations were established.

Pump Configuration	Inlet Flow Distribution Factor
Normal Four-Pump Operation	1.05
Three-Pump Operation	1.06

Subsequent to Cycle 1, TORC/CETOP methods have been applied. The core wide inlet and exit hydraulic boundary conditions inferred from the tests discussed above are used in TORC analyses which serve as a benchmark for the CETOP model.

4.4.2.4 Flux Tilt Consideration

An allowance for degradation in the power distribution in the x-y plane (commonly referred to as flux tilt) is provided in the protection limit setpoints even though little, if any, tilt in the x-y plane is expected.

The tilt along with other pertinent core parameters will be continually monitored during operation by the COLSS (described in Section 7.7) and included in the COLSS and CPC on-line thermal margin calculations.

4.4.2.5 Void Fraction Distribution

The core average void fraction and the maximum void fraction are calculated using the Maurer method (Reference 105) which is applicable under subcooled and low quality conditions. The void fractions discussed below are typical values when the reactor conditions are such that the hottest fuel rod experiences a 1.3 W-3 DNBR.

The core average void fraction is 1.1 percent while the local maximum void fraction is 44 percent and occurs at the exit of the hot channel. The channel average void fraction as a function of the nuclear enthalpy rise factor is shown in Figure 4.4-5, and the void fraction axial distribution in the hot channel is shown in Figure 4.4-6. The average void fraction in the hot channel is eight percent.

4.4.2.6 Core Coolant Flow Distribution

The core flow distributions, that form the basis for the plenum factors used in the core thermal margin evaluation, were obtained from reactor flow model tests. See Section 4.4.3.1.1 for a description of the tests and the results and Section 4.4.2.3.4 for a summary of the plenum factors.

Intentional selective orificing is not used in the core design.

4.4.2.7 Core Pressure Drops and Hydraulic Loads

4.4.2.7.1 Reactor Vessel Flow Distribution

The total coolant flow rate entering the four reactor vessel inlet nozzles is given in Table 4.4-1 for Cycle 1 and Table 4.4-2 for a typical recent cycle. The main coolant flow path in the reactor vessel is down the annulus between the reactor vessel and the core support barrel, through the flow skirt and lower support cylinder, up through the core support region and the reactor core, through the fuel alignment plate and out through the two reactor vessel outlet nozzles. A portion of this flow leaves the main flow path as shown schematically in Figure 4.4-7. Part of the bypass flow is used to cool the reactor internals in areas not in the main coolant flow path and to cool the CEAs. Table 4.4-3 lists the bypass flow paths and the percent of the total vessel flow rate that enters these paths for Cycle 1.

The thermal margin calculations conservatively assume a bypass flow rate of 3.5 percent of the total vessel flow rate as compared to the bypass flow rate of 3.2 percent as shown in Table 4.4-3. Cycle specific bypass flow rates are evaluated to ensure that the analytical value remains conservative.

Flow and temperature imbalances which can occur between steam generator loops may be divided into two categories: (1) steady state imbalances such as those which could be introduced by extensive steam generator tube plugging or significant variations in performance characteristics of the individual reactor coolant pumps and (2) transient imbalances which could be introduced by asymmetric secondary system malfunctions such as loss of load or loss of feedwater to a single steam generator.

Steady state flow or temperature imbalances are not anticipated during the initial operating period on the ANO-2 reactor, since very few, if any, steam generator tubes will be plugged and the individual reactor coolant pump characteristics are nearly identical based upon testing performed by the reactor coolant pump vendor prior to delivery to the ANO-2 plant site. Confirmation that no significant steady state asymmetry exists was a part of the startup test program for the ANO-2 reactor.

Steam generator tube plugging limits up to 10% $\pm$ 500 tubes with tube plugging asymmetry up to 1000 tubes (1564 tubes plugged for one steam generator, 564 tubes for the other steam generator), have been verified to be acceptable with respect to flow variations.

Asymmetric secondary system transients are not design basis events for the CPC system, because the asymmetric events are terminated by trips other than the thermal margin calculators, and require less initial margin than the loss of flow event. Nevertheless, the CPC core average power, DNBR and local power density algorithms are designed to provide conservative results under conditions of imbalance in the loop temperatures and flow rates. In addition, the effects of loop temperature and flow imbalances are included in the CPC core average power calculation in a manner that ensures that the uncertainty on the core average power used for DNBR and LPD calculations is not increased during these conditions.

4.4.2.7.2 Reactor Vessel and Core Pressure Drops

The irrecoverable pressure losses from the inlet to the outlet nozzles were calculated using standard loss coefficient methods which are verified by flow model tests (Refer to Section 4.4.3.1.1).

The calculated pressure losses at 100 percent power, 100 percent vessel flow rate and an operating pressure of 2,250 psia are listed in Table 4.4-4 together with the coolant temperatures that were used to calculate each pressure loss. The calculated pressure losses included both geometric and Reynolds number dependent effects. A comparison of the calculated nozzle-to-nozzle pressure loss, using the same methods as above, and the as-measured pressure loss on an operating plant indicates good agreement. Representative cycle core and total vessel pressure losses are listed in Table 4.4-2.

4.4.2.7.3 Hydraulic Loads on Internal Components

The significant steady state hydraulic loads which act on the reactor internals during steady state operation are listed in Table 4.4-5. These loads are derived from analyses which make use of reactor flow model and components test results. (Refer to Sections 4.4.3.1.1 and 4.4.4.3, respectively.) For clarity all hydraulic loads in Table 4.4-5 are based on the maximum expected system flow rate and a coolant temperature of 500 °F. Pressure variations axially and laterally within the core are not considered explicitly in fuel rod design. A potential effect of small lateral pressure gradients within assemblies on fuel rod vibration is examined by flow testing as described in Sections 4.2.1.2.3 and 4.2.1.3.6.2. The axial pressure gradient within a fuel assembly is considered in the calculation of fuel assembly uplift forces.

When other coolant conditions and core power levels result in more limiting loading for individual components, the loads in the table are adjusted in the detailed design analysis. The total design hydraulic loads for normal operation consist of the steady state loads given in Table 4.4-5 and the dynamic loads induced by pump pressure pulsations, turbulence, and vortex shedding.

Hydraulic loads for postulated accident conditions are given in Section 3.9.1.6.

4.4.2.8 Correlations and Physical Data

4.4.2.8.1 Heat Transfer Coefficients

The correlations used to determine cladding temperatures for nonboiling forced convection and nucleate boiling are discussed in Section 4.4.2.2.1.

4.4.2.8.2 Core Loss Coefficients

Irrecoverable pressure losses through the core occur as a result of friction and geometric changes. The pressure loss through the lower and upper end fittings is calculated using the standard loss coefficient method and has been verified by test. (Refer to Section 4.4.4.3.) The correlations used to determine frictional and geometric losses in the core are presented in Section 4.4.3.1.2.

4.4.2.8.3 Void Fraction Correlation

There are three separate void regions to be considered in flow boiling. Region 1 is highly subcooled in which a single layer of bubbles develops on the heated surface and remains attached to the surface. Region 2 is a transition region from highly subcooled to bulk boiling where the steam bubbles detach from the heated surface. Region 3 is the bulk boiling regime.

The void fraction in Regions 1 and 2 is predicted using the Maurer method, Reference 105. The calculation of the void fraction in the bulk boiling regime is discussed in Section 4.4.3.1.2.

4.4.2.9 Thermal Effects of Operational Transients

Design basis limits on DNBR and fuel temperature are established to assure that thermally induced fuel damage will not occur during normal steady state operation and during anticipated operational occurrences.

The COLSS provides information to the operator so that he can assure that proper steady state conditions exist. The RPS will prevent the design basis limits from being exceeded.

COLSS provides the reactor operator with a comparison of the actual core operating power to the licensed power and to continually calculated limiting powers based on DNBR and local power density. If the operating power reaches any one of the power limits, an alarm will be sounded. These limits are calculated by COLSS to provide sufficient margin so as not to exceed the design basis limits in the event that the most limiting anticipated operational occurrence occurs simultaneously with the operating power reaching a power limit.

For automatic protection of the core, the RPS is designed to effect a rapid shutdown in the event that the thermal hydraulic design basis limits are approached. The core minimum DNBR and maximum local power density are determined by a CPC which uses core parameters either measured or calculated as input.

For both the RPS and COLSS, an algorithm is developed to provide a rapid on-line calculation of DNBR. The algorithm, like the standard core analytical technique, uses the following core parameters either measured or calculated as input: core inlet temperature, pressure, flow, power, and power distribution. The DNBR calculated by the algorithm will always be less than or equal to that calculated by the standard analytical technique. Additional information concerning the RPS and COLSS is contained in Chapter 7, and additional discussion on the effects of thermal transients is contained in Sections 4.4.3.6 and 4.4.3.7. Analysis of anticipated operational occurrences to demonstrate that the fuel design limits are met is presented in Chapter 15.

4.4.2.10 Uncertainties in Estimates

4.4.2.10.1 Pressure Drop Uncertainties

The reactor vessel pressure losses in Table 4.4-4 are the best estimate values calculated for the design flow and correspond to the best estimate data from the flow model test programs being conducted at Combustion Engineering. Uncertainties due to experimental measurement and dimensional uncertainties on the reactor vessel and internals amount to approximately ± 10 percent in the pressure loss estimates.

4.4.2.10.2 DNBR Calculation

For a given heat flux distribution and local coolant conditions, the uncertainty in the DNB correlation is accounted for by using the limiting value of 1.3 for the W-3 DNBR, which is higher than the average value of 1.0 at which DNB occurs. The uncertainty associated with the 1.3 W-3 DNBR is discussed in Section 4.4.2.3.1. The uncertainty in the heat flux distribution is accounted for by using limiting values of nuclear peaking factors, which have uncertainty included, and by applying the engineering factors to account for manufacturing tolerances on the fuel rods. In Cycle 1 the uncertainty in the local coolant conditions was accounted for by taking conservative values for flow rate and hot channel factors such that the DNBR is minimized. Manufacturing tolerances are also accounted for in the engineering enthalpy rise factors. Statistical methods were used after Cycle 1 to combine manufacturing tolerance uncertainties and other uncertainties to local coolant conditions with the CHF correlation uncertainty in the DNBR limit as described in Section 4.4.2.3.2.

The COLSS and the RPS utilize the algorithm discussed in Section 4.4.2.9 to assure that the design bases on DNBR are not violated. The DNBR algorithm used in the RPS is biased to give limiting values of DNBR that are equal to or less than those calculated using the analytical method described in Section 4.4.3.4.

CETOP (also referred to as CETOP-D) is the thermal margin design code for Arkansas Nuclear One - Unit 2, starting with Cycle 2, and is the code used for all steady state DNBR analyses.

Steps (A) and (B) describe the sensitivity of DNBR to the enthalpy rise flow factor and the hot assembly radial peak.

A. Sensitivity to the Enthalpy Rise Flow Factor

   The enthalpy rise flow factor effectively increases the hot channel enthalpy rise over that due only to the heat input from the surrounding fuel rods. The factors affecting the enthalpy rise are discussed in detail in Section 4.4.2.3.4 on hot channel factors. Figure 4.4-8 shows the percent change in core power to a 1.30 W-3 DNBR as a function of the enthalpy rise flow factor. The percent change in the enthalpy rise factor may be thought of as a change in any of the enthalpy rise factors discussed in Section 4.4.2.3.4. The results are given for two axial power distributions, the design distribution for DNB calculations and a distribution peaked in the lower half of the core, both shown in Figure 4.4-2.

B. Sensitivity to Hot Assembly Radial Peak

   The hot assembly power, relative to the hot channel power, influences the openness of the core to divergent crossflow. In the COSMO/INTHERMIC methods applied in Cycle 1 the hot assembly is assumed to be closed and in parallel with other groups of closed assemblies representing the entire core while the hot channel is open to the hot assembly. Hence, when the hot assembly has a radial peak equal to that of the hot channel, the hot channel essentially has no divergent crossflow. As the hot assembly radial peak is reduced from the design value, the hot channel effectively becomes more open to the core. Figure 4.4-9 shows the change in the percent core power from the design value as the hot assembly radial peak is varied about the design value. The change in core power varies from a 1.5 percent increase if the hot assembly is open to the core to about 0.5 percent decrease if the hot assembly is assumed to have the same radial peak as the hot channel. Open core TORC/CETOP analyses have been carried out subsequent to Cycle 1.

To accommodate the effects of rod bowing, which is fuel burnup dependent, DNBR penalty factors were applied to the maximum radial power peak of each fuel batch in Cycle 1. A single net penalty for COLSS and CPC is determined from the penalties associated with each batch, to account for the offsetting margins from the lower radial power peaks in the higher burnup batches. DNBR penalty factors range from zero percent at BOC to 17.4 percent in the burnup range of 30-35 GWD/MTU, and were tabulated in Technical Specification 4.2.4.4. In Cycles 2, 3, and 4, a 2% rod bow penalty based on Reference 165 was included in the MDNBR for bundle burnups up to 30,000 MWD/MTU. Starting with Cycle 5, a 0.5% rod bow penalty based on Reference 169 was used. Starting with Cycle 16, a 0.6% rod bow penalty based on Reference 169 is used to account for bundle burnups up to 33,000 MWD/MTU. Bundles having burnups in excess of 33,000 MWD/MTU are not limiting with respect to DNB margin. Since the rod bow allowance is specifically included in the DNBR limit, there is no need for additional penalties on the rod radial peak in the Technical Specification. Therefore, Technical Specification 4.2.4.4 was deleted. Starting with Cycle 21 (full core of NGF assemblies), a 1% rod bow penalty is used to account for bundle burnups up to 33,000 MWD/MTU. Bundles having burnups in excess of 33, 000 MWD/MTU are not limiting with respect to DNBR margin.

4.4.2.10.3 Fuel and Clad Temperature Uncertainty

Uncertainty in the ability to predict the maximum fuel temperature is a function of the uncertainties associated with gap conductance, thermal conductivities, peak linear heat rate and heat generation distribution. Uncertainties in the gap conductance and thermal conductivity are taken into account in the analytical model. Uncertainties in the peak linear heat rate are accounted for by including the uncertainty in estimating the total nuclear peak and by including the uncertainties in fuel pellet density, enrichment, and pellet diameter in the engineering factor (See Section 4.4.2.3.4).

Uncertainty in predicting the cladding temperature at the location of maximum heat flux is due to uncertainty in the film temperature drop, which is minimal at this location where nucleate boiling occurs.

4.4.2.11 Plant Configuration Data

Plant configuration data for the thermal hydraulic and fluid systems external to the reactor are available in Chapters 5, 6, 9 and 15. Reactor configuration data are presented in Table 4.4-6.

4.4.3 EVALUATION

4.4.3.1 Core Hydraulics

4.4.3.1.1 Reactor Flow Model Tests

Design values for the reactor hydraulic parameters are obtained or verified by means of flow model tests. These flow model tests involve the use of scale reactor models and are part of the Combustion Engineering reactor development program. The test programs provide information on flow distribution in various regions of the reactor, on pressure loss coefficients, on hydraulic loads on vessel internal components, and on turbulence induced pressure and velocity fluctuations.

Combustion's PWR designs fall into seven basic geometric configurations as shown below:

Configuration	Reactor(s)	Distinguishing Hydraulic Features
1	Palisades	4 inlets, 2 outlets, cruciform control rods, 204 fuel assemblies
2	Fort Calhoun	4 inlets, 2 outlets, CEAs, 133 fuel assemblies
3	Maine Yankee	3 inlets, 3 outlets, CEAs, 217 fuel assemblies, 137 in. long core
4	Calvert Cliffs 1 & 2 St. Lucie 1 & 2 Millstone (Unit 2)	4 inlets, 2 outlets, CEAs, 217 fuel assemblies, 137 in. long core
5	ANO-2 Blue Hills Station	4 inlets, 2 outlets, CEAs, 177 fuel assemblies, 150 in. long core
6	San Onofre 2&3 Forked River Waterford 3, Pilgrim 2	4 inlets, 2 outlets, CEAs, 217 fuel assemblies, 150 in. long core
7	System 80	4 inlets, 2 outlets, 241 fuel assemblies, modified upper and lower plena design, 150 in. long core

Flow model tests have been conducted on the first four configurations and on System 80. The Palisades and Fort Calhoun flow tests were run under contract with Battelle Memorial Institute using air as the test medium. The Maine Yankee and the Configuration 4 reactor flow model tests were performed in a 15,000 gpm cold water facility in the Combustion Engineering Nuclear Laboratories.

The design hydraulic parameters required for Arkansas Nuclear One - Unit 2, Configuration 5, were obtained by interpolating from the results of the flow model tests on Configurations 1 through 4. Geometric differences between Configuration 5 and the earlier reactor configurations are accounted for by analytical means and by utilizing the experience gained from the earlier tests, during which numerous investigations were made of the effect of various internal components on flow distribution and pressure drop. For example, the Palisades tests were run with and without a flow skirt, with the core barrel concentric and eccentric in the vessel, and with the lower core support plates in place and removed. The Fort Calhoun tests were run with and without the thermal shield, with the lower core support structure removed and in place, and with the upper head guide structure and fuel alignment plate removed and in place. Earlier flow model test programs also investigated the effects of part loop operation and the degree of mixing of the coolant in the vessel upstream and downstream of the core.

The principal design hydraulic parameters include:

A. Inlet flow distribution enthalpy rise factor (or plenum factor)

B. Fuel assembly maximum inlet flow factor

C. Reactor pressure losses

D. Hydraulic loads on reactor internal components

The approaches for deriving the design hydraulic parameters for Arkansas Nuclear One - Unit 2 from results obtained from earlier reactor flow model tests are described as follows:

A. Inlet Flow Distribution Enthalpy Rise Factor

The inlet flow distribution enthalpy rise factor accounts for the effects of the non-uniform core inlet flow distribution on the hot subchannel enthalpy rise in COSMO/INTHERMIC methods; hydraulic boundary conditions are applied explicitly at the core inlet and exit in TORC/CETOP methods. In utilizing the flow distributions to determine the inlet flow distribution enthalpy rise factor (or plenum factor), it is assumed that the design value of the rod radial peaking factor can occur in any fuel assembly. However, since the assembly power is significantly lower for the peripheral fuel assemblies, the maximum permissible plenum factor is larger for peripheral assemblies, than for those in the interior. This fact is taken into account through a combination of the experimental flow distribution and the most conservative power distribution envelope to yield a single design value for the plenum factor. That value, when used with the designated design values for assembly power and rod peaking factor, results in the most limiting thermal margin. It is equal to or less than the thermal margin that would be calculated for each individual fuel assembly location using the local values of plenum factor and power (Further information on this subject is given in Reference 31).

The core flow distribution data from earlier model tests were used as the basis for establishing the Arkansas Nuclear One - Unit 2 enthalpy rise factor. The geometry in both the lower plenum and the core regions affect the core inlet flow distribution. Consequently, the evaluation of the flow model data took into consideration comparisons of the lower plenum and core geometries for reactor Configurations 1 through 5.

The comparison of lower plenum geometries is shown below:

	Length Ratios				
Reactor Config.	O.D. Core Support Barrel / I.D. Vessel	Height of Lower Plenum / I.D. Vessel	Core Support Structure / I.D. Vessel	Height of Flow Skirt / I.D. Vessel	O.D. Flow Skirt / I.D. Vessel
1	0.89	0.41	0.23	0.18	0.84
2	0.88	0.48	0.29	0.24	0.83
3	0.88	0.43	0.25	0.18	0.84
4	0.88	0.43	0.25	0.18	0.84
5 ANO-2	0.89	0.48	0.24	0.23	0.83

	Flow Rate Ratios		
Reactor Config.	$A_{\text{Flow Skirt}}$ / A_{core}	$A_{\text{Bottom Plate in Core Support Structure}}$ / A_{core}	$A_{\text{Core Support Plate}}$ / A_{core}
1	0.61	0.55	0.53
2	1.09	0.59	0.54
3	0.82	0.54	0.53
4	0.82	0.58	0.53
5 ANO-2	0.88	0.57	0.51

Examination of the dimensionless ratios describing the lower plenum geometries shows that the lower plenum designs for the five reactor configurations are very similar, except in one respect. Configurations 2 and 5 (Arkansas Nuclear One - Unit 2) have lower plenums with larger volumes on a relative basis compared to the remaining three configurations. This is evident from the ratios relating to the height of the lower plenum and to the height of the flow skirt. It can be postulated that as the lower plenum volume increases, the core inlet flow distribution will tend to become more uniform. This is supported by the flow model data.

The comparison of core geometries is shown below:

Reactor Config.	Rod Array in Fuel Assembly	Fuel Rod Length (ft)	No. Of Spacer Grids	Hydraulic Config. Diameter (ft)
1	15 x 15	11.7	8 or 9	0.0466
2	14 x 14	11.3	9	0.0449
3	14 x 14	12.2	9	0.0449
4	14 x 14	12.2	9	0.0449
5 ANO-2	16 x 16	13.5	12	0.0403

The configuration five fuel assemblies have design characteristics (longer length, more grids, smaller hydraulic diameter) that produce a larger axial hydraulic resistance relative to the other configurations. The larger core hydraulic resistance tends to produce a more uniform core inlet flow distribution. So for a given lower plenum geometry, the 16x16 core of Configuration 5 will have a flatter flow distribution than the 14 x 14 cores.

Results from the flow model tests on reactor Configurations 1 through 4 are tabulated below, along with the estimated flow distribution parameters for Arkansas Nuclear One - Unit 2.

Reactor Config.	No. of Inlets	No. of Outlets	No. of Assys.	Enthalpy Rise Factor $F_{\Delta H}^{PL}$	Measured Maximum Assy. Flow Rate $(W_i/\bar{W})_{Max}$
1	4	2	204	1.05	1.07
2	4	2	133	1.03	1.05
3	3	3	217	1.05	1.05
4	4	2	217	1.05	1.05
5 ANO-2	4	2	177	1.05 (Est)	1.05 (Est)

Generally, the results from the model tests on Configurations 1, 2 and 4, i.e. the 4-loop plants, show that there is quadrantal symmetry in the core inlet flow distribution and that the lowest assembly flow rates appear on the core periphery. More specifically, the Arkansas Nuclear One - Unit 2 reactor is most similar to Configurations 2 and 4. Since the enthalpy rise factor, $F_{\Delta H}^{PL}$, is 1.03 for Configuration 2, is 1.05 for Configuration 4, and is no greater than 1.05 for any of the tested configurations, it was concluded that 1.05 is an appropriate and realistic value for the enthalpy rise factor for Arkansas Nuclear One - Unit 2. Part loop plenum factors were established on the basis of part loop testing on the Configuration 2 model and are itemized in Section 4.4.2.3.4.

B. Fuel Assembly Maximum Inlet Flow Factor

The core inlet flow distribution is also used to define the maximum value of assembly inlet flow rate ratio, $(W_i/\overline{W})_{Max}$, for calculating the hydraulic uplift loads on the fuel assemblies. (See Section 4.4.2.7.3.) Results from flow model tests on Configurations 1 through 4 for $(W_i/\overline{W})_{Max}$ values are also listed in the table in Item A, above. The measured value of $(W_i/\overline{W})_{Max}$ for Configurations 4 and 2 (those most similar to Arkansas Nuclear One - Unit 2) is 1.05; hence, that value was selected for Arkansas Nuclear One - Unit 2.

C. Reactor Pressure Losses

Reactor vessel pressure losses are determined with a standard calculational model. This model was developed partly on the basis of pressure loss results from flow model tests on the earlier reactor Configurations 1 through 4 and partly on analytical methods available in the literature. The calculational model divides the flow path through the reactor into segments. The principal flow path segments are:

1. The inlet region
2. The thermal downcomer region
3. The lower plenum region
4. The core support structure region
5. The core region
6. The upper plenum region

A combination of analytical and/or empirical relationships are used for each flow path segment in the standard pressure loss calculational method. When empirical relationships are used for a new reactor, the loss coefficient(s) from the originating model tests are modified by analytical means to account for geometry variations between the original reactor geometry and that for the new reactor geometry.

Agreement between predictions by the standard calculational method and experimental pressure losses is found to be good. For example, from flow model tests on Configuration 4, the agreement between predicted and measured values for the segmental ΔP losses was within 15 percent while the nozzle-to-nozzle pressure losses agreed within 10 percent. The predicted nozzle-to-nozzle pressure losses were found to be systematically high relative to the measured values. Comparisons have also been made between nozzle-to-nozzle pressure drops measured in two Combustion Engineering reactors (Configurations 1 and 3) and values predicted by the standard calculational method. These latter comparisons show agreement within seven percent, again with the predicted values being higher than the measured values.

The vessel pressure losses for ANO-2 were estimated with the standard calculational method, taking into account the observed systematic differences between predicted and measured pressure losses.

D. Hydraulic Loads on Reactor Internal Components

Hydraulic loads were estimated for ANO-2 based on both experimental data from flow model tests on reactor configurations 1 through 4 and by analytical means. When experimental data are used, they are first reduced to dimensionless form in terms of a pressure difference coefficient,

$$E = \frac{P_{local} - P_{ref}}{\frac{\rho V^2_{ref}}{2g}}$$

a force coefficient,

$$C_F = \frac{F}{\frac{\rho V^2_{ref} A_{ref}}{2g}}$$

or a velocity ratio,

$$\frac{V_{local}}{V_{ref}}$$

The quantities with subscript "ref" represent appropriate reference values, for example, the average velocity or pressure at the particular flow path station of interest. These dimensionless quantities are then converted to absolute quantities by multiplying by the appropriate reference quantity, i.e. by

$$\frac{\rho V_{2ref}}{2g} \text{ or } V_{ref}.$$

Adjustment to the resulting absolute quantities are made by analytical means if there are substantial differences in geometry between the reactor configuration for which the test data were derived and the reactor configuration of interest.

Further discussion of the philosophy of Combustion Engineering flow model testing appears in Reference 6.

4.4.3.1.2 Core Pressure Drop Correlations

The total pressure drop along the active fuel region of the core is computed as the sum of the individual losses resulting from friction, acceleration of the fluid, change in elevation of the fluid and spacer grids. The individual losses are computed using the momentum equation and the consistent set of empirical correlations presented in Reference 126. In the following paragraphs, the correlations used are summarized and the validity of the scheme is demonstrated with a comparison of measured and predicted pressure drop for single-phase and two-phase flow in rod bundles with CEA-type geometry.

For isothermal, single-phase flow, the pressure drop due to friction for flow along the bare rods is based on the equivalent diameter of the bare rod assembly and the Blasius friction factor:

$$f = 0.184\ R_e^{\ -0.2}$$

The pressure drop associated with the HID-IL spacer grids in standard fuel is computed using a grid loss coefficient (K_{SG}) given by:

$$K_{SG} = 0.234 + 6.46R_e^{-0.2}$$

For the NGF assemblies, there are three (3) grid designs in the core. Non-mixing grids are in the lower portion of the core, and structural mixing grids are in the mid and upper portions of the core. IFM grids (2) provide improved thermal performance in the upper portion of the core. The pressure drop associated with these grids is computed using the following grid loss coefficient expressions:

$$K_{\text{unvaned grid}} = 0.343 + 6.946Re^{-0.20}$$

$$K_{\text{vaned grid}} = 0.437 + 8.843\ Re^{-0.20}$$

$$K_{\text{IFM grid}} = 0.259 + 3.851Re^{-0.20}$$

The coefficients were determined from pressure drop data obtained for a wide range of Reynolds Number for isothermal flow through rod bundles fitted with production grids. The data came from the fuel assemblies and components test program applicable to ANO-2. The standard error of estimate associated with the loss coefficient relation is 2σ or ~10% of the estimate and includes replication and instrument error.

To compute pressure drop either for heating without boiling or for subcooled boiling, the friction factor given above for isothermal flow is modified through the use of the multipliers given in Reference 126. It is important to recognize that the multipliers were developed in such a way as to incorporate the effects of subcooled voids on the acceleration and elevation components of the pressure drop as well as the effect on the friction losses. Consequently, it is not necessary to compute specifically either a void fraction for subcooled boiling or the individual effects of subcooled boiling on the friction, acceleration, or elevation components of the total pressure drop.

The effect of bulk boiling on the friction pressure drop is computed using a curve fit to the Martinelli-Nelson data (Reference 104) above 2000 psia or the Martinelli-Nelson correlation (Reference 104) with the modification given in References 126 and 167 below 2,000 psia. The acceleration component of the pressure drop for bulk boiling conditions is computed in the usual manner for the case of two-phase flow where there may be a nonunity slip ratio (See, for instance, Reference 115). The elevation and spacer grid pressure drops for bulk boiling are computed as for single-phase flow except that the bulk coolant density ($\overline{\rho}$) is used, where:

$$\overline{\rho} = \alpha\rho_V + (1 - \alpha)\,\rho_\ell$$

and α = Bulk boiling void fraction

ρ_V = Density of saturated vapor, lb/ft^3

ρ_ℓ = Density of saturated liquid, lb/ft^3

The bulk boiling void fraction used in computing the elevation, acceleration, and spacer grid losses is calculated by assuming a slip ratio of unity if the pressure is greater than 1,850 psia or by using the Martinelli-Nelson void fraction correlation (Reference 104) with the modifications presented in Reference 126 if the pressure is below 1,850 psia.

To verify that the scheme described above accurately predicts pressure drop for single-phase and two-phase flow through the Combustion Engineering fuel assembly, comparisons have been made of measured pressure drop and the pressure drop predicted by the Combustion Engineering design code, COSMO, for the rod bundles used in the DNB test program at Columbia University. (Refer to Section 4.4.4.2.) Figure 4.4.-10 shows some typical results for a 21-rod bundle (5x5 array with four rods replaced by a control rod guide tube). The excellent agreement demonstrates the validity of the methods described above. A comparison of TORC predictions with additional measured data in Reference 168 also showed excellent agreement.

4.4.3.2 Influence of Power Distributions

The Core Operating Limit Supervisory System (COLSS) will restrict operation of the plant such that power distributions which are permitted to occur will have adequate margin to satisfy the design bases during anticipated operational occurrences. Expected power distributions and the control of them are discussed in detail in Section 4.3, Nuclear Design. Figure 4.4-2 shows some axial power distributions which are used in design to give limiting values of DNBR and linear heat rate when used in conjunction with other design peaking factors and selected coolant conditions.

4.4.3.3 Core Thermal Response

Core steady state design parameters are summarized in Table 4.4-1 for Cycle 1 and in Table 4.4-2 for later cycles for normal 4-pump operation. Other combinations of temperature, power, and pressure will occur during reactor operation. The limit curves shown in Figure 4.4-11 for normal 4-pump operation show the sensitivity of the various operating conditions to each other at a W-3 DNBR = 1.3, and also show the margins that exist relative to the design conditions. For a given power, pressure, and power distribution, the curves give the maximum permissible temperature to reach the design basis limit on DNBR. The limit curves shown in the figure were calculated for the axial power distributions shown in Figure 4.4-2, a radial nuclear factor of 1.55, and engineering factors as specified in Tables 4.4-1 and 4.4-2. Other power distributions will produce limiting curves different from those shown in the figure. The Reactor Protective System (RPS) will trip the reactor before these limits are reached. The response of the core to transients is given in Chapter 15.

4.4.3.4 Analytical Techniques

4.4.3.4.1 Thermal Margin Analysis (Cycle 1)

In order to evaluate the thermal margin in the Cycle 1 core, an analytical model was established which defines a hypothetical hot channel containing the design radial peak rod and having all factors applied to it which cause it to be the most limiting channel in the core. There are three segmental phases to the calculation of the DNBR for the limiting channel:

A. Calculation of the core wide flow distribution and pressure drop;

B. Calculation of the hot channel coolant conditions; and,

C. Calculation of the DNBR.

These calculations are embodied in the COSMO and INTHERMIC computer codes (Appendices D and E of Reference 37). The following Sections A through D summarize these calculations which represent the design method for core thermal margin evaluations on Arkansas Nuclear One, Unit 2. Another procedure for calculating core thermal margin is embodied in the TORC computer code (Reference 37). This code is a three-dimensional representation of the open lattice core which determines the local coolant conditions at all points within the core. Comparisons between the results from the TORC model and from the COSMO/INTHERMIC model show that the COSMO/INTHERMIC model gives conservative results relative to TORC (See Reference 37). These comparisons are valid for application to the thermal margin results obtained with the COSMO/INTHERMIC model on Unit 2. Hence, the results from the procedure described in the following are a satisfactory representation of the Unit 2 core thermal margin.

A. Core Wide Flow Distribution

In routine design calculations utilizing COSMO, the core wide flow distribution is calculated by considering the core as an array of parallel closed pipe type flow paths with various flow areas and relative powers called zones. The thermal and hydraulic characteristics of each zone are used to calculate the core flow distribution with the provision that the pressure drops across all zones are equal. In this phase of the calculation, each zone is separate from the others and there is no energy or mass interchange between zones. The hot assembly which contains the hot channel, is included as one of the zones in this first phase of the calculations.

The overall core pressure drop is determined using the best estimate assembly peaking distribution which is much flatter than the distribution which accompanies the design peaking condition. The hot assembly peak is assumed at the design value.

B. Hot Channel Coolant Conditions

In the second phase of the calculations, the coolant conditions are determined in the hot channel of the core. A channel is defined as the coolant flow area bounded by four adjacent fuel rods. The limiting channel is assumed to be open to the hot assembly and to have the same axial pressure drop distribution as the hot assembly. The flow rate in the hot channel is calculated using the hot assembly pressure drop distribution determined during the core wide calculations. The resulting flow rate in the hot channel varies along the axial length in order that the hot assembly pressure distributions are matched.

In the calculation of the hot channel enthalpy rise, several factors are applied to the highest powered channel to account for core physics and hydraulics characteristics and for uncertainties due to manufacturing tolerances. These factors are applied simultaneously to the channel to ensure that it is the most limiting channel in the core.

These factors include (refer to Section 4.4.2.3):

1. Nuclear Heat Flux Factor

2. Nuclear Enthalpy Rise Factor

3. Engineering Heat Flux Factor

4. Engineering Enthalpy Rise Factor

5. Rod Pitch, Bowing and Clad Diameter Factor

6. Inlet Flow Distribution (plenum) Factor

7. Turbulent Interchange Thermal Mixing Factor

The Nuclear Factors (1) and (2) arise from the nonuniform heat generation in the core; Engineering Factors (3), (4) and (5) account for uncertainties due to manufacturing tolerances. Factor (6) accounts for the effect of the core inlet flow maldistribution, and Factor (7) relates the effect of turbulent interchange on the hot channel enthalpy rise.

The output of the hot channel analysis is the channel local coolant conditions, in terms of mass velocity, enthalpy, and quality as a function of axial position in the channel. These local conditions are the necessary input to the third phase of the calculations.

C. Determination of DNBR

The final phase of the calculations uses the hot channel coolant conditions and the local heat flux in conjunction with the W-3 correlation in Cycle 1 and the CE-1 correlation in subsequent cycles as discussed in Section 4.4.2.3 to determine the minimum DNBR in the core.

D. Turbulent Interchange

The effect of turbulent interchange or mixing between channels on the hot channel enthalpy rise in Cycle 1 is calculated by the INTHERMIC (Reference 38) computer code. INTHERMIC solves the energy and continuity relations for groups of parallel interconnected channels, taking into account the effect of turbulent interchange as described by an experimental relation described in Section 4.4.4.4.

Results of the INTHERMIC calculations are expressed as the "mixing hot channel factor", defined as the ratio of hot channel mixed to unmixed enthalpy rise. The mixing hot channel factor is not constant, but varies axially along the length of the channel. It has a value of unity at the channel inlet, where no lateral enthalpy gradient exists, and decreases progressively up the channel as the lateral enthalpy gradient builds up.

The geometry and the rod power distribution of the array of channels surrounding the hot channel, the axial and radial power distribution, and the presence of statistical engineering factors all affect the lateral enthalpy distribution and, hence, the mixing hot channel factor. The design value for the mixing hot channel factor is a conservative estimate based on an INTHERMIC case run with the flattest rod power distribution expected for any assembly over core life. This distribution minimizes the beneficial effects of mixing on the enthalpy rise in the hot channel.

4.4.3.4.2 Thermal Margin Analysis (Subsequent Cycles)

Thermal margin analysis of the reactor core is performed using the TORC and the CETOP codes which are based on the open core analytical method of the COBRA-IIIC code (Reference 170). A complete description of the TORC code and application of the code for detailed core thermal margin analyses is contained in CENPD-161 (Reference 37). The CETOP code is used for design thermal margin calculations. CETOP is described in detail in Reference 38. A brief description of the code and its use is given here.

The COBRA-IIIC code solves the conservation equations for mass, axial and lateral momentum, and energy for a collection of parallel flow channels that are hydraulically open to each other. Since the size of a channel in design varies from the size of fuel assembly or more to the size of a subchannel within a fuel assembly, certain modifications were necessary to enable a realistic analysis of thermal-hydraulic conditions in both geometries. The principal revisions to arrive at the TORC code, which leave a basic structure of COBRA-IIIC unaltered, are in the following areas:

A. Modification of the lateral momentum equation for core wide calculations where the smallest channel size is typically that of a fuel assembly.

B. Addition of the capability for handling non-zero lateral boundary conditions on the periphery of a collection of parallel flow channels. This capability is particularly important when analyzing the group of subchannels within the hot fuel assembly.

C. Addition of the capability to handle nonuniform core exit pressure distributions.

D. Insertion of standard C-E empirical correlations and the ASME fluid property relationships.

Details of the lateral momentum equations and empirical correlations used in the TORC code are given in Reference 37.

The application of the TORC code for detailed core thermal margin calculations typically involves three stages. The first stage consists of calculating coolant conditions throughout the core on the coarse mesh basis. The core is modeled such that the smallest unit represented by a flow channel is a single fuel assembly. The three-dimensional power distribution in the core is superimposed on the core coolant inlet flow and temperature distributions. The core inlet flow and core exit static pressure distribution are obtained from flow model tests discussed in Section 4.4.3.1.1 and the inlet temperature for normal four-loop operation is assumed uniform. The axial distributions of flow and enthalpy in each fuel assembly are then calculated on the basis that the fuel assemblies are hydraulically open to each other. Also determined during this stage are the transport quantities of mass, momentum, and energy which cross the lateral boundaries of each flow channel.

In the second stage, typically the hot assembly and adjoining fuel assemblies are modeled with a coarse mesh. The hot assembly is typically divided into four to five partial assembly regions. One of these regions is centered on the subchannels adjacent to the rod having the minimum DNBR. The three-dimensional power distribution is superimposed on the core coolant inlet flow and temperature distributions. The lateral transport of mass, momentum, and energy from the stage one calculations is imposed on the peripheral boundary enclosing the hot assembly and the neighboring assemblies. The axial distributions of flow and enthalpy in each channel are calculated as well as the transport quantities of mass, momentum, and energy which cross the lateral boundary of each flow channel.

The third stage involves a fine mesh modeling of the partial-assembly region which centers on the subchannels adjacent to the rod having the minimum DNBR. All of the flow channels used in this stage are hydraulically open to their neighbors. The output from the stage two calculations, in terms of the lateral transport of mass, momentum, and energy is imposed on the lateral boundaries of the stage three partial assembly region. Starting with Cycle 14, a more

detailed two-stage TORC model was used replacing the three-stage model. Stage 1 consists of calculating coolant conditions throughout the core on the coarse mesh basis. The core is modeled such that each flow channel is a quarter of a fuel assembly. Stage 2 involves a fine mesh modeling of the fuel assembly that contains the subchannels adjacent to the rod having minumum DNBR. The fuel assembly is modeled such that each flow channel is surrounded by fuel rods or guide tube. The output from the stage 1 calculations, in terms of lateral transport of mass, momentum, and energy is imposed on the lateral boundaries of the limiting fuel assembly in stage 2. Engineering factors are applied to the minimum DNBR rod and subchannel to account for uncertainties on the enthalpy rise and heat flux due to manufacturing tolerances. The local coolant conditions are calculated for each flow channel. These coolant conditions are then input to either the CE-1, ABB-NV, or WSSV-T CHF correlation and the minimum value of DNBR in the core is determined.

A more detailed description of this procedure with example is contained in Reference 37. This procedure is used to analyze in detail any specific three-dimensional power distribution superimposed on explicit core inlet flow and exit pressure distributions. The detailed core thermal margin calculations are used primarily to develop and to support the CETOP design core thermal margin calculational scheme discussed below.

Cycle 20 was a mixed core consisting of standard fuel assemblies and NGF assemblies. Since the mixing vane spacer grids of NGF fuel provide higher flow resistance compared to standard fuel assemblies, the hydraulic characteristics of these two fuel types were explicitly modeled in TORC thermal-hydraulic analyses to calculate coolant pressure drop and cross-flow between assemblies.

Starting with Cycle 21 (full NGF core), WSSV-T and ABB-NV CHF correlations were used to determine the minimum DNBR in the core as discussed in Section 4.4.2.3.2.

The CETOP code, a variant of the TORC code, is used as a design code for thermal margin analyses. The CETOP code uses transport coefficients for improved prediction of diversion cross flow and turbulent mixing between adjoining channels. Furthermore, a prediction-correction method is used to solve the conservation equations, replacing the iterative method used in the TORC code. CETOP is benchmarked against TORC DNBR data to ensure that CETOP DNBR results are accurate or conservative relative to TORC.

The method used for design calculations using CETOP is discussed in detail in Reference 38. In summary, the method is to use one limiting hot assembly radial power distribution for all analyses, to raise or lower the hot assembly power to provide the proper maximum rod radial power factor, and to use the core average mass velocity in all fuel assemblies except the hot assembly. The appropriate reduction for the hot assembly mass velocity was determined after completion of the flow model tests (see Section 4.4.3.1.1). This methodology is used in the thermal margin analyses of the System 80 reactors.

4.4.3.4.3 UO_2 Melting Point

An examination of the published data on the variation of the melting point of UO_2 with burnup shows a decrease at a nearly linear rate of -56 °F per 10,000 MWD/MTU (Reference 60). This rate results in a UO_2 melting point of 4,800 °F after a maximum local burnup of 50,000 MWD/MTU is achieved.

4.4.3.5 Hydraulic Instability Analysis

Flow instabilities leading to flow excursions or flow oscillations have been observed in some boiling flow systems containing one or more closed, heated channels. Flow instabilities are a concern primarily because they may lead to a reduction in the DNB heat flux relative to that observed during a steady flow condition. Flow instabilities of several types have been observed or postulated for closed channel systems. Although the state of the art does not permit detailed theoretical analyses for each type of flow instability, the available information on boiling systems indicates that flow instabilities will not adversely affect thermal margin of Combustion Engineering PWRs during normal operation or anticipated operational occurrences. Flow instabilities which have been observed have occurred almost exclusively in closed channel systems operating at pressures low relative to PWR operating pressures. As shown by the tests discussed in Section 4.4.3.10, the resistance to coolant crossflow among channels of a Combustion Engineering PWR fuel assembly is extremely small. It would be expected that the low resistance to crossflow between adjacent channels would have a stabilizing effect, and that expectation is confirmed by the results of Veziroglu and Lee (Reference 153), who found that flow stability in parallel heated channels was enhanced by having cross connections between the channels. Increasing pressure has been found to have a stabilizing influence in many cases where flow instabilities have been observed (Reference 50) and the high operating pressure characteristic of PWRs tends to minimize the potential for flow instability. Kao, Morgan, and Parker (Reference 93) who conducted flow stability experiments at pressures up to 2,200 psia with closed parallel heated channels, found that no flow oscillations could be induced at pressures above 1,200 psia for flow and power levels encountered in power reactors. Additional evidence that flow instabilities will not adversely affect thermal margin is provided by the data from the rod bundle DNB tests conducted by Combustion Engineering. (Refer to Section 4.4.4.2.) Many rod bundles have been tested over wide ranges of operating conditions with no evidence of premature DNB or of inconsistent data which might be indicative of flow instabilities in the rod bundle.

In summary, it is concluded that flow instabilities will not adversely affect thermal margin of Combustion Engineering PWR cores during normal operation and anticipated operational occurrences.

4.4.3.6 Temperature Transient Effects Analysis

A. Waterlogged fuel: The potential for a fuel rod to become waterlogged during normal operation is discussed in Section 4.2.1.3.4. In the event that a fuel rod does become waterlogged at low or zero power, it is possible that a subsequent power increase could cause a buildup of hydrostatic pressure to a level sufficient to yield the cladding, possibly causing the cladding to rupture. Such a condition requires that the defect which permitted initial waterlogging be so small that the pressure buildup is not relieved during the transient.

   Tests which have been conducted using intentionally waterlogged fuel pins (capsule drive core at SPERT) (References 141, 142) showed that the resulting failures did eject some fuel material from the rod and greatly deformed the test specimens. However, these test rods were completely sealed, and the transient rates used were several orders of magnitude greater than those allowed in normal operation.

   In those instances where waterlogged fuel rods have been observed in commercial reactors, it has not been clear that waterlogging was the cause, and not just the result, of associated cladding failures; and Combustion Engineering has not observed and is

not aware of any case in which material was expelled from waterlogged fuel rods or in which the fuel cladding was significantly deformed in a normal power reactor as a result of waterlogged fuel rods. It is therefore concluded that the effect of normal power transients on naturally waterlogged fuel rods will not be to produce the sort of postulated burst failures which could expel fuel material or damage adjacent fuel rods or fuel assembly structural components.

B. Intact fuel, but with high internal pressure: As noted in Section 4.2.1.3.13, the maximum fuel rod internal pressure in the peak power pin (highest energy output) is predicted to be less than the no-clad-lift-off (NCLO), as required by Reference 173, at all times. This methodology allows fuel rod pressures in excess of system pressures. Therefore, it is concluded that the presence of a substantial internal fuel rod pressure, such as is predicted for the Arkansas Nuclear One - Unit 2 fuel rods at End of Life (EOL), will not have an adverse effect on the fuel rods' performance during transients.

4.4.3.7 <u>Potentially Damaging Temperature Effects During Transients</u>

The thermal effects of anticipated operational occurrences on fuel rod and fuel assembly integrity may be divided into two categories: those which occur within and affect only a single fuel rod, and those which concern the interaction between the fuel rods and the fuel assembly frame (grids, end fittings, etc.) and between the fuel assemblies and the reactor vessel internals. These two categories are discussed in the following paragraphs.

A. Fuel rod thermal transient effects are basically manifested as the change in internal pressure, the changes in clad thermal gradient and thermal stresses, and the relative differential thermal expansion between pellets and clad.

   The first two of these effects are discussed in Section 4.4.3.6, and the third is covered in Section 4.2.1.3.7.

   Another possible effect of transients would be to cause an axial expansion of the pellet column against a flattened (collapsed) section of the clad. However, the Arkansas Nuclear One - Unit 2 fuel rod design includes specific provisions to prevent clad flattening, and, therefore, such interactions will not occur.

B. Thermal transient effects which involve the interaction of fuel rods, fuel assembly structure, and reactor internals include the differential thermal expansion between the fuel rods and the CEA guide tubes (longitudinal structural members in the fuel assembly frame) and the differential thermal expansion between the fuel assembly structure (Zircaloy) and the core barrel (stainless steel).

   The temperature of each end fitting is considered to be uniform and equal to the temperature of the coolant flowing through it. Because there is no connection between the end fittings and the fuel rods, the temperature of the end fittings has no direct effect on the interactions of fuel rods and assembly.

   The axial interaction between fuel rods and fuel assembly structure does not present a problem because:

   1. The fuel rods and fuel assembly are all Zircaloy-4, ZIRLO™, or Optimized ZIRLO™ and have only very small differential expansion;

2. The resistance force imparted by the fuel rod support grids is quite small in relation to the critical buckling load for the fuel tubes, and

3. The fuel assembly design includes sufficient axial clearance to accommodate both the peak differential thermal expansion and the maximum predicted axial fuel rod growth, thus precluding hard contact between the fuel rods and the fuel assembly upper end fittings.

The axial interaction between the fuel assembly structure and the reactor vessel internals is considered because, although the stainless steel internals expand thermally more than the fuel assembly, the fuel assembly is subject to irradiation induced growth. Therefore, if the fuel assembly grows excessively during hot operation, there is a possibility of axial interference between fuel assembly and reactor internals when the reactor is shut down.

In the Unit 2 design, interaction of this type is prevented by allowing sufficient clearance to accommodate the maximum predicted fuel assembly structure axial growth.

4.4.3.8 Energy Release During Fuel Element Burnout

The RPS provides fuel clad protection so that the probability of fuel element burnout during normal operation and anticipated operational occurrences is extremely low. Thus, the potential for fuel element burnout is restricted to low probability of occurrence events. The LOCA is the limiting event since it results in the larger number of fuel rods experiencing burnout. Thus, the LOCA analysis, which is very conservative in predicting fuel element burnout, provides an upper limit for evaluating the consequences of burnout. The LOCA analysis explicitly accounts for the additional heat released due to the chemical reaction between the Zircaloy, ZIRLO™, or Optimized ZIRLO™ clad and the coolant following fuel element burnout in evaluating the consequences of this accident.

4.4.3.9 Energy Release on Rupture of Waterlogged Fuel Elements

A discussion of the potential for waterlogging fuel rods and for subsequent energy release is presented in Sections 4.2.1.3.4 and 4.4.3.6.

4.4.3.10 Fuel Rod Behavior Effects from Coolant Flow Blockage

An experimental and analytical program was conducted to determine the effects of fuel assembly coolant flow maldistribution during normal reactor operation. In the experimental phase, velocity and static pressure measurements were made in cold, flowing water in an oversize model of a Combustion Engineering 14 x 14 fuel assembly in order to determine the three-dimensional flow distributions in the vicinity of several types of flow obstruction. The effects of the distributions on thermal behavior were evaluated, where necessary, with the use of a preliminary version of the TORC thermal and hydraulic code (Reference 37). Subjects investigated included:

A. The assembly inlet flow maldistribution caused by blockage of a core support plate flow hole. Evaluation of the flow recovery data indicated that even the complete blockage of a core support plate flow hole would not produce a W-3 DNBR of less than 1.0 even though the reactor might be operating at a power sufficient to produce a DNBR of 1.3 without the blockage; and,

B. The flow maldistribution within the assembly caused by complete blockage of one to nine channels. Flow distributions were measured at positions upstream and downstream of a blockage of one to nine channels. The influence of the blockage diminished very rapidly in the upstream direction. Analysis of the data for a single channel blockage indicated that such a blockage would not produce a W-3 DNBR of less than 1.0 downstream of the blockage even though the reactor might be operating at a power sufficient to produce a DNBR of 1.3 without the blockage.

Although the results quoted above are for the 14 x 14 assembly, those results are considered to represent satisfactorily the effects of similar blockages in the 16 x 16 assembly, particularly since the larger axial flow resistance of the 16 x 16 assembly will lead to a more rapid flow recovery.

4.4.4 TESTING AND VERIFICATION

4.4.4.1 Introduction

This section describes several Combustion Engineering testing and verification programs which yield thermal and hydraulic information germane to Combustion reactors. These are DNB tests, components tests, turbulence interchange measurements, and reactor testing and verification. Two other programs, reactor flow model tests, and fuel assembly flow distribution tests, are discussed in Sections 4.4.3.1 and 4.4.3.10, respectively.

4.4.4.2 DNB Testing

The margin to critical heat flux (CHF) or DNB is expressed in terms of the DNBR. The DNBR is defined as the ratio of the heat flux required to produce DNB at the calculated local coolant conditions to the actual heat flux.

The CE-1 correlation (Reference 16) was used with the TORC and the CETOP computer codes (References 37 and 38) to determine DNBR values for normal operation and anticipated operational occurrences. The CE-1 correlation was used in conjunction with the TORC code specifically for DNB margin predictions for fuel assemblies with standard spacer grids similar to those in Arkansas Nuclear One - Unit 2. Topical Reports CENPD-162 and CENPD-207 (Reference 16) provide detailed information on the CE-1 correlation and source data and also provide comparisons with other data and correlations. In brief, the correlation is based on data from tests conducted for C-E at the Chemical Engineering Research Laboratories of Columbia University. Those tests used electrically-heated 5 x 5 array rod bundles corresponding dimensionally to a portion of a 16 x 16 or 14 x 14 assembly with standard spacer grids. The test programs conducted for the 16 x 16 and 14 x 14 assembly geometries each included tests to determine the effects on DNB of the CEA guide tube, bundle heated length, axial grid spacing, and lateral and axial power distributions.

The uniform axial power CE-1 correlation (Reference 16) was developed from DNB data for six test sections with the following characteristics:

Fuel Assembly Geometry	No. Heated Rods	Lateral Power Distribution	Heated Length (ft)	Axial Grid Spacing (in)
16 x 16	25	Uniform	7	16.0
16 x 16	21	NonUniform	7	18.3
16 x 16	21	NonUniform	12.5	17.4
14 x 14	25	Uniform	7	14.3
14 x 14	21	NonUniform	7	14.3
14 x 14	21	NonUniform	12.5	14.3

Local coolant conditions at the DNB location were determined by using the TORC code in a manner consistent with the use of the code for reactor thermal margin calculations. The uniform axial power CE-1 correlation was developed from 731 DNB data for the following parameter ranges:

Pressure	1785 to 2415 psia
Inlet Temperature	382 to 644 °F
Heat flux	0.213×10^6 to 0.952×10^6 Btu/hr-ft^2
Local coolant quality	-0.16 to 0.20
Local mass velocity	0.87×10^6 to 3.21×10^6 lb/hr-ft^2

The uniform axial power CE-1 correlation predicted the 731 source data with a mean and standard deviation of the ratio of measured and predicted DNB heat fluxes of 1.000 and 0.068, respectively. However, the NRC has approved the use of 1.19 minimum DNBR for the 16 x 16 assembly based on a subset of the 731 source data as reported in CENPD-207 (Reference 16). The validity of the CE-1 correlation for predicting DNB for 16 x 16 fuel assemblies was further verified by the analysis of data obtained by repeating one of the tests for the 16 x 16 assembly geometry at the Winfrith Laboratory of the UKAEA.

For nonuniform axial power distributions, the uniform axial power CE-1 correlation is modified by the F-factor (Reference 151). The conservatism of that method of predicting DNB for 16 x 16 fuel assemblies with nonuniform axial flux shapes is demonstrated in CENPD-207 (Reference 16) which presents measured and predicted DNB heat fluxes for a series of tests using nonuniform axial power rod bundles representative of 16 x 16 or 14 x 14 fuel assemblies with standard spacer grids. Those test sections had the following characteristics:

Fuel Assembly Geometry	No. Heated Rods	Lateral Power Distribution	Axial Power Distribution	Heated Length (ft)	Axial Grid Spacing (in)
16 x 16	21	Nonuniform	1.46 symmetric	12.5	14.2
16 x 16	21	Nonuniform	1.47 top peak	12.5	14.2
14 x 14	21	Uniform	1.68 top peak	12.5	17.4
14 x 14	21	Nonuniform	1.68 bottom peak	12.5	17.4

The DNB data from those tests were evaluated using the CE-1 correlation modified by the F-factor and the TORC code used in a manner consistent with the use of the code for reactor calculations. That evaluation included DNB data within the following parameter ranges:

Pressure	1745 to 2425 psia
Inlet Temperature	333 to 631 °F
Local coolant quality	-0.27 to 0.20
Local mass velocity	0.81×10^6 to 3.07×10^6 lb/hr-ft^2

It was found that the mean and standard deviation of the ratio of measured and predicted DNB heat fluxes were 1.229 and 0.125, respectively, for the 369 DNB data within the parameter ranges mentioned above.

Testing was also conducted with rod bundles representative of the 16 x 16 fuel assembly to determine the effect on DNB of local perturbations in heat flux. Results are presented in CENPD-207 (Reference 16) for two nonuniform axial power rod bundles which were similar

except that one test bundle had a heat flux spike (23% higher heat flux for a 4-inch length) at the location where DNB was anticipated. The results show that there is no significant adverse effect on DNB due to that flux spike. Therefore, it is concluded that no allowance is required for the effect on DNB of local heat flux perturbations less severe than that tested.

One important factor in the prediction of DNB and local coolant conditions is the treatment of coolant mixing or turbulent interchange. The effect of turbulent interchange on enthalpy rise in the subchannels of 16 x 16 fuel assemblies with standard spacer grids is calculated in the TORC code by:

$$\hat{P}_e = \frac{\omega'}{\overline{G}\,\overline{D}_e}$$

where:

$\hat{P}_e$ = inverse Peclet number

ω' = turbulent interchange between adjacent subchannels, lb/hr-ft

$\overline{D}_e$ = average equivalent diameter of the adjacent subchannels, ft

$\overline{G}$ = average mass velocity of the adjacent subchannels, lb/hr-ft^2

The inverse Peclet number of 0.0035 for the 16 x 16 assembly with standard grids was verified with data obtained in the tests conducted at Columbia University (Reference 16) as described in Section 4.4.4.4.

The design basis requires that the minimum DNBR for normal operation and anticipated operational occurrences be chosen to provide a 95% probability at the 95% confidence level that DNB will not occur on a fuel rod having that minimum DNBR. Statistical evaluation of the CE-1 correlation (Reference 16) and relevant data shows that the appropriate minimum DNBR is 1.13. Based on review of CENPD-162 (Reference 16) the NRC requires use of a minimum DNBR of 1.19 with C-E standard grid fuel assemblies.

For the CE-1 correlation, this minimum DNBR has been increased to 1.25 to account for system parameter uncertainties as described in Section 4.4.2.3.2.

The ABB-NV correlation (Reference 193) may also be used with the TORC and CETOP computer codes (References 37 and 38) to determine DNBR values for normal operation and anticipated operational occurrences. Topical Report CENPD-387 (Reference 193) provides detailed information on the ABB-NV correlation, source data and comparisons with other correlations. With respect to non-mixing vane fuel, the ABB-NV correlation was developed as a new correlation form to incorporate the following improvements in the CE-1 correlation:

A. Special geometry effects for the grid, heated length, and guide tube to improve the fit and probability of the CHF data,

B. Optimization of the constants for the Tong F_C shape factor to the ABB-CE non-uniform CHF data, and

C. Use of the primary CHG indication from each test run vs. multiple CHF indications used in development of CE-1.

The CHF test data for ABB-NV were taken from the Columbia University Heat Transfer Research Facility between 1971 and 1977. The majority of CHF tests used in the correlation databases for ABB-NV are the same tests used to develop and support CE-1. Several tests were added to the CE-1 non-mixing vane database to support the special geometry terms for the correlation form and for validation of the correlation. The ABB-NV correlation does not supersede the CE-1 correlation. The CE-1 correlation may still be used if desired.

Statistical evaluation of the ABB-NV correlation (Reference 193) indicates a minimum DNBR limit of 1.13 will provide a 95 probability with 95 percent confidence of not experiencing CHF on a rod showing the limiting value. For the ABB-NV correlation, this minimum DNBR has been increased to 1.23 to account for system parameter uncertainties as described in Section 4.4.2.3.2.

The range of applicability for the ABB-NV correlation is as follows:

Pressure	1750 to 2415	psia
Local mass velocity	0.8×10^6 to 3.16×10^6	$lbm/hr\text{-}ft^2$
Local quality	-0.14 to 0.22	
Heated length, inlet to CHF location	48 to 150	in
Grid spacing	8 to 18.86	in
Heated hydraulic diameter ratio	0.679 to 1.08	Dhm/Dh

For NGF assemblies, the WSSV-T critical heat flux correlation (Reference 196) is used with the TORC and CETOP computer codes to predict DNBR. Reference 196 provides detailed information on the WSSV-T correlation along with the source data. The correlation was developed to:

A. Accurately reflect thermal performance of the NGF design with side supported mixing vane grids in CE PWRs with the 16 x 16 fuel lattice and multiple grid spacing.

B. Extend the quality range to be applicable to local quality higher than 30% in the hot channels.

The CHF test data for the WSSV-T correlation was taken from the Columbia University Heat Transfer Research Facility between 1993 and 2003. Data was taken on grids with side-supported vanes for 14 x 14 and 16 x 16 fuel geometries. Statistical evaluation of the WSSV-T correlation given in Reference 196 indicates a minimum DNBR limit of 1.12 will provide a 95 percent probability with 95 percent confidence of not experiencing critical heat flux on a rod showing the limiting value. For the WSSV-T correlation, this minimum DNBR has been increased to 1.23 to account for system parameter uncertainties as described in Section 4.4.2.3.2.

The range of applicability for the WSSV-T correlation is as follows:

Pressure	1,495 to 2,450	psia
Local mass velocity	0.90 to 3.46	Mlbm/hr-ft^2
Local coolant quality	< 0.34	
Heated length, HL	48* to 150	inches
Grid spacing	10.28 to 18.86	inches
Heated hydraulic diameter ratio	0.679 to 1.00	Dhm/Dh
Matrix heated hydraulic diameter (Dhm)	0.4635 to 0.5334	inches

* Set as minimum HL value, applied at all elevations below 48 inches.

4.4.4.3 Components Testing

Components test programs have been conducted in support of all Combustion Engineering reactors. The tests subject a full-scale reactor core module comprising one to four fuel assemblies. Some of the tests included a Control Rod Assembly (CRA) and extension shaft, Control Element Drive Mechanism (CEDM), and reactor vessel internals to reactor conditions of water chemistry, flow velocity, temperature, and pressure under the most adverse operating conditions allowed by the design. Two objectives of the programs are to confirm the basic hydraulic characteristics of the components' lifetime. When the reactor design or fuel assembly design is revised, a new program embodying the important aspects of the latest design is conducted. Thus, component tests have been run on the Palisades design, with cruciform control rods, on the Fort Calhoun design with CEAs and rack-and-pinion CEDMs and on the Maine Yankee and later designs, with dual CEAs and magnetic jack CEDMs.

During the course of the tests, information was obtained on fuel rod fretting, on CEA/CEDM trip behavior, and on fuel assembly uplift and pressure drop. For new fuel designs, the tests include fuel rod fretting, rod and assembly vibration data, and pressure drop data. The first two subjects are discussed in Section 4.2. The third is discussed below.

As part of the assessment of fuel assembly margin to uplift in the reactor, measurements are made of fuel assembly net weight, to the point of liftoff for an isothermal temperature range of 150 °F to 600 °F at a system pressure of 350 psi to 2,100 psi. To obtain the desired information, one of the fuel assemblies of the module is mounted on load beams so that the assembly net weight can be measured as a function of flow rate and temperature. Data reduction involves the calculation of an uplift coefficient, describing the hydraulic uplift force acting on the assembly; the coefficient is defined as follows:

$$K_{up} = [Wo]/[\rho V^2 A/2g_c]$$

where

Wo = Wet weight of assembly with no flow, lb

V = Flow velocity in assembly at the point of liftoff, ft/sec

A = Envelope area of assembly, ft^2

ρ = Water density, lb/ft^3

A plot of the Kup data shows that they can be fitted by the relation:

$$K_{up} = \alpha a \, R_e^{-\beta}$$

where αa and β are peculiar to the particular components tests being run and R_e is the Reynolds Number, and where the standard error of estimate for the latest test is 3.7 percent, including replication and instrument error. An analytical control volume model is used to evaluate new fuel designs where the model has been confirmed to be valid based on test data or previous fuel designs.

The uplift coefficient and its associated uncertainty are employed in the analysis of the uplift forces on the fuel assemblies in the reactor. The force is determined for the most adverse assembly location for startup and normal operating conditions. Additional input to the calculation includes analytical corrections to the coefficient for the absence of the CEA, for crud formation, and for small geometrical differences among the fuel assemblies for the different reactor designs all nominally describable by the same components test.

Pressure drop measurements are also made during components test programs to verify the accuracy of the calculated loss coefficients for various fuel assembly components. Direct reduction of the pressure drop data yields the loss coefficients for the lower and upper end fitting region, while the spacer grid loss coefficient is evaluated by subtracting a calculated fuel rod friction loss from the measured pressure drop across the fuel rod region.

Experience has shown that the experimental end fitting loss coefficients are essentially independent of Reynolds Number and, with their sample standard deviations, are in reasonable agreement with the predicted values used in the calculation of core pressure drop (See Section 4.4.2.7). The experimental spacer grid loss coefficients are based upon experimental results from ANO-2/3410 fuel assembly components test programs.

4.4.4.4 Turbulent Interchange Testing

In 1966, a series of single-phase tests on coolant mixing through turbulent interchange was run on a "prototype" fuel assembly which was geometrically similar to the Palisades assembly. The model enabled determination of vertical channel flow rates using pressure instrumentation and the average level of turbulent interchange using dye injection and sampling equipment.

The tests yielded the value of Inverse Peclet Number characteristic of turbulent interchange in the prototype geometry. The Inverse Peclet Number is a dimensionless parameter defined by the relation:

$$\hat{P}_e = \frac{\hat{\omega}}{\overline{G}\,\overline{D}_e}$$

where

$\hat{\omega}$ = Turbulent interchange between channels, lb/hr-ft

$\overline{D}_e$ = Average equivalent diameter of two neighbor channels between which turbulent interchange occurs, ft.

$\overline{G}$ = Average mass velocity of two neighbor channels, lb/hr-ft²

In the test geometry, the value of $\hat{P}_e$ was found to be 0.00366, with a sample standard deviation of 16 percent. The value was shown during the course of the tests to be insensitive to coolant temperature and mass velocity. The best estimate value of the Inverse Peclet Number was established at 0.0035 on the basis of the experimental results. The value used in Combustion Engineering thermal and hydraulic calculations is that best estimate value.

As part of a Combustion Engineering sponsored research and development program, a new series of single-phase dye injection mixing tests was conducted in 1968. The tests were performed on a model of a portion of a CEA-type fuel assembly which was sufficiently instrumented to enable measurement (via a data reduction computer program) of the individual lateral flow across the boundaries of 12 channels of the model. The Inverse Peclet Number calculated from the average of 56 individual turbulent interchange flow values (two across each channel boundary) was 0.0034. With respect to general turbulent interchange, therefore, the more recent study on the CEA verifies the constancy of the Inverse Peclet Number for moderately different fuel assembly geometries and confirms the design value of that characteristic.

Verification of the Inverse Peclet Number of 0.0035 for the 16x16 assembly was obtained from data taken as part of the DNB test programs at Columbia University (See Section 4.4.4.2). Figure 4.4-13 shows measured and predicted subchannel coolant temperature rise values for some experiments conducted with an electrically-heated rod bundle representative of the 16x16 assembly. The test section used was a 5x5 array rod bundle with 25 heated rods, a heated length of seven feet, uniform axial and lateral power distributions, and Combustion Engineering standard spacer grids at 14.3-inch axial spacing. (See Reference 16 for additional detail on the test section and test procedure.) The subchannel coolant temperature rise values were determined from coolant temperature measurements made with thermocouples located in the individual subchannels at the downstream end of the heated length. Subchannel coolant temperature measurements made with thermocouples located in the individual subchannels at the downstream end of the heated length. Subchannel coolant temperature rise predictions were made using the TORC subchannel analysis code and an Inverse Peclet Number of 0.0035. For clarity, the results for subchannels similar by symmetry were averaged for each experiment. Figure 4.4-13 shows results for four experiments, two with highly subcooled coolant at the bundle outlet (no subcooled boiling predicted) and two with slightly subcooled coolant at the outlet (substantial subcooled boiling predicted). The good agreement of the measured and predicted subchannel coolant temperature rise values provides confirmation of the Inverse Peclet Number of 0.0035 for the 16x16 assembly with standard spacer grids. Similar tests have shown that the Inverse Peclet Number of 0.0035 is also applicable to the NGF 16 x 16 assembly with the side supported vane.

4.4.4.5 Reactor Testing

During reactor startup, data descriptive of thermal and hydraulic conditions within the reactor vessel were obtained. These included core exit temperature distribution, hot and cold leg temperature, loop flow rates, and core power distributions. The data was evaluated and compared with design calculations and parameters to assure that the reactor thermal and hydraulic behavior was as predicted.

4.4.5 INSTRUMENTATION REQUIREMENTS

The in-core instrumentation system will be used to confirm core power and temperature distributions, perform periodic calibrations of the ex-core flux measurement system, and provide inputs to the Core Operating Limit Supervisory System (COLSS). Further descriptions are contained in Section 7.6.

4.5 STARTUP PROGRAM

The planned startup test program associated with core performance is outlined below. These tests verify that core performance is within the assumptions of the safety analysis and provide information for continued safe operation of the unit. Some of the tests also provide the data needed for adjustment of addressable constants in the CPCS and COLSS.

4.5.1 PRECRITICAL TEST

4.5.1.1 Control Element Assembly (CEA) Drop Time Test

Precritical Control Element Assembly drop times are recorded for all CEAs (81) at hot full flow conditions before low power physics testing begins. Acceptance criteria state that the average CEA drop time from fully withdrawn to 90% inserted shall be less than or equal to 3.2 seconds at the stated conditions and that the individual CEA drop time from fully withdrawn to 90% inserted shall be less than or equal to 3.7 seconds at the stated conditions.

4.5.2 LOW POWER PHYSICS TEST

The following describes a test program conducted using traditional techniques (i.e., utilizing a reactimeter). A reduced scope of physics testing may be performed as described in Topical Report WCAP-16011-P-A, “Startup Test Activity Reduction Program,” commonly referred to as the STAR program. Within the limits of Technical Specification surveillance requirements, the STAR program may be used in place of traditional techniques. The intent of testing under the STAR program is to ensure that the core can be operated as designed, while employing normal operating procedures in the startup evolution (i.e., elimination of reactimeter measurements).

4.5.2.1 Critical Boron Concentration

Initial criticality can be achieved by either dilution or by pulling rods. Typically with control rods inserted, the RCS is deborated to an estimated critical boron concentration based on predictions and desired control rod configurations. The control rods are then withdrawn in sequential order to achieve criticality. The critical boron concentration is calculated by correcting the actual boron concentration for any deviation of CEA position from the reference CEA position for the predicted critical boron concentration and by correcting for any deviation of temperature from the reference temperature. Acceptance criteria state that the critical boron concentration shall be within 100 ppm of the predicted value.

4.5.2.2 CEA Reactivity Worth

CEA worths will be measured using the CEA Exchange technique. This technique consists of measuring the worth of a "Reference Group" via standard boration/dilution techniques, then exchanging this group with other groups to measure their worths. The groups to be measured by exchange will be "assigned" to a specific test group, depending on their predicted worths. This measurement technique provides verification that individual group CEA reactivities are within the engineering design safety analysis prediction for all CEA groups. Acceptance criteria state that the measured reference group worth shall be within $\pm$10% of the predicted value, the measured individual group worths shall be within $\pm$ 15% or $\pm$ 0.1% $\Delta k/k$ (whichever is larger) of the predicted values, and the total worth of all the groups shall be within $\pm$ 10% of the predicted value.

4.5.2.3 Temperature Reactivity Coefficient

The isothermal temperature coefficient (ITC) is measured at approximately the all CEA withdrawn configuration. The average coolant temperature is varied by decreasing and increasing temperature. During the change in temperature, reactivity feedback is compensated for by discrete CEA motion; change in reactivity is then calculated by the summation of reactivity associated with the temperature change. Acceptance criteria state that the measured value shall not differ from the predicted value by more than $\pm$ 0.3 x 10^{-4} $\Delta\rho$/°F.

The moderator temperature coefficient (MTC) of reactivity is calculated in conjunction with the isothermal temperature coefficient measurement. After the ITC has been measured, a predicted value of fuel temperature coefficient of reactivity is subtracted to obtain the moderator temperature coefficient. The moderator temperature coefficient value must be less positive than the upper COLR MTC curve and less negative than - 3.8 x 10^{-4} $\Delta\rho$/°F.

Criteria have been established that allow the near two thirds of expected core burnup MTC surveillance (at power) to be eliminated (see TS surveillance 4.1.1.4.2.c). This surveillance may be eliminated providing the inferred and predicted MTC values at earlier surveillance intervals (see TS surveillance 4.1.1.4.2.a and 4.1.1.4.2.b) are within a tolerance of 0.16 x 10^{-4} Δk/k/°F. Inferred and predicted MTC values that are within this tolerance provide assurance that the MTC will be maintained within acceptable values throughout the remainder of the fuel cycle. CE NPSD 911-A, "Analysis of Moderator Temperature Coefficients in Support of a Change in the Technical Specifications End of Cycle Negative MTC Limits", with Amendment 1-A, provide the basis for the above tolerance. The option to eliminate the near two thirds of expected core burnup MTC measurement also requires that the reload analysis and predicted MTC calculation be performed using the CE methodology.

4.5.3 POWER ASCENSION TESTS

Following completion of the Low Power Physics Test sequence, reactor power will be increased in accordance with the power ascension controlling procedure. The power ascension will be monitored by an off-line NSSS performance and data processing computer algorithm. This computer code will be periodically executed in parallel with the power ascension to monitor CPC and COLSS performance relative to the processed plant data against which they are normally calibrated. If necessary, the power ascension will be suspended while necessary data reduction and equipment calibrations are performed. Thus, the monitoring algorithm ensures conservative CPC and COLSS operation while optimizing overall efficiency of the test program.

4.5.3.1 Reactor Coolant Flow

Reactor coolant flow will be measured by either calorimetric calculation or using reactor coolant pump differential pressure instrumentation (COLSS) at steady state conditions in accordance with Technical Specifications. Acceptance criteria will require that the measured flow be within allowable limits and that the CPCS reactor coolant flow rate is within calibration requirements relative to measured flow.

4.5.3.2 Core Power Distribution

Core power distribution data using fixed in-core neutron detectors is used to verify proper core fuel loading and consistency between the as-built and engineering design models. This is accomplished using measurement data from three power plateaus.

The first power distribution measurement is performed after the turbine is synchronized and prior to exceeding 30% of rated power. The objective of this measurement is primarily to identify any fuel misloading that results in power asymmetries or deviations from the reactor physics design. Because of the decreased signal-to-noise ratio at low powers and the absence of xenon stability requirements, radial and azimuthal symmetry criteria are emphasized, whereas pointwise absolute and statistical acceptance criteria are relaxed.

At the intermediate power plateau (40% - 70% power), a core power distribution analysis is performed to again verify proper fuel loading and consistency with design predictions. The intermediate power acceptance criteria ensure that the power distribution is consistent with predictions and that reactor power may be increased to 100% and remain within the design limits.

The final power distribution comparison is performed with equilibrium xenon at approximately 100% power. At this plateau, axial and radial power distributions are compared to design predictions as a final verification that the core is operating in a manner consistent with its design within the associated design uncertainties.

For the first power distribution measurement, the measured results are compared to the predicted values in the following manner:

1) The measured and predicted relative power density (RPD) shall agree within ± 10% for each assembly with a predicted RPD ≥ 0.9 and within 0.1 RPD units for each assembly with a predicted RPD < 0.9.

2) The power in each operable symmetric detector shall be within ± 10% of the average power in its symmetric detector group.

3) The vector tilt shall be less than 3%.

The measured results are compared to predicted values in the following manner for the intermediate and full power distribution analyses:

1) The measured radial power distribution is compared to the predicted power distribution by calculating the root mean squared deviation from predictions of the relative radial power density distribution for each of the 177 fuel assemblies. This RMS error may not exceed 5%.

2) The measured radial power distribution is additionally compared to the predicted power distribution using a box-by-box comparison of the relative radial power density for each of the 177 fuel assemblies. The acceptance criteria state that, for each assembly with a predicted relative power density ≥ 0.9, the measured and predicted relative power density values must agree within ± 10%, and for each assembly with a predicted relative power density below 0.9, the measured and predicted relative power density values must agree within ± 15%.

3) The measured axial power distribution is also compared to the predicted power distribution. The acceptance criteria state that the RMS error between the measured axial power distribution and the predicted axial power distribution shall not exceed 5%.

4) The measured values of total planar radial peaking factor (Fxy), total integrated radial peaking factor (Fr), core average axial peak (Fz), and 3-D power peak (Fq) are compared to predicted values. The acceptance criteria state that the measured values of Fxy, Fr, and Fz shall be within ± 10% of the predicted values and that COLSS and CPC constants shall be adjusted to appropriately reflect the measured values.

4.5.3.3 Shape Annealing Matrix (SAM) and Boundary Point Power Correlation Coefficients (BPPCC)

The values for SAM and BPPCC constants can either be determined by measurement or by verification of Cycle Independent SAM (CISAM) values. Either approach is used during power ascension testing.

The SAM and BPPCC values are determined from a linear regression analysis of the measured ex-core detector readings and the corresponding core power distribution determined from the in-core detector signals. The spectrum of axial shapes encountered during the power ascension will be used for the calculation of the matrix elements. In-core, ex-core, and related data are recorded, and analysis is performed using the CECOR code. This provides the necessary power distribution ex-core detector data to perform the least squares fitting. The data are processed and compiled by the off-line NSSS performance and data processing algorithm.

Appropriate CPC constants are modified, if needed, based upon the results of the measurements. The CISAM and BPPCC values are verified in a similar manner as the SAM and BPPCC values are determined. The same data are collected and the same computer codes are used. A new SAM is determined if the installed CISAM is determined to be unacceptable as a result of the verification process.

4.5.3.4 Radial Peaking Factor (RPF) and CEA Shadowing Factor (RSF) Verification

The RPF for the "all CEA's out" (or ARO) configuration is calculated using in-core and ex-core detector data measured at steady state ARO conditions. Appropriate CPC and COLSS addressable constants are modified based upon the results of the measurement. Additional modification of the constants is made as needed, based upon the measurement results, to ensure conservatism in the applied peaking factors for CEA configurations not measured during the test.

The RSFs are not measured. The CPC database and addressable constants include allowances for using predicted CEA shadowing factors.

4.5.3.5 Temperature Reactivity Coefficient

During the ITC and the MTC measurement, turbine load is used to increase RCS average temperature, which decreases reactor power, and then to decrease RCS average temperature, which increases reactor power. This manipulation yields a ratio of RCS temperature change to reactor power change. Using a predicted power coefficient with the measured average ratio, an ITC is inferred. Using a predicted fuel temperature coefficient with the inferred ITC yields an MTC. The difference between the predicted and inferred ITC shall be less than 0.3×10^{-4} $\Delta\rho/°F$. The MTC shall be less negative than $- 3.8 \times 10^{-4}$ $\Delta\rho/°F$ but less positive than the upper COLR MTC curve.

Criteria have been established that allow the near two thirds of expected core burnup MTC surveillance (at power) to be eliminated (see TS surveillance 4.1.1.4.2.c). This surveillance may be eliminated providing the inferred and predicted MTC values at earlier surveillance intervals (see TS surveillance 4.1.1.4.2.a and 4.1.1.4.2.b) are within a tolerance of 0.16 x 10^{-4} Δk/k/°F. Inferred and predicted MTC values that are within this tolerance provide assurance that the MTC will be maintained within acceptable values throughout the remainder of the fuel cycle. CE NPSD 911-A, “Analysis of Moderator Temperature Coefficients in Support of a Change in the Technical Specifications End of Cycle Negative MTC Limits”, with Amendment 1-A, provide the basis for the above tolerance. The option to eliminate the near two thirds of expected core burnup MTC measurement also requires that the reload analysis and predicted MTC calculation be performed using the CE methodology.

4.5.3.6 <u>HZP to HFP Reactivity Difference</u>

When STAR program techniques are applied to the startup test program (see Section 4.5.2), the change in critical boron concentration (determined using chemical analysis) between hot zero power and hot full power will be determined. Acceptance criteria state that the difference between measured and predicted boron concentration shall be within 50 ppm.

4.5.4 PROCEDURE IF ACCEPTANCE CRITERIA ARE NOT MET

If the acceptance criteria for any test are not met, an evaluation is performed before the test program is continued. The results of all tests will be reviewed by the plant's reactor engineering group. If acceptance criteria are not met, an evaluation will be performed by the plant's reactor engineering group with assistance from on-site and off-site nuclear engineering personnel and the fuel vendor. The results of this evaluation will be presented to the On-Site Safety Review Committee. Resolution will be required prior to power escalation.

If the BOC MTC measurements are not within the 0.16 x 10^{-4} Δk/k/°F tolerance described in Sections 4.5.2.3 and 4.5.3.5 and the discrepancy cannot be resolved, the EOC MTC surveillance must be performed.

In the event that STAR program test results fall outside of test criteria, the safety analysis and STAR program applicability requirements will be shown to remain satisfied or application of the STAR program to the current fuel cycle will be discontinued.

Table 4.2-3A

**FUEL ROD CLADDING TEMPERATURE
DURING NORMAL AND ANTICIPATED OPERATIONAL OCCURRENCES
ORIGINAL DESIGN VALUES**

Occurrence	Maximum Cladding Midwall Temperature
Normal Operation	[ ]†
Uncontrolled CEA Withdrawal	
a. Subcritical conditions	[ ]†
b. 1% power	≤ normal operation temp.*
c. Full power	[ ]†
CEA Drop	≤ normal operation
Four Pump Loss of Flow	≤ normal operation
Idle Loop Startup	≤ normal operation
Loss of External Load	[ ]†
Loss of Feedwater	≤ normal operation
Loss of Offsite Power	≤ normal operation
Excess Heat Removal	
a. Feedwater malfunction	[ ]†
b. Steam bypass malfunction	[ ]†

* Maximum calculated temperature was less than the maximum predicted for normal operation.

† See ANO-2 Proprietary Information letter submittal for actual values.

Table 4.2-4

STRESS LIMITS FOR REACTOR VESSEL INTERNAL STRUCTURES

Operating Conditions	Stress Categories & Limits of Stress Intensities
1. Normal plus Upset	Figure NG 3221.1 including notes.
2. Emergency	Figure NG 3224.1 including notes.
3. Faulted	Appendix F, "Rules for Evaluating Faulted Conditions," Section F-1380 and Table F-1322 including notes.

The above listed stress categories and limits for Normal plus Upset, and the Emergency operating conditions are defined in the March, 1973, draft of Subsection NG of the ASME Code, Section III.

Table 4.2-4A

REACTOR INTERNALS HOLDDOWN RING NET DOWN LOADS
(Historical Information)

	Design Best Flow (10^3 gpm)	Estimate Flow	Active Fuel Length (in.)	No. Fuel Ass.	Holdown Ring Load (10^3 lbs.)	Total* Down Load (10^3 lbs.)	Max. Assumed Flow	Hydraulic Lift (10^3 lbs)	Net Down** Load (10^3 lbs.)
Omaha	190	108%	128.0	133	453	799	115%	284	515
Maine Yankee	325	120%	136.7	217	508	1085	126%	555	530
Calvert Cliffs	324	124%	136.7	217	547	1049	125%	525	524
ANO-2	322	113%	150.0	177	828	1329	120%	805	524

* Comprises the weight of the reactor vessel internals plus fuel.

**Net Down Load = Total Down Load - Hydraulic Lift

Table 4.2-5

STRESS LIMITS FOR PRESSURE HOUSINGS

Loading Conditions and Categories	Stress Categories & Limits of Stress Intensities(*)
1. Normal & Upset: Normal Operating Loading plus Operating Basis Earthquake Forces	Figures NB-322-1 and 3222-1 including notes.
2. Emergency: Normal Operating Loadings plus Design Basis Earthquake Forces	Figure NB-3224-1 including notes.
3. Faulted: Operating Loadings plus Design Basis Earthquake Forces plus Pipe Rupture Loadings	Table F-1322.1-1, Appendix F, "Rules for Evaluating Faulted Conditions".

For the above listed conditions and categories, the following limits regarding function apply:

1. Normal and Upset:	The CEDMs are designed to function normally during and after exposure to these conditions.
2. Emergency:	The CEDMs are designed to permit tripping of the CEAs during and after exposure to these conditions.
3. Faulted:	The deflections of the CEDM are limited so that the CEAs can be inserted after exposure to these conditions. Those deflections which could influence the ability to move CEAs are limited to less than 80 percent of the deflections required to prevent CEA movement.

(*) References listed are taken from the ASME Code, Section III.

Table 4.3-1

NUCLEAR DESIGN CHARACTERISTICS

General Characteristics	
Fuel Management	3-batch
Maximum Fuel Rod Burnup	58,726*MWD/T (includes a +750 MWD/T uncertainty)
Number of Control Element Assemblies	
Full Length	81
Burnable Poison Rods	
Number/Material	8000 / Zr_2B_2 – UO_2
Dissolved Boron	
Dissolved Boron Concentration for Criticality, ppm, (CEAs withdrawn, BOC) Hot Full Power, Equilibrium Xe	1446*
Dissolved Boron Content (ppm) for: Refueling	2,500
Inverse Boron Worth, ppm/%$\Delta\rho$	
HFP, BOC	127*
HFP, EOC	93*
Neutron Parameters*	
Neutron Lifetime (minimum), Microseconds	
BOC	13.0*
EOC	36.0*
Delayed Neutron Fraction	
BOC	0.0064*
EOC	0.0052*

* These values vary slightly with core and fuel batch designs.

Table 4.3-2

EFFECTIVE MULTIPLICATION FACTORS AND REACTIVITY DATA
(All data are Cycle 1 values; values vary with cycle)

(No Control Element Assemblies or Dissolved Boron[1])

	k_{eff}	ρ
Cold (68 °F)	1.227	0.185
Cold (68 °F) at Minimum Refueling Boron Concentration (2500 ppm)	0.906	-0.104
Hot, 545 °F, Zero Power	1.175	0.149
Hot, Full Power, Equilibrium Xe (For Depletion)	1.112	0.101
Reactivity Decrease, HFP Xe Zero to Full Power, BOC	___	0.011

Table 4.3-3

COMPARISON OF CORE REACTIVITY COEFFICIENTS WITH THOSE USED IN VARIOUS SAFETY ANALYSES

	MTC ($\Delta\rho/°F x10^{-4}$)	Doppler[1] Coefficient	Density Coefficient ($\Delta\rho$/gm/cc)
Full Power, ARO			
BOC	-0.437	Fig. 4.3-24	N/A[3]
EOC	-3.732	Fig. 4.3-24	N/A[3]
Coefficients Used in Accident Analyses			
CEA Withdrawal[5] Full Zero Power	0.5 / +0.5	0.85	N/A
CEA Misoperation (Full length)[5]			
Misaligned CEA	-3.5	1.15	N/A
Dropped CEA	-3.5	1.15	N/A
Loss of Flow[5]	0.5	0.85	N/A
CEA Ejection[5]			
Full/Zero Power	0.5 / +0.5	.85 W_R / .85 W_R[2]	N/A
Loss of Coolant Accident	N/A[4]	1.15	-0.077

(1) Nominal values of the Doppler coefficient ($\Delta\rho$/°F) as a function of the fuel temperature are shown in Figure 4.3-24. The numbers entered in the Doppler column of this table are the multipliers applied to the nominal value for analysis of designated accident (See Note 5). The SBLOCA and LBLOCA analyses used the EOC data in Figure 15.1.0-4, which includes a 1.4 multiplier.

(2) W_R is a reactivity dependent factor, the origin of which is explained in Section 15.1.20.2.1.

(3) Not applicable.

(4) A Curve of Reactivity vs Moderator Density is used for the LOCA evaluation. The value of density coefficient shown here is the initial slope of this curve for the LBLOCA evaluation. SBLOCA used an initial slope of -0.007 $\Delta\rho$/gm/cc.

(5) Values may have varied for cycle specific analyses. See Chapter 15 accident analysis descriptions for more current information.

Table 4.3-4

REACTIVITY COEFFICIENTS

Moderator Temperature Coefficients	MTC $\Delta\rho/°F x 10^{-4}$

Pressure, psia	2250	2250
Coolant Inlet Temperature, °F	553.5	553
Vessel Outlet Temperature, °F	612	611
Core Bulk Outlet Temperature, °F	614	613
Total Primary Coolant Flow, Million lb/hr	120.4	147.8
External Leakage, %	3.5	3.7
Coolant Flow Through Core, Million lb/hr	116.2	142.6
Hydraulic Diameter Nominal Channel, ft.	.03928	0.04445
Core Flow Area, ft^2	44.7	53.2
Average Mass Velocity, Million lb/hr-ft^2	2.60	2.68
Average Coolant Velocity in Core, ft/sec	16.4	16.8
Core Average Heat Flux, Btu/hr-ft^2	185,000	205,000
Total Heat Transfer Area, ft^2	51,000	55,000
Film Coefficient at Average Conditions, Btu/hr-ft^2-°F	6200	6200
Average Film Temperature Difference,°F	31	34
Average Linear Heat Rate of Rod, kw/ft		
(For Fraction Generated Avg. Rod)	5.41	6.92
Specific Power, kw/kg	38.3	35.7
Power Density, kw/liter	96.6	94.7
Average Core Enthalpy Rise, Btu/lb	82.7	81.1
Heat Flux Factors		
Rod Radial Nuclear Factor	1.55	1.55
Nuclear Heat Flux Factor	1.03	1.03
Total Heat Flux Factor	2.35	2.60
Enthalpy Rise Factors		
Factors Affecting Heat Input:	1.53	1.5
Engineering Factor on Enthalpy Rise	1.03	1.03
Total Heat Input Enthalpy Rise Factor	1.57	1.545
Factors Affecting Flow:		
Plenum Factor	1.05	1.03
Rod Pitch, Bowing, and Clad Diameter	1.05	1.05

Table 4.4-1 (continued)

General Characteristics	ANO-2	San Onofre Units 2 & 3 Docket #50-361 & 362
Total Enthalpy Rise Flow Factor	1.10	1.08
Total Enthalpy Rise Factor	1.84	1.68
(ΔH Hot Channel/ΔH Core)	1.84	1.68
Enthalpy Rise Factors		
Factors Affecting Heat Input:	1.53	1.5
Engineering Factor on Enthalpy Rise	1.03	1.03
Total Heat Input Enthalpy Rise Factor	1.57	1.545
Factors Affecting Flow:		
Plenum Factor	1.05	1.03
Rod Pitch, Bowing, and Clad Diameter	1.05	1.05
Total Enthalpy Rise Flow Factor	1.10	1.08
Total Enthalpy Rise Factor	1.84	1.68
(ΔH Hot Channel/ΔH Core)	1.84	1.68
Hot Channel and Hot Spot Parameters		
Maximum Heat Flux, Btu/hr-ft2	433,800	533,000*
Maximum Linear Heat Rate of Rod, kw/ft (For fraction generated in Hot Rod)	12.7**	18.0
UO2 Temperature, Steady State, Maximum during Fuel Life, °F	3420	4010*
Maximum Clad Surface Temperature, °F	657.6	657*
Hot Channel Outlet Temperature, °F	652.6	646*
Hot Channel Outlet Enthalpy, Btu/lb	703.7	687*
DNB Ratio (W-3 Correlation), Steady State	2.14	2.11

* These parameters are revised as indicated in Supplement 1 to CENPD-46, "Analysis of Combustion Engineering 3410 Mwt Plant Emergency Core Cooling System Performance in Accordance with AEC Interim Acceptance Criteria," July 7, 1972

**To get the maximum linear heat rate of a rod apply the appropriate Augmentation factor for the particular axial power distribution.

Table 4.4-2

Arkansas Nuclear One Unit 2 Cycle 25
Thermal-Hydraulic Parameters at Full Power

General Characteristics	Units	Cycle 24 (NGF)	Cycle 25 (NGF)
Total Heat Output (Core Only)	Mw_{th}	3026	3026
	10^6 Btu/hr	10328	10328
Fraction of Heat Generated in Fuel Rod	---	0.9755	0.9755
Primary System Pressure (Nominal)	psia	2200	2200
Primary System Pressure (Minimum in Steady State)	psia	2000	2000
Primary System Pressure (Maximum in Steady State)	psia	2300	2300
Inlet Temperature (Maximum Indicated)	°F	554.7	554.7
Total Reactor Coolant Flow (Minimum Steady State)	gpm	315,560	315,560
	10^6 lbm/hr	117.7	117.7
Coolant Flow Through Core (Minimum)	10^6 lbm/hr	113.6	113.6
Hydraulic Diameter (Nominal Channel)	ft	0.041	0.041
Core Average Mass Velocity	10^6 lbm/hr-ft^2	2.46	2.46
Pressure Drop Across Core (at Minimum Steady State Core Flow Rate)	psi	21.0	21.0
Total Pressure Drop Across Vessel (Based on Nominal Dimensions and Minimum Steady State Flow)	psi	40.5	40.5
Core Average Heat Flux (Accounts for Fraction of Heat Generated in Fuel Rod and Axial Densification Factor)	Btu/hr-ft^2	197,405(1)	197,405(1)
Total Heat Transfer Area (Accounts for Axial Densification Factor)	ft^2	51023 (1)	51023 (1)
Film Coefficient at Average Conditions	Btu/hr-ft^2-°F	5997	5997
Average Film Temperature Difference	°F	32.92(1)	32.92(1)
Average Linear Heat Rate of Undensified Fuel Rod (Accounts for Fraction of Heat Generated in Fuel Rod)	kw/ft	5.65(1)	5.65(1)
Average Core Enthalpy Rise	Btu/lb	90.9	90.9
Maximum Clad Surface Temperature	°F	653.8(1)	653.8(1)
Engineering Heat Flux Factor	---	1.025(2),(3)	1.025(2),(3)
Engineering Factor on Hot Channel Heat Input	---	1.020(2),(3)	1.020(2),(3)
Rod Pitch, Bowing and Clad Diameter Factor	---	1.05(2),(3)	1.05(2),(3)
Fuel Densification Factor (Axial)	---	1.002	1.002

Notes:

(1) Based on 0 shims in the core.

(2) These factors have been combined statistically with other uncertainty factors at 95/95 confidence/probability level and included in the design limit on WSSV-T and ABB-NV minimum DNBR.

(3) These values are generic based on fuel design drawing tolerances and are also applicable to NGF.

Table 4.4-3

REACTOR COOLANT FLOW RATES IN BYPASS CHANNELS

Bypass	Percent of Total Vessel Flow Rate
Outlet Nozzle Clearances	0.4
Alignment Keyways	0.4
Support Cylinder Holes	0.3
Core Shroud Clearances	0.4
Guide Tubes	1.7
TOTAL BYPASS	3.2

Table 4.4-4

**REACTOR VESSEL ORIGINAL ESTIMATES
PRESSURE LOSSES AND COOLANT TEMPERATURES**

	Pressure Loss, psi	Temperature, °F
Inlet Nozzle and 90° Turn	4.3	553
Downcomer, Lower Plenum and Support Structure	8.9	553
Fuel Assembly	13.7	584
Fuel Assembly Outlet to Outlet Nozzle	7.1	614
	34.0	

Table 4.4-5

DESIGN STEADY STATE HYDRAULIC LOADS ON VESSEL INTERNALS*

Component	Load Description	Load Value
1. Core Support Barrel	Steady-state radial pressure differential directed inward opposite inlet duct	73 psi
2. Core Support Barrel and Upper Guide Structure	Steady-state uplift load	1,036,000 lb
3. Flow Skirt	Steady-state radial drag load, directed inward	3400 lb/ft of circumference, average; 7100 lb/ft maximum
4. Bottom Plate	Steady-state drag load directed upward	44,000 lb
5. Core Support Plate	Steady-state drag load directed upward	59,000 lb
6. Fuel Assembly	Steady-state uplift load	2500 lb
7. Core Shroud	Steady-state radial pressure differential directed outward	34 psi at bottom, zero psi at top
8. Upper Guide Structure	Steady-state load directed upward	401,000 lb
9. Fuel Alignment Plate	Steady-state drag load directed upward	109,000 lb
10. Upper Guide Plate	Steady-state load directed downward	47,500 lb
11. CEA Shrouds	Steady-state lateral drag load	4100 lb
12 CEA Shrouds	Steady-state radial pressure differential directed inward	12 psi

* Loads listed are at 500 °F, 120 percent design flow, core in place.

Table 4.4-6

REACTOR CONFIGURATION DATA

Region	Flow Path Length (ft)	Height & Liquid Level (ft)	Bottom Elevation(1) (ft)	Minimum Flow Area (ft^2)	Volume (ft^3)
Inlet Nozzle (each)	3.2	2.5	- 1.25	4.9	17.5
Downcomer	24.6	32.3	- 29.2	26.7	856.0
Lower Plenum	6.6	9.4	- 26.1	22.7	670.9
Below Active Core	.4	.4	- 19.8	35.9	25.0
Active Core	12.5	12.5	- 19.4	44.8	555.0
Above Active Core	1.9	1.9	- 6.9	19.8	116.6
Outlet Plenum	8.0	9.2	- 5.0	25.3	599.9
CEA Shrouds	13.1	14.3	- 5.0	5.2	375.1
Upper Head	4.0	7.9	4.6	.5	493.2
Outlet Nozzle (each)	3.8	3.5	- 1.75	9.6	39.4

(1) Relative to reactor vessel nozzle centerline.

(2) Flow rates, temperatures and pressures in the above regions may be obtained from Table 4.4-4.

Table 4.4-6A

STEADY STATE PARAMETERS

Comparison of W-3 and CE-1 DNBR**

Inlet Temp. (°F)	Pressure (psia)	Power (% 2815 Mwt)	W-3 DNBR	CE-1 DNBR
580	2400	105	1.30	1.50
	2250	99	1.30	1.49
	2000	91	1.30	1.39
	1750	*	1.30	*
556.5	2400	124	1.30	1.40
	2250	117	1.30	1.43
	2000	108	1.30	1.36
	1750	100	1.30	1.15
525	2400	149	1.30	1.30
	2250	142	1.30	1.32
	2000	131	1.30	1.33
	1750	120	1.30	1.19

* core saturation limit occurs before W-3 DNBR reaches 1.30

**based on axial power distribution with 1.26 peak at 85 percent point (ASI = 0.07)

NOTES

1) PRODUCT SHALL BE IN ACCORDANCE WITH CENPD SPEC. NO. 00000-FEA-6106 & CENPD DWG. NO. E-6370-165-020.
2) ELECTRO-ETCH ASSEMBLY IDENTIFICATION PER FORMAT SHOWN IN BOX. UNDERLINED HOLDERS (EG. 'XX') TO BE ASSIGNED PER LEGEND. LETTERING TO BE 1/8" HIGH NOMINAL, EXCEPT FOR TWO (2) DIGITS, 'C-C' WHICH ARE TO BE ¼" HIGH NOMINAL, IN TWO PLACES 180 APART.
3) FOR SCOPE OF SUPPLY & AS BUILT INFORMATION, SEE M-2001-K3-090, SHEET 2.
4) PROCESSED TO IMQP CHART NO. 310-9546 (WHERE SP'S & QP'S ARE REFERENCED).
5) ADAPTOR CONFIGURATION SHALL NOT EXCEED .937" DIA. OVER SPECIFIED LENGTH.
6) ALL $\boxed{\text{BSC}}$ DIMENSIONS TO BE ± 1/8".
7) BULLET NOSE SURFACES & JOINTS TO BE SMOOTH & FREE FROM SHARP EDGES. POLISH TO 32 OR BETTER.
8) ITEMS 10 THRU 16 MUST BE ASSEMBLED SO THAT EACH IS EVENLY HELIXED AROUND ITEM 18 MAKING AT LEAST 1 REVOLUTION, BUT NO MORE THAN 1½ REVOLUTIONS EVERY 40 cm.
9) O.S.T SHALL BE PURGED FREE OF AIR & BACKFILLED WITH HELIUM @ 1 ATMOSPHERE PRESSURE MINIMUM.
10) AFTER PROCESSING O.S.T., THE DIAMETRICAL CLEARANCE OF THE DETECTORS & THERMOCOUPLE TO THE CENTRAL MEMBER ASS'Y & OUTER SHEATH TUBE TO BE $^{+.004}_{-.000}$

4A FUEL RECONSTITUTION

4A.1 INTRODUCTION

Reference 1 discusses the replacement of failed fuel rods or fuel reconstitution. Fuel assemblies containing failed fuel rods have been repaired by replacing the failed rods with either discharged fuel rods or with inert replacement rods. The latter method is preferred since fuel rod handling is minimized. Stainless steel rods of essentially identical geometry to the fuel rods that they replace are employed to preserve the flow geometries and minimize changes in local neutronics properties.

When reconstitution is needed, guidance has been provided for the repairs using inert replacement rods. The guidance has typically limited fuel rod replacement to the use of stainless steel replacement rods and has defined the number and allowed location for such replacements. Limitations regarding the number and locations of replacement rods were formulated from calculations performed to evaluate the effects of replacement rods on core peaking and incore power distribution monitoring system response.

4A.2 CONCLUSION

Reference 1 provides guidance for replacement of failed fuel rods and has concluded:

(a) Rod replacements denoted as Class A replacements which satisfy the following guidelines may be made without further justification or cycle specific analyses:

[Proprietary Information - See Reference 1]

(b) Inert rod replacements which fall outside of the Class A criteria given in Reference 1 may be implemented only after evaluation of the explicit replacement geometry. These evaluations will address the effects of the replacement to assure that:

i. The applicable safety analysis and thermal margin calculation remain conservative with respect to previously approved limits.

ii. The cycle specific CECOR library constants are updated, if necessary, to assure that the online thermal margin and peak power surveillance remain conservative with respect to previously defined limits.

If the number of inert rod replacements exceed the approved/allowable number of inert rods [Proprietary Information - See Reference 1] per fuel assembly, then explicit fuel mechanical design performance analyses may be necessary.

5 REACTOR COOLANT SYSTEM

5.1 SUMMARY DESCRIPTION

The reactor is a pressurized water reactor with two coolant loops. The Reactor Coolant System (RCS) circulates water in a closed cycle, removing heat from the reactor core and internals and transferring it to a secondary (steam generating) system. In a Pressurized Water Reactor (PWR), the steam generators provide the interface between the reactor coolant (primary) system and the main steam (secondary) system. The steam generators are vertical U-tube heat exchangers in which heat is transferred from the RCS to the main steam system. The RCS is a closed system preventing the release of radioactive materials into the containment. The arrangement of the RCS is illustrated in Figures 5.1-1 and 5.1-2.

System pressure is controlled by the pressurizer, where steam and water are maintained in thermal equilibrium. Steam is formed by energizing immersion heaters in the pressurizer, or is condensed by the pressurizer spray to limit pressure variations caused by contraction or expansion of the reactor coolant.

The average temperature of the reactor coolant varies with power level and the fluid expands or contracts, changing the pressurizer water level.

The charging pumps and letdown control valves in the Chemical and Volume Control System (CVCS), Section 9.3.4, are used to maintain the programmed pressurizer water level. A continuous but variable letdown purification flow is maintained to keep the RCS chemistry within prescribed limits. The charging flow is also used to alter the boron concentration or chemical content of the reactor coolant.

Overpressure protection is provided by two spring-loaded ASME Code safety valves connected to the top of the pressurizer. These valves discharge to the quench tank, where the steam is released under water to be condensed and cooled. If the steam discharge exceeds the capacity of the tank, the tank is relieved to the containment atmosphere via a rupture disc. When the Reactor Coolant System is at low temperature a Low Temperature Overpressure Protection (LTOP) system provides protection from overpressurization.

Overpressure protection for the secondary side of the steam generators is provided by spring-loaded ASME Code safety valves located in the main steam lines upstream of the main steam isolation valves. Air-operated steam dump and bypass valves are provided to limit opening of the main steam safety valves following a load rejection.

Components and piping in the RCS are insulated with a material compatible with the temperatures involved to reduce heat losses and protect personnel from high temperatures. All insulation material used has a low soluble chloride and other halide content to minimize the possibility of stress corrosion of stainless steel. No aluminum insulation (foil or structural) has been used.

Design parameters of the RCS are listed in Table 5.1-1.

T_{cold} ramps as a function of power. T_{cold} increases from 545 °F at zero power to 551 °F at full power. Inconel 600 material concerns are evaluated for T_{hot} conditions. Reload and safety analyses bound this temperature range and remain conservative with respect to operating limits specified.

5.1.1 SCHEMATIC FLOW DIAGRAM

The principal coolant volumes of major components are listed in Table 5.1-2. The principal pressures, temperatures and flow rates of major components are listed in Table 5.1-3. Instrumentation provided for operation and control of the RCS is described in Chapter 7.

5.1.2 PIPING AND INSTRUMENT DIAGRAM

Figure 5.1-3 provides a simplified diagram of the RCS. The entire system is located within the containment. Fluid systems which are connected to the RCS and which are within the limits of the reactor coolant pressure boundary as defined in 10CFR50.55a are identified, and the appropriate piping and instrument diagrams in other sections of the SAR are referenced.

Two charging nozzles and one letdown nozzle are provided on the reactor coolant piping. Other reactor coolant loop penetrations are the four safety injection inlet nozzles, one in each reactor vessel inlet pipe; one outlet nozzle to the shutdown cooling system; two pressurizer spray nozzles; vent and drain connections; sample connections and instrument connections. RCS nozzles are shown in Figure 5.1-1.

The steam generator tubes and tube sheet constitute the barriers or points of separation between the reactor coolant (heat transport) system and the secondary (heat utilization) system.

5.1.3 ELEVATION DRAWING

Drawings are provided in Chapter 1 which show the relationship of the RCS to the surrounding concrete structures (See Figures 1.2-2 through 1.2-11).

5.2 INTEGRITY OF REACTOR COOLANT PRESSURE BOUNDARY

This section discusses the measures employed to provide and maintain the integrity of the Reactor Coolant Pressure Boundary (RCPB) throughout the facility design lifetime. The RCPB is defined in accordance with Section 50.2 of 10 CFR 50 to include all pressure-containing components such as pressure vessels, piping, pumps, and valves which are:

A. Part of the Reactor Coolant System (RCS).

B. Connected to the RCS, up to and including any and all of the following:

   1. The outermost containment isolation valve in system piping which penetrates the containment;

   2. The second of two valves normally closed during normal reactor operation in system piping which does not penetrate the containment.

   3. The RCS Code safety valves.

Components which are connected to the RCS and are part of the RCPB may be excluded from the above definition provided:

A. For postulated failure of the component during normal reactor operation, the reactor can be shut down and cooled down in an orderly manner assuming makeup is provided by the reactor coolant makeup system only.

B. The component is or can be isolated from the RCS by two valves (both closed, both open, or one closed and the other open). Each open valve must be capable of automatic actuation. Its closure time must be such that for postulated failure of the component during normal reactor operation, the reactor can be shut down and cooled down in an orderly manner assuming makeup is provided by the reactor coolant makeup system only.

5.2.1 DESIGN OF REACTOR COOLANT PRESSURE BOUNDARY COMPONENTS

The methods, procedures and criteria for the design of the RCS components are discussed in this section.

5.2.1.1 Performance Objective

The function of the RCS is to remove heat from the reactor core and internals and transfer it to the secondary system by the forced circulation of pressurized borated water which serves both as a coolant and neutron moderator. The RCS is designed for the normal operation of transferring 3044 MWt, (3026 MWt from the reactor core and 18 MWt from the reactor coolant pumps) to the steam generators.

The RCS also serves as a pressure boundary having a high degree of leak tightness during normal operation. The integrity of this pressure boundary is assured by appropriate recognition of operating, seismic and/or accident stress loadings.

The system design temperature and pressure are conservatively established and exceed the combined normal operating values and the anticipated operational transients (ANS N18.2 Condition I and II events). The change due to the anticipated operational transients also includes the effect of reactor core thermal lag, coolant transport time, system pressure drop and the characteristics of the code safety valves.

The plant NSSS system hydrostatic test was performed in accordance with Section III requirements at a hydrostatic test pressure of 1-1/4 times design pressure prior to initial operation. Components replaced within the NSSS system subsequent to the initial hydrostatic test are pressure tested within the system in accordance with ASME Section XI requirements. The number of cycles of hydrostatic testing are determined as part of the design process in accordance with the ASME Code.

System variations which affect the design parameters in normal, upset, emergency and faulted conditions are discussed in Section 5.2.1.5.

5.2.1.2 Design Parameters

The design parameters from the RCS are listed in Table 5.1-1.

5.2.1.3 Compliance With 10CFR50.55a

The codes and component classifications are listed in Table 5.2-1, and are in accordance with the provisions of 10CFR50.55a (except where specific relief has been granted by the NRC).

5.2.1.4 Applicable Code Cases

The following code cases have been applied to components within the RCPB:

Component	Code Case	Subject
Reactor Vessel Supports	1557	Steel Products Refined by Secondary Melting for Section III
Pressurizer	N-405-1	Socket Welds, Section III
Steam Generators	N-20-3	SB-163 Nickel-Chromium-Iron Tubing (Alloys 600 and 690) and Nickel- Iron-Chromium Alloy 800 at Specified Minimum Yield Strength of 40.0 ksi and Cold Worked Alloy 800 at a Yield Strength of 47.0 ksi, Section III, Division 1, Class 1
	N-474-1	Design Stress Intensities and Yield Strength for UNS NO6690 with Minimum Specified Yield Strength of 35 ksi, Class 1 Components, Section III, Division 1
	2142-1	F-Number Grouping for Ni-Cr-Fe Classification UNS NO6052 Filler Metal
	2143-1	F-Number Grouping for Ni-Cr-Fe Classification UNS W86152 Welding Electrode

Component	Code Case	Subject
Control Element Drive Mechanism	1337	Requirements for Special Type 403 Modified Forgings or Bars, Section III
	1334	Requirements for Corrosion Resisting Steel Bars and Shapes, Section III
	1588	Electro-etching of Section III Code Symbol
Reactor Coolant Pump	1604	Hydrostatic Testing of Pumps Constructed According to the Rules of Section III.
Piping	N-411	Use N-411 methodology to analyze seismic response (OBE and DBE) in analyzing RCS tributary piping, Pressurizer Code Safety Tail Pipe and LTOP piping.
PT/LTOP	N-641	This code case allows using an alternate means of determining LTOP and P/T fracture toughness but limits the maximum pressure in the vessel to 100% of the pressure using the KIC.

5.2.1.5 Design Transients

The design bases and normal system function in this section are those used for the integrated design of the RCS or those which apply to all of the system components. Design parameters for both normal and transient conditions are derived from the performance objectives of the system and its components.

The following design transients are used in the fatigue analyses required by the applicable codes. The basis for each transient is indicated and the number of occurrences assumed is to provide a system/component design which will not be limited by expected cyclic operation over the life of the plant. The design life is not dependent on years of service, but on fatigue cycles. A renewed operating license extends the license term from 40 years to 60 years for ANO-2. The actual numbers of transient occurrences were extrapolated to 60 years. The extrapolated numbers of occurrences do not exceed the numbers of occurrences selected for the original design. System integrity is further assured by using conservative methods of predicting the range of pressure and temperature for the transients. The list of transients is intended to include normal plant power range operation, controller or instrument failure, equipment malfunction, and operator errors which result in reactor trips. An explanatory discussion of each transient is also given. The applicable operating condition category as designated by the ASME Code Section III is also indicated in each case. The system and component service and test limits (operating condition category) have been established in accordance with design specification. Service limit designations Level A (normal conditions) and Level B (upset conditions) transients are based on nominal plant operating conditions exclusive of instrument uncertainties. Consistent with this, non-safety grade plant control systems (such as the Pressurizer Pressure Control System, Pressurizer Level Control System, Steam Dump & Bypass Control System, and Feedwater Control System) are assumed operational. Level C (emergency) and Level D (faulted) transients include the effect of response characteristics of the reactor protective and control systems. Additionally, the transients represent conservative estimates for design purposes only and may not be accurate representations of actual transients or actual procedures.

The transients listed include allowance for less severe transients, such as rod withdrawal incident or boron dilution incident. Component cyclic or transient limit programs are required by Technical Specification 6.5.5, and during operation a record is maintained of the number of transients which could have a significant effect on the cumulative usage factor. The number of cyclic or transient occurrences listed in SAR Section 5.2.1.5, items A, D, E, F, H, and I, are included in this program and are tracked to ensure components are maintained within the design limits.

Pressure and temperature transients resulting from these events are established by computer simulations of the RCS. Time-dependent parameters are included in the equipment specifications and used as the basis for fatigue design.

Fatigue analysis for each component of the RCS is performed in accordance with the applicable codes. The combined effects of the mechanical loads and thermal transients for each condition of the cyclic operation are evaluated. The evaluations are performed in a manner to yield the maximum range in stress intensity during the particular cyclic condition under consideration. In those cases where conservative results are produced, peak stresses due to pressure may be combined with those due to thermal transients by direct superposition. In addition, the results of analysis obtained for the most severe transient condition in a group may be applied in evaluating the cumulative effects of the entire group. Beginning with Cycle 15, the basis for these transients and the number of occurrences assumed were reevaluated to account for replacement of the steam generators. The following transients were considered in the fatigue analysis:

A. Five hundred heatup and cooldown cycles (350 for the replacement steam generator and 80 cycles for the replacement pressurizer) during the design life of the components in the system with heating and cooling at a rate of 100 °F/hr between 70 °F and 545 °F (200 °F/hr between 70 °F and 653 °F for pressurizer heat up and cool down). The heatup and cooldown rate of the system is administratively limited to assure that these limits will not be exceeded. This is based on consideration of both historical plant transient history and projections of transient lifetime occurrences for the components. Category: Normal Condition.

B. Fifteen thousand power change cycles (12,000 for the replacement steam generator) over the range of 15 percent to 100 percent of full load at five percent of full load per minute increasing and decreasing. This is based on consideration of both historical plant transient history and projections of transient lifetime occurrences for the components. Category: Normal Condition.

C. One million cycles of normal cyclic variations (step changes) of ± 100 psi and ± 10 °F (± 20 °F for the replacement pressurizer) when at operating temperature and pressure. For the replacement steam generator primary and secondary manway studs/bolts, the normal cyclic variations of ± 50 psi and ± 5 °F apply when at operating temperature and pressure. Note that temperature and pressure fluctuations from 0% to 15% power are part of this category. This is selected based on one million cycles approximating an infinite number of cycles so that the limiting stress is the endurance limit. This is based on consideration of both historical plant transient history and projections of transient lifetime occurrences for the components. Category: Normal Condition.

D. One cycle (ten cycles for the replacement pressurizer) of system hydrostatic testing at 3110 psig (3125 psia for the replacement pressurizer) and at a temperature at least 60 °F above the Nil Ductility Transition Temperature (NDTT) of the component having the highest NDTT value. This is based on one initial hydrostatic test. Note that when

system hydrostatic tests for repair or replacement items impose test pressure and temperature in conflict with the Technical Specification, ASME Code Section XI permits a system leakage test at nominal operating pressure and temperature. Category: Test Condition.

E. Two hundred cycles (zero for the replacement steam generator and fifty cycles for the replacement pressurizer) of leak testing at 2,250 psia. Generally, leak testing at nominal operating pressure is performed in conjunction with normal plant operation. There is no requirement to analyze leak testing with respect to fatigue considerations for the steam generator. Category: Test Condition.

F. Four hundred and eighty reactor trip transients (five hundred trip transients for the replacement pressurizer). This is based on 400 reactor trips from full load, 40 turbine trips from full load with a delayed reactor trip, and 40 complete loss of reactor coolant flow events (i.e., loss of power to the reactor coolant pumps). These transients exhibit similar thermal hydraulic characteristics and were combined into one transient via definition of a composite transient. Category: Upset Condition.

G. Two hundred stress cycles of a seismic event equal to one-half the Design Basis Earthquake (DBE). The number of cycles is based on the postulation of five seismic events occurring during the life of the plant with 40 full cycles per occurrence of significant motion peaks. Category: Upset Condition.

H. Five cycles of complete loss of secondary pressure from either steam generator while in modes 1, 2, or 3. This transient results from a steam line break. A steam line break is not considered credible. However, it is included to ensure that components will not fail should it happen. This transient is considered to represent all rare plant conditions which might produce a significant temperature change (e.g., a feedwater line break, inadvertent opening of the Steam Dump & Bypass Valves). The number of occurrences is arbitrary. Category: Emergency Condition.

I. The design cycle or transient for spray operation is the opening and closing of either the main or auxiliary spray valve(s) with spray water to pressurizer $\Delta T > 200$ °F. The cyclic or transient limit for spray operation is one hundred pressurizer spray cycles per year with pressurizer to spray water $\Delta T > 200$ °F. If these cycles are exceeded, the acceptable number of cycles is based on determination of the cumulative usage factor for the spray nozzle and nozzle fatigue evaluations in accordance with ASME Section III. Category: Normal Condition.

Pressure and thermal stress variations associated with the above design transients are considered in the design of the RCS components, piping and supports, including surge and spray lines; of the letdown piping and valves up to and including the regenerative heat exchanger; and of all other valves and piping within the RCPB.

In addition, the loads resulting from the design transients are included in the design of major support foundations and interfacing support structures for the above equipment.

All components that are designed and fabricated as Class 1 vessels are analyzed in accordance with the ASME Code requirements. It is demonstrated that the maximum stress intensities and cumulative usage factors are in compliance with Code values. The analyses are performed for steady state and cyclic conditions required by the Certified Design Specifications. Certified Analytical Reports are required for the components. Verification of the adequacy of the calculations and compliance with Code and Design Specification Requirements are assured by an independent review.

Thermal stresses induced in the reactor vessel wall by gamma ray heating, in combination with stresses produced by other loading conditions, are considered in the design of the vessel. The stresses due to gamma ray heating are low in magnitude and do not contribute significantly to the maximum primary plus secondary stresses which are within design limits.

In addition to the operating and testing (transient) conditions listed above and included in the fatigue analyses, the loadings produced by the vibratory motion of the DBE and the dynamic effects resulting from postulated pipe rupture conditions were also applied in the design of components and supports of the RCS. These additional conditions were categorized as faulted conditions and, in combination with other coincident loadings, were appropriately evaluated by the applicable rules of ASME Code, Section III, Subsection NB, including Appendix F. The few load cycles associated with the faulted conditions are exempt from fatigue evaluations (cumulative effects) and, therefore, the small number of load cycles produced by the DBE and postulated pipe rupture conditions are not specified.

The following design loading combinations are applied in the design of all ASME Class 1 components and supports, as appropriate:

Loading Combination 1 - normal operating loads plus transients plus OBE loads;

Loading Combination 2 - normal operating loads plus DBE loads; and

Loading Combination 3 - normal operating load plus DBE loads plus pipe rupture loads.

The design stress limits applied in evaluating Loading Combination 1 are in accordance with the rules of ASME Code, Section III, Subsection NB, for Upset Conditions, except as noted below.

The ASME Class 1 piping and supports that are part of the Pressurizer Relief and LTOP piping system were treated as follows: For Loading Combination 1, where the transient loads included the short duration, dynamic effects of a safety valve discharge, the design stress limits applied are in accordance with the rules of ASME Code, Section III, Subsection NB, for Emergency Conditions.

The dynamic system analysis used to determine the loadings produced by the DBE and pipe rupture conditions is based upon elastic methods. Accordingly, the stress criteria applied in the design of components and supports for Loading Combinations 2 and 3 are also based upon elastic methods of analysis. The rules applied in evaluating Loading Combinations 2 and 3 are in accordance with the applicable paragraphs of ASME Code, Section III, Subsection NB, including Appendix F, for Faulted Conditions (elastic analysis).

For supports integral with the Nuclear Steam Supply System (NSSS) components, transient and steady state thermal conditions were considered. Original temperature distributions were obtained by use of a finite difference method programmed for digital computer solution. The code makes use of the general heat balance equations derived by Hellman, Habetler & Babrov. CE designation of the code is CHAT-12100 (see Section 5.2.1.10 and related Section 5.2.1.15). More recent analysis may have used other computer codes listed in Section 5.2.1.10.1.

In the design of the reactor vessel support columns both steady state and transient thermal effects were considered.

5.2.1.6 Identification of Active Pumps and Valves

Pumps and valves within the RCPB can be classified as either active or inactive components. Active components are those whose operability is relied upon to perform a safety function, as well as reactor shutdown function, during the transients or events considered in the respective operating condition categories. Inactive components are those whose operability, e.g., valve opening or closure, pump operation or trip, is not relied upon to perform the system function during transients or events considered in the respective operating condition categories. Thus, certain pumps and valves (classified as active components) within the RCPB are required not only to serve as pressure-retaining components (as in the case of passive components such as vessels and piping) but also to operate reliably to perform a safety function such as safe shutdown of the reactor and mitigation of the consequences of a pipe break accident under the loading combinations considered in design. Table 5.2-2 is a list which classified valves within the RCPB as either active or inactive. The letdown valve is isolated by the Safety Injection Actuation Signal (SIAS) in the event of a Loss of Coolant Accident (LOCA) (Refer to Section 7.3 for a discussion of SIAS and other engineered safety features signals). No pumps within the RCPB are classified as active per this discussion.

All containment isolation valves (including those which are active RCPB valves) were originally designed and tested by the manufacturer to close in a maximum of 20 seconds. Actual closing times are controlled by the Inservice Testing Program and Technical Specifications. All other active RCPB valves were originally designed and tested by the manufacturer for standard closing times, which for gates are twelve (12) inches per minute and for globes four (4) inches per minute.

The operator sizing is accomplished by calculating a maximum force, based on system operating parameters that the valve will have to close or open against. This is converted to stem torque required to move the disc at the required speed. An operator with adequate horsepower and torque output is then chosen for the given conditions. Testing is performed at ambient conditions.

Leak tight integrity is assured by testing by the manufacturer of all valves with water under pressure. Maximum allowable leakage permitted is 2 cc/hr/in of valve size. For containment isolation valves the above leak test is required and, in addition, a 65 psig air test is required with no discernible leakage permitted.

For inactive pumps and valves, as appropriate, the stress criteria for vessels, are applied in evaluating the emergency and faulted conditions (elastic analysis). These limits are consistent with the "Design by Analysis" method of NB-3200 of the ASME Code, Section III, which is applied in the design calculations.

5.2.1.7 Design of Active Pumps and Valves

For active components, additional requirements have been imposed on the design to assure operability during the faulted condition. As appropriate, these additional requirements consist of simulated test and/or supplementary calculations which demonstrate that the active component will perform its required function during the specified conditions. Where calculations are employed, the primary stresses produced by the faulted conditions are limited to the emergency condition limits of Subparagraph NB-3224.1 of the ASME Code, Section III in all regions of the active component where deformations may impair the required function.

For design conditions other than those explicitly addressed by the ASME Code, Section III and where design calculations are used to evaluate stresses and deformations in pumps and valves, the methods and criteria applied are in accordance with the Subarticle NB-3200 of the ASME Code, Section III. The calculations include the effects of gross and local structural discontinuities and the loadings produced by geometrical eccentricities. Current state-of-the-art analytical methods, including finite element techniques, are employed in the calculations.

For the active Class 1 safety injection check valves, additional calculations were performed to determine the amount of distortion associated with the pressure and temperature conditions for the faulted condition. These calculations demonstrated that the distortion was not sufficient to impair operability of the valves.

5.2.1.8 Inadvertent Operation of Valves

Valves not relied upon for performing action during transients or normal operating categories and located within (or interfaced with) the RCPB are classified as inactive components. These components, by definition, are therefore not required to perform a safety function and/or a reactor shutdown operation under the aforementioned circumstances. Inadvertent operation of these inactively classified valves will initiate automatic responses from the Reactor Protective System (RPS) and/or manual control room responses. In all cases, these automatic and/or manual responses will mitigate the potential compound consequences of inadvertent valve operation during transients or normal functioning categories.

For example, the inadvertent operation of any of the following list of valves will not compound the effects of normal operating events or transients.

The following valves interface the RCPB and the Chemical and Volume Control System (CVCS) (Section 9.3.4):

A. Charging line valves 2CV4831-2, 2CV4827-2, and 2CV-4840-2;

B. Auxiliary spray line valve 2CV4824-2; and,

C. Letdown line valves 2CV4820-2 and 2CV4821-1.

The following valves are all located within the RCPB and can be remotely operated from the control room:

D. Safety injection leakoff valves, 2CV-5021-1, 2CV5001-1, 2CV5061-2, 2CV5041-2 (See Section 6.3);

E. Shutdown cooling suction valves 2CV5084-1, 2CV5086-2 (see Section 9.3); and,

F. Pressurizer spray valves 2CV4652, 2CV4651 (see Figure 5.1-3).

5.2.1.8.1 Charging Line Valves (2CV4831-2, 2CV4827-2, 2CV4840-2)

The 2-inch motor-operated valves are normally open. Under normal or transient conditions, inadvertent closure of the globe valves 2CV-4831-2 and 2CV-4827-2 would have little effect on the plant conditions as a spring check valve would lift and bypass charging flow around valve 2CV-4827-2. If gate valve 2CV4840-2 inadvertently closed, charging would be accomplished through the HPSI header.

5.2.1.8.2 Auxiliary Spray Line Valve (2CV4824-2)

This 2-inch motor-operated globe valve is normally closed. The ultimate result of inadvertent opening of this valve would be a low pressure trip. The auxiliary spray line is used to cool the pressurizer during cooldown when the RCS pressure is below that required to operate the reactor coolant pumps. Inadvertent operation (closing) of this valve during pressurizer cooldown would slow pressurizer cooldown.

5.2.1.8.3 Letdown Line Valves (2CV4820-2 and 2CV4821-1)

These 2-inch motor-operated globe valves are normally open. Inadvertent closure of one of these valves during a normal sequence of operations would generate a high pressurizer level error. Low flow and pressure alarms in the CVCS would alert the operator immediately and the letdown line could be returned to service or the charging pump(s) stopped.

Under transient or emergency conditions, inadvertent operation will have no effect on reactor plant conditions. With an SIAS present, these valves cannot be inadvertently operated as the SIAS will override any signal from the control panel switch. The same is true for 2CV4821-1 on a CIS also.

5.2.1.8.4 Safety Injection Leakoff Valves (2CV5021-1, 2CV5001-1, 2CV5061-2, 2CV5041-2)

Operating category events would not be affected by unexplained operation of one of these normally closed 1-inch globe valves.

5.2.1.8.5 Shutdown Cooling Suction Valves (2CV5084-1, 2CV5086-2)

Inadvertent operation of one of these normally closed (locked closed) 14-inch motor operated gate valves would have no effect on operating events or sequences. These valves, in addition, are interlocked to prevent opening unless conditions are consistent with shutdown cooling system design parameters.

5.2.1.8.6 Pressurizer Spray Valves (2CV4652, 2CV4651)

These 3-inch motor-operated angle valves, which are part of the primary pressure control system, function normally in the automatic mode of operation. No serious consequence would result from inadvertent operation of these valves. For example, during a power excursion, if an operator acted to close a normally open valve, the final result would be a high pressure trip. During a ramp decrease in power, opening a normally closed spray valve would ultimately result in a low pressure trip.

5.2.1.9 Stress and Pressure Limits

The stress criteria applied in evaluating the emergency and faulted conditions for components of the RCPB within the scope of Subsection NB of the ASME Code Section III, are as follows:

A. Vessels

The rules of Paragraph NB-3224 are applied in evaluating emergency conditions.

The primary stress limits of Paragraph NB-3221 (Appendix F, F-1331 for the steam generators), using an S_m value equal to the lesser of 2.4 times the tabulated S_m value or 0.70 times the tensile strength, S_u, for materials included in Table I-1.2 and 0.70 times S_u for materials included in Table I-1.1, with material properties taken at the appropriate temperature, are applied in evaluating faulted conditions (elastic analysis).

B. Piping

The rules of Paragraph NB-3655 are applied in evaluating emergency conditions.

The rules of Paragraph NB-3655 are applied in evaluating faulted conditions (elastic analysis). As an alternate to Subparagraph NB-3655.1, the primary stress limits supplied in evaluating faulted conditions for vessels may be applied when the "Design by Analysis" method of NB-3200 is used.

5.2.1.10 Stress Analysis for Structural Adequacy

As discussed in Sections 3.9.1 and 3.6.3, elastic methods of analysis are normally employed in the system or subsystem analysis performed to establish the loadings applied in the design of components, piping, and supports. When an elastic system analysis is employed, elastic stress analysis methods are also applied in the design.

5.2.1.10.1 Computer Programs for Analysis of Major NSSS Components

The following computer programs were used on the major NSSS components:

A. TMCALC

This program is described in Section 3.7.3.4.2.

B. FORCE

This program is described in Section 3.7.3.4.2.

C. MEC-21

MEC-21, Piping Flexibility Analysis Program, was used for static analysis. This is a recognized program in the public domain. It is implemented at CE on the CDC-7600. The version used has been shown to give identical results with the IBM based version (Reference 5).

D. ANSYS

ANSYS is a general purpose element program with structural and heat transfer capabilities. This program was used for steady state and transient thermal analysis. The code is in the public domain. Additional verification is not required. The version used originally by CE was Engineering Analysis System UP144, Revision 2, CE-7600.

ANSYS was also used by Westinghouse Electric Company for structural and thermal analysis of the steam generators. The version used by Westinghouse Electric Company was ANSYS 5.5.

ANSYS was also used by Westinghouse Electric Company for the analysis of the Replacement Pressurizer. The version used by Westinghouse Electric Company was ANSYS 7.1 and ANSYS 8.1.

E. CHAT-12100

CHAT-12100 is a general purpose finite difference heat transfer program. This program was used for steady state and transient thermal analysis. The program has been verified by comparison with hand calculations. A sample comparison of program and hand calculations for four problems is given in Table 5.2-14.

F. SEAL SHELL II

SEAL SHELL II computes stresses and deformations of axismmetric shells for pressure and thermal loads. The program is in the public domain as WAPD-TM-39B.

G. FLANGE FATIGUE PROGRAM - BCH10102

This program computes the redundant reactions, forces, moments, stresses and fatigue usage factors in a reactor vessel head, head flange, closure studs, vessel flange and upper vessel wall for pressure and thermal loadings. Classical shell equations are used in the interaction analysis.

H. NOZZLE FATIGUE PROGRAM – BCH 10105

This program computes the redundant reaction, forces, moments and fatigue usage in the primary nozzles.

I. EDGE COEFFICIENTS - BCH10026

This code calculates the coefficients for edge deformations of conical cylinders and tapered cylinders when subjected to axisymmetric unit shears and moments applied at the edges. A comparison of program results with hand solutions was used for verification. The results are given in Table 5.2-15.

J. GENERALIZED 4X4-BCH10124

This program computes the redundant reactions, forces, moments, stresses and fatigue usage factors for the reactor vessel wall at the transition from a thick to thinner section and at the bottom head juncture.

K. REINFORCEMENT ANALYSIS OF SKEWED PENETRATIONS AND NON-RADIAL NOZZLES - OBC10147

This program computes the limits of reinforcement for penetrations that are non-radial or skewed in a hemispherical head.

L. A THREE VARIABLE SUMMATION PROGRAM FOR COMPUTER THERMAL STRESSES - OBC10126

This program computes the stress at each time increment of a transient at various locations along a nozzle as a function of the thermal stress, k, and the product of the shear and moment, H and M with their respective coefficients C_1 and C_2.

In general form: $\sigma = k+C_1H+C_2M$

M. WESTEMS

This program is a PC-based integrated diagnostics and monitoring system and stress analysis tool. It is modular in design, utilizing project-based models and a family of plug-in programmable components. This system is used by Westinghouse engineers to perform ASME design stress and fatigue analysis using NB-3200 criteria.

N. WECAN

WECAN is a Westinghouse Electric Company general purpose finite element program with structural and heat transfer capabilities. It was used for structural and thermal analysis of the steam generators. The versions used were WECAN 1995 and WECAN/Plus 1997.

Items G, H, J, K, and L have not been verified according to "Acceptability of Computer Programs Analysis of Mechanical Components and Equipment" dated 5/24/73, because the design preceded this interpretation of the design control measures of 10 CFR 50, Appendix B. Verification of these computer programs was performed at CE as standard engineering practice, but the results of this verification were not formally recorded. The user engineer examined the calculational results for reasonableness, compared them to other similar results, and checked the results by hand calculations when appropriate. Item N verification of the computer program was performed by Westinghouse consistent with the design control measures of 10 CFR 50, Appendix B.

CE supplied ASME Class 2 and 3 components were purchased in accordance with design and design quality assurance requirements existing at the time of purchase of the equipment in 1971. CE subcontractors for these components were not required to validate computer codes used in design by set procedures. Reliance was placed upon industry standards, on accepted engineering practices, and on the accumulated experience of the suppliers. These computer program verification measures taken by CE met the original design control measure requirements of 10 CFR 50, Appendix B then in effect. Since that time, CE has completed a program for recorded verification of the referenced computer programs, developed in conjunction with the Blue Hills Station Units 1 and 2 PSAR and described in Dockets 50-510 and 50-511.

5.2.1.10.2 Computer Programs for Stress Analysis of Piping

For stress analysis of piping not included in Section 5.2.1.10.1, the following computer programs were used:

A. ME 210 - Local Stresses in Cylindrical Shells Due to External Loading

ME 210 presents a method of analyzing and determining local stresses in cylindrical shells due to external moments and forces acting on rigid attachments of elliptical, circular or rectangular shape. This program is based on a paper "Local Stresses in Spherical and Cylindrical Shells due to External Loadings" by Wichman, Hopper & Mershon, published in Welding Research Council Bulletin No. 107, August 1965. Values from Bijlaard curves are obtained by interpolation procedures.

B. ME 602 - The Simplified Seismic Analysis of Small Diameter Piping Systems

ME 602 performs the seismic analysis of piping systems using the modified response spectrum method described in BP-TOP-1 (Revision 2). The program generates a set of tables of seismic spans, support reactions and stresses for various pipe sizes.

C. ME 604 - Nuclear Class 1 Piping Stress Analysis

This program is used to calculate piping stresses in accordance with the simplified method of NB-3650 of the ASME Section III Code.

The stresses are calculated in accordance with Equations 9 through 14 defined in Section NB-3650 of the ASME Code. The stresses and usage factor are printed out for each data point in the analysis.

D. ME 632 - Piping System Analysis

ME 632, developed by Bechtel Power Corporation, performs stress analysis of three-dimensional piping systems. The effects of thermal expansion, uniform load of the pipe, pipe contents and insulation, concentrated loads, movements of the piping system supports, and other external loads, such as wind and snow, may be considered.

A response spectrum analysis may be performed to analyze the effect of earthquake forces on the piping system. Time history analyses for transient effects of water hammer, steam hammer, or other impulsive type dynamic loading are also handled by the program.

E. ME 641 - Time History Analyzer

ME 641 produces time history listings and Calcomp 1036 or Zeta graphs for all the parameters in ME 632. The word parameter is used as a catchall for displacement, force, moment and stress. ME 641 can be run with ME 632 or it can stand alone as a separate program.

F. ME 643 - Thermal Stress Program

To determine the temperature and stress distributions within a body as a function of time when subjected to thermal and/or mechanical loads. The program is valid for axisymmetric or plane structures.

G. ME 909 - Spectra Curves Merging Program

This program envelops all appropriate response spectra curves for a given piping system. It also makes Calcomp 1036 or Zeta plots of these curves, and produces data cards for ME 632 seismic analysis.

H. MRI/STARDYNE

The MRI/STARDYNE, static and dynamic structural system which is developed by Mechanics Research, Inc., of Los Angeles, California, is available at CYBERNET Center of Control Data Corporation on the CDC 6600 machine.

The MRI/STARDYNE consist of a series of compatible computer programs which analyze linear elastic structural models under static or dynamic loads. It is used to calculate time history responses of a piping system under fluid transient loads.

I. ANSYS

The ANSYS, Engineering Analysis Computer Program, which was developed by Swanson Analysis Systems, Inc., is a general purpose finite element program featuring analysis capabilities for structures including static and dynamic analysis with elastic, plastic and creep properties.

It is used to calculate the time history responses of piping systems during a pipe break event.

J. PIPESTRESS (PS+CAEPIPE)

PIPESTESS, developed by SST Systems, Inc., is a group of interrelated computer programs for performing linear elastic analysis of three-dimensional piping systems subjected to a variety of loading conditions. This program has advanced static and dynamic analysis capabilities including detailed uniform and multilevel response spectrum analyses, time history and fatigue calculations, and multiple load cases and combinations.

K. ME101

ME101, developed by Bechtel Power Corporation, is a family of computer programs that perform linear elastic analysis of piping systems using standard beam theory techniques. ME101 also performs static and dynamic load analysis of piping systems, effective weight calculations, and ASME Section III Nuclear Class 2 & 3 code stress checks. ME101 also provides stress evaluation of cylindrical shell, thermal transient across pipe wall, spectral merging, and ASME Section III Nuclear Class 1 Stress analysis.

The following computer codes have also been used in the stress analysis of piping (all computer programs are well recognized and program descriptions are available but not supplied in the remainder of the section):

PISOL - EDS Nuclear Inc.

NUPIPE - Nuclear Services Corporation

SAPIPE - PMB Systems Engineering Inc.

TPIPE - PMB Systems Engineering Inc.

PISTAR - NUTECH Technology Inc.

All programs are well recognized and they all have sufficient history of use to justify their applicability and validity. Verification documents including program theory, solutions to test problems or bench mark problems, or comparison with known programs are available. They constitute a very bulky package however and for that reason were not submitted with the application.

Bechtel supplied ASME Class 1, 2 and 3 components were purchased in accordance with design and design quality assurance requirements existing at the time of purchase of the equipment. Bechtel subcontractors for these components were not required to validate computer codes used in design by set procedures. Reliance was placed upon industry standards, on accepted engineering practices, and on the accumulated experience of the suppliers.

5.2.1.11 Analysis Method for Faulted Condition

The dynamic system analysis used to establish loadings sustained by ASME Code Class 1 components and supports during the plant faulted conditions is based upon elastic methods. Accordingly, elastic methods of stress analysis and elastic design stress limits, in accordance with the appropriate paragraphs of ASME Code, Section III, Subsection NB, are also applied in the design calculations performed to demonstrate the adequacy of the components.

5.2.1.12 Protection Against Environmental Factors

The major components of the RCS are protected against environmental effects, including flooding and missiles. Refer to Chapter 3, particularly Sections 3.4 and 3.5, for a detailed discussion.

5.2.1.13 Compliance With Code Requirements

Detailed discussions of the analytical calculations are provided in Sections 3.6, 3.7 and 3.9, showing the manner in which loadings are developed for confirmation that the design requirements of the ASME Code, Section III, Subsection NB, are met.

5.2.1.14 Stress Analysis for Emergency and Faulted Condition Loadings

Elastic methods of stress analysis are used in evaluating the Emergency and Faulted Condition Loadings. The specific stress criteria applied is discussed in Section 5.2.1.9.

5.2.1.15 Stress Levels in Seismic Category 1 Systems

A discussion of Seismic Category 1 systems, analytical models and stress levels is presented in Section 3.7. The analysis of combined seismic and faulted conditions is included. Sketches showing details of the modeling are also included. The stress levels at points of high changes in flexibility in the RCS during the plant faulted condition, are presented on Figure 5.2-34.

The six components of force or moment (Fx, Fy, Fz, Mx, My, Mz) at the supports and various sections of the pressurizer surge line piping were computed separately for each of the two horizontal directions and in the vertical direction of seismic excitation by response spectrum dynamic analysis. The co-directional components of force or moment from one horizontal and the vertical directions of excitation were combined by absolute summation to define the seismic loading condition at the particular piping location for one horizontal and the vertical excitations. A second seismic loading condition was also defined by repeating the absolute sum combination for the other horizontal and the vertical excitations. Each load set was compared to, and shown to be less governing than, the seismic loadings specified for design of the piping. The load combinations were calculated and verified by hand. In no case has algebraic summation been used for combining the effects of horizontal and vertical seismic excitations for systems within the NSSS scope.

Time histories of the six components of force or moment (Fx, Fy, Fz, Mx, My, Mz) at various sections of the RCS main loop piping were computed separately for each of two horizontal directions and in the vertical direction of seismic excitation. Each component of force or moment from one horizontal direction of excitation was combined by absolute summation on a time basis with the corresponding co-directional component of force or moment from the vertical direction of excitation. The maximum combined value over all time of each of the six

components or force or moment were chosen to define the seismic loading condition at the particular piping location for one horizontal and the vertical excitations. A second seismic loading condition was also defined by vertical excitations. Each load set was compared to, and shown to be less governing than, the seismic loadings specified for design of the piping.

Since the combination of loads was performed after the completion of the dynamic analysis portion of the computation, the appropriateness of the results of the combination was verified by field observation of the uncombined inputs and the combined output.

Stresses in pumps and valves in the RCPB have been determined in accordance with the ASME Code, Section III.

5.2.1.16 Analytical Methods Used to Evaluate Pump Speed and Bearing Integrity

Analytical methods are employed to assure that no critical speed is within ±25 percent of normal operating speed. The shaft and bearings are designed to withstand any combination of the normal operating loads, anticipated transients, accident loads and the Design Basis Earthquake (DBE). Failures resulting from critical speed problems are not likely to result in a violation of the integrity of the RCPB. However, the pump vendor analyzes the entire reactor coolant pump/motor assembly and determines the fundamental and harmonic modes of lateral vibration of rotating elements of arbitrary flexural rigidity. The computational method is based on a transfer matrix representation of the rotor shaft which includes the effect of multiple supports with dissimilar elasticity and damping in the bearings and with a dissimilar elasticity and mass of the bearing supports. The natural frequencies, lateral deflections for the determination of rotor stresses, running clearances, and severity of vibration at the different resonant frequencies are calculated. Vibration amplitudes of the bearing supports are also calculated for determining support resonant frequencies and for obtaining an optimum design through modifications of the bearing and their supports.

For the analysis, the continuous rotating element is represented as a sequence of massless sections with constant bending stiffness and an equal number of concentrated masses between the massless sections. In addition, the computational model provides the option of adding masses of unbalance to any of the section masses to study vibration characteristics of the system under various conditions of unbalance.

Transfer equations relating deflections ψ, slopes θ, bending moments M, and shears V, at the two ends of a shaft section are derived from the beam equations and are given by:

$$V = dM/dx$$

$$M = EI\, d\theta/dx$$

$$\psi = d\psi/dx$$

Referring to Figure 5.2-35, which shows a typical beam segment, the following equilibrium equations can be written:

$$V_{i+1} = V_i + \omega^2 M_i \psi_i$$

$$M_{i+1} = M_i + V_i \ell_i + \omega^2 M_i \psi_i \ell_i$$

By successive integration, the slope and deflection relationships are derived:

$$\theta_{i+1} = \frac{\ell_i^2}{2EI_i} V_i + \frac{\ell_i}{EI_i} M_i + \theta_i + \frac{\omega^2 m_i \ell_i^2}{2EI_i} \psi_i$$

and

$$\psi_{i+1} = \frac{\ell_i^3}{6EI_i} V_i + \frac{\ell_i^2}{2EI_i} M_i + \ell_i \theta_i + \frac{\omega^2 m_i \ell_i^3}{6EI_i} \psi_i$$

These transfer equations can be conveniently represented by a 4 x 4 transfer matrix. When the contributions due to the mass of unbalance are added, the transfer matrix must be expanded to a 5 x 5 matrix.

This matrix describes any section, n, of a weightless shaft and a disk when the rotor is supported on rigid supports and with conditions of unbalance and mass moment of inertia included. Through pre-multiplication of the section matrices for successive beam elements, a transfer matrix for each bearing span is developed. Boundary conditions specified at each support location prescribe the slope, displacement, and moment across the support.

When the system is rotating with fluid lubricated bearings on elastic supports, the deflections calculated for rigid supports must be modified to include the deflections of the supports. These modifications are accomplished through the use of dynamic influence coefficients.

The assumptions, methods and detailed descriptions by which the necessary parameters and influence coefficients were calculated in the evaluation of pump speed and bearing integrity with fluid lubricated bearings on elastic supports are found in References 3, 6 and 7.

The supports themselves are represented as a combination of springs, masses, and dampers such that the dynamic stiffness of each support is defined at each speed. Since the system is rotating with fluid lubricated bearings on elastic supports, dynamic influence coefficients were calculated by applying a unit force of unbalance at an initial section of a span containing a support. The coefficients are obtained with the system rotating at the speed under consideration and all masses set equal to zero, except the unit force of unbalance at the support selected.

These influence coefficients are then related to the support reaction when they are substituted into the equation defining the differences in the distances at the ends of the section between the curve of the centerline of the rotor with the masses equal to zero and the bearing forces equal to those reactions which exist when the masses are their true value and rotating at the given speed and the curve of the centerline of the rotor with the masses at true value rotating at the given speed with corresponding bearing reactions, which is:

$$[f_{uv} - f_{u-1,v}] = \sum_{q=1}^{z+1} [C_{uvoq} - C_{u-1,voq}] R_{oq}$$

where

$f_{uv} - f_{u-1,v}$ is the difference in curves defined above

$C_{uvoq} - C_{u-1,voq}$ is the difference in the influence coefficients, in-lb

R_{oq} is the support reaction at section O of span q, lb

The rigid supports were modified to account for elastic supports by including damping and stiffness coefficients for the fluid film and support flexibility in the calculations. Figure 5.2-35 illustrates the procedure.

The analysis is performed for operating transient loading conditions. In addition, pump vibration levels are checked during the pump performance tests. Any evidence of critical speed problems would be detected during these tests.

5.2.1.17 Operation of Active Valves Under Transient Loading

Design of valves which form a part of the RCPB is discussed in Sections 5.2.1.6 and 5.2.1.7, and the design is based in part on the service consistent with the transients listed in Section 5.2.1.5.

All pumps and valves that are designed and fabricated as Class 1 are analyzed in accordance with the ASME Code requirements. It is demonstrated that the maximum stress intensities and cumulative usage factors are in compliance with Code values. The analyses are performed for steady state and cyclic conditions as required by the Design Specifications. Certified analytical reports are required for the components. Verification of the adequacy of the calculations and compliance with Code and Design Specification requirements are assured by an independent review.

System design thermal transients are used in the fatigue analyses required by the applicable codes. The basis for the number of occurrences is to provide system/component design which is not limited by expected cyclic operation over the life of the plant. The number of occurrences selected for design purposes far exceeds the expected number. System integrity is further assured by using conservative methods of predicting the range of pressure and temperature for the transients. The transients include normal plant power range operation, controller or instrument failure, equipment malfunction, and operator errors which result in reactor trips.

Fatigue analysis for each component of the RCS is performed in accordance with the applicable codes. The combined effects of the mechanical load and thermal transients for each condition of the cyclic operation are evaluated. The evaluations are performed in a manner which yields the maximum range in stress intensity during the particular cyclic condition under consideration. In those cases where conservative results are produced, peak stresses due to pressure may be combined with those due to thermal transients by direct superposition. In addition, the results of analysis obtained for the most severe transient condition in a group may be applied in evaluating the cumulative effects of the entire group.

Pressure and temperature transients resulting from these events are established by computer simulations of the RCS. Time-dependent parameters are included in the equipment specifications and used as the basis for fatigue design.

5.2.1.18 Field Run Piping

There is no field run piping in the RCPB.

5.2.1.19 Design of Reactor Coolant System and Lower Pressure System Interfaces

There are several points of interface with the RCS that have a design pressure less than the design pressure of the RCS. The degree of conformance of these interfaces with General Design Criteria 14 and 55 is given in Table 5.2-13.

5.2.2 OVERPRESSURE PROTECTION

Overpressure protection for the RCS and steam generator is accomplished by the pressurizer code safety valves, steam generator safety valves, and the RPS. The design is in accordance with ASME Section III, NB-7000. RCS low temperature overpressure protection is described in Section 5.2.2.4.

The two pressurizer safety valves are located on top of the pressurizer. They are totally enclosed, back pressure compensated, spring-loaded safety valves. Parameters for these valves are given in Table 5.5-10.

Overpressure protection for the shell side of the steam generators and the main steam line piping up to the main steam isolation valve is provided by spring-loaded, open-bonnet ASME Code safety valves discharging to the atmosphere. Safety valves are mounted outside the containment on each of the two main steam lines upstream of the steam line isolation valves. Parameters for these valves are given in Table 5.5-11.

The pressurizer safety valves pass sufficient pressurizer steam to limit the primary system pressure to less than 110 percent of design. An addendum to the ANO-2 Overpressure Protection Report verified the RCS pressure limit is not exceeded as a result of installation of the replacement steam generators and power uprate. The reactor is assumed to trip on a high pressurizer pressure signal. In determining the maximum steam flow through the pressurizer safety valves, the main steam safety valves are assumed to be operational. Conservative values for all system parameters, delay times, and core moderator coefficient are assumed. Overpressure protection is provided to the RCS considering pump head, flow pressure drops, and elevation heads.

The pressurizer safety valves discharge through the relief line piping into the quench tank. The design allowable backpressure for the pressurizer safety valves is 700 psig. This value is consistent with the current state-of-the-art for bellows sealed designs.

The pressure, mass flow rate, and forcing functions were determined for the Code Safety Relief Valve Discharge Piping System using a computer model to analyze the time history. The results of the backpressure analyses indicated that the maximum calculated backpressure, due to actuation of either the Low Temperature Overprotection System (LTOP) or the Code Safety Relief valves, did not exceed the relief valve discharge piping design pressure (700 psig) or the Pressurizer Code Safety Valves allowable backpressure (also 700 psig).

The peak backpressure on the pressurizer safety valves during overpressure conditions did not affect the pressurizer safety valve flow capacity. The downstream fluid-containing parts, including the bellows, are hydrostatically tested in the shop at 1,050 psig. For the bellows, this is equivalent to an at-temperature pressure of approximately 960 psig. The valve, therefore, will function to relieve its rated capacity up to 960 psig back pressure. Above this value the bellows may rupture, causing the disk to cycle closed and then open depending on the magnitude of the rupture and the characteristics of the valve.

In addition, a steam dump and bypass system is provided. The system utilizes steam dump valves and turbine bypass valves to accommodate certain load rejections without resulting in a reactor trip or lifting any main steam supply valves. The dump valves discharge to the atmosphere and the turbine bypass valves discharge to the main condenser. Normal operation utilizes the turbine bypass valves and downstream ADVs in automatic, set to actuate (open) on

high steam pressure, which accommodates load rejections up to 49% power. The bypass valves are also utilized to control steam line pressure in hot standby, thereby removing decay heat from the reactor coolant system. This system is further described in Chapter 10.

5.2.2.1 Location of Pressure-Relieving Devices

The locations of pressure-relieving devices for the RCS and auxiliary and emergency systems connected to the RCS are shown on the respective piping and instrument diagram (Figures 5.1-3, 6.3-2, 9.3-4). The steam generator safety valves are shown in Figure 10.2-3. The diagrams also show connections to the discharge side of the pressure-relieving devices.

5.2.2.2 Mounting of Pressure-Relieving Devices

The mounting of pressure-relieving devices within the RCPB and on the main steam lines outside the containment is in accordance with the applicable provisions of the ASME Code, Section III.

The pressurizer safety valves are flange connected to nozzles on the pressurizer. The loads which the nozzles experience during normal plant operation and when the valves are relieving are included in the specification for the pressurizer.

In addition, limiting loads which may be applied to the outlet connections of the valves by the discharge piping are documented in calculations, and based upon these calculations the arrangement and support of this piping is such that the limiting loads are not exceeded for normal and relieving conditions.

For the main steam safety valves, the full discharge thrust loads of the valve have been combined with pressure, weight, seismic and thermal loads for computing stresses in the mounting nozzle and the header. Bending and torsional stresses in the main steam line were computed considering various combinations of the five safety valves discharging, resulting in bounding loads for the header and support. Supports and restraints have been provided in the pipe line to keep stresses within allowable limits.

5.2.2.3 Report on Overpressure Protection

Overpressure protection for the Reactor Coolant and Main Steam Systems has been evaluated for steam generator replacement and power uprate conditions and documented in a revised "Report on Overpressure Protection." In order to maintain sufficient margin following power uprate, the report establishes PSV rated capacity according to ASME Section III, 1989 Edition Section NB-7734. This revised PSV capacity is based on the use of the Napier Factor, which is permitted by the later code. Discussions and analytical assumptions that follow provide the original sizing bases for the PSVs and MSSVs.

5.2.2.3.1 Introduction

Overpressure protection for the reactor vessel, steam generators, and RCS is in accordance with the requirements set forth in the ASME Boiler and Pressure Vessel Code, Section III. Overpressure protection is ensured by means of primary safety valves (pressurizer safety valves), secondary safety valves (main steam safety valves), and the RPS. Analysis of all reactor and steam plant transients causing pressure excursions is conducted. The worst case transient, loss-of-load, in conjunction with a delayed reactor trip is the design basis for the primary safety valves. The primary safety valves, secondary safety valves, and RPS maintain

the RCS below 110 percent of design pressure during worst case transients. The secondary safety valves are sized to maintain steam pressure to less than 110 percent of steam line design pressure during the bounding transient (Loss of Condenser Vacuum). Table 5.2-19 summarizes equipment protected by these safety valves and the valve specifications as evaluated in the Report on Overpressure Protection. (See Tables 5.5-10 and 5.5-11 for current safety valve parameters).

5.2.2.3.2 Analysis

The loss of load event description which follows relates to the analysis assumptions and results utilized in the design sizing considerations of the primary and secondary safety valves. Section 15.1.7 presents a similar loss of load event. Changes in plant operation, replacement steam generators, and cycle specific considerations are assessed in Section 15.1.7 to ensure the primary and secondary safety valves will still maintain the maximum pressure following a loss of load within 110% of design pressure.

5.2.2.3.2.1 Method

CE has performed a parametric study to determine the design basis incident for sizing the primary safety valves. The design basis incident is a loss-of-load in conjunction with loss of condenser vacuum event parameters and a delayed reactor trip. The analysis is performed using digital computer codes which accurately model the thermal, hydraulic, and nuclear performances of the reactor coolant and steam systems. The digital codes used in the transient analysis include reactor kinetics, thermal and hydraulic performance of the RCS, and the thermal and hydraulic performance of the steam generators. The computer simulation includes effects of reactor coolant pump performance, elevation heads, inertia of surge line water and friction drop in the surge line. Highly conservative initial conditions and nuclear parameters are assumed for the parametric analysis. The performance of the digital codes employed in the analysis has been verified by transient data from operating plants.

5.2.2.3.2.2 Assumptions

A. At the onset of the loss-of-load transient the reactor coolant and main steam systems are at maximum rated output plus a two percent uncertainty.

B. Positive moderator coefficients between $+0.5 \times 10^{-4}$ $\Delta K/K/^{\circ}F$ and $+1 \times 10^{-4}$ $\Delta K/K/^{\circ}F$ are used in the loss-of-load analysis. The coefficient (1×10^{-4} $\Delta K/K/^{\circ}F$) maximizes pressure/power excursions. The moderator coefficient used is substantially more positive than will occur in actual plant operation.

C. A Doppler coefficient of $-.8 \times 10^{-5}$ $\Delta K/K/^{\circ}F$ is used in the loss-of-load analysis.

D. No credit is taken for letdown, charging, pressurizer spray, secondary dump and bypass, or feedwater addition after turbine trip in the loss-of-load analysis.

E. The analysis reflects consideration of plant instrumentation error and safety valve setpoint errors.

F. Plant pressure at the onset of the incident is 2,200 psia; the pressurizer water level is within normal operating limits.

5.2.2.3.2.2.1 Secondary Safety Valve Sizing

The discharge piping serving the secondary safety valves is designed to accommodate rated relief capacity without imposing unacceptable backpressure on the safety valves. The secondary safety valves are sized to pass a steam flow equivalent to the plant's ultimate power level. This limits steam generator pressure to 110 percent of steam generator design pressure during worst case transients. A plant's secondary safety valves typically lift at staggered set pressures. The valves are spring loaded safety valves procured in accordance with ASME Boiler and Pressure Vessel Code, Section III. [The original MSSVs were bellows type valves. These valves were subsequently replaced by safety valves which do not have bellows.] This type of safety valve was considered in reevaluation of the "Report on Overpressure Protection" performed for operation subsequent to replacement of the steam generators.

Figure 5.2-48 depicts the steam generator pressure transient for this loss-of-load incident. As can be seen in Figure 5.2-48; the steam generator pressure remains below 110 percent of design pressure during the incident.

5.2.2.3.2.2.2 Pressurizer Code Safety Valve Sizing

The reactor quench tank, inlet and discharge piping are sized to preclude unacceptable pressure drops and backpressure which would adversely affect valve operation.

The original design basis incident for sizing the primary safety valves was a loss of turbine-generator load in which the reactor is not immediately tripped. No credit is taken for any pressure-reducing devices except the primary safety valves and secondary safety valves. In reality, the incident would be terminated by a number of delayed reactor trips. These include:

A. Steam generator low level trip;

B. High pressurizer pressure trip, and;

C. Manual trip.

In order to determine the effects beyond the point where delayed reactor trips would have terminated the incident, the calculation is allowed to continue until the pressurizer fills.

A series of loss-of-load studies are run with various sizes of primary safety valves. As can be seen in Figure 5.2-49, after the safety valve capacity increases to a certain size, additional increase in capacity has a negligible effect in reducing the maximum system pressure experienced during the loss-of-load transient. The primary safety valves are chosen so as to minimize the maximum pressure experienced during the loss-of-load transient. The minimum specified safety valve capacity is identified on Figure 5.2-49.

Figures 5.2-50 and 5.2-51 present curves of maximum RCS pressure and core power versus time for the loss of turbine generator load. As can be seen on Figure 5.2-50, the maximum pressure remains below 110 percent of design pressure during this worst case transient. Following turbine trip, the reactor power increases (See Figure 5.2-51) due to the conservative moderator and Doppler coefficients assumed. Reactor coolant temperature rises and expanding coolant causes a rise in pressure as the pressurizer steam space is compressed.

The first, second, and third banks of secondary safety valves open at approximately 4.5, 5, and 7 seconds, respectively. The secondary safety valves remove energy from the RCS and thus mitigate the pressure surge. The primary safety valves open at the RCS design pressure approximately five seconds after initiation of the upset condition.

The loss of load transient presented above is considered to be the original design basis transient for safety valve sizing only. The limiting design transients for overpressure protection which include the effects of the replacement steam generator are the loss of condenser vacuum event (see Section 15.1.7 for the analysis results).

The combined action of the primary and secondary safety valves and the RPS limits the RCS pressure to less than 110 percent of design pressure.

5.2.2.3.3 Conclusions

The reactor vessel, steam generators, and RCS are protected from over-pressurization in accordance with the guidelines set forth in the ASME Boiler and Pressure Vessel Code, Section III. Peak RCS and secondary system pressures are limited to 110 percent of design pressures.

Overpressure protection is afforded by primary safety valves, secondary safety valves, and the RPS.

5.2.2.4 Low Temperature Overpressure Protection

To protect the RCS from over-pressurization during low temperature conditions, Low Temperature Overpressure Protection (LTOP) design modifications were added. The physical modification was the addition of redundant LTOP relief valves 2PSV-4732 and 2PSV-4742, and two LTOP isolation valves. Two LTOP over-pressurization events were analyzed from water-solid conditions in the RCS and with a relief valve setpoint of 430 psig to determine maximum transient pressures. The most limiting energy addition event, a single idle RCP start with a secondary-to-primary temperature differential of 100 °F, produced a higher maximum pressure (539 psia) than the most limiting mass addition event, simultaneous injection to the RCS from one HPSI and three charging pumps resulting from an inadvertent SIAS (522.2 psia). Thus, the energy addition event is the design basis for the LTOP system, with the peak transient pressure of 539 psia. The relief setpoint is ≤ 430 psig, with a high temperature alarm. The LTOP valves are operator enabled during cooldown between 275 °F and 270 °F, and isolated during heatup between 275 °F and 280 °F. The Technical Specifications require LTOP to be enabled when any RCS cold leg temperature is ≤220 °F. The LTOP modifications, including administrative controls, alarms for improper lineup, procedures, and test requirements are described fully in Sections 7.6.1.3, Low Temperature Overpressure Protection (LTOP), and 7.6.2.3, LTOP.

An evaluation of the LTOP pressure-temperature limits, generated using the methodology of ASME Code Case N-641, has the following limitations that must be adhered to.

Both relief valves are aligned to the RCS for protection;

RCS heatup and cooldown rates are restricted in accordance with the Technical Specifications;

A secondary-to-primary temperature differential less than 100 °F, and a pressurizer water volume less than 910 ft^3 is maintained to ensure acceptable results following a single idle RCP start;

A maximum of one HPSI pump is capable of injecting into the RCS; and

RCP operation is restricted to no more than two RCPs at 70 °F $\leq T_c \leq$ 220 °F and no more than three RCPs at T_c >220 °F, where T_c is indicated cold leg temperature, with 20 °F instrument uncertainty included.

5.2.2.5 Diverse Scram System (DSS) Overpressure Protection

RCS overpressure protection due to an ATWS event is provided by the DSS which trips the reactor upon reaching a pressurizer pressure of 2450 psia nominal. Refer to Section 7.7.1.6 for a description of the DSS.

5.2.3 GENERAL MATERIAL CONSIDERATIONS

5.2.3.1 Material Specifications

The pressure-retaining ferritic and austenitic stainless materials for the major components in the RCS are listed in Table 5.2-3. Valves are fabricated from austenitic stainless steel. Material specifications for valves are given in Section 5.5.

To reduce irradiation embrittlement in service, low residual requirements were imposed on plate and weld material in the reactor vessel beltline. The content of this material as determined by chemical analysis is given in Table 5.2-4. Generic Letter 92-01, Revision 1, Supplement 1, requested licensees to locate all data relevant to the determination of vessel integrity. In response to the generic letter, the design and fabrication records were evaluated. As a result of this evaluation, it was determined that the “best-estimate” values for the copper and nickel content for the reactor vessel beltline material needed to be revised. Table 5.2-20a provides the new “best-estimate” chemistry values.

5.2.3.2 Compatibility With Reactor Coolant

Materials used in the pressure containing boundary of the RCS are listed in Table 5.2-3, and materials in contact with reactor coolant are described by an asterisk. These materials have been selected to minimize corrosion and have given satisfactory performance in operating reactor plants. Controls imposed on reactor coolant chemistry conform with recommendations of Regulatory Guide 1.44, "Control of Sensitized Stainless Steel."

5.2.3.3 Compatibility With External Insulation and Environmental Atmosphere

Materials used in the RCPB or exposed to reactor coolant have been selected to minimize corrosion and have shown satisfactory performance in other existing operating reactor plants. A listing of materials is given in Table 5.2-3. The table shows materials of component construction as well as internal surface material normally exposed to the reactor coolant. Valve materials in contact with the reactor coolant will generally be austenitic stainless steel, stellite or a design approved, low cobalt hard surfacing material equivalent to stellite such as Norem 04, Deloro 40, Deloro 50, etc. External nonmetallic insulation to be used on austenitic stainless steel components conforms with the recommendations of Regulatory Guide 1.36, "Nonmetallic Thermal Insulation for Austenitic Stainless Steels."

Some components of the RCPB and components adjacent to the RCS may be exposed to boric acid corrosion due to leakage of the reactor coolant (boric acid solutions) onto ferritic surfaces. Industry experience and testing in association with GL 88-05 indicate that dripping the boric acid through either calcium silicate insulation or fiberglass insulation, meeting USNRC Reg. Guide 1.36, will not quantitatively influence the boric acid corrosion, or rate thereof, of the carbon steel component. Based upon this information, nothing within the insulation will contribute to the potential effect of boric acid upon the integrity of the pressure boundary.

All piping and equipment within the RCPB, except the reactor vessel head, are insulated with stainless steel reflective insulation or fiberglass blanket insulation meeting Reg. Guide 1.36 Rev. 1 to eliminate the possibility of chloride stress corrosion. The reactor vessel head is insulated with stainless steel encapsulated calcia-alumina-ferrosilicate glass fiber. All other piping and equipment inside containment is insulated with either stainless steel reflective or stainless steel-jacketed conventional insulation. All insulation on ASME Code Section III, Class 1, 2, or 3 components is removable.

5.2.3.4 <u>Chemistry of Reactor Coolant</u>

Controlled water chemistry is maintained within the RCS. Control of the reactor coolant chemistry is the function of the CVCS and is described in Section 9.3.4. Water chemistry limits applicable to the RCS are described in detail in Section 9.3.4.

5.2.3.5 <u>Compliance With Regulatory Guide 1.66</u>

Components originally supplied by CE did not in all respects comply with the recommendations of Regulatory Guide 1.66. The nondestructive examination requirements imposed by CE for tubular products were those specified by Section III of the ASME Code.

5.2.3.6 <u>Compliance with Regulatory Guide 1.71</u>

Components originally supplied by CE did not comply with the specific requirements of Regulatory Guide 1.71. Performance qualifications, for personnel welding under conditions of limited accessibility were conducted and maintained in accordance with the requirements of ASME B&PV Code Sections III and IX. A requalification was required when (1) any of the essential variables of Section IX were changed or (2) when authorized personnel had reason to question the ability of the welder to satisfactorily perform to the applicable requirements. Production welding was monitored for compliance with the procedure parameters and welding qualification requirements were certified in accordance with Sections III and IX. Assurance of acceptable welds in areas of limited accessibility was verified by the performance of the required nondestructive examination.

5.2.4 FRACTURE TOUGHNESS

5.2.4.1 <u>Compliance With Code Requirements</u>

5.2.4.1.1 <u>Reactor Vessel</u>

Carbon and low-alloy steel materials which form a part of the pressure boundary meet the requirements of the ASME Code, Section III, Paragraph N-330 at a temperature of +40 °F. Charpy tests were performed and the results used to plot a transition curve of impact values vs. temperature extending from fully brittle to fully ductile behavior. The actual NDTT of inlet and

outlet nozzles, vessel and head flanges and shell and head materials was determined by drop weight tests per ASTM E208. NDT was established by Charpy test. Drop weight tests were conducted and are presented in Table 5.2-5.

The maximum NDTT as obtained from the drop weight test is 30 °F. The maximum temperature corresponding to the 50 ft-lb value of the C_v fracture energy is 68 °F. The minimum upper shelf C_v energy value for the strong direction is 105 ft-lbs. The data for the weak direction was not obtained. The Charpy V-Notch results are shown in Figures 5.2-1 through 5.2-27.

5.2.4.1.2 Steam Generator, Pressurizer, and Reactor Coolant Piping

Impact properties of ferritic steel materials for the pressurizer and reactor coolant piping which form a part of the pressure boundary meet the requirements of the ASME Code per Table 5.2-1, at a temperature of 60 °F below the lowest service temperature. The results for the pressurizer and reactor coolant piping are presented in Tables 5.2-8 and 5.2-9. The impact properties for ferritic steel materials for the steam generators that form a part of the pressure boundary meet the requirement of the ASME Code, Section III, 1989 Edition, no addenda. The results for the steam generators are presented in Tables 5.2-6 and 5.2-7.

5.2.4.1.3 Location of Limiting Values

The identification and location of the material relating to the limiting values identified above are as follows:

Reactor Vessel Flange	Forging
Reactor Vessel Outlet Nozzle Extension	Forging
Closure Head Dome	Plate
Upper Shell Plate	Plate
Closure Head Dome	Plate

5.2.4.1.4 Reactor Vessel Beltline Materials

For 32 EFPY, the highest predicted adjusted reference temperature (ART) for the materials in the reactor vessel beltline is 113 °F. This value is based on Regulatory Guide 1.99, Revision 2 and includes a shift of 101 °F for an inside surface fluence of 3.791 x 10^{19} n/cm^2 at 32 EFPY. For 48 EFPY, the highest predicted ART for the materials in the reactor vessel beltline is 117 °F. This value is based on Regulatory Guide 1.99, Revision 2, and includes a shift of 105.1 °F for an inside surface fluence of 5.277 x 10^{19} n/cm^2 at 48 EFPY (Reference 24). Testing results of the unirradiated baseline samples from the reactor vessel surveillance program are in Table 5.2-16.

The minimum uppershelf energy values for the unirradiated beltline region plates is 134 ft-lb for the strong direction (Table 5.2-5). The minimum uppershelf energy for the weak direction is 125.5 ft-lb based on the baseline surveillance test results, (Table 5.2-16). Both the weld zone materials (weld and HAZ) had higher unirradiated uppershelf energies (146 and 151.5 ft-lb, respectively). The minimum uppershelf energy value accepted for continued reactor operation toward end of service life of the vessel is 50 ft-lb or greater, depending upon the results of the inservice inspection program.

5.2.4.2 Acceptable Fracture Energy Levels

Fracture toughness requirements for the reactor vessel are established in accordance with the applicable provisions of the ASME Code, Section III as discussed in Section 5.2.1.

In order to take into consideration irradiation effects, the design of the reactor internals and of the water annulus between the active core and vessel wall is such that, for reactor operation at the maximum expected output and an 80 percent plant capacity factor, the vessel fluence (E > 1 Mev) at the inner (wetted) clad surface will not exceed 3.791 x 10^{19} n/cm^2 for 32 EFPY nor 5.277 x 10^{19} n/cm^2 for 48 EFPY. The values of 32 EFPY and 48 EFPY are based on full power operation for 40 years and 60 years, respectively, assuming an 80 percent reactor capacity factor.

The fluence analysis is discussed in section 4.3.3.3.

The reactor vessel beltline region consists of steel having controlled residual element content. Based on the copper and nickel content in A-533B material, the maximum predicted ART for the predicted fluence is calculated to be 113 °F at 32 EFPY and 117 °F at 48 EFPY per Regulatory Guide 1.99, Revision 2. As of May 1988, the NRC issued Regulatory Guide 1.99, Revision 2 as an acceptable approach for calculating the effects of neutron radiation embrittlement of the low-alloy steels currently used for light water cooled reactor vessels. Previous shift predictions were based on Figure 5.2-28 (developed from the references given in Table 5.2-10).

The actual NDTT shift will be monitored and determined from the reactor vessel material surveillance program and the resulting operating limits can then be established throughout plant life.

5.2.4.3 Operating Limitations During Startup and Shutdown

Limitations on pressurization and heatup of the RCS are defined by the RCS material exhibiting the "lowest service temperature" until irradiation effects on the reactor vessel become more limiting. The maximum heatup and cooldown rate of the reactor vessel is specified to be 100 °F per hour for design evaluation purposes.

The maximum allowable RCS pressure at any temperature is based upon the stress limitations for brittle fracture considerations. These limitations are derived by using the rules contained in Section III of the ASME Code including Appendix G, Protection Against Nonductile Failure and the rules contained in 10 CFR 50, Appendix G, Fracture Toughness Requirements.

The reactor vessel beltline consists of six plates, the longitudinal welds in the intermediate and lower shell course, and the girth weld joining those two shell courses. In order to estimate the adjusted reference temperature after exposure to neutron irradiation, values are needed of the initial reference temperature (RT_{NDT}) and chemical content (copper and nickel content) for each of the beltline materials. The data used as the basis for estimating are shown in Table 5.2-20 and Table 5.2-20a. The copper and nickel contents were obtained from material certification test reports and supporting records. The initial RT_{NDT} was obtained from one of the following sources:

Longitudinal Weld Seams -

> Generic value for submerged arc welds (Reference: "Evaluation of Pressurized Themal Shock Effects due to Small Break LOCA's with Loss of Feedwater for the Combustion Engineering NSSS," Combustion Engineering, Inc., report CEN-189, December 1981).

Girth Weld and Plate C-8009-3 -

Pre-irradiation surveillance material tests in accordance with NB-2330 of the ASME Boiler and Pressure Vessel Code, Section III (see also Table 5.2-17).

Remaining Plates -

Estimated based on drop weight test and longitudinally oriented Charpy V-notch impact tests in accordance with Branch Technical Position MTEB 5-2, "Fracture Toughness Requirements," from NUREG-0800, USNRC Standard Review Plan, Section 5.3.2, Revision 1, July 1981.

Similar testing was not performed on all remaining material in the RCS. However, sufficient impact testing was performed to meet appropriate design code requirements and a conservative RT_{NDT} of 50 °F has been established for those materials.

The initial reference temperature, RT_{NDT}, of the reactor vessel and closure head flanges was determined using the certified material test reports for the two components. Because it could not be ascertained that the Charpy specimens were oriented normal to the principal working direction, paragraph B.1.1(3) (b) of Branch Technical Position MTEB 5-2 was followed. The material properties are summarized below:

Component	Identification Number	NDTT	Tcv+20°F	RT_{NDT}
Vessel Flange	C-8001	30°F	30°F	30°F
Closure Head Flange	C-8002	0°F	30°F	0°F

Where Tcv is the lowest Charpy test temperature at which at least 50 ft-lb and 35 mils lateral expansion was exhibited, and 20 °F is added to Tcv following Branch Technical Position MTEB 5-2. As a result of fast neutron irradiation in the beltline region of the reactor vessel, there will be an increase in RT_{NDT} with operation. One technique used to predict the integrated fast neutron ($E \geq 1$ Mev) fluence of the reactor vessel is described in Section 5.2.4.2.

Since the neutron spectra and flux measured at the samples and reactor vessel inside radius should be nearly identical, the measured reference transition temperature shift for a sample can be applied to the adjacent section of the reactor vessel for later stages in plant life equivalent to the difference in calculated flux magnitude. The maximum exposure of the reactor vessel will be obtained from the measured sample exposure by application of the calculated azimuthal neutron flux variation. The maximum integrated fast neutron ($E \geq 1$ Mev) exposure of the reactor vessel including tolerance is computed to be 3.791×10^{19} n/cm^2 for 32 EFPY (5.277×10^{19} n/cm^2 for 48 EFPY) assuming operation at 2815 Mwt through Cycle 15 and 3026 Mwt for Cycle 16 to end of life and 80 percent load factor. The predicted RT_{NDT} shift for 32 EFPY and 48 EFPY are 101 °F and 105 °F, respectively, using the methods of Regulatory Guide 1.99, Revision 2. The actual shift in RT_{NDT} will be established periodically during plant operation by testing of reactor vessel material samples which are irradiated cumulatively by securing them near the inside wall of the reactor vessel as described in Section 5.2.4.4.2 and shown in Figure 5.2-29. To compensate for any increase in RT_{NDT} caused by irradiation, limits on the pressure-temperature relationship are periodically changed to stay within the stress limits during heatup and cooldown. During the first two years of reactor operation, conservatively high fluence of 1.8×10^{18} n/cm^2 is assumed which corresponds to 2,900 MWt and an 80 percent load factor. The corresponding RT_{NDT} shift is 20 °F, based on the curve shown in Figure 5.2-28. Thus, for this interval, the upper limit to the RT_{NDT} is (initial + shift) or 0 °F + 20 °F = 20 °F. As of

May 1988, the NRC issued Regulatory Guide 1.99, Revision 2 as a means of predicting the shift in RT_{NDT} due to irradiation embrittlement. This guide describes general procedures acceptable to the NRC staff for calculating the effects of neutron radiation embrittlement of the low-alloy steels currently used for light water cooled reactor vessels.

5.2.4.3.1 32 EFPY P/T Limits

Calculations of ART were performed for operation out to 32 EFPY following Regulatory Position 1.1 of Regulatory Guide 1.99, Revision 2. The initial material properties given in Tables 5.2-20 and 5.2-20a, and a calculated peak vessel inside surface neutron fluence of 3.791×10^{19} n/cm^2 (E > 1 MeV) were used to compute the ART at the 1/4t (where t is vessel thickness) and 3/4t locations. The limiting (highest) ART values were 113 °F at the 1/4t and 99 °F at the 3/4t for plate C-8010-1 corresponding to 32 EFPY operation.

The limit lines in Technical Specification (TS) Figures 3.4-2A, 3.4-2B, and 3.4-2C are based on the following:

A. The pressure/temperature (P/T) limit curves for the Arkansas Nuclear One Unit 2 (ANO-2) reactor vessel at 32 effective full power years (EFPY) of operation including an estimated increase in fluence due to a 7.5% power uprate, which was implemented at the beginning of Cycle 16. The data used to develop these operational limits are based on the evaluation of the ANO-2 reactor vessel surveillance capsule (BAW-2399, Ref. 21). Pressure-temperature limits are developed for normal heatup and cooldown operating conditions and inservice leak and hydrostatic (ISLH) test conditions. These new limits take into account the effects of irradiation on the reactor vessel materials. Details for the development of the P/T limit curves are in Reference 22.

   10 CFR 50.60 requires that pressure/temperature (P/T) limits be established for reactor pressure vessels during normal operating and hydrostatic or leak rate testing conditions using the criteria of 10 CFR 50, Appendix G. Appendix G of 10 CFR 50 specifies that the requirements for these limits are the ASME Section XI, Appendix G limits. The new P/T analyses credit the use of Code Case N-641, *"Alternative Pressure-Temperature Relationship and Low Temperature Overpressure Protection System Requirements"* (January 27, 2000). Code Case N-641 permits the postulation of a circumferentially oriented flaw (in lieu of an axially oriented flaw) for the evaluation of the circumferential welds in RPV P/T limit curves. Code Case N-641 also permits the use of an alternate reference fracture toughness (K_{IC} fracture toughness curve instead of K_{IA} fracture toughness curve) for reactor vessel materials in determining the P/T limits.

   Case N-641 for ANO-2 ensures an acceptable margin of safety. The approach is justified by consideration of the over-pressurization design basis events and the resulting margin to reactor vessel failure.

   Pressure/temperature limits for the ANO-2 reactor vessel are calculated to satisfy the requirements of 10 CFR Part 50, Appendix G using analytical methods and acceptance criteria of the ASME Boiler and Pressure Vessel Code, Section XI, Appendix G and ASME Code Case N-640 for use of the K_{IC} fracture toughness curve and ASME Code Case N-588 for influence coefficient solution for K_{IT} and explicit method for calculating membrane correction factor (M_m). The methods and criteria employed to establish operating pressure and temperature limits are described below. The objective of these limits is to prevent non-ductile failure during normal operating conditions, including anticipated operational occurrences and system hydrostatic pressure and leak tests.

Of all the components of the RCPB that are subject to the requirements of 10 CFR 50, Appendix G, the only regions that regulate the pressure/temperature limits are the closure head flange, inlet and outlet nozzle, and beltline regions of the reactor vessel. The closure head region can be significantly stressed at relatively low temperatures due to mechanical loads resulting from bolt preload and pressure. High stresses, of the order of two to three times the shell membrane stress, can also occur at the inside corners of the reactor vessel nozzles due to local stress concentrations. Typically, the closure head and nozzle regions influence the pressure/temperature limits only during the first several service periods, prior to significant neutron embrittlement of the reactor vessel beltline materials. After several years of exposure to neutron irradiation, the increase in the RT_{NDT} of the beltline region materials is such that the RCPB pressure/temperature limits are usually controlled by the beltline region of the reactor vessel. The pressure/temperature limits contained in this report are established by determining the minimum allowable pressure, as a function of fluid temperature, considering the closure head, the inlet and outlet nozzles, and the beltline regions of the reactor vessel.

The analytical procedures used to calculate P/T limits are based on linear elastic fracture mechanics methods for calculating stress intensity factors at the maximum depths of postulated semi-elliptical surface flaws.

The basic equation for allowable pressure is:

$$P_{allow} = \frac{K_{IR} - K_{IT}}{SF \times \hat{K}_{IP}}$$

where,

P_{allow}	=	allowable pressure
K_{IR}	=	reference stress intensity factor (K_{Ia} or K_{Ic})
K_{IT}	=	thermal stress intensity factor
$\hat{K}_{IP}$	=	unit pressure stress intensity factor (due to 1 psig)
SF	=	safety factor

For each analyzed transient and steady state condition, the allowable pressure is determined as a function of reactor coolant temperature considering postulated flaws in the reactor vessel beltline, inlet nozzle, outlet nozzle, and closure head. In the beltline region, flaws are presumed to be present at the 1/4t and 3/4t locations of the controlling material (shell plate or weld), as defined by the fluence adjusted RT_{NDT}. The nozzle flaw is located at the inside juncture (corner) of the nozzle. The closure head flange limit is not explicitly calculated. However, for the condition when the core is not critical, the uncorrected closure flange allowable pressure of 622 psig (20% of preservice hydrostatic test pressure of 3110 psig) is maintained as the limit for temperatures up to 150 °F (30 °F RT_{NDT} + 120 °F margin) per Table 1, item 2.b of 10 CFR 50, Appendix G. Above, 150 °F, the closure flange allowable pressure is 2500 psig. P/T limits for the beltline and nozzle regions are calculated using a factor of safety of 2 for normal operation and 1.5 for ISLH operation. These location specific P/T limits are calculated using the FRA-ANP proprietary computer code PTPC. The maximum allowable pressure at a particular fluid temperature is taken as the minimum value of allowable pressure calculated for each flaw

location and operating condition, including steady state. A P/T limit curve is then constructed as the collection of points that define the maximum allowable pressures as a function of fluid temperature for a particular mode of reactor operation. The P/T limit curves provided in the TS are adjusted for sensor location but do not include instrument error. They are, "refined" as necessary to eliminate regions of negative slope by lowering the allowable pressure for temperatures less than that corresponding to the minimum pressure. The criticality limit temperature is obtained by satisfying the requirement of Item 2.d in Table 1 of 10 CFR 50, Appendix G. It requires the minimum temperature to be the larger of minimum permissible temperature for inservice system hydrostatic pressure test (taken as the leak test temperature corresponding to the ISLH limit pressure of 2500 psig with heatup and cooldown rates up to 10 ^{o}F/hr) or the RT_{NDT} of the closure flange material + 160 ^{o}F.

Primary aspects of the calculational procedures utilized in the development of P/T limits are discussed below.

Fracture Toughness

The fracture toughness of reactor vessel steels is expressed as a function of crack-tip temperature, T, indexed to the adjusted reference temperature of the material, RT_{NDT}. Pressure/temperature limits developed in accordance to ASME Code, Section XI, Appendix G utilize the expression for crack arrest fracture toughness,

$$K_{IA} = 26.8 + 1.233 \exp [0.0145 (T - RT_{NDT} + 160 \,^{o}F)]$$

Exemptions to 10CFR50, Appendix G, that cite ASME Code Case N-640 (utilized in the generation of the P/T limits in the TS), utilize the crack initiation fracture toughness,

$$K_{IC} = 33.2 + 2.806 \exp [0.02 (T - RT_{NDT} + 100 \,^{o}F)]$$

The upper shelf fracture toughness is limited to an upper bound value of 200 ksi $\sqrt{}$in. The crack-tip temperature needed for these fracture toughness equations is obtained from the results of a transient thermal analysis, described in BAW-2405 (Ref. 22).

C. For plant heatup, the thermal stress is compressive at the reactor vessel inside wall and is tensile at the reactor vessel outside wall. Internal pressure creates a tensile stress at the inside wall as well as the outside wall locations. Consequently, the outside wall location has the larger total stress when compared to the inside wall. However, neutron embrittlement, (shift in material RT_{NDT} and reduction in fracture toughness) is greater at the inside location than the outside. Therefore, both the inside and outside flaw locations must be analyzed to assure that the most limiting condition is achieved.

For each analyzed transient and steady state condition, the allowable pressure is determined as a function of reactor coolant temperature considering postulated flaws in the reactor vessel beltline, inlet nozzle, outlet nozzle, and closure head. In the beltline region, flaws are presumed to be present at the 1/4t and 3/4t locations of the controlling material (shell plate or weld), as defined by the fluence adjusted RT_{NDT}.

The P/T curves provided in the TS are adjusted for sensor location but do not include instrument uncertainty. Protection against non-ductile failure is ensured by using these curves to limit the reactor coolant pressure. The P/T limits for normal heatup (including criticality core limits) at 32 EFPY are provided on the revised TS

Figure 3.4-2A. The criticality limit temperature is 190 ^{o}F. It is based on the RT_{NDT} of the closure flange material (30 ^{o}F) plus 160 ^{o}F which is larger than the 175 ^{o}F value that corresponds to the ISH limit pressure of 2500 psig. Considering all the ramp and step cooldown transient scenarios, composite cooldown P/T limits for cooldown are shown in TS Figure 3.4-2B. The ISH P/T limits are shown in TS Figure 3.4-2C. Acceptable pressure and temperature combinations for reactor operation are below and to the right of the pressure-temperature limit curves.

For normal heatup operation, TS Figure 3.4-2A, four ramped heatup transient conditions are considered in the evaluation. These transient conditions are simulated by increasing the reactor coolant system (RCS) cold leg temperature from 50 °F to 560 °F at constant rates of 50, 60, 70 and 80 °F/hr. The ISH test condition contained in TS Figure 3.4-2C is also evaluated using the above RCS cold leg temperature ranges, at a ramp rate of 10 °F/hr.

For normal cooldown operation, TS Figure 3.4-2B, the following temperature dependant rates for ramped and stepped cooldown transients are considered in the evaluation. Except for these cooldown rates not including a margin for instrument uncertainty they are identical to those used in the previous TS P/T curves contained in the TSs. The assumptions also include that only two RCPs are in operation while in the LTOP region of the curves.

For 32 EFPY P/T Limits (Reference 22):

A maximum cooldown rate of 100 °F per hour (constant or 50 °F in any half hour period (step) for RCS cold leg temperatures between 50 °F and 560 °F.

For 48 EFPY P/T Limits (Reference 25):

Actual RCS Cold Leg Temperature	Maximum Cooldown Rate
200 ^{o}F < T_c	100 °F/hr (constant) or 50 °F in any half hour period (step)
120 ^{o}F ≤ T_c ≤ 200 ^{o}F	60 °F/hr (constant) or 30 °F in any half hour period (step)
T_c < 120 ^{o}F	25 °F/hr (constant) or 12.5 °F in any half hour period (step)

A step change is also included in the ramped and step cooldown transients to simulate the temperature change that occurs at the initiation of shutdown cooling when the last reactor coolant pump is secured.

D. Results of the thermal and fracture mechanics analyses performed for the ANO-2 reactor vessel are presented in the form of P/T curves for (three) operating conditions; normal heatup, normal cooldown, and ISLH operations. These P/T curves are location adjusted to account for the differences between the controlling pressure location and the point of system pressure measurement in the pressurizer. They do not account for instrument error.

Protection against nonductile failure is ensured by using these curves to limit the reactor coolant pressure. Acceptable pressure and temperature combinations for reactor operation are below and to the right of the pressure-temperature limit curves.

Restrictions on allowable operating conditions and equipment operability requirements have been established to ensure that operating conditions are consistent with the assumptions of the accident analysis. Specifically, RCS pressure and temperature must be maintained within the heatup and cooldown rate dependent pressure/temperature limits established.

5.2.4.3.2 48 EFPY P/T Limits

Adjusted reference temperatures (ARTs) were calculated for all ANO-2 beltline materials out to 48 EFPY following Regulatory Positions 1.1 and 2.1 of Regulatory Guide 1.99, Revision 2. The initial material properties given in Tables 5.2-20 and 5.2-20a, and a calculated peak vessel inside surface neutron fluence of 5.277 x 10^{19} n/cm^2 (E > 1 MeV) were used to compute the ART at the 1/4t and 3/4t locations. The limiting (highest) ART value is 117 °F at the 1/4 t and 104 °F at the 3/4t for plate C-8010-1 corresponding to 48 EFPY operation.

The pressure/temperature limit lines in Technical Specification Figures 3.4-2A, 3.4-2B, and 3.4-2C remain based on 32 EFPY of operation. Revised curves for extended operation will be prepared and submitted prior to reaching 32 EFPY. For license renewal, the pressure/temperature limits were evaluated to 48 EFPY using the methods described in Section 5.2.4.3.1 and were acceptable for operation (Reference 23). See Section 18.2.1.3 for further discussion.

5.2.4.3.3 Response to Generic Letter 92-01, Revision 1, Supplement 1

On May 19, 1995, the NRC issued Generic Letter 92-01, Revision 1, Supplement 1 to require licensees to identify, collect, and report any new data pertinent to the analysis of the structural integrity of their reactor pressure vessels (RPV) and to assess the impact of that data on their RPV integrity analyses relative to the requirements of 10 CFR 50.60, 10 CFR 50.61, Appendices G and H of 10 CFR 50, and any potential impact on low temperature overpressure (LTOP) limits or pressure/temperature (P/T) limits.

To fulfill the purpose of the supplement, the NRC has required licensees to provide the following information:

1. A description of those actions taken or planned to locate all data relevant to the determination of RPV integrity, or an explanation of why the existing data base is considered complete as previously submitted;

2. An assessment of any change in best-estimate chemistry based on consideration of all relevant data;

3. A determination of the need for use of the ratio procedure in accordance with the established Position 2.1 of Regulatory Guide 1.99, Revision 2, for those licensees that use surveillance data to provide a basis for the RPV integrity evaluation; and,

4. A written report providing any newly acquired data as specified above and (1) the results of any necessary revisions to the evaluation of RPV integrity in accordance with the requirements of 10 CFR 50.60, 10 CFR 50.61, Appendices G and H to 10 CFR 50, and any certification that previously submitted evaluations remain valid. Revised evaluations and certifications should include consideration of Position 2.1 of Regulatory Guide 1.99, Revision 2, as applicable, and any new data.

In response to the generic letter, the CEOG Reactor Vessel Working Group (RVWG) initiated a project to evaluate the design and fabrication records for CE reactor vessels. As a result of this evaluation, it was determined that the “best-estimate” values for the copper and nickel content for the reactor vessel beltline material needed to be revised. Table 5.2-20a provides the new “best-estimate” chemistry values. It should be noted that the “best-estimate” values were determined as the mean of measured values for the plate or weld. This is consistent with the definition provided in 10 CFR 50.61.

It should be noted that Position 2 of Regulatory Guide 1.99, Revision 2 is applicable “[w]hen two or more credible surveillance data sets become available from the reactor in question.” At that time, only one surveillance data set had been examined. This data set was the 97° surveillance capsule. Battelle Columbus Laboratories issued a report on their examination, testing, and evaluation of the specimen on May 1, 1984, (Reference 18). In addition there are no “sister vessels” for the six beltline plates in ANO-2 (Reference 19). This regulatory position is therefore not applicable to ANO-2. Therefore, the adjusted Reference Temperatures will be calculated using Position 1.1 of Regulatory Guide 1.99, Revision 2.

Based on the information provided above, several vessel evaluations were performed to identify the impact on current limits. These evaluations include the determination of the limiting component, validating the current P/T and LTOP limits, determining the revised RT_{PTS}, and the decrease in the Upper Shelf Energy.

5.2.4.3.4 Evaluation of the Second ANO-2 Reactor Vessel Specimen and Summary of Results

10 CFR 50, Appendix H, *"Reactor Vessel Material Surveillance Program Requirements,* " defines the material surveillance program required to monitor changes in the fracture toughness properties of ferritic materials in the reactor vessel beltline region resulting from exposure to neutron irradiation and the thermal environment. Fracture toughness test data is obtained from material specimens contained in capsules that are periodically withdrawn from the reactor vessel. This data permits determination of the conditions under which the vessel can be operated with adequate safety margins against non-ductile fracture throughout its service life.

The reactor vessel surveillance program for ANO-2 included six capsules designed to monitor the effects of neutron and thermal environment on the materials of the reactor pressure vessel core region. The capsules, which were inserted into the reactor vessel before initial plant startup, were positioned inside the reactor vessel between the core support barrel and the vessel wall. Capsule W-104 was irradiated in the 104° position during the time of irradiation in the reactor vessel (cycles 1 through 14).

Capsule W-104 was removed during the 2R14-refueling outage (Fall of 2000). The capsule contained Charpy V-notch (CVN) impact test specimens fabricated from one base metal plate (SA-533, Grade B, Class 1), heat-affected-zone (HAZ) material, a weld metal representative of the ANO-2 reactor vessel beltline region intermediate and lower shell longitudinal welds, and a Standard Reference Material (SRM). The SRM is a standard heat of SA-533, Grade B, Class 1 material. The tensile test specimens were fabricated from the same base metal plate, HAZ, and

weld metal. The number of specimens of each material contained in Capsule W-104, the chemical compositions of the surveillance materials, and the location of the individual specimens within the capsule is contained in Framatome report BAW-2399 (reference 21). This document satisfies the reporting requirements established in 10CFR50, Appendix H.

All base metal CVN and tensile specimens were machined from the 1/4t location of the plate material. The base metal specimens were oriented such that the longitudinal axis of each specimen was perpendicular to the principal working direction of the plate (transverse orientation). The HAZ and weld metal specimens were oriented such that the longitudinal axis of each specimen was perpendicular to the weld seam. The CVN HAZ and weld metal specimens had the notch oriented parallel to the weld seam. Capsule W-104 contained dosimeter wires of copper, iron, nickel, titanium, sulfur, aluminum-0.17 weight percent cobalt (cadmium-shielded and unshielded), and uranium-238. Thermal monitors fabricated from four low-melting alloys were included in the capsule. The thermal monitors were sealed in quartz tubes and inserted in spacers.

10 CFR 50, Appendix G, also requires a minimum initial Charpy Upper Shelf Energy (C_vUSE) of 75 ft-lbs for all beltline region materials. The C_VUSE value requirements are to be obtained from Charpy V-notch specimens oriented in the transverse (weak) direction for base material and along the weld for weld material according to the ASME Code. Table 5.2-5 provides C_VUSE values for the longitudinal (strong) direction for the RPV beltline materials. In accordance with MTEB No. 5-2, Section B.1.2, if tests were only made on longitudinal specimens, the values should be reduced to 65% of the longitudinal values to estimate the transverse (weak) properties. Table 5.2-21 provides the RPV beltline material C_VUSE values for the transverse (weak) direction required by 10 CFR 50 Appendix G.

No action is required for a material that does not meet the initial 75 ft-lbs requirement provided that the irradiation embrittlement does not cause the C_VUSE to drop below 50 ft-lbs throughout the life of the vessel. Based on the results of the capsule analysis (at 15.7 EFPY and 2.937E+19 n/cm^2), the measured USE for ANO Unit 2 (W-104 capsule) surveillance materials do not fall below the 50 ft-lbs minimum requirement (Section 7 of BAW-2399, ref. 21). The measured percent decrease in C_VUSE for the surveillance base metal plate, weld metal, HAZ, and SRM are within reasonable agreement with the values predicted using Regulatory Guide 1.99, Revision 2.

Based on predictions of percentage decrease in C_VUSE values of beltline materials due to irradiation to 48 EFPY using Positins 1.2 and 2.2 with Figure 2 in Reg. Guide 1.99, Revision 2, it is expected that C_VUSE values will be maintained above the 50 ft-lb minimum, which is required by 10 CFR 50, Appendix G. As shown in Table 5.2-22 and independently confirmed under Section 4.2.1.2 of NUREG 1828, the lowest C_VUSE value conservatively predicted for all beltline materials at 48 EFPY is above the 50 ft-lb minimum requirement (limiting material is weld 2-203 A). C_VUSE analysis to 48 EFPY includes the current licensing period (32 EFPY) through the expiration of the period of extended operation for the ANO-2 reactor vessel.

The analysis of the reactor vessel material contained in the second surveillance capsule, Capsule W-104, removed for evaluation as part of the Arkansas Nuclear One Unit 2 Reactor Vessel Surveillance Program, led to the following conclusions:

The capsule received an average fast neutron fluence of 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV).

The 30 ft-lb transition temperature for the Base Metal Plate C-8009-3, Heat C8182-2, in the transverse orientation, increased 53 °F after irradiation to 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV). In addition, the C_VUSE for this material decreased 31%.

The 30 ft-lb transition temperature for the Weld Metal, C-8009-1/C-8009-2, Heat 83650 increased 17 °F after irradiation to 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV). In addition, the C_VUSE for this material decreased 19%.

The 30 ft-lb transition temperature for the heat affected zone increased 113 °F after irradiation to 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV). In addition, the C_VUSE for this material decreased 20%.

The 30 ft-lb transition temperature for the Standard Reference Material, HSST Plate 01, increased 132 °F after irradiation to 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV). In addition, the C_VUSE for this material decreased 40%.

The measured upper-shelf energies for the Arkansas Nuclear One Unit 2 Capsule W-104 surveillance materials do not fall below the required 50 ft-lbs limit after the irradiation to 2.937 x 10^{19} n/cm^2 (E > 1.0 MeV).

The ART for the reactor vessel beltline region materials are calculated in accordance with Regulatory Guide 1.99, Revision 2. The ART is calculated by adding the initial RT_{NDT}, the predicted radiation-induced ΔRT_{NDT}, and a margin term to cover the uncertainties in the values of initial RT_{NDT}, copper and nickel contents, fluence, and the calculational procedures. The predicted radiation induced ΔRT_{NDT} is calculated using the respective reactor vessel beltline materials copper and nickel contents and the neutron fluence applicable to 32 EFPY and 48 EFPY including an estimated increase in flux due to a proposed power uprate. The 1/4t and 3/4t wall locations for each beltline material are determined by adding the thickness of the cladding to the distance into the base metal at the 1/4t and 3/4t locations. The 1/4t and 3/4t ART results for the ANO-2 reactor vessel beltline region materials applicable to 32 EFPY are presented in the Framatome Report BAW-2405 (Reference 22). The 1/4t and 3/4t ART results for the ANO-2 reactor vessel beltline region materials applicable to 48 EFPY were calculated to support the ANO-2 license renewal. Based on these results, the controlling beltline material for the ANO-2 reactor vessel is the lower shell plate C-8010-1. The applicability of 32 EFPY is also consistent with the removal schedule for the next capsule as shown in ANO-2 SAR Table 5.2-12.

The process used for fluence evaluation involving the W-104 capsule and current prediction was under BAW-2241. Framatome ANP, Inc. has developed a calculational based fluence analysis methodology in Topical Report BAW-2241P-A, Revision 1, *"Fluence and Uncertainty Methodology"* dated April 1999 which closely predicts the fast neutron fluence in the reactor vessel using surveillance capsule dosimetry or cavity dosimetry (or both) to verify the fluence predictions. This methodology was developed through a full-scale benchmark experiment which demonstrated that the accuracy of a fluence analysis that employs the Framatome ANP methodology would be unbiased and have a precision well within the U.S. Nuclear Regulatory Guide 1.190 limit of 20%.

The NRC safety evaluation report (SER) to BAW-2241P-A, Revision 1 concluded that "the proposed methodology is acceptable for referencing in licensing applications for determining the pressure vessel fluence of Westinghouse, CE, and B&W designed reactors." In addition, there were three limitations imposed on the SER for Revision 0 of the topical. These limitations involved analysis of reactor designs not included in the BAW-2241P-A database (e.g. partial length fluence assembly designs), changes in cross sections from those reviewed by the Staff, and any other changes in methodology. As discussed in BAW-2399 (ref. 21), none of these limitations are applicable to the analysis performed for ANO-2.

The Framatome ANP methodology was used to calculate the neutron fluence exposure to the 104° (W-104) capsule of the ANO Unit 2 nuclear reactor. The methodology was also used to estimate fluences on the inner surface of the reactor vessel, as well as at specified weld locations on the vessel surface. The fast neutron fluence (E >1.0 MeV) at each location was calculated in accordance with the requirements of Regulatory Guide 1.190. The energy-dependent flux on the capsule was used to determine the calculated activity of each dosimeter. Neutron transport calculations in two-dimensional geometry were used to obtain energy dependent flux distributions throughout the core. Reactor conditions were representative of an average over the cycle 1-9 and 10-14 irradiation periods. These periods were separated in order to adequately represent a water temperature reduction that occurred between cycles 9 and 10. Geometric detail was selected to explicitly represent the dosimeter holder and the reactor vessel.

The dosimetry of the W-104 capsule was located in the reactor for a total irradiation time of 5726 effective full power days (EFPDs) for cycles 1-14. The rated thermal power for the fourteen cycles was 2815 MWt. The fluence on the center of the capsule must be estimated in order to allow for analysis of the Charpy and tensile specimens. As a result, the entire cycle 1-14 analysis results in a maximum capsule fluence of 2.937 X 10^{19} n/cm^2. Based on an extrapolated flux incorporating power uprate conditions, the projected 32 EFPY peak fast fluence of the ANO-2 reactor vessel beltline region clad surface was determined to be 3.791 X 10^{19} n/cm^2.

R.G. 1.99, Revision 2, Position 2.1 requires that if there is evidence that the copper/nickel content of the surveillance specimen differs from that of the vessel, the measured values of ΔRT_{NDT} should be adjusted by multiplying them by the ratio of the chemistry factor for the vessel material to that for the surveillance specimen. The surveillance data would be fitted to obtain the relationship of ΔRT_{NDT} to fluence by calculating the chemistry factor for the best fit by ratioing each adjusted ΔRT_{NDT} by its corresponding fluence factor. The results of the second specimen evaluation have been performed in accordance with this position and are reported in Table 3-2 of the BAW-2405 report (ref. 22).

A pressurized thermal shock (PTS) evaluation for the ANO-2 reactor vessel beltline materials was performed for 32 EFPY in accordance with 10 CFR 50.61. The results of the PTS evaluation are shown in Table 4-1 of the BAW-2405 report (ref. 22). These results demonstrate that the ANO-2 reactor vessel beltline materials will not exceed the PTS screening criteria before 32 EFPY. The controlling beltline material for the ANO-2 reactor vessel with respect to PTS is the lower shell plate C-8010-1, with a RT_{PTS} value of 118.8 °F that is well below the PTS screening criterion of 270 °F. The PTS evaluation for ANO-2 was extended to 48 EFPY to support the ANO-2 license renewal. The 48 EFPY results demonstrate that the ANO-2 reactor vessel beltline materials will not exceed the PTS screening criteria before 48 EFPY. The controlling beltline material for the ANO-2 reactor vessel with respect to PTS remains the lower shell plate C-8010-1, with a RT_{PTS} value of 122.6 °F that is well below the PTS screening criterion of 270 °F.

5.2.4.4 Reactor Vessel Material Surveillance Program

5.2.4.4.1 Nil Ductility Transition Temperature Determination

The reactor vessel is designed and fabricated in such a manner that significant operational limitation will not be imposed on the RCS resulting from shifts in reactor vessel NDT temperature. The vessel material monitoring program will be conducted within the guidelines of ASTM E-185, "Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels."

The pre-irradiated NDT temperature of the reactor materials has been established using drop weight tests in accordance with ASTM E-208, and correlations have been made with Charpy impact specimen tests conducted in accordance with ASTM E-23. This correlation, along with the Charpy impact specimens irradiated in the surveillance program, will be used to monitor the NDTT shift of the vessel materials.

The test specimen used in establishing the unirradiated NDTT of the base metal were obtained from (1/4)T (where T is plate thickness) locations of sections of the plate used in the core region. The HAZ samples were taken from the (1/4)T locations of the same plate used for base metal tests. The weld metal samples were taken from the inner region of the deposited weld metal. The thermal history of the test materials is representative of similar materials in the reactor vessel. The impact properties of the specimen locations are representative of the material through the entire thickness. Use of the NDT values obtained from samples taken from the inner regions of the test materials represents a conservative approach for establishing the initial minimum operating temperature and the base for the predicted minimum operating temperature after irradiation because the advantages of the more favorable NDT properties of the surface regions are not taken into consideration.

Samples oriented in the WR (weak) direction are included in the Surveillance Program. Code requirements for initial operation are satisfied by analysis of samples in the RW (strong) direction only. The minimum upper shelf energy value that is acceptable for continued operation toward the end of service life of the vessel will be dependent upon the results of the inservice inspection program with respect to crack size and locations, and the service requirements of the vessel at that point in life, i.e., the fluence to which the materials have been exposed and the number and size of the flaws, if any.

5.2.4.4.2 Surveillance Program

The surveillance program will monitor the radiation induced changes in the mechanical and impact properties of the pressure vessel materials. Changes in the impact properties of the material will be evaluated by the comparison of pre- and post-irradiation Charpy impact test specimens. Changes in mechanical properties will be evaluated by the comparison of pre- and post- irradiation data from tensile test specimens. ASTM E-185 establishes the criteria which are followed in the conduct of the surveillance tests, and the surveillance program described herein satisfies the intent of the proposed Appendix H 10 CFR Part 50 as published in the Federal Register on July 3, 1971. The differences between the plant surveillance program and the requirements presented in Appendix H are the following:

A. Appendix H, Section II.C - Attachments to Reactor Vessel

   The surveillance program allows for attachment of surveillance capsules to the inside wall of the reactor vessel in the beltline region. This modification to 10 CFR 50, Appendix H, Section II.C.2 was described in Topical Report CENPD-155-P, "CE Procedures for Design, Fabrication, Installation and Inspection of Surveillance Specimen Holder Assemblies," September 1974. The NRC reviewed CENPD-155-P and has considered all the procedures described therein as acceptable (See Reference 9).

B. Appendix H, Section II.C - Capsule Replacements

   The surveillance capsule holders will permit installation of replacement capsule assemblies during those shutdown periods when the reactor internals are removed.

Three metallurgically different materials representative of the reactor vessel are investigated. These are base metal, weld metal, and weld HAZ material. A complete record of the chemical analysis, fabrication history and mechanical properties of all surveillance test materials is maintained.

The results of the chemical analyses for the six plates of the beltline region of the vessel are presented in Table 5.2-4. The weld chemistry is from an analysis of the longitudinal seam weld deposit from the lower shell course and is representative of the weldments in the beltline region. See also Table 5.2-20a.

Table 5.2-11 gives the type, quantity, location and orientation of the test specimens in each of the surveillance capsules. The test materials, taken from the materials used in the beltline of the reactor vessel, include base metal and HAZ from the same heat and weld metal. The manufacture of both the test materials and the test specimens has been carried out in accordance with the requirements of Paragraph 3.0 of ASTM E-185. A sufficient amount of base metal, weld metal and HAZ test material to provide two additional test specimens has been retained with full documentation and identification for the future evaluation should the need arise. Each of the test materials were analyzed for approximately 21 elements, including all those listed in Paragraph 3.1.3 of ASTM E-185. The pre-irradiation NDTT of each plate of the intermediate and lower vessel shell courses has been determined from the drop weight tests and correlated with Charpy impact tests.

Base metal specimens were fabricated from sections of that plate in the core region of the vessel which could become the limiting plate with respect to reactor operation during its lifetime. This material was selected on the basis of initial transition temperature, upper shelf energy, estimated increase in NDTT, considering chemical composition and fluence. HAZ samples were obtained by welding sections from the same plate used for base metal specimens to another plate from the core region. Weld metal specimens were fabricated from the deposited weld metal produced using the same heat of filler material and the same production welding conditions as those used in joining the intermediate and lower shell courses.

Seventy-two of a total of 120 base metal Charpy impact specimens are oriented in the WR (transverse) direction of the plate metals. The remaining 48 base metal specimens are oriented in the RW (longitudinal) direction. All 72 weld metal impact specimens are oriented perpendicular to the longitudinal axis of the weld seam as are all 72 HAZ impact specimens.

The materials used for weld metal and HAZ test specimens are adjacent to the test material used for ASME Code, Section III tests and are at least one plate thickness from any water quenched edge. The procedures used for making the shallow girth welds in the reactor vessel are followed in the preparation of the weld metal and HAZ test material. The procedures for inspection of the reactor vessel welds are followed for inspection of the welds in the test materials. The welded plates are heat treated to a condition representative of the final heat treated condition of the completed reactor vessel.

The test specimens will be placed within six corrosion resistant irradiation capsules to prevent deterioration of the test specimens during irradiation. The axial position of the capsules is bisected by the midplane of the core. The circumferential locations include the peak flux regions.

The location of the surveillance capsule assemblies is shown in Figure 5.2-29. A typical surveillance capsule assembly is shown in Figure 5.2-30. A typical tensile monitor compartment assembly is shown in Figure 5.2-32. The capsule assembly holders and holder attachments to the reactor vessel wall are designed to withstand the forces due to deadweight, flow, differential thermal expansion, and flow induced pressures at normal operation and anticipated transients. The structural and fatigue analyses are performed in accordance with the ASME Code, Section III. The capsule assemblies are contained within the capsule holders.

They are axially loaded by a locking device and held securely at various intervals against the inside surface of the holders to prevent relative motion. Each compartment enclosure of the capsule assembly is internally supported by the surveillance specimens and is externally pressure tested to 3,125 psi during final fabrication. Fission threshold detectors are inserted into each surveillance capsule to monitor the fast neutron flux. Ni, ALCO, Fe, U, S, Ti, and Cu with known Co content are used for this application because their effective threshold energies are in the low Mev range. Selection of threshold detectors is based on the recommendations of ASTM E-261, "Method for Measuring Neutron Flux by Radioactive Techniques." Activation of the specimen material may also be analyzed to determine the amount of exposure.

The capsule assemblies containing the individual surveillance specimens can be removed during reactor refueling. No provision has been made for insertion of additional surveillance capsules after the reactor becomes operational without fully removing the vessel internals.

The maximum temperature of the encapsulated specimens will be monitored by including in the surveillance capsules small pieces of low melting point eutectic alloys or pure metals individually sealed in separate containers. The melting point of the thermal monitors will be in the operating range of the reactor.

Correlation monitor specimens included in the surveillance capsules (Charpy V-notch specimens machined from standard reference material) will be irradiated along with the surveillance test specimens. The standard reference material has been obtained from the USAEC Heavy Section Steel Technology Program. Use of standard reference material test specimens will permit correlation of the post-irradiated data obtained in the course of this surveillance program with data obtained from other surveillance programs or irradiated experiments. In addition, changes in impact properties of the correlation monitors will provide a cross check on the neutron dosimetry.

The test specimens used for monitoring the neutron induced property changes of the reactor vessel materials will be positioned near the inside wall of the reactor vessel so that the flux spectrum, fluence, and temperature of the specimens resemble as closely as possible the irradiation conditions of the reactor vessel. (The neutron fluence of the test specimens is expected to be about 15 percent greater than that of the adjacent vessel wall at any given time). The NDTT changes of these specimens will, therefore, closely approximate the NDTT changes of the materials in the reactor vessel. The surveillance holder brackets are welded to the vessel cladding. The joint geometry, fillet welds on both sides of the brackets, plus the welding procedure assure that these welds will never penetrate through the stainless steel clad into the carbon steel base metal. In addition, the results of detailed stress analyses of the attachment vessel wall region demonstrate that stress intensities are well within acceptable limits. Therefore, the presence of these attachments will not jeopardize the safety of the vessel. The rectangular tubes that hold the assemblies are positioned relative to the centerline of the core. The specimens will remain in the reactor until desired fluence levels have been attained, at which time they will be removed and tested.

Test specimens removed from the surveillance capsules will be tested in accordance with ASTM Standard Test Methods for Tension and Impact Testing. The data obtained from testing the irradiation specimens will be compared with the unirradiated data and an assessment of the neutron induced property changes of the pressure vessel materials made. This assessment of the NDTT shift will be based on the temperature shift in the average Charpy curves, the average curves being considered representative of the material.

The mechanical properties of the unirradiated reactor vessel surveillance materials are summarized in Table 5.2-16 and their chemical content in Table 5.2-17. The NDTT's for the base metal (both longitudinal and transverse orientations), weld metal and HAZ materials were determined in accordance with ASTM E-208. The standard reference material NDTT was obtained from HSST program data (see Reference 13). The 30 ft-lb fix temperature, RT_{NDT} and upper shelf energy data were obtained from Charpy impact tests of the surveillance and reference materials. The impact data, including both impact energy and lateral expansion as a function of test temperature, are shown in Figures 5.2-36 through 5.2-45. Impact tests were conducted in accordance with ASTM E-23. Room temperature and elevated temperature properties of the surveillance materials are reported in Table 5.2-18. The tensile tests were conducted in accordance with ASTM E-8 and ASTM E-21. These unirradiated properties of the surveillance and reference materials will form the basis for subsequent analysis of the response of the reactor vessel to neutron irradiation.

The periodic analysis of the surveillance samples will permit the monitoring of the neutron radiation effects upon the vessel materials. If, with due allowance for uncertainties in the NDTT determination, the measured NDTT shift turns out to be greater than predicted, the appropriate limitations would be imposed on permissible operating pressure-temperature combination and transients to ensure that the existing reactor vessel stresses are low enough to preclude brittle fracture failure.

An in-place annealing operation (see Section 5.2.4.5) could be conducted, if required. A sufficient number of surveillance capsules are included in the surveillance program to determine the recovery in properties resulting from such an annealing treatment without the need for installation of additional unirradiated specimens.

All surveillance capsules are inserted into their designated holders during the final reactor assembly operation. Each capsule remains in the reactor for the tentative time period listed in Table 5.2-12.

5.2.4.5 Reactor Vessel Annealing

The chemical composition of the reactor vessel shell courses is given in Table 5.2-4. Use of this material in the reactor vessel beltline region makes it unlikely that in-place annealing of the vessel will be necessary to reduce the NDTT shift later in plant life. If such annealing should become necessary, however, it can be accomplished by utilizing reactor coolant pump heat to maintain the primary system temperature at approximately 640 °F for one week. At this temperature, there is greater mobility of the radiation induced defects and much of the ductility loss due to irradiation will be restored.

The preparation required for the annealing process consists of removing the fuel from the reactor vessel and replacing some standard instrumentation with special test instrumentation. RCS pressure would be maintained between 2,390 psia and 2,440 psia during the annealing process to provide adequate reactor coolant pump NPSH. Design pressures and temperatures throughout the plant are consistent with the annealing conditions and would not be violated.

5.2.5 AUSTENITIC STAINLESS STEEL

5.2.5.1 Cleaning and Contamination Protection Procedures

Specific requirements for cleanliness and contamination protection are included in the equipment specifications for components fabricated with austenitic stainless steel. In addition, any external nonmetallic insulation to be used on austenitic stainless steel components conforms with the recommendations of Regulatory Guide 1.36, "Nonmetallic Thermal Insulation for Austenitic Stainless Steels." The provisions described below indicated the type of procedures utilized for components originally supplied by Combustion Engineering to provide contamination control during fabrication, shipment and storage.

Contamination of 300 series austenitic stainless steels by compounds which can alter the physical or metallurgical structure and/or properties of the material was avoided during all stages of fabrication. Painting of 300 series stainless steels is prohibited. Grinding was accomplished with resin or rubber bonded aluminum oxide or silicon carbide wheels which were not previously used on materials other than austenitic-ferrite alloys. Outside storage of partially fabricated components was avoided and, in most cases, prohibited. Exceptions were made with certain structures provided they were dry, completely covered with a waterproof material, and kept above ground.

Internal surfaces of completed components were cleaned to produce an item which was clean to the extent that grit, scale, corrosion products, grease, oil, wax, gum, adhered or embedded dirt or extraneous material were not visible to the unaided eye. Cleaning was affected by either solvents (acetone or isopropyl alcohol) or inhibited water (30-200 ppm hydrazine or 0.5 - .75 w/o trisodium phosphate). Water conformed to the following requirements:

Halides	
Chloride (ppm)	< 0.60
Fluoride (ppm)	< 0.40
Conductivity (μmhos/cm)	< 5.0
pH	6.0 - 8.0
Visual clarity	No turbidity, oil or sediment

Prior to shipment, RCS components were packaged in such a manner that they have been protected from the weather, wind, water spray and any other extraneous environmental conditions encountered during shipment and subsequent site storage. The environment within the package and/or component was maintained clean and dry. In some instances, use of a dessicant-breather system was utilized. The shipment package was employed for site storage and was not removed until the component was installed within the containment. Once in the containment, with the shipping package removed, the component was maintained clean and dry, either by covering with a polyethylene cover, or placing in a clean area.

To prevent halide-induced, intergranular corrosion which could occur in aqueous environment with significant quantities of dissolved oxygen, solutions were inhibited via additions of hydrazine. Many experiments conducted by CE have proven this inhibitor to be completely effective. Operational chemistry specifications restrict concentrations of halides and oxygen, both prerequisites of intergranular attacks. (Refer to Section 9.3.4.)

5.2.5.2 Solution Heat Treatment Requirements

All raw austenitic stainless steel material, both wrought and cast, employed by CE in the fabrication of the major components in the RCS, is supplied in the annealed condition as specified by the pertinent ASTM or ASME Code; viz, 1850 - 2050 °F for ½ - 1 hour per inch of thickness and water quenched to below 700 °F. The time at temperature is determined by the size and type of component. For example, reactor coolant pump casings which are cast from CF8M are usually subject to more than one solution anneal and, therefore, the time at temperature is limited to ½ hour per inch of thickness.

Solution heat treatment is not performed on completed or partially-fabricated components. Rather, the extent of chromium carbide precipitation is controlled during all stages of fabrication as described in Section 5.2.5.5.

5.2.5.3 Material Inspection Program

Extensive testing on stainless steel mockups, fabricated using production techniques, has been conducted to determine the effect of various Combustion Engineering welding procedures on the susceptibility of unstabilized 300 series stainless steels to sensitization induced intergranular corrosion. Only those procedures and/or practices demonstrated not to produce a sensitized structure are used by CE in the fabrication of RCS components. The ASTM Standard A393 (Strauss Test) is the criterion used to determine susceptibility to intergranular corrosion. This test has shown excellent correlation with a form of localized corrosion peculiar to sensitized stainless steels. As such, ASTM A393 is utilized as a go/no-go standard for acceptability.

As a result of the above tests, a relationship was established between the carbon content of T304 stainless steel and weld heat input. This relationship is used to avoid weld heat affected zone sensitization as described in Section 5.2.5.5 for CE fabricated components.

5.2.5.4 Unstabilized Austenitic Stainless Steels

The unstabilized grades of austenitic stainless steel with a carbon content of more than 0.03 percent used for components of the RCS are T304 and T316. These materials are furnished in the solution annealed condition. Combustion Engineering prohibits exposure of completed or partially-fabricated components to temperatures ranging from 800 °F to 1500 °F wherever possible. Exceptions may arise where valves contain stellite seats which cannot be quenched and the temperature range cannot be avoided during cooling.

Duplex, austenitic stainless steels, containing more than 5 v/o delta ferrite (weld metal, cast metal, weld deposit overlay), are not considered unstabilized since these alloys do not sensitize - that is, form a continuous network of chromium-iron carbides. Specifically, alloys in this category are:

CF8M CF8	Cast Stainless Steels
T308	Singly and combined.
T309	Stainless Steel weld filler
T312	metals. (Delta ferrite
T316	controlled to 5-18 v/o as deposited.

In duplex austenitic/ferritic alloys, chromium-iron carbides are precipitated preferentially at the ferrite/austenitic interfaces during exposure to temperatures ranging from 1,000 to 1,500 °F. This precipitate morphology precludes intergranular penetrations associated with sensitized 300 series stainless steels exposed to oxygenated or otherwise fault environments.

5.2.5.5 Avoidance of Sensitization

Exposure of unstabilized austenitic 3XX stainless steels to temperatures ranging from 800 to 1600 °F will result in carbide precipitation. The degree of carbide precipitation, or sensitization, depends on the temperature, the time at that temperature and, also, the carbon content. Severe sensitization is defined as a continuous grain boundary chromium-iron carbide network. This condition induces susceptibility to intergranular corrosion in oxygenated aqueous environments, as well as those containing halides. Such a metallurgical structure will readily fail the Strauss Test, ASTM A393. Discontinuous precipitates, i.e. an intermittent grain boundary carbide network, are not susceptible to intergranular corrosion in a PWR environment.

CE avoids weld heat affected zone sensitized austenitic stainless steels which will fail the Strauss Test (ASTM A393) by careful control of the following:

A. Weld Heat Input

A weld heat input of less than 60 kj/inch is used during most fabrication stages of T304 stainless steel core support structure. Higher heat inputs are used in some heavy section weld joints. Freedom from weld HAZ sensitization in these higher heat input weldments is demonstrated with weld runoff samples produced at the time of component welding in material having a carbon content greater than or equal to the highest carbon content of those heats of steel being fabricated. Specimens so provided are subjected to the Strauss Test, ASTM A393.

B. Interpass Temperature

The interpass temperature in all multipass welds is controlled to 350 °F maximum. Carbon content is controlled at a maximum of 0.08 w/o in all sections of less than 1½-inch unstabilized austenitic stainless steel subject to welding.

C. Carbon Content

Tests have shown that T304 less than 1½ inches thick and having CE's controlled carbon content are not subject to sensitization when welded with processes having a heat input less than 100 kJ/inch. In heavier sections more than 1½ inches where the material section provides a large heat sink, carbon content is not limited to a level lower than that specified by ASTM or ASME - viz, 0.08 w/o.

When stainless steel safe ends are required on component nozzles or piping, fabrication techniques and sequencing require that the stainless steel piece be welded to the component after final stress relief. This is accomplished by welding an Inconel overlay on the end of the nozzle. Following final stress relief of the component, the stainless steel safe end is welded at the Inconel overlay, using Inconel weld rods.

Some carbide precipitation will occur as a result of welding annealed stainless steel piping, such as the pressurizer surge line, charging line and safety injection lines. Metallographic examination of such welds and HAZs is used to confirm that only discontinuous grain boundary precipitates are present.

5.2.5.6 Retesting Unstabilized Austenitic Stainless Steels Exposed to Sensitizing Temperature

Sensitization, which may be susceptible to intergranular corrosion, is avoided during welding as described in Section 5.2.5.5. Homogeneous or localized heat treatment of unstabilized stainless steels in the temperature range 800-1,500 °F is prohibited except in the case of the core support structure.

This complex structure is thermally stabilized at 900 ± 25 °F for seven hours after fabrication and prior to final machining. Such a treatment produces only minor, discontinuous precipitates.

In addition to thermocouple records during this heat treatment, a sample of T304 stainless steel having a carbon content greater than or equal to the highest carbon heat of material present in the structure is included as a monitor sample. After heat treatment, the monitor sample is subjected to the Strauss Test, ASTM A393, as well as a metallographic examination verifying freedom from sensitization.

5.2.5.7 Compliance with Interim Position MTEB 5-1 on Regulatory Guide 1.31

In order to preclude microfissuring in austenitic stainless steel welds, CE has complied with the requirements of the Interim Position (Branch Technical Position MTEB 5-1) on Regulatory Guide 1.31, Control of Stainless Steel Welding, in the following manner.

A. Major NSSS Components, Excluding Reactor Coolant Pumps

The delta ferrite content of A-7 austenitic stainless steel filler metal, except for 16-8-2, used by Combustion Engineering in the fabrication of major components of the RCS, has been controlled to 5-15 v/o. Delta ferrite content was predicted by magnetic measurement or chemical analysis, in conjunction with the Schaeffler or McKay Diagram, performed on undiluted weld deposits. In the case of the filler metal used with a non-consumable electrode processes, the delta ferrite content may have been predicted by chemical analysis of the rod, wire or consumable insert in conjunction with the stainless steel constitution diagram.

The ferrite requirement was met for each heat, lot or heat/lot combination of weld filler material.

The average delta ferrite content of production welds in the reactor internals is three percent with no indication less than one percent when measured by a calibrated ferrite measuring instrument. Measurement of production weld ferrite content is performed on an audit type basis.

The ferrite content of stainless welds in other major NSSS components has been controlled by the use of filler metal ferrite content.

B. NSSS Vendor Supplied Auxiliary Components and Reactor Coolant Pumps

Although Regulatory Guide 1.31 and interim position MTEB 5-1 were not issued at the time of purchase of most auxiliary components, CE did comply with the requirements of MTEB 5-1 for pneumatic operated and manual valves supplied for the safety injection system and CVCS.

The quality and structural adequacy of welds in other CE supplied auxiliary components were assured by the use of controls on materials, procedures and personnel. These controls were selected to be pertinent to the component functional safety level required and, generally, were imposed through the appropriate ASME Code.

5.2.5.8 Control of the Use of Sensitized Stainless Steel

A. Major NSSS Components, Excluding Reactor Coolant Pumps

CE originally complied with the requirements of Regulatory Guide 1.44 as described in Section 5.2.5.1 through 5.2.5.6, with the exception of the criteria used to demonstrate freedom from sensitization in fabricated unstabilized austenitic stainless steel components. CE uses the ASTM A393 Strauss Test, in lieu of the ASTM A262 Method E Modified Strauss Test, since the former test has shown through experimentation, excellent correlation with the type of corrosion observed in severely sensitized austenitic stainless steel components of NSSSs.

B. NSSS Vendor Supplied Auxiliary Components and Reactor Coolant Pumps

Although Regulatory Guide 1.44 was not issued at the time of purchase of most auxiliary components, the component suppliers were directed by CE to minimize sensitization of austenitic stainless steels by proper control of manufacturing processes for the pressurizer safety valves and CE supplied nuclear service pneumatic operated, motor operated and manual valves in the safety injection system and CVCS.

For other CE supplied auxiliary components, sensitization of austenitic stainless steel was minimized by the use of controls on materials procedures and personnel. These controls were imposed through the appropriate ASME Code and were reviewed by CE personnel. Specifically, austenitic stainless steel was supplied in the solution annealed condition. Also welding procedures were written in a manner to control heat input and minimize sensitization.

5.2.6 PUMP FLYWHEELS

5.2.6.1 Compliance With Regulatory Guide 1.14

This section consists of a discussion of the design, fabrication and testing of the reactor coolant pump flywheels in relation to the recommendations of Regulatory Guide 1.14. The results of an analysis of pump and flywheel performance during a LOCA are also discussed.

A. The material used to manufacture the motor flywheels for 2P32 B, C & D is pressure vessel quality Vacuum Improved Steel Plate (V.I.P.) produced to ASTM-A-533, Gr. B, CLI. The material used to manufacture the motor flywheel for 2P32A is Vacuum Improved ASTM-A-508 Class 5. The acceptance criteria for flywheel design are compatible with the safety philosophy of the Pressure Vessel Research Committee (PVRC) primary coolant pressure boundary criteria as appropriate considering the inherent design and functional requirement differences between the pressure boundary and the flywheel.

1. The NDTT of the material for motor flywheels 2P32B, C, & D, as obtained from the Dropweight Tests (DWT) performed in accordance with the specifications ASTM E-208, is +10 °F. The NDTT of the material for motor flywheel 2P32A as obtained from the DWT performed in accordance with the specification ASTM E-208 is -60°C (-76 °F).

2. The Charpy V-notch (Cv) upper shelf energy level in the weak direction for motor flywheels 2P32B, C, & D, as obtained per ASTM-A-370, is 63 Ft-Lb. At least three Cv specimens were tested from each plate or forging. The Charpy V-notch upper shelf energy level in the weak direction for motor flywheel 2P32A as obtained per ASTM-A-370 was determined to be greater than 115 Ft-Lbs. Thirty-eight Cv specimens were tested from the forging at various temperatures.

3. The minimum fracture toughness of the materials at the normal operating temperature of the flywheels for 2P32B, C, & D is equivalent to a dynamic stress intensity factor (K_{IC} dynamic) of at least 100 ksi root inches. Compliance has been demonstrated by use of a lower bound fracture toughness curve obtained from tests on the same type of material. The curve was translated along the temperature coordinate until the K_{IC} dynamic value of 45 ksi root inches is indicated at the NDT of the material, as obtained by dropweight tests. The lower bound fracture toughness curve is shown in Figure 5.2-33.

   The extension of the RCP flywheel inspection to every 10 years used a different approach for determining the fracture toughness for flywheels 2P32B, C, & D (2CAN020202). In the material testing of original ANO-2 flywheels, the nil-ductility transition temperature (NDTT) was determined for the two applicable melts (-20 °F for Melt B5070 and 10 °F for Melt B5083). Charpy values were also determined at a temperature of 150 °F. Absorbed energies were greater than 100 ft-lbs for Melt B5070 and 63, 68, and 65 ft-lbs for Melt B5083. The reference nil-ductility temperature (RT_{NDT}) was used together with Figure A-4200 of ASME Code Section XI to determine the fracture toughness at the operating temperature of the flywheel. The 50 ft-lb transition temperature (TT_{50}) was estimated from the Charpy data at 150 °F and the conservative slope of the transition region of the Charpy impact energy curve, 2 °F per ft-lb, for the A-533, Grade B material. Using the Charpy values of 68 ft-lbs for Melt B5083, the results conclude that the K_{IC} value of 100 ksi root inch reported in the fracture mechanics evaluation of the ANO-2 RCP flywheel in Topical Report SIR-94-080-A (Ref. 3) is met by this analysis at a operating temperature of 112 °F. The flywheels were shown to operate at a minimum of 112 °F.

   The minimum fracture toughness of the material at the normal operating temperatures of the flywheel for 2P32A is equivalent to a dynamic stress intensity factor (K_{IC} dynamic) of at least 100 ksi root inches. Compliance has been demonstrated by the use of a fracture toughness curve developed from 38 Charpy V-notch tests and appropriate correlations. Testing was performed on actual flywheel test samples taken from the forging. The fracture toughness curve is shown in Figure 5.2-33A.

4. Each finished flywheel was subjected to a 100 percent volumetric ultrasonic inspection from the flat surface per ASME Code, Section III. This inspection was performed on the flywheel after final machining and overspeed test. No loss of back reflection of 50 percent or more was found and no material repairs were performed.

5. The flywheels were flame cut. At least one-half inch of stock was left on the outer and bore radii, for machining to final dimensions.

6. The flywheels were subjected to a magnetic-particle examination per the ASME Code, Section III before final assembly. The inspection was performed on finished machined bores, key-ways, and on both flat surfaces to a radial distance of eight inches minimum beyond the final largest machined bore diameter but not including small drilled holes. There were no stress concentrations such as stamp marks, center punch marks, or drilled or tapped holes within eight inches of the edge of the largest flywheel bore. The examination showed no defects.

B. The flywheels have been designed to withstand normal operating conditions, anticipated transients, and the design basis LOCA combined with the DBE.

The following criteria are satisfied:

1. The combined stresses, both centrifugal and interference, at normal operating speed do not exceed 30 percent of the minimum specified yield strength for the material selected in the direction of maximum stress.

2. The design overspeed of the flywheel is 10 percent above the speed resulting from a turbine-generator overspeed event, or 125 percent of normal operating speed.

3. The combined centrifugal and interference stresses at design overspeed do not exceed 35 percent of the minimum specified yield strength. Design overspeed is defined as turbine-generator overspeed plus 10 percent, or 125 percent, of normal operating speed.

4. The motor and pump shaft and bearings will withstand any combination of normal operating loads, anticipated transients, and the design basis LOCA combined with the DBE.

C. Each flywheel has been tested for one minute at design overspeed of 1,125 rpm.

D. The flywheel is accessible for 100 percent in-place volumetric ultrasonic inspection. The flywheel-motor assembly is designed to allow such inspection with a minimum of motor disassembly.

5.2.6.2 <u>Additional Data and Analyses</u>

An assumed break in the suction piping will produce a high reverse flow through the pump. If power is interrupted, the pump will decelerate and be held by the anti-reverse rotation device described in Section 5.5.1.2. This device will prevent a pump/flywheel overspeed transient during a cold leg break in the suction piping.

An assumed break in the discharge piping will produce a high flow through the pump in the forward or normal direction. This flow will tend to accelerate the pump/motor/flywheel assembly during blowdown. The original analysis though conservative, has shown that the resultant maximum predicted speed under LOCA conditions to be 2,359 rpm, 260 percent of normal speed. It is known that a spinning steel disk may burst when the average tangential stress

reaches a value between 0.6 and 0.9 times the material tensile strength (Reference 14). On this basis, the bursting speed for the Unit 2 flywheel would be between 2,704 and 3,311 rpm, or between 15 percent and 40 percent greater than the conservatively calculated maximum LOCA overspeed. Analysis performed in preparation for replacement of the steam generators considered leak-before-break. This assumption reduced the original assumed break size, resulting in a maximum predicted pump/flywheel overspeed below that predicted under the original analysis.

A fracture mechanics analysis of the flywheel has also been performed. Assuming the predicted accident overspeed of 2,359 rpm and a K_{IC} of 150 ksi root inches (see Figure 5.2-33), the critical crack length is 1.8 inches. Postulating a crack initiating at the keyway, which is one inch deep, the crack extension required to reach the critical crack length is 0.8 inch. Current ultrasonic testing methods will detect flaws or cracks 0.5 inch in length, and the margin is thus 60 percent of the minimum detectable crack. The detailed evaluation of the reactor coolant pump overspeed during LOCA is presented in F.M. Stern's letter to R.C. DeYoung dated September 20, 1973.

5.2.7 REACTOR COOLANT PRESSURE BOUNDARY LEAKAGE DETECTION SYSTEMS

RCPB leakage detection systems are provided as required by General Design Criterion 30. This criterion requires, in part, that means be provided for detecting, and to the extent practical, identifying the location of the source of reactor coolant leakage. Detection systems with diverse modes of operation are provided to ensure adequate surveillance with sufficient sensitivity such that small increases in leakage rates, regardless of source, can be detected while the total leakage rate is still below a value consistent with safe plant operation.

5.2.7.1 Leakage Detection Methods

Several diverse methods are provided to alert the operator to the presence of leakage from the RCS. Detection of leaks can be accomplished by any one or a combination of the below listed means.

5.2.7.1.1 Containment Monitoring

Equipment is provided which continuously monitors the environmental conditions within the containment such that a background level is established which is representative of the normal level of leakage from the primary systems and components. Deviations from normal containment environmental conditions will provide positive indication in the control room of increases in leakage rates. The entire RCS is located within the containment and any coolant leakage to the containment atmosphere will be in the form of fluid and vapor. The fluid will drain to the sump and vapors will be condensed in the containment coolers and also reach the sump.

Containment parameters monitored to detect coolant leakage include gaseous and air particulate activity levels, containment sump level, humidity, and containment pressure and temperature.

RCS leakage in the containment will be monitored by the Containment Atmosphere Monitoring System (CAMS). CAMS continuously monitors airborne particulate and gaseous isotopes using an Air Particulate Detector (APD) and a radioactive gas detector. Changes in the reactor coolant leakage rate in the containment will cause changes in the control room indication of the containment atmosphere activities.

The Containment Atmosphere Monitoring System (CAMS) provides two functions. Its primary function is to identify RCS leakage. Its second function is to provide containment building pressure, oxygen, and hydrogen control during power operations (Modes 1-4). The CAMS is used to control RCB pressure. The design of the CAMS allows fresh air into the RCB to aid in maintaining oxygen level concentrations at levels acceptable for human occupancy.

The APD takes continuous flowing air samples from the containment atmosphere and measures the air particulate gamma radioactivity. The samples are drawn outside the containment, and are monitored by a gross gamma scintillation counter-filter paper detector assembly. The filter paper collects particulate matter on its constantly moving surface, which is viewed by a hermetically sealed combination scintillation crystal (NaI) photomultiplier. This monitor has a sensitivity of 1.5(-10) μCi/cc of Cs-137 in a 2.5 mr/hr background.

The filter paper mechanism and electromagnetic assembly which controls the filter paper movement are provided as an integral part of the detector unit.

The detector assembly is in a completely closed housing. The detector output is amplified by a preamplifier and transmitted to the radiation monitoring system cabinet in the control room. Lead shielding is provided to reduce the background radiation level to an intensity which does not interfere with the detector's sensitivity.

The activity is indicated on meters and recorded by a multipoint recorder. High-activity alarm indications are displayed on the radiation monitoring cabinets. Alarms provide operational status of supporting equipment such as pumps, motors and flow and pressure controllers.

The air particulate and radiogas monitor have a pump unit common to both monitors. The pump unit consists of:

A. A pump to obtain the air sample;

B. A flowmeter to indicate the flow rate;

C. A flow control valve to provide flow adjustment; and,

D. A flow alarm assembly to provide low and high flow alarm signals.

The radiogas monitor measures the gaseous beta radioactivity in the containment by taking the continuous air samples from the containment atmosphere. The samples first pass through the APD where particulate matter is removed, and then pass through a sealed system to a gas monitor assembly. After passing through the gas monitor the gas sample is normally returned to the containment atmosphere.

Each sample is constantly mixed in fixed, shielded volumes, where it is viewed by a beta sensitive scintillator. This monitor has a sensitivity of 1.0(-5) μCi/cc of Xe-133 in a 2.5 mr/hr background.

The detector is in a completely enclosed housing containing the beta-gamma G.M. tube mounted in a constant gas volume container. Lead shielding is provided to reduce the background radiation level to a point which does not interfere with the detector's sensitivity. A pre-amplified and impedance matching circuit is mounted at the detector.

The detector outputs are transmitted to the radiation monitoring system cabinets in the control room. The activity is indicated by meters and recorded by a multipoint recorder. High-activity alarm indicators are displayed on the control board annunciator in addition to the radiation monitoring system cabinets.

Changes in the containment sump water level are an indication of overall gross leakage from all water and steam systems within the containment. Containment water level is monitored by a containment sump level detection system and a reactor building flood level monitoring system which provide control room operators alarm and indication readout of containment water level.

The containment sump water level is monitored by the Plant Monitoring System (PMS). During Modes 1 through 4, the PMS utilizes an algorithm which calculates sump level increase rate-of-change and subsequently provides an alarm in the control room if the containment sump level increase exceeds one gallon per minute within one hour. The monitoring and alarming of the containment sump level rate of change along with the other reactor coolant pressure boundary leakage detection systems already in place in the ANO-2 containment ensures ANO-2 meets the guidelines of Regulatory Guide 1.45 (Reference 15). The ability to comply with the guidelines of RG 1.45 allows ANO-2 to reference Topical Report CEN-367-A (Reference 16) when relying on leak before break technology to preclude the need to protect against dynamic effects associated with the postulated rupture of piping. The NRC Safety Evaluation that approves the use of leak before break technology is documented in Reference 17.

Containment humidity monitoring provides another method of measuring overall gross leakage from all water and steam systems within the containment.

The basis of operation of these elements is the behavior of a hygroscopic solid. When dry lithium chloride is exposed to the atmosphere under average room conditions, it will absorb moisture and dissolve, forming a salt solution. If this solution is heated, the water tends to escape back to the atmosphere. A state of equilibrium is reached at a temperature where the tendency of water to escape is equal to the tendency of salt to absorb moisture. At this equilibrium point, the temperature of the salt and the saturated solution (temperature of the dewcell element) is a measure of the partial pressure of water vapor in the surrounding atmosphere, i.e. dewpoint temperature. The range of the dewpoint temperature measuring system is 0 to 100 °F. Dew cell accuracy is ± 1.5 °F.

Containment pressure and temperature provides a final method of detecting overall gross leakage from all water and steam systems within the containment.

5.2.7.1.2 <u>Reactor Coolant Inventory Monitoring</u>

RCPB leakage will be indicated by performing a primary coolant inventory. This inventory will be performed by the operator as required by the Technical Specifications. By measuring total inflow and total outflow with all other systems stable, a primary coolant leak of approximately one gpm can be detected.

Leakage will also be indicated by any of the following:

A. Low pressurizer level and charging pump operation.

   During normal operation only one positive displacement charging pump is operating. If gross leakage of reactor coolant occurred, the pressurizer level would decrease and cause another charging pump to start. Pressurizer level and charging pump operation are indicated in the control room.

B. High reactor drain tank level.

The reactor drain tank collects controlled bleed-off flow from the reactor coolant pump seals during plant heatup and cooldown, leakage from the reactor coolant pump gasket leakoffs, reactor head gasket leakoffs, safety injection tank check valve leakage, quench tank drain and leakage from auxiliary systems as well as the four reactor coolant loop drains.

5.2.7.1.3 Pressurizer Safety Valve Leakage

Overpressure protection of the RCS is provided by two spring-loaded safety valves mounted on top of the pressurizer. These valves are piped to the quench tank. Piping is provided with temperature sensors which read out in the control room. Any temperature increase will indicate leakage through the safety valves.

In addition, an acoustical valve monitoring system provides the control room operator with open/closed position indication of the safety valves on annunciator panel 2K10. This system is required by NUREG-0578, Item 2.1.3a.

5.2.7.1.4 Reactor Coolant Leakage to Other Systems

Coolant leakage to other systems is possible through several methods. Means to detect this leakage is provided as shown below.

A. Steam Generator Tube Leakage

Reactor coolant leakage through a steam generator tube may be detected several ways as described below. The steam generator sample monitors, main steamline monitors and condenser off-gas monitor all read out on the secondary system trend recorder on panel 2C14 in the control room.

Steam generator tube leakage is detected by the steam generator sample cooler radiation monitoring system. This system will detect leakage between the primary and secondary side of the steam generator by monitoring condensed steam out of the sample cooler before it enters the liquid waste management system. The system has a sensitivity of 3.0×10^{-7} µCi/ml of Cs-137 and is indicated in the control room and alarmed for high radiation level.

Steam generator tube leakage is also detected in the main condenser air discharge radiation monitoring system as described in Section 11.4.2.2. Presence of radioactivity in this line would indicate primary to secondary leakage in the steam generator. The predominant isotope detected is Xe-133 and the system will detect 1.0×10^{-5} µCi/ml of Xe-133. The monitor consists of a single channel with provisions for automatic control with indication in the control room.

Further indication of steam generator tube leakage is obtained by monitoring the steam generator blowdown system. The blowdown system is required to remove suspended solids and chemicals from the steam generator water. In the event of tube leakage the blowdown water could contain some fission products. To prevent this from being discharged a scintillation detector sensitive enough to detect 3.0×10^{-7} µCi/ml of Cs-137 is installed on the blowdown system. This system is instrumented for high radiation with indication in the control room.

Additional indication of steam generator tube leakage is obtained by monitoring the Main Steam Line Area Monitors. Each monitor channel consists of a Geiger-Mueller type detector with a range of 0.1 mR/h to 10,000 mR/h. Readout is provided in the control room on the control modules, chart recorder on 2C14, and the SPDS computer.

The most recent addition, and the one considered to be the most accurate indication of steam generator tube leakage, is the Steam Generator N-16 Monitoring System. Each monitoring channel consists of a scintillation type detector and computer control system. The computer control system has been programmed to provide indication of primary-to-secondary leakage in gallons per day whenever plant power is above 20%. The designed minimum detectable leakage is 5.25 GPD. The calculated leakrate is provided to the Plant Monitoring System where it is displayed in Leak Rate (GPD), Leak Rate (GPM), and Leak Rate Rate of Change. The Plant Monitoring System also provides three N-16 Monitoring System related alarms on 2K11.

B. Primary Coolant Leakage to the Service Water System

The service water circulates through the plant for cooling purposes. Since some components which are cooled could potentially allow leakage from the RCS, a monitoring system is provided which consists of one channel downstream of each pair of containment cooling coils and one channel downstream of each shutdown cooling heat exchanger. Every heat exchanger that has the possibility of releasing radiation to the service water system via a tube leak is monitored.

The monitor downstream of each pair of containment cooling coils and each shutdown cooling heat exchanger is sensitive enough to detect 5.0 X 10^{-6} µCi/ml of Cs-137. It is monitored in the control room and annunciates an alarm on indication of high radiation.

C. Primary Coolant Leakage to the Component Cooling Water System

The component cooling system circulates water in a closed loop cooling several plant processes including the reactor coolant pumps. Two component cooling system radiation monitors are provided which are sensitive enough to detect 5.0 X 10^{-6} µCi/ml of Cs-137 or equivalent amounts of other isotopes.

5.2.7.2 Indication in Control Room

Leakage from the RCPB may be detected by any of the methods discussed previously. All radiation monitors are indicated, recorded and alarmed in the control room. Containment humidity, pressure, temperature and sump level are indicated in the control room and recorded by the plant computer.

5.2.7.3 Limits For Reactor Coolant Leakage

Any leakage from the RCS is a serious problem with respect to inplant contamination. Although some leak rates on the order of gallons per minute may be tolerable regarding dose limits, leaks on the order of drops per minute through any of the walls of the RCS could be indicative of material failure. If depressurization, isolation and/or other safety measures are not taken promptly, these leaks could develop into larger leaks and possibly result in gross pipe failure. Therefore, a maximum allowable total leakage rate of 10 gpm is established by the Technical Specifications.

The maximum leakage rate specified in the Technical Specifications from unidentified sources (excluding normal evaporative losses) is 1 gpm.

5.2.7.4 Unidentified Leakage

The anticipated normal total leakage of reactor coolant from the RCPB is essentially zero.

The response times of the subsystems to departure from the normal leakage rate is presented in Section 5.2.7.1.

The maximum allowable leakage rate from unidentified leaks is established at 1 gpm in the Technical Specifications. This limitation is sufficiently above the minimum detectable leakage rate to provide indication of leakage and is held low to minimize the chance of a crack progressing in a potentially unsafe condition without detection.

A. A through-wall crack having an equivalent diameter of approximately 0.04 inch to 0.05 inch would result in a leak at the assumed limit.

B. There is no precise way of relating this to crack length. The longest crack which could be masked by a laminar flow and thus escape detection is three inches. This postulated 3-inch crack, if it propagated through the wall, would leak at a rate greater than 1 gpm. A through-wall crack three inches in length is approximately 12 percent of the critical crack length for an axial crack and about eight percent of the critical crack length for a circumferential crack.

5.2.7.5 Maximum Allowable Total Leakage

The maximum allowable total leakage as specified in the Technical Specifications is 10 gpm and the normal capacity of the CVCS is 132 gpm.

Normal drainage of the containment sump is achieved by gravity flow through a 4-inch pipe to the auxiliary building sump. The flow capacity is 180 gpm.

5.2.7.6 Differentiation Between Identified and Unidentified Leaks

Leakage detection systems have been designed to aid operating personnel in differentiating between possible sources of detected leakage within the containment atmosphere and to other systems and, to the extent possible, locating the general area of a leak. Containment entry for visual inspection is the only positive method of identifying the exact location and magnitude of a leak.

The primary means of identifying a RCPB leak within the containment is the containment atmosphere monitoring system. Increases in containment activity levels will indicate a leak in the RCPB. The capability of drawing monitoring samples from several containment locations allows localization of the general area of leakage since activity levels will be somewhat higher in the vicinity of the leakage source. If the containment humidity detector, pressure indicators, and temperature indicators detect increases in containment humidity, pressure, and temperature without corresponding increases in containment activity, the indicated source of leakage would normally be a non-radioactive system.

Tube failure or leakage in the steam generators is indicated by the methods described in Section 5.2.7.1.4. Leakage of the shutdown cooling heat exchangers, and containment cooling coils is detected as shown in Section 5.2.7.1.4. Leakage in any of the heat exchangers cooled by the component cooling system is indicated by the component cooling water radiation monitors, but identifying location by this method is not possible.

Less sensitive methods of leak detection such as unexplained increases in reactor makeup flow, and changes in containment sump level will provide positive indication of RCPB leakage. Leakage rates of the magnitude necessary to be detectable by these methods are expected to be noted first by the more sensitive radiation and moisture detection equipment.

5.2.7.7 Sensitivity and Operability Tests

Periodic testing of leakage detection systems will be conducted in order to verify the operability and sensitivity of detector equipment. These tests include installation calibrations and alignments, periodic channel calibrations, functional tests, and channel checks.

The CAMS will undergo complete detector calibrations upon installation using typical isotopes of interest for each of the channels to determine proper detector response. Subsequent periodic calibrations using detector check sources consisted of single-point calibrations to confirm detector sensitivity based on the known correlation between the detector response and the check source standard. This procedure will adequately measure instrument sensitivity since the geometry of the sampler cannot be significantly altered after the initial calibration. Channel checks to verify acceptable channel operability during normal operation and functional testing to verify proper channel response to simulated signals will also be conducted on a regular basis.

The humidity and temperature detectors and indicators will also be periodically checked to ensure proper operation. The humidity detector performance will be verified by comparison to actual measurements made by dry and wet bulb thermometers. Similarly the temperature detector performance will be verified by comparison to independent temperature measurement.

The sump level detector and indicator performance was verified during preoperational testing of the plant. A water source was introduced to the sump and the increase in sump level indicated was compared with local level measurements.

The RCPB leakage detectors were tested and calibrated by their respective manufacturers prior to installation and sensitivity curves will be provided.

5.2.8 INSERVICE INSPECTION PROGRAM

The RCPB has been designed and arranged to provide adequate clearances for inservice inspection. The design and arrangement conform to the requirements of paragraphs IS-141 and IS-142 of Section XI of the ASME Boiler and Pressure Vessel Code, 1971 Edition with Summer 1971 Addenda. Based on the date of issuance of the ANO-2 construction permit, 10 CFR 50.55a(g) mandated this edition of the Code for design and access provisions.

The Unit 2 Inservice Inspection program was developed using the criteria of 10 CFR 50.55a, Paragraph g. These require that the program use the code in effect six months prior to the issuance of a construction permit. This established the 1971 Edition and Summer 1971 Addenda of the ASME Boiler and Pressure Vessel Code, Section XI as the effective code.

The initial Inservice Inspection Program has been updated and modified as much as practicable to include the requirements of the Summer 1973 Addenda. The Summer 1973 Addenda reflect a number of significant state of the art advancements in ultrasonic testing.

The current Inservice Inspection Program is conducted in accordance with 10 CFR 50.55a(g) and Section XI of the applicable ASME Code.

5.2.8.1 Provisions for Access

5.2.8.1.1 Reactor Vessel and Closure Head

The reactor vessel and closure head welds are accessible for examination as follows:

A. From inside the vessel:

   All longitudinal and circumferential shell welds;

   Nozzle to vessel, nozzle to transition piece and transition piece to pipe welds;

   Cladding in the cylindrical portion of the vessel, except those areas covered by surveillance capsules or internal structural attachments;

   Internal structural attachments (visual examination);

   The bottom head area is accessible from the inside, to the extent necessary to permit a determination of whether or not any mechanical or structural failure of reactor internals has occurred.

B. From outside the vessel:

   The bottom head area, including meridional and circumferential seam welds;

   Meridional and circumferential seam welds;

C. Cladding:

   From outside the closure head;

   Meridional and circumferential seam welds including head to flange weld;

   Control element assembly and instrument tube welded and mechanical joints.

D. From flange faces:

   Vessel to flange and head to flange welds;

   Bolt holes and ligaments.

The reactor vessel and closure head access provisions described above have been incorporated into the design.

5.2.8.1.2 Primary Piping

Biological shielding around the transition piece-to-nozzle welds in the area of the reactor vessel limits access to these circumferential welds. The inspection of these welds is performed from the I.D. of the piping during the vessel examination. These volumetric examinations are performed using automated ultrasonic techniques.

Most piping and major components are provided with removable insulation in the areas of all welds and adjacent base metal requiring examination as defined by the ASME Section XI Code.

5.2.8.1.3 Steam Generators

All external welds on the steam generator which are required to be inspected in accordance with ASME Section XI are accessible and have removable insulation in the areas of the welds and adjacent base metal to gain access for inspection.

Access for the inspection of steam generator tubing is provided through the channelhead primary manway. An inservice inspection program for the steam generator tubing is consistent with NEI 97-06, Steam Generator Program Guidelines. This program of systematic periodic inspection of steam generator tubes is described fully in Section 6.5.9 of the Technical Specifications.

5.2.8.1.4 Other Components

All other components, including portions of the steam generators, pressurizer and primary piping are accessible for manual examination from the outside surface.

5.2.8.2 Equipment for Inservice Inspection

Remotely operated automated ultrasonic equipment will be used for the examination of the reactor vessel circumferential and longitudinal welds and the primary nozzle-to-shell welds.

5.2.8.3 Recording and Comparing Data

Volumetric and surface examination results will be recorded and compared with the results of pre-service and prior inservice examinations as required by the ASME Code, Section XI.

5.2.8.3.1 Automated Ultrasonic Examinations

The examination of the reactor vessel is conducted utilizing an automated system which manipulates the ultrasonic search units in such a manner as to provide complete volumetric coverage, where practical, of each weld and adjacent base material. The data will be acquired and stored in a format suitable for comparison with the recorded results of the pre-service and prior inservice examinations.

5.2.8.3.2 Manual Examinations

A written report will be provided for all manual ultrasonic examinations. The report will consist of recording the instruments used and settings as well as the procedures employed. Results of the examination will be in a format so that direct comparison between baseline and subsequent inservice examinations can be achieved.

5.2.8.3.3 Visual Examinations

A written report will be provided.

5.2.8.3.4 Surface

A written report will be provided.

5.2.8.3.5 Radiographic

Where applicable, a written report will be provided and the radiographic film retained.

5.2.8.4 Reactor Vessel Acceptance Standards

During the pre-service examinations, flaw indications, if present, were recorded in accordance with requirements of IS-233 of Section XI (1971 Edition through the Summer 1973 Addenda) in terms of location, size, shape, orientation and distribution within the component. Acceptability of the reactor vessel was established by applying the "rules" of the "Proposed Revision of IS-311 -- Standards for Examination Evaluations," Draft 7, dated September 28, 1972, and scheduled for incorporation in the Summer of 1973 Addenda.

Section XI Code activity will be reviewed and applicable sections will be incorporated into the Inservice Inspection Program insofar as acceptance criteria is affected.

5.2.8.5 Coordination of Inspection Equipment with Access Provisions

The CE Inservice Inspection Group developed and implemented the Inservice Inspection Program for the first inservice inspection interval. During the design and construction of the plant, CE coordinated the efforts of the Architect/Engineer and equipment vendors. By serving as the NSSS supplier as well as an inservice inspection vendor, CE was able to ensure that the inservice inspections could be performed.

Arkansas Nuclear One took over the Inservice Inspection Program from Combustion Engineering after the first interval.

5.2.8.6 Inservice Inspection of ASME Code Class 2 and 3 Components

An ESF (Engineered Safety Feature) in-service inspection program has been established for ASME Code Class 2 and 3 ESF systems' components that will provide a satisfactory degree of assurance of the integrity of the ESF systems.

5.2.8.7 Inservice Testing of ASME Code Class 1, 2, & 3 Pumps and Valves

A program for inservice testing of ASME Code Class 1, 2, & 3 pumps and valves will be carried out in accordance with Technical Specification 6.5.8.

5.2.8.8 Inservice Monitoring of Vibration and Loose Parts

Vibrations within the RCS and reactor core are monitored by the Vibration and Loose Parts (V&LP) monitoring system. This system has vibration and acoustic channels, and consists of piezoelectric sensors, preamplifiers, a signal processor unit, and other peripheral equipment.

The sensors detect vibration from flow-induced or rotating-equipment sources, loose parts in the coolant systems, and other signals. The signals from these channels are compared with preset levels to generate alarms when abnormal conditions are detected. Various diagnostic equipment is available to further identify the source of the problem.

To provide optimum effectiveness of the V&LP, the transducers for the reactor primary system are placed on the lower vessel, upper vessel, and steam generators.

In the lower vessel, an accelerometer is positioned as close to the reactor vessel as is practical for inspection and replacement. An accelerometer is located in the upper vessel region to quantitatively monitor the control rod extensions and vessel internal for vibration. Location of this sensor is on the control rod drive extension tube protection shroud. The steam generators have accelerometers mounted on the steam generator channelhead.

The loose parts, and core internals channels monitor the major reactor primary system components in which an anomaly could occur. The selection provides a qualitative difference indication of vibration throughout the primary loop. The nuclear channels provide reactivity-related indication of fuel pin, control rod, and core structure motion. The core internals signals are obtained from the ex-core power range ion chamber buffer amplifiers.

The Vibration Loose Parts Monitoring System (VLPMS) uses piezoelectric sensors and preamps in containment for both vibration and acoustic monitoring. Sensor signals are input to the analog signal conditioning module which also provides power to the remote charge converter. The input signal to the computer is separated into two signals; one signal is band pass filtered and is used for analysis, the other is the wide band signal, which is used for monitoring the background noise and vibration.

By not alarming on relatively slow transients such as pump starts, the dual alarm method provides defense against false alarms. The fixed alarm prevents false alarms in low background noise situations where the floating alarm level is low and easily triggered. Additionally the fixed alarm may be used as a screening method in situations where the plant continues to operate with loose part indication.

The Loose Parts Monitoring Signal Conditioning System is rack mounted and consists of individual signal conditioning cards, one for each sensor channel. The key features of the system are:

- Capable of stand alone operation.
- Provides means to monitor the background vibration in all channels.

The system is comprised of four module types; Master Control Module, Signal Conditioning Module, Audio Monitor, and the Neutron Noise Module.

- The Signal Conditioning (SC) Module interfaces directly to the accelerometers and line drivers used to detect the acceleration caused by vibration or metallic impact.
- The Master Control Module is the communication device between the PC and the individual channel SC Modules. In the PC control mode, (set by switch on the front panel) the PC issues commands which set the full scale range and the floating and fixed setpoints. If any one of the SC Modules senses an alarm, the PC is triggered and the event data is captured. The module contains the relay used to provide alarm contacts to the plant annunciator.

- The Excore Nuclear Instrumentation Amplifier (Neutron Noise) module provides an amplified signal of the AC component that exists on the plant excore nuclear instrumentation signals.

- The Audio Monitor Module is an audio amplifier and speaker that permits the switching of 16 loose part channel inputs. Besides channel selection, the operator can select between wide band, filtered or recorded data.

If a loose part event occurs, the computer transfers the data from all data acquisition cards to the computer. If a loose part is determined, the computer stores the data on the hard disk. Time stamped data from each new event is added to a file and recorded on the hard drive for future analysis. The VLPMS provides the capability of loose parts audio recording through outputs from the Audio Monitor Module.

5.3 THERMAL HYDRAULIC SYSTEM DESIGN

5.3.1 ANALYTICAL METHODS AND DATA

The principal thermal and hydraulic data for the Reactor Coolant System (RCS) is included in Table 5.3-2. The effect on core flow rate of inoperative pumps is discussed in Section 5.3.4.

The reactor design described in Chapter 4 established hot and cold leg temperatures, minimum reactor coolant flow and maximum reactor vessel pressure drop. The thermodynamic and hydrodynamic data are used in the design of the steam generators, reactor coolant pumps, and reactor coolant piping. The data are covered in Table 5.3-2. The RCS temperature control program is shown in Figure 5.3-1. The secondary pressure as a function of power is shown in Figure 5.3-2.

5.3.1.1 Steam Generator

The steam generators are described in Section 5.5.2. The vertical U-tube steam generators are designed to transfer the design heat load from the reactor coolant to the secondary side, producing steam at warranted pressure and quality. The pressure drop on the reactor coolant side is determined by summing the losses due to friction in the tubes, the bend losses, tube sheet entrance and exit losses, and the inlet and outlet plenum and nozzle losses.

5.3.1.2 Reactor Coolant Pump

The design flow for the reactor coolant pump is established by the required reactor mass flow. This mass flow is converted to volumetric flow at the full power cold leg temperature to determine the pump design flow.

The maximum pressure loss at the design flow rate for the reactor vessel, original steam generator, and piping was determined by adding an allowance for uncertainty to the best estimate of each pressure drop. These maximum values were used to establish the reactor coolant pump design head. The reactor coolant pump was designed to produce a minimum reactor design flow at the maximum expected system pressure loss.

The original uncertainty associated with the flow rate measurement was established prior to the preoperational and startup tests on ANO-2. This uncertainty was based on performance and acceptance testing done at the pump vendor's facility and on the instrumentation used at that facility and at the Arkansas site in connection with flow measurement. The test measurements onsite yielded the best estimate reactor coolant flow rate to which the pre-determined uncertainty was applied to obtain the maximum and minimum values of flow rate. The flow rate itself originated in measurements of pressure differential across a pair of taps in each pump casing inlet and outlet. The individual loop flows were determined from plots of pump flow vs pump Δp developed from calibration measurements made at the vendor's test facility. The total system flow was obtained by summing the loop flows.

Reactor coolant flow rates are currently measured by calorimetric calculation or by using pump differential pressure instrumentation. Instrument and calibration uncertainties appropriate for each method are applied to acceptance criteria of flow surveillances.

5.3.1.3 Reactor Coolant Piping

The reactor coolant piping is designed to withstand the maximum expected reactor coolant pressure and temperature in accordance with the ASME Code, Section III. The piping is sized to provide reasonable fluid velocities which are below those which would cause significant erosion or cavitation.

5.3.2 OPERATING RESTRICTIONS ON PUMPS

The minimum RCS pressure at any given temperature is limited by required Net Positive Suction Head (NPSH) for the reactor coolant pumps during portions of plant heatup and cooldown. To ensure that the pump NPSH requirements are met under all operating conditions, an operating curve is used which gives permissible RCS pressure as a function of reactor coolant temperature.

The reactor coolant pump NPSH restriction on this curve is determined by using the NPSH requirement for one pump operation (maximum flow, hence, maximum required NPSH) and correcting it for pressure and temperature instrument errors and pressure measurement location. The NPSH required versus pump flow is supplied by the pump vendor. Pump operation below this curve is prohibited. At low reactor coolant temperatures and pressures, other considerations require that the minimum pressure versus temperature curve be above the NPSH curve.

5.3.3 POWER-FLOW OPERATING MAP (BWR)

Arkansas Nuclear One - Unit 2 is a PWR. This section is not applicable.

5.3.4 TEMPERATURE - POWER OPERATING MAP (PWR)

Plant flow is given as a percent of 4-pump flow. The maximum temperature of the hot leg and cold leg will be less than the maximum temperatures for design power at design flow. Reactor operation at power requires all four pumps to be operating. However, decay heat may be transferred to the steam generator with one (or more) pumps operating or under natural circulation conditions.

The adequacy of natural circulation for decay heat removal after reactor shutdown has been verified analytically and by tests on the Palisades reactor. The core ΔT in the analysis has been shown to be lower than the normal full power ΔT; thus the thermal and mechanical loads on the core structure are less severe than normal design conditions.

To assess the margin available in a post-coastdown situation, a study was made assuming termination of pump coastdown 100 seconds after reactor trip, with immediate flow decay to the stable natural circulation condition. It should be recognized that pump rotation will continue for substantially longer than 100 seconds. With the maximum decay heat load 100 seconds after trip, the system will sustain stable natural circulation flow adequate to give a thermal power-to-flow ratio of less than 0.9.

Heat removed from the core during natural circulation may be rejected either by dumping to the main condenser or to the atmosphere; the rate of heat removal may be controlled to maintain core ΔT within allowable limits. The analytical techniques are verified by tests completed on the Palisades reactor (Docket No. 50-255).

Historical data removed. To review wording, refer to Section 5.3.4 of the FSAR.

5.3.5 LOAD FOLLOWING CHARACTERISTICS

The design features of the RCS influence its load following and transient response. The RCS is capable of following transients identified in Section 5.2.1, including a ramp change from 15 percent to 100 percent power at a rate of 5 percent per minute and at greater rates over smaller load change increments, up to a step change of 10 percent (as designed). These requirements are considered when sizing the pressurizer spray and heater capacities and control setpoints and the charging/letdown system control setpoints are selected through detailed computer simulation studies. In addition, the feedwater valve stroke speed and feedwater regulating system control setpoints are selected through computer analysis of these transients.

Finally, these transients are included in the equipment specification for each RCS component to ensure the structural integrity of the system.

Load changes are initiated by the operator at the load control portion of the electrohydraulic control system. The operator sets the desired load with the load selector. Different load change rates are selectable. The electrohydraulic control system alters the turbine control valve position while maintaining turbine speed and sensing first stage turbine pressure. Turbine first stage is also used by the Reactor Regulating System as indicative of turbine power. From this the RRS develops a reference reactor coolant temperature setpoint that can be used in the operators positioning of CEAs. The feedwater regulating system is a 3-element control system which senses changes in steam flow, feedwater flow and water level and acts to maintain level at the desired point.

Pressurizer pressure and level control systems respond to deviations from preselected setpoints caused by the expansion or contraction of the reactor coolant and actuate the spray or heaters and the charging or letdown systems as necessary to maintain pressure and coolant volume.

5.3.6 TRANSIENT EFFECTS

The effects of normal operating transients such as load changes and startup of an inactive loop, as well as the effects of anticipated operational occurrences such as loss of coolant flow, are considered in the fatigue analyses required by code on all RCS components (Refer to Section 5.2).

Concerns have been expressed regarding postulated pressurized thermal shock transients involving rapid overcooling of the reactor vessel with subsequent repressurization (NUREG-0737, Item II.K.2.13). The Unit 2 reactor vessel is a later generation vessel with controlled residual element weld and plate material. For such vessels, analysis indicates that no operator action is required to mitigate the consequences of a steam line break over 40 years of plant operation. This issue was resolved as documented in the Safety Evaluation Report issued June 5, 1984 (0CNA068413). Pressurized thermal shock of the ANO-2 reactor vessel has been evaluated for license renewal. All beltline material was demonstrated to be below the 10 CFR 61 screening criteria at 48 EFPY. Details of reactor vessel irradiation and EOL properties are in Section 5.2.4.

With regard to the small break LOCA analysis documentation requirements of NUREG-0737, Item II.K.2.13, ANO has referenced the C-E Owners Group report, CEN-189, "Evaluation of Pressurized Thermal Shock Effects due to Small Break LOCAs With Loss of Feedwater for Combustion Engineering NSSS," dated December 1981. The analytical results are contained in CEN-189 appendices, with the results for the ANO-2 vessel in Appendix G.

5.3.7 THERMAL AND HYDRAULIC CHARACTERISTICS TABLE

Principal thermal hydraulic characteristics are listed in Table 5.3-2.

5.4 REACTOR VESSEL AND APPURTENANCES

5.4.1 PROTECTION OF CLOSURE STUDS

To preclude damage to the closure stud threads the procedure utilized during reactor vessel head removal requires that reactor vessel studs be removed from the lower vessel flange, plugs are installed in the vessel stud holes, and the studs are parked back in their respective holes in the vessel head flange prior to reactor vessel head removal. The plugs are designed with a seal to prevent water from entering the stud hole during refueling. Removal of the reactor vessel studs from the lower vessel flange during the head removal operation therefore assures they will not be exposed to the borated refueling water. To prevent borated water spillage on the vessel head from entering the annuli around the studs when the head is installed, a concentric groove is machined in the reactor vessel head flange to form a drip line. The spillage is directed onto a chamfered portion of the vessel flange and to the refueling seal flange.

5.4.2 SPECIAL PROCESSES FOR FABRICATION AND INSPECTION

5.4.2.1 Nondestructive Tests

Prior to and during fabrication of the reactor vessel, nondestructive tests based upon Section III of the ASME Boiler and Pressure Vessel Code were performed on all welds, forgings, and plates as indicated below:

All full-penetration, pressure-containing welds were 100 percent radiographed to the standards of the ASME Code, Section III. Weld preparation areas, backchip areas, and final weld surfaces were magnetic-particle or dye-penetrant examined. Other pressure-containing welds, such as used for the attachments of nonferrous nickel-chromium-iron mechanism housing, vents, and instrument housings to the reactor vessel head, were inspected by liquid-penetrant tests of the root pass, the lesser of 1/3 of the thickness of each ½-inch of weld deposit, and the final surface. Additionally, the base metal weld preparation area was magnetic-particle examined prior to overlay with nickel-chromium-iron weld metal.

All forgings were inspected by ultrasonic testing, using longitudinal beam techniques. In addition, ring forgings were tested using shear wave techniques. Rejection under longitudinal beam inspection, with calibration so that the first back reflection was at least 75 percent of screen height, was based on indications causing complete loss of back reflection (when not associated with geometrical configuration).

All carbon-steel and low alloy forgings and ferritic welds were given a magnetic-particle examination after stress relief. Rejection was based on relevant indications of:

A. Any cracks and linear indications;

B. Rounded indications with dimensions greater than 3/16 inch;

C. Four or more rounded indications in a line separated by less than 1/6 inch edge to edge;

D. Ten or more rounded indications in any six square inches in the most unfavorable locations, with the major dimension of this area not to exceed six inches.

Plates were subjected to ultrasonic examination using straight beam techniques. Rejection was based on areas producing a continuous total loss of back reflection with a frequency and instrument adjustment that produced a minimum of 50 to a maximum of 75 percent of full scale reference back reflection from the opposite side of a sound area of the plate.

Any defect that showed a total loss of back reflection that could not be contained within a circle whose diameter was the greater of three inches or one-half the plate thickness was unacceptable. Two or more defects smaller than described above which cause a complete loss of back reflection were unacceptable unless separated by a minimum distance equal to the greatest diameter of the larger defect, unless the defects were contained within the area described above. Repair welds on plates are magnetic-particle or liquid-penetrant inspected, except those with a depth exceeding the lesser of 3/8 inch or 10 percent of plate thickness, which were radiographed.

Nondestructive testing of the vessel was performed throughout fabrication, with strict adherence to the nondestructive testing requirements of the ASME Code, Section III. Strict quality control was maintained in critical areas such as calibration of test instruments. Weld wire was checked for chemistry and weld rod, wire and flux were tested to requirements of the Code. The weld rods were prepared under metallurgical surveillance.

When final shape of a part of the vessel was of irregular geometry, ultrasonic examination for flaws was conducted after a preliminary machining to a suitable geometry.

All reactor vessel bolting material, regardless of size, was inspected both before and after threading by the wet magnetic-particle technique. In addition, bolting material greater than 2-inch nominal diameter was ultrasonically examined prior to threading by a straight beam radial scan over its entire surface. Bolting material which was greater than 4-inch nominal diameter was also examined prior to threading by an ultrasonic straight beam longitudinal scan over an entire end surface.

All inspections, equipment, calibration techniques and acceptance standards were in accordance with the requirements of the ASME Code, Section III.

Upon completion of all post-weld heat treatments, the reactor vessel was hydrostatically tested, after which all accessible ferritic weld surfaces, including those of welds used to repair material, were magnetic-particle inspected in accordance with the ASME Code, Section III.

5.4.2.2 Additional Tests

During design and fabrication of the reactor vessel, other tests and inspections not specifically included in the requirements of the ASME Code, Section III, were performed.

The supplier works with various ASME Code committees and is cooperating with the Pressure Vessel Research Committee program and other programs in developing information for reactor vessels relative to materials, inspection, and significance of flaws. The supplier also cooperates in the development of new and better steels for use in reactor vessels.

An analysis of major constituents was performed on both ends of each coil of carbon, low alloy, and stainless steel filler metal. Also a wet chemical analysis was made on each heat of carbon and low alloy filler metal.

During manufacture of the reactor vessel, quality control by the supplier in addition to, and in areas not covered by, the ASME Code, Section III, included such items as: (1) preparation of detailed purchase specifications requiring vacuum degassing for all ferritic plates, forgings, and bolting; (2) specification for fabrication of plates and forgings to provide control of material prior to receipt and during fabrication; (3) use of written instructions and manufacturing procedures which enable continual review based on past and current manufacturing experiences; (4) performance of chemical analysis of materials for welding, thereby providing continuous control over welding materials; and (5) test programs on fabrication of plates up to 15 inches thick to provide information about material properties as thickness increases.

All material was retested by the supplier on full thickness samples to code requirements. Longitudinal wave ultrasonic testing was performed on 100 percent of all plate material. Inspection was performed on plates with acceptable size ultrasonic indications during fabrication stages to evaluate the effects of fabrication upon the configuration and size of the indication.

Cladding for the reactor vessel is a continuous integral surface of corrosion-resistant material, having 7/32-inch nominal thickness, and a 1/8-inch minimum thickness. The detailed procedure used, i.e., type of electrodes, welding position, speed of welding, and nondestructive testing requirements, is in compliance with the ASME Code, Section III.

The cladding in completed reactor vessels has been examined and such tests have not shown the need for 100 percent ultrasonic examination for bond of weld-deposited cladding after fabrication. The clad surface is ultrasonically inspected, transverse to the direction of welding, for lack of bond at intervals of 12 inches or 1.4 times the base metal thickness, whichever is less. The clad surface is also dye-penetrant examined after a post-weld heat treatment for surface discontinuities. Also, all nonferritic weld surfaces are dye-penetrant inspected following the vessel hydrostatic test.

5.4.2.2.1 Arkansas In-Process Inspection

The ASME Code, Section XI, requires that volumetric examinations of pressure boundary welds be performed after the hydrostatic test to establish baseline information as a reference for future inservice examinations. Ultrasonic examination techniques were used during fabrication in addition to the radiography required for Class 1 vessel welds by the ASME Code Section III. This added in-process inspection was performed prior to final heat treatment of the weld to provide maximum assurance that unacceptable reflections requiring removal and repair would not be discovered during the baseline inspection performed after final heat treatment and hydrostatic test (The baseline inspection is discussed in Section 5.4.2.3).

Table 5.4-1 summarizes the reactor vessel inspection program during fabrication.

5.4.2.3 Baseline Examination

The reactor vessel for Unit 2 was given a baseline examination after the shop hydrostatic test, using remote manual ultrasonic test techniques equivalent to those intended for use during subsequent inservice examinations. This baseline examination constitutes the preservice examination required by Section XI for the purpose of comparison with the results of subsequent inservice inspections.

Indications which exceeded the equivalent limits of acceptability of the ASME code, Section III were repaired.

Baseline impact data for the reactor vessel surveillance program have been collected during baseline testing of surveillance specimens. These impact data include RT_{NDT} values for the limiting plate, a weld heat-affected-zone, and weld metal from the reactor vessel baseline region.

5.4.3 FEATURES FOR IMPROVED RELIABILITY

The quality assurance, in-process, and baseline examination programs described in Section 5.4.2 provide assurance of reactor vessel reliability.

5.4.4 QUALITY ASSURANCE SURVEILLANCE

The reactor vessel for Unit 2 was fabricated by Combustion Engineering, Inc. (CE), the NSSS supplier. The quality assurance program is described in the Quality Assurance Program Manual (QAPM).

5.4.5 MATERIALS AND INSPECTIONS

Reactor vessel materials are listed in Section 5.2, Table 5.2-3. Inspections are described in Section 5.4.2. Tensile strength and toughness data for the reactor vessel closure stud material is listed in Table 5.4-3 and in Figures 5.4-2 and 5.4-3.

5.4.6 REACTOR VESSEL DESIGN DATA

5.4.6.1 Design Basis

The reactor vessel is designed to contain the fuel assemblies, the Control Element Assemblies (CEAs), and the internals necessary for support of the core and for direction of coolant flow. The vessel is designed for the transients listed in Section 5.2.1.5 so that code allowable stress limits are not exceeded for the specified number of cycles.

5.4.6.2 Reactor Vessel Description

The reactor vessel is shown in Figure 5.4-1.

The reactor vessel is a right circular cylinder with two hemispherical heads. The lower head is welded to the vessel shell; the upper closure head can be removed to provide access to the reactor internals. The head flange is drilled to match the vessel flange stud bolt locations. The stud bolts are fitted with spherical crowned washers located between the closure nuts and the head flange to maintain stud alignment during head flexing due to boltup.

The vessel flange is a forged ring with a matched ledge on the inside surface to support the core support barrel. The flange is drilled and tapped to receive the closure studs and is machined to provide a mating surface for the reactor vessel closure seals. An externally tapered transition section connects the flange to the reactor vessel shell.

Sealing is accomplished by using two silver-plated, NiCrFe alloy, self-energized O-rings. The space between the two rings is monitored to detect any inner-ring coolant leakage.

Nozzles are provided on the closure head for nuclear instrumentation, Control Element Drive Mechanisms (CEDMs), and a vent.

The inlet and outlet nozzles are located radially on a common plane just below the vessel flange. Extra thickness in this vessel course provides the reinforcement required for the nozzles. Additional reinforcement is provided for the individual nozzle attachments. A boss located around the outlet nozzles on the inside diameter of the vessel wall provides a mating surface for the internal structure which guides the outlet coolant flow. This boss and the outlet sleeve on the core support barrel are machined to a common contour to minimize core bypass leakage. Shell sections are joined to the nozzle region by a transition section.

Snubbers, built into the lower portion of the reactor vessel shell, limit the amplitude of flow-induced vibrations in the core support barrel. Core stops are also built into the reactor vessel to limit the downward drop of the core if the core support barrel should fail. (Refer to Section 4.2.)

The reactor vessel is supported by three vertical columns below the vessel coolant nozzles as described in Section 5.5.14.

The vessel closure contains 54 studs, 6-1/2 inches in diameter with eight threads per inch. The stud material conforms to ASTM-A-540, Grade B24, with a minimum yield strength of 130,000 psi. The tensile stress in each stud, when elongated for operational conditions, is approximately 40,000 psi. Calculations show that 32 symmetrically distributed broken studs or four adjacent broken studs will result in 0-ring leakage. Failure of at least 16 adjacent studs is necessary before the closure could fail by zippering open.

The vessel studs are stressed as they are elongated by the stud tensioners during the initial installation of the vessel head and during each refueling. Significant changes in the elongation properties of the studs could result in being unable to meet the acceptance criterion for elongation. Studs which fail to meet elongation requirements during the head installation, or receive damage to the threads, will be replaced before returning the vessel to pressure operations.

5.4.6.3 Design Data

Basic Reactor Coolant System (RCS) design parameters are listed in Table 5.1-1. Physical parameters of the Unit 2 reactor vessel are listed in Table 5.4-2.

5.4.6.4 Evaluation

It has been demonstrated by analysis in accordance with the ASME Code, Section III requirements for Class 1 vessels, that the reactor vessel is adequate for all normal operating and transient conditions during the life of the facility. The reactor vessel has been hydrostatically tested and has been tested using nondestructive techniques as specified in the ASME Code, Section III. Further assurance of the structural integrity of the reactor vessels is provided by the inservice inspection program, designed to meet the requirements of the ASME Code, Section XI.

5.4.7 REACTOR VESSEL SCHEMATIC (BWR)

The Arkansas Nuclear One - Unit 2 reactor is a Pressurized Water Reactor (PWR). This section of the standard format is not applicable.

5.5 COMPONENT AND SUBSYSTEM DESIGN

5.5.1 REACTOR COOLANT PUMPS

5.5.1.1 Design Bases

In addition to the criteria described in Section 5.2, the reactor coolant pumps which circulate the reactor coolant through the Reactor Coolant System (RCS) are designed to:

A. Provide sufficient moment of inertia to reduce the flow decay through the core upon loss of pump power, ensuring that fuel design limits are not exceeded;

B. Prevent reverse rotation of the pump upon loss of pump power with the other pumps operating; and,

C. Operate without cooling water for period up to ten minutes without incurring seal damage.

5.5.1.2 Description

The reactor coolant is circulated by four vertical, single bottom suction, horizontal discharge, centrifugal motor-driven pumps as shown in Figure 5.5-1. Figure 5.5-2 provides a simplified diagram of the reactor coolant pump. The design parameters for the pumps are given in Table 5.5-1.

The reactor coolant pump assembly consists of the pump case, rotating assembly containing the impeller which is keyed and locked to the shaft, the pump case cover, motor adapter and motor. The motor is connected to and supported by the pump case through the motor mount adapter. There are two openings on opposite sides of the motor mounts that provide access for assembly of the flanged rigid coupling between the motor and pump and for seal cartridge replacement.

The pump rotating assembly consists of impeller, water lubricated radial hydrostatic bearing rotor, seal coolant recirculating impeller and rotating elements of the seal cartridge assembly. The radial bearing, one of three used for pump motor shaft support, is located just above the pump impeller. The upper radial bearing and the axial thrust bearing are located on the motor shaft. The seal cartridge and recirculating impeller are located above the thermal barrier formed by the close clearance between the pump shaft and the pump case cover.

The pump case cover assembly includes the coiled tubing heat exchanger which cools the seal cartridge and thermal barrier, the seal cartridge assembly, the thermal barrier, the radial bearing stator and the upper and lower impeller labyrinth seals.

The seal cartridge consists of a four stage mechanical seal; three full pressure seals mounted in tandem and a fourth low pressure vapor seal designed to withstand system operating pressure when the pumps are not operating. A controlled bleed-off flow through the seals is used to cool the seals and to equalize the pressure drop across each seal. The controlled bleed-off flow is collected by either the reactor drain tank of the Boron Management System (BMS) or the volume control tank of the Chemical and Volume Control System (CVCS) during plant heatup and cooldown. During normal operations, controlled bleed-off is collected by the volume control tank. Leakage past the vapor seal is collected in the Waste Management System (WMS) through drainage to the reactor drain tank.

The seal cartridge assembly is cooled by circulating the controlled leakage through a coiled tube heat exchanger integral with the pump case cover. The seal coolant recirculation is done by the recirculating impeller located directly below the seal cartridge. The seals are capable of operation without cooling water for up to ten minutes without incurring damage. The seal cartridge concept reduces the time required for seal maintenance thereby lowering personnel radiation exposure time. The seal cartridge can be removed without draining the pump case. Details of the seal cartridge are shown in Figure 5.5-3.

Each seal is designed to accept the full operating pressure of the RCS; however, the first three seals of the cartridge assembly normally operate with a pressure differential equal to one-third of the operating pressure and with only a slight pressure differential across the vapor seal. The seal rotating and stationary materials are described in Table 5.5-1.

The reactor coolant pump and motor assembly is supported by spring hangers attached to the four support lugs welded to the pump case. The spring hangers permit motion in the horizontal and vertical directions to compensate for thermal and seismic movement.

The pump motor assembly includes a once-through air cooler, motor and pump seal coolant heat exchangers, bearing lubrication and lube oil cooling systems, oil lift pumps, motor-pump shaft upper radial and axial support bearings, flywheel, and anti-rotation device. The cooling water to the motor coolers is supplied from the component cooling system. Two oil lift pumps, driven by a common 3 HP AC motor, are used to support the pump-motor shaft assembly during startup and during normal shutdown of the pumps. The motor-pump bearing support system includes a Kingsbury double acting thrust bearing and a radial hydrostatic bearing located above the pump impeller. The flywheel and motor-pump rotating assembly has a total moment of inertia of 136,400 lb_m-ft^2 sufficient to improve the coastdown characteristics of the pumps to meet the system requirements during a loss of pump power condition. The motor flywheel assembly is shown in Figure 5.5-4.

Each reactor coolant pump motor contains approximately 150 gallons of lube oil within its bearing lubrication system. To collect any lube oil leakage and prevent leakage from spreading, each pump has a reactor coolant pump oil collection system installed. To increase collection capacity of any oil from piping external to the motor (including flanged connections, gauges, and filler lines), collection pans and spray deflectors have been added to each motor.

The pumps include an anti-rotation device shown in Figure 5.5-5 to prevent reverse rotation caused by backflow through the impeller. The anti-reverse device will stop a pump when it decelerates from normal speed (900 rpm nominal) while the remaining pumps continue to operate. The device consists of concentric inner and outer races, a complement of sprags between those races, and a bearing to maintain concentricity between the races.

If reverse rotation of the motor shaft is attempted, the sprags wedge between the inner and outer races, preventing rotation. Rotation in the forward direction frees the sprags, and free forward rotation is thus permitted.

This is accomplished by having the line of action of the sprags inclined from a true radial line such that wedging occurs on reverse rotation by reducing the angle between the true radial line of action of the sprag. The outer race of the device is secured to the shaft such that it rotates with the shaft and the inner race is held stationary. The sprags rotate with the outer race and are shaped so that their centers of gravity are located such that centrifugal force causes the incline angle between a radial line and the sprag to increase and thereby produce clearance between the inner end of the sprags and the stationary inner race. Wear of the sprags and races is, therefore, eliminated for full-speed forward rotation.

The pump performance curve is shown in Figure 5.5-6. The pump motor is conservatively sized at a higher horsepower rating to enable continuous operation at the flows resulting from 4-pump operation with 0.74 specific gravity water. The motors are designed to start and accelerate to speed under full load when 80 percent or more of their normal voltage is applied. The motors are contained within NEMA Standard Ng-1-1.20 drip-proof enclosures and are equipped with electrical insulation suitable for a zero to 100 percent humidity and radiation environment of 30 R/hr of gamma.

5.5.1.3 Evaluation

The reactor coolant pumps are sized to deliver flow that equals or exceeds the design flow rate utilized in the thermal hydraulic analysis of the RCS. Analysis of steady state and anticipated transients is performed assuming a conservative flow rate. Tests are performed to evaluate reactor coolant pump performance during the post-core load hot functional testing to verify adequate flow.

Leakage from the pump via the pump shaft is controlled by the shaft seal assembly. Coolant entering the seal chambers is cooled and collected in closed systems so that reactor coolant leakage to containment is essentially zero. The seal cavities are piped to funnel drains near each reactor coolant pump to collect any water vented off the cavity. In the event of seal malfunctions, instrumentation is provided to alert the operator to this potential problem.

The design overspeed of flywheel is 125 percent of rated speed. An overspeed test of each flywheel at the design overspeed was performed prior to assembly. Refer to the discussion of Regulatory Guide 1.14 in Section 5.2.6.

In the event of a break in the reactor coolant pump suction piping, the anti-reverse rotation device will prevent impeller rotation in the reverse direction. In the event of a discharge pipe break, increased flow through the pump will tend to accelerate the pump impeller. Further evaluation relating to the integrity of the flywheel is presented in response to Regulatory Guide 1.14 in Section 5.2.6.

Component cooling water to the reactor coolant pumps is not needed to assure (1) the integrity of the Reactor Coolant Pressure Boundary (RCPB), (2) the capability to shutdown the reactor and maintain it in a safe shutdown condition, or (3) the capability to prevent or mitigate the consequences of accidents which could result in potential off-site doses comparable to the guideline doses of 10 CFR 100. Low pump cooling flow to each pump is alarmed in the control room. Thermal lag in the reactor coolant pump and motor makes them relatively insensitive to loss of cooling water flow.

The Unit 2 pumps, by design and field experience, are not susceptible to a LOCA due to seal failure resulting from loss of seal cooling water. The pumps are equipped with four series-arranged face seals all of which are designed for 2,500 psi $\Delta\rho$. The maximum $\Delta\rho$ across any one of the three main seals during normal operation is 750 psi. The loss of any single seal would result in a maximum $\Delta\rho$ of approximately 1,100 psi. A seal leakage chamber structurally designed for 2,500 psia is provided to collect controlled seal leakage and conduct it to a closed system. The fourth face seal is provided as an integral part of the seal leakage chamber to prevent liquid or gaseous leakage from escaping to the atmosphere. This seal is designed to operate normally against a back pressure of 25 to 250 psia, and is capable of holding against full pressure (2,500 psia) in the static condition and during coastdown following failure of the three series-arranged main seals. When holding against 2,500 psia in the static condition, the seal leakage should not exceed the normal operating seal leakage.

Four reactor coolant pumps with seals of similar design have been operated for up to 40 minutes with no component cooling water flow. While there was some increase in controlled seal leakage (to the closed system), the mechanical seals were subsequently dismantled and refurbished without finding major damage such as broken pieces in the seals. Therefore, a loss of component cooling water flow to the Unit 2 reactor coolant pumps for up to 40 minutes is not expected to result in a Loss of Coolant Accident (LOCA) due to seal failure.

In the event of an accident that causes actuation of containment isolation the reactor coolant pumps are stopped resulting in no requirement for component cooling water. The containment isolation signal is only given by two of four high containment pressure signals. High containment pressure can be reached by the following accidents: (1) a LOCA; (2) a major steam line break inside containment; or (3) a feedwater line break inside containment. In the event of these accidents, plant conditions may result in reactor coolant pumps being tripped and Component Cooling Water (CCW) containment isolation valves being closed. Emergency Operating Procedures provide guidance for opening CCW isolation valves and restoration of forced circulation when applicable criteria are satisfied.

5.5.1.4 Tests and Inspections

The reactor coolant pump pressure boundary was nondestructively inspected as required by the ASME Code, Section III, for Class 1 components. The pump casing inspections included complete radiography and liquid penetrant or ultrasonic testing. The pump received a hydrostatic pressure test with the reactor coolant system in the plant. Inservice inspection of the pump pressure boundary is performed during plant life in accordance with the ASME Code, Section XI.

All rotating parts of the pump were structurally and dynamically balanced in two planes. Where possible, balancing was done for the entire assembly.

The pump assembly was performance tested in the vendor's shop in accordance with the Standards of the Hydraulic Institute to verify hydraulic performance as well as the ability of the pumps to function as required by the specifications. The vibration levels were monitored during this test. Evidence of the pumps operating near a critical speed would have been noted as excessive vibration.

Full scale seal testing was performed at rated pressure, temperature, water chemistry and speed to demonstrate the capability of the seals to satisfactorily perform their design function.

5.5.2 STEAM GENERATOR

5.5.2.1 Design Bases

The steam generators are designed to

A. Transfer the heat generated in the RCS to the secondary system;

B. Provide steam to the secondary system at the design flow rate with a moisture content no greater than 0.1 percent during steady state operation with water at the normal operating level;

C. Meet the following conditions, in addition to the transients listed in Section 5.2:

1. Four thousand cycles of pressure differentials of 92 psi across the divider plate caused by starting and stopping the reactor coolant pumps (normal condition);

2. One cycle of hydrostatic testing of the secondary side at 1,375 psig and of the primary side at 3125 psig (test condition);

3. Eight hundred cycles of tube leak testing of the secondary side at 200 to 840 psi (test condition);

4. Ten thousand two hundred cycles of adding 70 °F feedwater to the plant during heatup, hot standby, and cooldown conditions. Additional requirements include five hundred cycles of ramping power from 0 to 15 percent and five hundred cycles of ramping power from 15 to 0 percent power (evaluated separate from the plant loading and unloading transient cycles) (normal condition); and,

5. Twenty cycles of adding 32 °F emergency feedwater with flow initiated after a loss of normal feedwater (emergency condition).

D. Ensure that critical vibration frequencies will be well out of the forcing function frequency range expected during normal operation and during abnormal conditions. The tubing and tube supports are designed and fabricated with considerations given to both secondary side-flow induced vibrations and reactor coolant pump induced vibrations. In addition, the tubing and tube supports are designed so that the structural integrity of the pressure boundary (tubes) will be maintained during a postulated main steam line break event.

5.5.2.2 Description

The Nuclear Steam Supply System (NSSS) utilizes two steam generators (Figure 5.5-7) to transfer the heat generated in the RCS to the secondary system. The design parameters for the steam generators are given in Table 5.5-2. The steam generator is a vertical U-tube heat exchanger with the reactor coolant on the tube side and the secondary fluid on the shell side.

The steam generator design features and tube material have been developed and selected to minimize the potential for tube degradation. The design features minimize the potential for concentration of chemical species that can be detrimental to high nickel alloy tubing material. The tube material, tubing fabrication methods, and installation techniques provide tubes that are highly resistant to corrosion.

The steam generators are designed with the objective of minimizing crevices or contact areas between tubes and tubesheet or other internals. All tubes are initially tack expanded on the tube end, welded to the cladding, then expanded into the tube sheet for the full depth of the tube hole by the hydraulic expansion process. This process has the advantages of expanding the tube into essentially metal to metal contact with the tube hole without excessively cold working the tube wall, as might be done with a mechanical rolling process. The hydraulic expansion process provides more precise dimensional control than an explosive expansion. Also, hydraulic expansion is not subject to dynamic rebound. Strict tolerances and other quality control measures are applied to the expansion process to ensure that the tubes are expanded essentially over the full depth of the tubesheet.

Tube support plates of the flat-contact broached trifoil tube hole design are used to support the tubes. The tube support plates are sized to provide sufficient strength that the tubes maintain structural integrity during a seismic event. The clearance between the tube and tube support and the spacing between the supports is sized to minimize the potential for excessive vibration of the tubes. The tube support plates are made of corrosion resistant Type 405 ferritic stainless steel. Use of this material prevents significant corrosion of the tube support plates and thus precludes tube denting. The tube hole design reduces the tube-to-tube support plate crevice area while providing for maximum steam and water flow in the open areas adjacent to the tube. The flat land contact provides additional dryout margin.

The U-tubes are fabricated of nickel-chromium-iron Alloy 690. The tubes undergo thermal treatment following tube-forming operations. The thermal treatment subjects the tubes to elevated temperatures for a prescribed period of time to improve the grain structure of the material. Thermally treated Alloy 690 has been shown in laboratory tests and operating nuclear power plants to be very resistant to primary water stress corrosion cracking (PWSCC) and outside diameter stress corrosion cracking (ODSCC).

Reactor coolant enters the steam generator through the 42-inch ID inlet nozzle, flows through 0.688-inch OD (0.040-inch average wall) tubes, and leaves through two 30-inch ID outlet nozzles. A divider plate in the channel head separates the inlet and outlet plenums. The channel head is a low alloy steel forging with low cobalt stainless steel cladding. The tubesheet is low alloy steel with the reactor coolant side of the tube sheet clad with Ni-Cr-Fe Alloy 690.

Feedwater enters the steam generator through the 18-inch Schedule 80 feedwater nozzle where it is distributed via an elevated feedwater distribution ring which directs the flow into the downcomer. The downcomer is the annular passage formed by the inner surface of the steam generator shell and the cylindrical wrapper that encloses the vertical U-tubes. The feedwater distribution ring is welded to the feedwater nozzle to minimize the potential for draining the ring. The connection between the nozzle and the feedwater ring is a thermal sleeve that minimizes the effect of cold feedwater addition transients on the feedwater nozzle. The feedwater ring is located above the elevation of the feedwater nozzle to minimize the time required to fill the feedwater nozzle during a cold water addition transient. The feedwater is discharged through inverted J-nozzles installed on the top of the ring. These features reduce the thermal fatigue loading on the feedwater nozzle, eliminate steady state thermal stratification in the feedwater nozzle and feedwater piping elbow at the feedwater nozzle entrance, and minimize the potential for bubble collapse water hammer generated in the feedwater distribution ring.

At the bottom of the downcomer, the secondary water is directed upward past the U-tubes where heat transferred from the reactor coolant side produces a steam water mixture. Anti-vibration bars installed in the U-bend portion of the tube bundle minimize the potential for excessive vibration. The anti-vibration bars are fabricated from Type 405 stainless steel. The construction minimizes the gaps between the anti-vibration bars and tubes.

Upon rising above the U-tube heat transfer surface, the steam water mixture enters centrifugal type separators. These impart a centrifugal motion to the mixture and separate the water from the steam. The water leaves the separator through the perforated separator housing and flows by gravity into the downcomer where it is mixed with the feedwater. Final drying of the steam leaving the centrifugal separators is accomplished by passing the steam through eight single-tier dryer banks. The moisture content of the outlet steam is no greater than 0.1 percent at design flow during steady state operation with water at the normal operating level.

The steam generator shell is constructed of low alloy steel. Manways and handhole openings in the shell provide access to the steam generator internal structures. Manways on the inlet and outlet side of the channel head permit access to the tube sheet for inspection and tube plugging if required.

The steam generators are mounted on bearing plates which allow controlled lateral motion due to thermal expansion of the reactor coolant piping. The top of each steam generator is restrained from sudden lateral movement by keys and hydraulic snubbers mounted rigidly to the concrete structure.

The steam generators are located at a higher elevation than the reactor vessel. The elevation difference creates natural circulation capability sufficient to remove core decay heat following coastdown of all reactor coolant pumps.

5.5.2.3 Evaluation

Each steam generator is designed for the design transients listed in Sections 5.2 and 5.5.2.1 such that no component is stressed beyond the allowable limit as prescribed in the ASME Code, Section III.

Each steam generator is capable of withstanding these conditions for the prescribed number of cycles without exceeding the allowable cumulative usage factor as prescribed in the ASME Code, Section III.

5.5.2.3.1 Tube Vibration

Potential sources of tube excitation are considered, including primary fluid flow within the U-tubes, mechanically induced vibration, and secondary fluid flow on the outside of the U-tubes. The effects of primary fluid flow and mechanically induced vibration, including those developed by the reactor coolant pump, are acceptable during normal operation. The primary source of potential tube degradation due to vibration is the hydrodynamic excitation of the tubes by the secondary fluid. This area has been emphasized in both analyses and tests, including evaluation of steam generator operating experience.

Three potential tube vibration mechanisms related to hydrodynamic excitation of the tubes have been identified and evaluated. These include potential flow-induced vibrations resulting from vortex shedding, turbulence, and fluid-elastic vibration mechanisms.

Non- uniform, two-phase turbulent flow exists throughout most of the tube bundle. Therefore, vortex shedding is possible only for the outer few rows of the inlet region. Moderate tube response caused by vortex shedding is observed in some carefully controlled laboratory tests on idealized tube arrays. However, no evidence of tube response caused by vortex shedding is observed in steam generator scale model tests simulating the inlet region. Bounding calculations consistent with laboratory test parameters confirmed that vibration amplitudes would be acceptable small, even if the carefully controlled laboratory conditions were unexpectedly reproduced in the replacement steam generators.

Flow-induced vibrations due to flow turbulence are also small. As evaluated, the root mean square amplitudes are less than allowances used in tube sizing. These vibrations cause stresses that are below fatigue limits for the tubing material; therefore, neither unacceptable tube wear nor fatigue degradation due to secondary flow turbulence is anticipated.

Fluid-elastic tube vibration is potentially more severe than either vortex shedding or turbulence because it is a self-excited mechanism. Relatively large tube amplitudes can feed back proportionally large tube driving forces if an instability threshold is exceeded. Tube support spacing in both the tube support plates and the anti-vibration bars in the U-bend region provides tube response frequencies such that the instability threshold is not exceeded for secondary fluid flow conditions for tubes effectively supported. This approach provides large margins against initiation of fluid elastic vibration for tubes effectively supported by the tube support system.

Pressure pulsations from the reactor coolant pumps and acoustic effects have been evaluated in the past for hydrodynamic excitation of the tubing, and experience has demonstrated that these mechanisms have minimal contribution to tube response.

The steam generator includes a number of features that minimize the potential for tube wear at tube supports and anti-vibration bars. Provisions to minimize the potential for wear include the spacing between the tube supports, the configuration of the broached hole through the support plate, the surface finish of the broached hole in the tube support plate, the clearance between the tube and the hole in the tube support plant, tube support plate material selection, and the configuration of the anti-vibration bar assemblies.

As outlined, analyses and tests demonstrate that unacceptable tube degradation resulting from tube vibration is not expected for the steam generators. Operating experience with steam generators having the same size tubes and similar flow conditions supports this conclusion.

5.5.2.3.2 Tube Corrosion

Several corrosion mechanisms have been identified in operating nuclear power plant steam generators that can result in unacceptable tube degradation. The ANO-2 steam generator design addresses these degradation mechanisms and provides a design that is very resistant to tube corrosion. Given that appropriate water chemistry is maintained, the steam generators are designed for a cumulative operating service of 40 years. The ANO-2 replacement steam generators (RSGs) were installed in 2000, thus their 40-year design life extends to 2040. License renewal extends the ANO-2 operating license to 2038, prior to the end of the design life of the RSGs.

Tube wastage is a corrosion mechanism that results in a general thinning of the tubing. This mechanism was associated with phosphate chemistry. The use of all volatile treatment (AVT) water chemistry has eliminated the occurrence of tube wastage.

Several features in the ANO-2 steam generator design minimize crevice areas and the deposition of contaminants from the secondary-side flow. Such crevices and deposits could otherwise produce a local environment allowing adverse conditions to develop and result in material corrosion.

Corrosion of carbon steel support plates in early model steam generators in some cases resulted in denting of the tubes. Corrosion of the plate can reduce the size of the drilled hole in the plate since the corrosion product has a larger specific volume that the original steel. Continued progression of the corrosion can lead to a tight crevice and a reduction of the tube diameter. These conditions result in a concentration of chemicals and higher stress in the tubes. This may result in stress corrosion cracking.

The use of corrosion resistant Type 405 ferritic stainless steel support plates precludes the denting of the tubes. The use of a trifoil hole minimizes the potential for concentration of chemicals at the interface between the tube and support plate. It provides high sweeping velocities at the tube and the tube support plate intersections. The sweeping velocities through the support plate reduce the sludge accumulation in the tube-to-tube support crevices. This support plate design contributes to a high circulation ratio. The higher circulation ratio results in increased flow in the interior of the bundle, as well as horizontal velocity across the tubesheet, which reduces the tendency for sludge deposition.

The tubes are tack expanded, welded at the tube end, and hydraulically expanded essentially over the full depth of the tubesheet. Expansion of the tube provides the capability to control secondary water ingress to the tube-to-tubesheet crevice. The transition between the expanded and unexpanded portions of the tube is a location of residual stress. The use of a roller to effect the expansion would leave a relatively high residual stress at the transition. The use of an explosive expansion would reduce the residual stress, but there would be less control on the vertical location of the transitions and the interference fit between the tubesheet and the tube. Therefore, roll expansion and explosive expansion are not used for the steam generator tubes. The use of a hydraulic expansion process in the steam generators produces residual stresses smaller than from other expansion methods in the transitions. Residual stresses are minimized by tight control of the pre-expansion clearance between the tube and tubesheet hole. The length of the expansion is carefully controlled to minimize the potential of an over-expanded condition above the tubesheet and the extent of unexpanded tube at the top of the tubesheet. Along with measurement of the tubesheet thickness, hydraulic expansion minimizes the crevice between the tube and tubesheet. These features minimize the potential for outside diameter stress corrosion cracking at the top of the tubesheet.

Thermally treated (TT) nickel-chromium-iron Alloy 690 used for the steam generator tubes is very resistant to corrosion in steam generator applications. Alloy 690TT has been proven through both laboratory testing and operational experience to provide increased corrosion resistance compared to mill annealed Alloy 600 with regard to PWSCC and ODSCC. Alloy 690TT has been determined to be the material of choice for steam generator application based on extensive industry testing.

Industry corrosion tests subjected the steam generator tubing material to simulated steam generator water chemistry. These tests indicated that the loss due to general corrosion over the 40-year operating design objective is small compared to the tube wall thickness. Testing to investigate the susceptibility of heat exchanger construction materials to stress corrosion in caustic and chloride aqueous solutions indicate the Alloy 690TT provides as good or better corrosion resistance as either Alloy 600 or nickel-iron-chromium Alloy 800. Alloy 690TT also resists general corrosion in severe operating water conditions.

High margins against primary water stress corrosion cracking exist with the specification of thermally treated Alloy 690 tubing. Alloy 690 is resistant to primary water stress corrosion cracking over the range of anticipated operating environments. The tubing is thermally treated according to a laboratory-derived treatment process.

5.5.2.3.3 <u>Tube Plugging</u>

The replacement steam generators, prior to installation, required one (1) tube to be plugged in Steam Generator B due to a over expansion beyond the tubesheet face and the removal of the expansion mandrel at the manufacturers facility. All tube plugging at the manufacturer's facility was performed in accordance with ASME Code, Section III. All tube plugging subsequent to installation of the steam generators is performed in accordance with ASME, Section XI. The plugging/repair limit for tubing is defined in the Technical Specifications.

5.5.2.3.4 Allowable Tube Wall Degradation

The acceptance criteria for allowable tube wall degradation is defined in the Technical Specifications.

The program for the inservice inspection of steam generator tubing is in conformance with the guidance of NEI 97-06, Steam Generator Program Guidelines and the ASME Code, Section XI. ANO-2 TS 6.5.9 establishes requirements on the sample size and the inspection interval. ASME Code, Section XI establishes the standards for examination and allowable flaws in tubing.

The steam generator tubes, existing originally at their minimum wall thickness and reduced by a conservative general corrosion and erosion loss, provide an adequate safety margin (sufficient wall thickness) so that the maximum stress is less than the allowable stress limit, as defined by the ASME Code, Section III.

In addition to the analysis required by the ASME Code, an analysis (Reference 20) to establish the minimum wall thickness of the tubes using the guidance of Regulatory Guide 1.121 was performed for the steam generators. This analysis supports the allowable tube wall degradation as defined in the Technical Specifications. The Regulatory Guide 1.121 analysis is performed for loads corresponding to full power operation as well as the full range of normal operating transients and accident conditions. The limiting stresses for normal operation and operating transient conditions are the primary membrane stresses due to the primary to secondary pressure differential across the tube wall. For the Faulted plant condition, the postulated Level D Service conditions events are Loss of Coolant Accident, Main Steam Line Break, Main Feed Line Break, and Design Basis Earthquake. The tube integrity evaluation is performed for the blowdown loads in conjunction with the DBE loads. The initial conditions for these events correspond to 100% full power conditions, thus maximizing the resulting tube loadings.

Based upon the above, the most restrictive conditions were analyzed to determine the minimum allowable tube wall thickness for uniform tube wear and for wear over a limited axial extent at the tube support plate and anti-vibration bar intersections. The analyses confirm a defined structural limit of 57.5% allowable defect depth in the most limiting case and the 40% plugging limit for the tubing defined in the Technical Specifications. The tube wall is capable of meeting the applicable requirements with adequate allowance for eddy current measurement uncertainties and an assumed allowance for continued degradation.

5.5.2.3.5 Potential Effects of Tube Rupture

The postulated rupture of a steam generator tube results in leakage from the RCS to the main steam system. Radioactivity in the reactor coolant mixes with water in the shell side of the affected steam generator. This radioactivity is transported to the turbine and then to the condenser, or directly to the condenser via the main steam dump and bypass system. Non-condensible radioactive gases in the condenser are removed by the condenser vacuum pump air ejectors and released to the vent. The analysis of a postulated steam generator tube rupture is presented in Section 15.1.18.

Experience with PWR steam generators indicates that the probability of complete severance of a tube is remote. The material used to fabricate the U-tubes is a ductile Ni-Cr-Fe alloy. The more probable modes of tube failure are those which result in smaller leaks, as a result of the occurrence of small cracks in the tube, or those involving a larger break flow as a result of

mechanical wear related to tube thinning. The tube wear is typically caused by fretting between a tube and a foreign object. Detection and control of steam generator tube leakage is described in Section 11.2.

5.5.2.3.6 Composition of Secondary Fluid

Radioactivity concentration in the secondary side of the steam generator is dependent upon the activity level of the RCS, the primary to secondary leak rate, and the operation of the steam generator blowdown system. An evaluation of shell side radioactivity concentration is given in Section 11.2.

The recirculating water within the steam generators will contain volatile additions necessary for proper pH chemistry control. These and other chemistry considerations of the main steam system are discussed in Sections 10.3 and 10.4. The all volatile treatment (AVT) control program minimizes the possibility of the tube wall thinning phenomenon. Successful AVT operation requires maintenance of low concentrations of impurities in the steam generator water. This reduces the potential for formation of highly concentrated solutions in low-flow zones, which is a precursor of corrosion. By restricting the total alkalinity in the steam generator and prohibiting extended operation with free alkalinity, the all volatile treatment program minimizes the possibility for intergranular corrosion in localized areas due to excessive levels of free caustic.

Laboratory testing shows that Alloy 690TT tubing is compatible with the AVT environment. Isothermal corrosion testing in high-purity water shows Alloy 690TT exhibiting normal microstructure tested at normal engineering stress levels is not susceptible to intergranular stress corrosion cracking in extended exposure to high-temperature water. These tests also show that no general type corrosion occurred. Field experience with Alloy 690TT tubing in operation since 1989 has been excellent.

5.5.2.3.7 Tests and Inspections

The steam generators are tested in accordance with ASME Code, Section III which requires the nondestructive tests during fabrication listed in Table 5.5-3.

During design and fabrication of the steam generator, additional operations beyond the requirements of the ASME Code, Section III were performed. These included ultrasonic testing for defects in tube sheet clad and ultrasonic testing of weld clad for bond integrity.

Hydrostatic tests of the primary and secondary sides of the steam generator have been conducted in accordance with the ASME Code, Section III. Leak tests were also performed. Following satisfactory performance of the hydrostatic tests, magnetic-particle inspections were made on all accessible welds.

Steam generator performance was verified during initial startup tests and was verified as part of post installation testing of the replaced steam generators.

5.5.3 REACTOR COOLANT PIPING

5.5.3.1 Design Basis

The reactor coolant piping is designed and analyzed for all transients specified in Section 5.2. Loading combinations and stress criteria associated with faulted conditions are presented in Section 5.2. In addition, certain nozzles are subjected to local transients which are included in

the design and analysis of the areas affected. Thermal sleeves are installed in the surge nozzle, safety injection nozzles and charging nozzles to accommodate these additional transients. Principal parameters are listed in Table 5.5-4.

The piping is Seismic Category 1. Additional discussions on seismic and dynamic analysis and criteria for the reactor coolant piping are contained in Sections 3.7.3 and 3.9.1, respectively.

Vibration testing of reactor coolant piping is discussed in Section 14.1.1.5.

Reactor coolant piping vibrations are also monitored by the Vibration and Loose Parts (V&LP) monitoring system which is described in Section 5.2.8.8.

5.5.3.2 Description

Each of the two heat transfer loops contains five sections of pipe: one 42-inch internal diameter pipe between the reactor vessel outlet nozzle and steam generator inlet nozzle, two 30-inch internal diameter pipes from the steam generator's two outlet nozzles to the reactor coolant pumps suction nozzle, and two 30-inch internal diameter pipes from the pumps discharge nozzle to the reactor vessel inlet nozzles. These pipes are referred to as the hot leg, the suction legs, and the cold legs, respectively.

The other major piece of reactor coolant piping is the surge line, a 12-inch schedule 160 pipe between the pressurizer and the hot leg in Loop 2P32A/B. The arrangement of this piping is shown in Figure 5.1-1.

To minimize the possibility of stress corrosion cracking, the reactor coolant piping is fabricated from SA 516 GR 70 base material mill clad with Type 304L stainless steel. A minimum clad thickness of 1/8 inch is maintained. Small lines such as the surge lines, spray lines, and other small lines are stainless steel. Nozzles are shop fabricated with safe ends, to preclude dissimilar-metal field welds. Where stainless steel or Ni-Cr-Fe nozzle or safe end material is used, the safe ends are welded to the assembly after final stress relief to prevent furnace sensitization. Other precautions that are used in the shop and during field assembly of the piping are described in Section 5.2. In addition, to ascertain the integrity of the piping during plant life, necessary inservice inspections required by the ASME Code, Section XI are performed where required on the reactor coolant piping. To facilitate such inspections, longitudinal weld seams have been oriented at the 90-degree and 270-degree locations where feasible. Removable insulation is installed to provide access to the welds.

5.5.3.3 Evaluation

The piping is shop fabricated and shop welded into subassemblies to the greatest extent practicable to minimize the amount of field welding. Welding procedures and operations meet the requirements of Section IX of the ASME Boiler and Pressure Vessel Code. All welds are 100 percent radiographed and liquid-penetrant or magnetic-particle tested and all reactor coolant piping penetrations are attached in accordance with the requirements of ASME III. Cleanliness standards consistent with nuclear service are maintained during fabrication and erection. There are no dissimilar metal field welds.

Stress corrosion cracking of the stainless steel piping requires the presence of halides (chlorides and fluorides) or sulfates. The reactor coolant chemistry control described in Section 9.3.4 assures that the halide or sulfate concentration in the RCS is below the level required for the development of stress corrosion cracking. Other material considerations are addressed in Section 5.2.

The transients for the piping design are listed in Section 5.2. The seismic design of the system is described in Section 3.7.

Thermal sleeves are installed in the surge line, charging and inlet shutdown cooling nozzles to reduce thermal shock effects from auxiliary systems. Clad sections of piping are fitted with safe ends for field welding to stainless steel components, i.e., the reactor coolant pumps and the surge line.

The 42- and 30-inch pipe diameters were selected to obtain coolant velocities which provide a reasonable balance between erosion-corrosion, pressure drop, and system volume. The surge line is sized to limit the frictional pressure loss through it during the maximum in-surge so that the pressure differential between the pressurizer and the heat transfer loops is no more than five percent of the system design pressure.

5.5.3.4 Tests and Inspections

Prior to and during fabrication of the piping, nondestructive testing based on the requirements of the ASME Code is applied. The component inspection program during fabrication and construction is summarized in Table 5.5-5.

Inservice inspection of the RCS piping is discussed in Section 5.2. Tests for RCS integrity following normal opening, modification or repair are specified in the Technical Specifications Section 4.4.10.1.

5.5.4 MAIN STEAM FLOW RESTRICTIONS

Each steam generator has a steam flow-limiting device (flow restrictor), consisting of seven venturis installed into integral holes in the steam outlet nozzle of the steam generator. The steam generator main steam outlet nozzle flow restrictor, in the event of a main steam line rupture, will limit the flow from a rupture. The restrictor reduces the rate of mass and energy release from the steam generators prior to closure of the main steam isolation valves in the event of a steam line break. If the steam line rupture is downstream of the main steam isolation valves, closure will terminate blowdown. If the rupture is upstream of the main steam isolation valves the steam generator associated with the ruptured line will continue blowing down until empty. The analysis of this accident is discussed in Section 15.1.14.

5.5.5 MAIN STEAM ISOLATION SYSTEM

5.5.5.1 Design Bases

The main steam line isolation system is designed for automatic or manual operation to isolate the steam generator secondary side from the main steam lines in the event of a main steam line rupture or for maintenance.

5.5.5.2 Description

Each main steam line is provided with an air-operated isolation valve outside containment (refer to Chapter 10). The valves are closed automatically by the occurrence of a low steam generator pressure signal or high high containment pressure which generates the main steam isolation signal (refer to Section 7.3).

5.5.5.3 Evaluation

The system and its supports and restraints are designed to ensure that an inadvertent isolation or a main steam line rupture will not result in failure of any associated component, i.e., feedwater lines or intact steam line. The piping and associated supports and restraints of the main steam system from the steam generator to the downstream side of the isolation valves are Seismic Category 1 and are designed to ASME Section III, Class 2. Further safety considerations are discussed in Section 10.3.3.

5.5.5.4 Testing and Inspection

The components of the main steam isolation system are inspected visually where practicable. Additionally, the actuation signals, automatic and manual, are tested periodically to ensure operability of the valves and the actuation signals.

5.5.6 REACTOR CORE ISOLATION COOLING SYSTEM

This system is unique to BWRs and is not a part of the Unit 2 design.

5.5.7 RESIDUAL HEAT REMOVAL SYSTEM

As noted in Section 3.1 in the response to General Design Criterion 34, (10 CFR 50, Appendix A), residual heat removal is accomplished by the main steam system when the reactor coolant temperature is above 275 °F and by the shutdown cooling system at temperatures below 275 °F. The main steam system is described in Chapter 10. The shutdown cooling system is one of the process auxiliary systems and is described in Section 9.3.6.

The condensing shutdown mode is a BWR operating mode and is not applicable to Unit 2.

5.5.8 REACTOR COOLANT CLEANUP SYSTEM

This system is unique to BWR's and is not a part of the Unit 2 design. An analogous function for PWRs is provided by the Chemical and Volume Control System (CVCS), described in Section 9.3.4.

5.5.9 MAIN STEAM LINE AND FEEDWATER PIPING

The main steam system is not a part of the RCS in a PWR such as Unit 2. This piping is described in Chapter 10.

5.5.10 PRESSURIZER

5.5.10.1 Design Bases

The pressurizer is designed and analyzed for the transients specified in Section 5.2 and the following additional requirements. During heatup and cooldown of the plant, the allowable rate of temperature change for the pressurizer is 200 °F per hour as a design requirement.

The pressurizer is designed to:

A. Maintain RCS operating pressure;

B. Compensate for changes in coolant volume during load changes;

C. Contain sufficient volume to prevent draining the pressurizer as a result of reactor trip;

D. Limit the water volume to minimize the energy release during LOCA;

E. Prevent uncovering of the heaters by the out-surge of water following load decreases - 10 percent step decrease and five percent per minute ramp decrease;

F. Provide sufficient volume to accept the reactor coolant in-surge resulting from a loss of load without the water level reaching the safety valve nozzles;

G. Provide sufficient volume to yield acceptable pressure response to normal system volume changes during load change transients;

H. Achieve a total coolant volume change and associated charging and letdown flows which are as small as practical and are compatible with the capacities of the volume control tank, charging pumps and letdown control valves during load following transients; and,

I. Ensure that the minimum pressure observed during transients is above the setpoint of the safety injection actuation signal, and that the maximum pressure is below the high pressure trip.

The heater capacity is selected to provide an adequate pressurizer heatup rate during plant startup.

The pressurizer is Seismic Category 1.

5.5.10.2 Description

The pressurizer is shown in Figure 5.5-8 and the design parameters are given in Table 5.5-6.

The pressurizer is a cylindrical carbon steel vessel with stainless steel or Ni-Cr-Fe clad internal surfaces. A spray nozzle on the top head is used in conjunction with heaters in the bottom head to provide pressure control. Overpressure protection is provided by two safety valves. An acoustical valve monitoring system provides the control room operator with open/closed position indication of the safety valves on annunciator panel 2K10. This system is required by NUREG-0578, Item 2.1.3a. Pressurizer level control is discussed in Section 9.3.4. The pressurizer is supported by a cylindrical skirt welded to the bottom head. A surge line connects the pressurizer to the reactor coolant piping in loop 2P32A/B hot leg.

The pressurizer is designed and fabricated in accordance with the ASME Code listed in Table 5.2-1. The interior surface of the cylindrical shell and upper head is clad with weld deposited stainless steel. The lower head is clad with Ni-Cr-Fe alloy to facilitate welding of the Ni-Cr-Fe alloy heater sleeves to the shell. A stainless steel safe end is provided on the pressurizer nozzles after vessel final stress relief to facilitate field welds to the stainless steel surge line piping.

The total volume of the pressurizer is established by consideration of the factors given in Section 5.5.10.1. To account for these factors and to provide adequate margin at all power levels, the water level in the pressurizer is programmed as a function of average coolant temperature as shown in Figure 5.5-9. High or low water level error signals result in the control actions shown in Table 5.5-13 and described below.

Pressure is maintained by controlling the temperature of the saturated liquid volume in the pressurizer. At full load conditions, slightly more than one-half the pressurizer volume is occupied by saturated water, and the remainder by saturated steam. In order to maintain the programmed pressure the corresponding saturation temperature must be maintained. To maintain this temperature approximately one-third of the heaters are kept energized to compensate for heat losses through the vessel and to raise the continuous subcooled pressurizer spray flow to the saturation temperature.

During load changes, the pressurizer limits pressure variations caused by expansion or contraction of the reactor coolant. The average reactor coolant temperature is programmed to vary as a function of load as shown in Figure 5.3-1. A reduction in load is followed by a decrease in the average reactor coolant temperature to the programmed value for the lower power level. The resulting contraction of the coolant lowers the pressurizer water level causing the reactor system pressure to decrease. This pressure reduction is partially compensated by flashing of pressurizer water into steam. All pressurizer heaters are automatically energized on low system pressure, generating steam and further limiting pressure decrease. Should the water level in the pressurizer drop sufficiently below its setpoint, the letdown control valves close to a minimum value and additional charging pumps in the CVCS are automatically started to add coolant to the system and restore pressurizer level.

When steam demand is increased, the average reactor coolant temperature is raised in accordance with the coolant temperature program. The expanding coolant from the reactor coolant piping hot leg enters the bottom of the pressurizer through the surge line, compressing the steam and raising system pressure. The increase in pressure is moderated by the condensation of steam during compression and by the decrease in bulk temperature in the liquid phase. Should the pressure increase be large enough, the pressurizer spray valves open, spraying coolant from the reactor coolant pump discharge (cold leg) into the pressurizer steam space. The relatively cold spray water condenses some of the steam in the steam space, limiting the system pressure increase. The programmed pressurizer water level is a power dependent function. A high level error signal produced by an in-surge causes the letdown control valves to open, releasing coolant to the CVCS and restoring the pressurizer to the prescribed level. Small pressure and coolant volume variations are accommodated by the steam volume which absorbs flow into the pressurizer and by the water volume which allows flow out of the pressurizer.

The pressurizer heaters are single unit, direct immersion heaters which protrude vertically into the pressurizer through sleeves welded in the lower head. Each heater is internally restrained from high amplitude vibrations and can be individually removed for maintenance during plant shutdown.

Approximately one-third of the heaters are connected to proportional controllers which adjust the heat input as required to compensate for steady state losses and to maintain the desired steam pressure in the pressurizer. The remaining backup heaters are connected to on-off controllers. These heaters are normally de-energized but are turned on by a low pressurizer pressure signal or high level error signal. This latter feature is provided since load increases

result in an in-surge of relatively cold coolant into the pressurizer, thereby decreasing the bulk water temperature. The CVCS acts to restore level, resulting in a transient pressure below normal operating pressure. To minimize the extent of this transient, the backup heaters are energized, contributing more heat to the water. A low-low pressurizer level signal de-energizes all heaters to protect the heaters should they uncover.

The pressurizer proportional heater feeders are furnished with power (watt) transducers providing an analog value of the circuit power to the Safety Parameter Display System. The magnitude of the power indicates the operational status and integrity of the heater bank.

To assure sufficient pressurizer control for natural circulation flow at hot standby following a loss of off-site power, the proportional heaters circuit breaker was modified to enable the operator to re-energize the proportional heaters from the diesel generator safety buses. The capability for manual transfer of 150 kW of pressurizer heaters to each safety bus following a loss of off-site power and an Safety Injection Actuation Signal (SIAS) originally existed. Operating procedures require that the operator monitor and maintain the diesel generator within its load limits. The 7-day rating will not be exceeded with the heaters actuated, thus giving ample time to determine loads that can be shed for continuous operation.

Establishing the adequacy of this modification from an operational and safety standpoint requires two separate justifications:

A. Adequacy of 300 kW of pressurizer heaters for providing pressure control; and,

B. Capability of each diesel generator to accept 150 kW of pressurizer heaters.

The 150 kW of pressurizer capacity powered from an assured power source will ensure, for 588,000 BTU/hr ambient losses, that RCS subcooling margin will be maintained $\geq$ 20 °F for a period of 45 hours following loss of off-site power. This time period includes a period of one-half hour at the beginning of the transient in which the heaters are unavailable.

Actual heat losses from the pressurizer, from startup testing data, is 596,000 BTU/hr or 8,000 BTU/hr greater than that assumed above. However, this 8,000 BTU/hr increase in losses would only require a 2.345 kW increase to offset this loss increase and, therefore, will have little impact on the 45 hours calculated above.

This calculation is conservative in that the actual heat losses would decrease during the transient as RCS pressure and temperature decreases, thereby heater capacity would more closely approach the pressurizer ambient losses and hence prolong the time to reach 20 °F margin to saturation.

The capability of the Unit 2 diesel generators to carry maximum ESF loads including 150 kW of pressurizer heaters is demonstrated by design calculation. See Section 8.3.1.1.7 and Table 8.3-1.

The pressurizer spray is supplied from each of the reactor coolant pump cold legs in loop 2P32A/B to the pressurizer spray nozzle. Automatic spray control valves control the amount of spray as a function of pressurizer pressure; both of the spray control valves function in response to the signal from the controller. To improve spray valve control and reliability, motor actuators have been installed in place of the hydraulic actuators on spray valves 2CV4651 and 2CV4652. Hand switches have been installed on panels 2C04 and 2C80 for remote manual spray valve control. Handswitch 2HS4655, with dual indicating lights, has been installed on

Panel 2C04 to provide dual control of isolation valves 2CV4655 and 2CV4656. These valves were installed at management discretion to provide an operational contingency for a failed spray valve. The valves have no specified safety function to close, throttle or isolate flow. They are not credited in any accident analysis. Handswitch 2HS4653, with dual indicating lights, has been installed on Panel 2C04 to provide dual control of isolation valves 2CV4653 and 2CV4654. These valves were installed at management discretion to provide an operational contingency for a failed spray valve. The valves have no specified safety function to close, throttle or isolate flow. They are not credited in any accident analysis.

These components are sized to use the differential pressure between the pump discharge and the pressurizer to pass the amount of spray required to maintain the pressurizer steam pressure during normal load following transients. A small continuous flow is maintained through the spray lines at all times to keep the spray lines and the surge line warm to reduce thermal shock during plant transients. The continuous flow serves to keep the chemistry and boric acid concentration of the pressurizer water the same as that of the coolant in the heat transfer loops. An auxiliary spray line is provided from the charging pumps to permit pressurizer spray during plant heatup, or to allow cooling if the reactor coolant pumps are shut down.

In the event of an abnormal transient which causes a sustained increase in pressurizer pressure at a rate exceeding the control capacity of the spray, a high pressurizer pressure reactor trip will be initiated. This trip setpoint was increased to 2,362 psig, eliminating a 23 psig dynamic allowance for instrument response which test data demonstrated was not required.

To provide ample venting capacity for venting of non-condensable gases during long-term cooldown and following an accident, remotely operated high point vents were added to the RCS at the pressurizer and the reactor vessel. This is primarily to prevent the collecting non-condensable gases from interrupting natural circulation flow.

The Unit 2 analysis of combustible gas control in containment is given in Section 6.2.5. This analysis shows that Unit 2 is provided with hydrogen control systems which meet the design criteria of Regulatory Guide 1.7. The release of hydrogen through the RCS vents will not change the total volume of hydrogen released to the reactor building. Therefore, compliance with 10 CFR 50.44 will not be affected by addition of RCS vents.

The ESFAS pressurizer pressure bypass is provided to allow plant depressurization for maintenance and testing without undesired actuation of ESF equipment. This bypass must be initiated manually by switches in each protective channel and is possible only below the bypass permissive, which is less than 400 psia. This bypass is automatically removed before pressurizer pressure rises to 500 psia.

5.5.10.3 Evaluation

It is shown by analysis made in accordance with the requirements of the ASME Code, Section III that the pressurizer is adequate for all normal operating and transient conditions expected during the life of the plant. Following fabrication, the pressurizer was hydrostatically tested and then nondestructively tested in accordance with the ASME Code, Section III.

During hot functional testing, the transient performance of the pressurizer is checked by determining its normal heat losses and maximum pressurization and depressurization rates. This information is used in setting the pressure controllers.

Further assurance of the structural integrity of the pressurizer during plant life is obtained from the inservice inspections performed in accordance with the ASME Code, Section XI and described in Section 5.2.

Overpressure protection of the RCS is provided by two ASME code spring-loaded safety valves.

5.5.10.4 Tests and Inspections

Prior to and during fabrication of the pressurizer, nondestructive testing was performed in accordance with the requirements of the ASME Code. The results of the pressurizer inspection program are summarized in Table 5.5-7.

5.5.11 QUENCH TANK (PRESSURIZER RELIEF TANK)

5.5.11.1 Design Basis

The quench tank is designed to receive and condense the normal discharges from the pressurizer safety valves and prevent the discharge from being released to the containment. The quench tank is sized to receive and condense discharges from the anticipated operational occurrences (AOOs) and not the extended blowdown that has been calculated during postulated accidents. The quench tank is not safety related (Q listed), and the quenching of the steam internal to the tank is not a required safety related function. The safety related function that must be ensured is the maintenance of a discharge flow path for the pressurizer safety valves and the Low Temperature Overpressure Protection (LTOP) relief valves. A rupture disk is provided on the quench tank that will release excess steam to the containment building and maintain the discharge flow path for the pressurizer safety valves and the LTOP relief valves.

The tank volume was originally based on the need to condense steam from the pressurizer safety valves resulting from a loss of load followed immediately by an uncontrolled rod withdrawal, with no coolant letdown or pressurizer spray. The calculated total (integral) steam release for these two consecutive events was originally 625 lbs.

Analyses have been completed which have resulted in a different release mass to the quench tank than the mass released to the pressurizer from the original quench tank sizing analysis. The Uncontrolled Rod Withdrawal from 1% Power transient now credits the CPC generated variable overpower trip for initiating a reactor trip, and the calculated pressure during this transient does not increase to the safety valve setpoints. The steam release resulting from a Loss of Load combined with a Loss of Condenser Vacuum transient is calculated to be 731 lbs of steam during this transient with the safety valve setpoints at the nominal value of 2500 psia. These analyses verified this mass addition to the quench tank would not result in pressures that would cause the rupture disc to burst.

5.5.11.2 Description

The tank, shown in Figure 5.5-11, is an austenitic stainless steel vessel suitable for prolonged contact with borated or demineralized water. Nozzles are provided for the safety valve discharge line, vents, drains, instrumentation, makeup water, nitrogen addition, and the rupture disc.

The tank is designed and fabricated in accordance with the ASME Code, Section VIII, Division 1. The design parameters are given in Table 5.5-8.

The tank contains demineralized water and gas. During power operation, a nitrogen blanket is maintained on the tank. The sparger, spray header, nozzles and rupture disc fittings are stainless steel. The steam discharged into the quench tank from the pressurizer valves is discharged under water by the sparger to enhance condensation.

The contents of the quench tank are cooled by draining a portion of the contents and refilling with reactor makeup water. Quench Tank water level indication and high and low water level alarms are provided in the control room along with a 0-100 psig pressure indicator, temperature indicators, and alarms.

Leakage or discharge from the pressurizer safety valves is indicated and alarmed in the control room by temperature measurements and acoustical flow monitoring system in each valve pipe line to the quench tank header.

5.5.11.3 Evaluation

Evaluations beyond the requirements of the ASME Code, Section VIII, include the tank head in accordance with Welding Research Council Bulletin #95. Compliance with this reference results in a tank head which is thicker than Section VIII design methods.

The tank is analyzed to ensure that no tank or support failures will occur during a DBE and to ensure that the natural frequency of the tank is greater than 20 cps so that resonance will not occur. The sparger is analyzed for both seismic forces and blowdown forces.

5.5.12 VALVES

5.5.12.1 Design Basis

The safety-related function of valves within the RCPB is to act as pressure retaining boundaries and leaktight barriers during normal plant operation, accidents and seismic disturbances.

These valves are designed in accordance with ASME Code, Section III, Class 1 or Class 2 requirements, except as provided for in 10 CFR 50.55a(c)(2), and must withstand the effects of transients listed in Section 5.2, plus other transients associated with the location or service requirements. The valves must also meet Seismic Category 1 requirements. Backseats on manual and motor operated gate and globe valves can be used to minimize potential leakage. Functional requirements for each valve are detailed in the individual valve specifications.

Materials of construction are specified to ensure compatibility with the environment and contained fluids. Loadings and stresses for valves in Seismic Category 1 systems that require analysis are in accordance with Section 3.9.

5.5.12.2 Description

All valves in the RCS are constructed primarily of stainless steel. Other materials in contact with the coolant, such as for hard facing and packing, are compatible materials. Fasteners, packing glands and yoke fasteners are also constructed of stainless steel to eliminate corrosion.

There are two full capacity motor-operated spray valves in the RCS. The design parameters are given in Table 5.5-9. The spray valves are located near the top of the pressurizer. The valves are automatically operated by the pressurizer pressure control system to maintain pressurizer pressure control in conjunction with the pressurizer heater during load changes and expected transients.

5.5.12.3 Evaluation

All valves within the RCPB are stress analyzed as required by ASME Code, Section III, Class 1, except as provided for in 10 CFR 50.55a(c)(2), taking into consideration cyclic loadings. Valve leakage is minimized by design features as discussed above.

The position of each valve on loss of actuating signal (failure position) is selected to ensure safe operation of the system and plant. System redundancy is considered when specifying the failure position of any given valve. Valve position indication is provided on the control panel for each of these valves necessary to ensure safe operation of the plant.

The only WASH-1400 Event V valve configurations at Unit 2 are located between the RCS high pressure piping and the low pressure injection system, and consist of two check valves in series with a motor operated isolation valve. To ensure integrity and protection of the low pressure piping, periodic leak tests are performed in accordance with the technical specification surveillance requirements. Additionally, pressure upstream of the first check valve off the RCS is alarmed in the control room. None of these valves have been known or found to lack integrity.

Gate valves in the RCS have backseats which can be used to limit stem leakage when in the open position. Globe valves are installed with flow entering the valve under the seat. This arrangement will reduce stem leakage during normal operation or when closed.

In addressing IE Bulletin 81-02 two Borg Warner motor operated valves in the ECCS vent line had to be evaluated for the ability to close against differential pressure. Installation of the LTOP system resulted in the removal and sparing of one of the two valves in question. The remaining valve, 2CV-4698-1, has been modified in accordance with Borg Warner instructions such that it is certified to open at differential pressures up to 2,585 psig, and to close at differential pressures up to 1,416.9 psig. Since the current use of 2CV-4698-1 is to provide one means of depressurizing the RCS to allow adequate High Pressure Safety Injection (HPSI) flow, it does not need to close against high differential pressures and the certified capability to close at differential pressures up to 1,416.9 psig is adequate. In addition, a valve of a different type has been installed in series with the ECCS vent valve.

5.5.12.4 Tests and Inspections

In addition to the hydrostatic test required by the ASME Code, Section III, valves are tested for seat leakage, packing leakage, and cyclic operation. They are checked for minimum wall thickness and end-to-end dimensions and for failure position.

5.5.13 SAFETY AND RELIEF VALVES

5.5.13.1 Design Basis

There are no power-operated relief valves in the RCS. The safety valves on the pressurizer are designed to protect the system, as required by Section III of the ASME Boiler Code.

The design basis for establishing the relieving capacity of the pressurizer safety valves is presented in Section 5.2.2.3.1. For the postulated transients presented in Chapter 15, the results indicate that the pressurizer will not go 'solid' and that the relieving capacity of the safety valves is sufficient to provide overpressure protection in accordance with Section III of the

ASME Code. Safety valves on the steam side of each steam generator are designed to protect the steam system, as required by the ASME Code, Section III. They are conservatively sized to pass a steady state steam flow equivalent to the maximum expected power level.

5.5.13.2 Description

The RCS has two safety valves to provide overpressure protection. The design parameters are given in Table 5.5-10. These valves are flange mounted on the top of the pressurizer. Because these pressurizer relief valves are mounted directly on the pressurizer nozzles, there is no ASME Class 1 piping affected by them. They are direct acting, spring-loaded safety valves meeting ASME Code requirements. They have an enclosed bonnet and have a balanced bellows for superimposed back pressure.

The safety valves pass sufficient pressurizer steam to limit the reactor coolant system pressure to 110 percent of design (2,750 psig). An addendum to the ANO-2 Overpressure Protection Report verified the RCS pressure limit is not exceeded as a result of the installation of the replacement steam generators. Values for the system parameters, delay times and core moderator coefficient are given in Chapter 15.

During low temperature RCS operations, overpressure protection for the RCS is provided by two Low Temperature Overpressure Protection (LTOP) relief valves or an equivalent or larger opening in the RCS. Examples of RCS openings are removal of the steam generator primary manway on the hot leg, removal of the pressurizer code safety valve, removal of the pressurizer manway, or removal of the reactor vessel head. A single LTOP relief valve will prevent overpressurization of the RCS during the design basis overpressurization event such that the applicable pressure-temperature limits are not exceeded (See Section 7.6.1.3). Each LTOP relief valve is isolated from the RCS by two isolation valves. The LTOP valves are operator enabled during cooldown between 275 °F and 270 °F and isolated during heatup between 275 °F and 280 °F. The lift pressure for the LTOP valves is ≤ 430 psig.

Overpressure protection for the shell side of the steam generators and the main steam line up to the inlet of the turbine stop valve is provided by 10 flanged, spring-loaded, direct acting, ASME Code safety valves which have open bonnets and discharge to atmosphere. Five of these safety valves are mounted on each of the main steam lines upstream of the steam line isolation valves but outside the containment. The opening pressure of the valves is set in accordance with ASME Code allowances. Parameters for the main steam safety valves are given in Table 5.5-11.

An acoustical valve monitoring system with redundant sensors on each safety valve is supplied to provide direct indication of safety valve position (i.e., open or closed) in accordance with Regulatory Guide 1.97. An alarm is provided in the control room to sound when either valve is opened, and analog indication will be displayed for each valve. The acoustic monitoring system has been tested and found to be seismically and environmentally qualified. The system sensor cables have been routed in channelized seismic Class 1 raceways, but the system is supplied with only single channel safety grade power which is consistent with the requirements of Regulatory Guide 1.97 category 2 variables.

5.5.13.3 Evaluation

Overpressure protection is discussed in Section 5.2.2. The ASME Code "Report on Overpressure Protection" is described in Section 5.2.2.3.1.

5.5.13.4 Tests and Inspections

The valves are inspected during fabrication in accordance with ASME III Code requirements. The inlet is hydrostatically tested and the outlet is pneumatically tested. Seal leakage is checked by a steam test at 93 percent of set pressure. Set pressure and blowdown are adjusted using steam.

5.5.14 COMPONENT SUPPORTS

5.5.14.1 Design Basis

The criteria applied in the design of the RCS supports are that the necessary function of the supported equipment be achieved during all normal, earthquake, and LOCA conditions. The supports are designed to support and restrain the RCS components under the combined Design Basis Earthquake (DBE) and LOCA loadings in accordance with the stress and deflection limits listed in Section 3.6.

Analytical methods used to determine an adequate safety margin to brittle fracture are described in the CE Report, "Fracture Mechanics Procedures for Primary Component Support Toughness Evaluations."

5.5.14.2 Description

5.5.14.2.1 Reactor Vessel Supports

The reactor vessel is supported by three vertical columns located under the reactor vessel nozzles (see Figure 5.5-12). The columns are sufficiently flexible to allow radial thermal expansion of the vessel. Keyways on the sides of the integral support pads under the nozzles guide the vessel during thermal expansion and maintain the location of the vessel vertical centerline. A key on the lower vessel head provides additional seismic restraint.

5.5.14.2.2 Steam Generator Supports

The steam generator is supported at the bottom by a sliding base bolted to an integrally attached cylindrical skirt. The sliding base rests on low friction bearings which allow unrestrained thermal expansion of the RCS. Structural analysis has concluded that there will not be excessive movement of the bottom of the steam generator under the loads generated by a seismic event or BLPB.

A system of keys and snubbers located on the uppershell guide the top of the steam generator during expansion and contraction of the RCS and provide restraint during seismic events and following a BLPB or a steam line break.

The steam generator supports are shown in Figure 5.5-13.

5.5.14.2.3 Reactor Coolant Pump Supports

Each reactor coolant pump is provided with four vertical spring-type hangers which provide support for normal operation and seismic conditions. In addition each pump has two horizontal hydraulic snubbers to dampen torsional oscillation of the pump on the main coolant piping under seismic conditions. The CE report, "Fracture Toughness - Response to Item 1 Subtopic 4 of

NRC's August 5, 1980 Letter," describes the fracture evaluation of the reactor coolant pump seismic snubber lugs. This evaluation compares the stress intensity factor computed assuming large flaws to the lower bound toughness suggested by NUREG-0577, and demonstrates an adequate safety margin against brittle fracture.

The reactor coolant pump supports are shown in Figures 5.5-14 and 5.5-15.

5.5.14.2.4 Pressurizer Supports

The pressurizer is supported by a cylindrical skirt welded to the pressurizer and bolted to the support structure. The skirt is designed to withstand dead weight and normal operating loads, seismic events, and LOCA.

5.5.14.3 Evaluation

The RCS supports are designed to the criteria for load combinations and stresses which are presented in Section 5.2. The criteria is used to determine the loads the support must react with as a result of the effects of pipe rupture and seismic conditions.

The design and construction of Arkansas components supports preceded the applicable dates for mandatory compliance to Subsection NF. In this regard, however, the supports which are an integral part of the reactor vessel, steam generator and pressurizer were designed to the stress limits of the parent vessel which were designed and constructed per the ASME Codes shown in Table 5.2-1. The same is true for the reactor coolant pump except that its applicable code is ASME Section III 1971 Edition. The reactor vessel column supports complied with the AISC Code, Manual of Steel Construction, seventh edition. The steam generator sliding base was originally analyzed in accordance with the 1971 ASME B&PV Code, Section III through Winter 1973 Addenda including Appendix F and Subsection NF.

5.5.14.4 Testing and Inspection

Tests were conducted on materials similar to that being used for the reactor vessel and steam generator sliding supports to demonstrate that the maximum static coefficient of friction does not exceed 0.15 at a design loading of 5,000 psi. All sliding supports were 100 percent liquid penetrant inspected at the vendor's shops. The steam generator base was ultrasonically and magnetic-particle inspected.

The steam generator snubbers were tested in the vendor's shop at the rated load capacity in both tension and compression. The piston creep velocities were measured during these tests for compliance with specification limits. Tests were also conducted for initiation of snubber action on both the tension and compression directions.

Supports integral to the RCS components received quality assurance inspections in accordance with the ASME Code, Section III, during fabrication.

During preoperational testing of the RCS, the support displacements were monitored for agreement with calculated displacements and/or clearances. Inservice inspections of supports which are integral with RCS components are conducted in accordance with the ASME Code, Section XI.

5.6 INSTRUMENTATION REQUIREMENTS

The measurement channels necessary for operational control and protection of the Reactor Coolant System (RCS) are described below and listed in Table 5.6-1. A brief explanation of the purpose of each measurement channel is made and a summary of resulting actions is given. A detailed description of critical instrument channel actions may be found in Chapter 7.

Four independent measurement channels are provided for each parameter which initiates protective system action. Two independent signals are required to initiate protective action, thereby preventing spurious actions resulting from the failure of one measurement channel. The 2-out-of-4 arrangement results in a high degree of protective measurement channel reliability in terms of initiating action when required and avoiding unnecessary action from spurious signals. Two independent measurement channels are provided for parameters which are important to operational control. These control channels are separate from the protective measurement channels. To avoid control conflicts, control action is derived from only one channel at any time, while the second channel serves as a backup. This allows continued operation if one channel fails and permits maintenance on the accessible portion of the failed channel during operation.

5.6.1 TEMPERATURE

5.6.1.1 Hot Leg Temperature

Each of the two hot legs contains nine dual element narrow-range RTD channels to measure coolant temperature leaving the reactor vessel. Originally, there were five RTDs per hot leg. Four provided inputs to the safety-related Core Protection Calculators (CPCs) and the fifth provided an input to the Reactor Regulating System (RRS). During startup power testing, a hot leg temperature anomaly, characterized by flips in T_h, was observed in the CPCs. To provide a more representative temperature signal to the CPCs, four additional narrow range RTDs were installed on each hot leg opposite the existing RTDs. An average of the two RTD temperature signals is used by each CPC.

The hot leg temperature channels associated with the CPCs are monitored by the plant computer and are displayed in the control room. The second temperature element on Channels 3 and 4 provide signals to the Safety Parameters Display System (SPDS) and the RCS margin-to-saturation monitors. Margin-to-saturation is displayed on a 2-pen recorder in the control room.

One hot leg RTD channel per loop provides a signal to the Reactor Regulating System (RRS). This channel is also monitored by the plant computer and SPDS. The RRS uses hot leg (T_h) and cold leg (T_c) inputs to compute average temperatures for each loop. These are averaged again to produce an RCS average temperature (T_{avg}), which is displayed on a digital read-out in the control room. The RRS also generates a reference temperature signal (T_{ref}) based on turbine first stage pressure. Both T_{avg} and T_{ref} can be displayed and trended in the control room on the plant computer. The operator is responsible for ensuring that these two values are matched. In addition to the indication, this channel is alarmed on high temperature in the control room.

5.6.1.2 Cold Leg Temperature

Each of the four cold legs contains three temperature measurement channels. The cold leg RTDs are located downstream of the reactor coolant pumps. Two RTDs from each cold leg (four per heat transfer loop) are used to furnish a cold leg coolant temperature signal to the CPCs. The second element on Channel 3 and 4 goes to the RCS saturation monitors (TSAT). Indication of all eight of these cold leg temperature measurements is provided in the control room.

The two cold leg temperature RTDs, one on each cold leg, are routed to a channel selector switch (one per heat transfer loop). This selector switch enables either cold leg temperature to be recorded on a wide-range temperature recorder in the main control room. The remaining channel of each loop provides a signal to generate the average temperature in the reactor regulating system.

5.6.1.3 Surge Line Temperature

This measurement channel provides an indication of surge line temperature in the control room. A low surge line temperature condition activates an alarm in the control room. A low temperature alarm during normal operation is an indication that the continuous spray rate has decreased.

5.6.1.4 Pressurizer Temperature

The pressurizer water phase RTD is located at an elevation below the top of the pressurizer heaters. This channel provides a wide-range temperature indication in the control room and is used during plant heatup and cooldown.

5.6.1.5 Spray Line Temperature

An RTD in each spray line provides a temperature indication and a low temperature alarm in the control room for each spray line. A low temperature alarm during normal operation is an indication that the continuous spray rate has decreased.

5.6.1.6 Relief Line Temperature

Temperatures in the primary safety valve discharge lines are measured and indicated in the control room. A high temperature in one of these lines is an indication that the associated valve may be leaking. High temperature alarms are provided to alert the operator to this condition.

5.6.1.7 Quench Tank Temperature

The temperature of the water in the quench tank is indicated in the control room. A high temperature alarm is provided to alert the operator to pressurizer code safety valve leakage.

5.6.2 PRESSURIZER PRESSURE

5.6.2.1 Protection

Four independent narrow range pressure and four independent wide range channels are provided for initiation of protective system action. The pressure transmitters are connected to the upper portion of the pressurizer via the upper level measurement nozzles and measure

pressurizer vapor pressure. All four channels are indicated in the control room and separate high- and low-low pressure alarms in the control room are actuated by the reactor protective system.

The protection actions these pressure signals initiate are:

A. Reactor trip on high primary system pressure (narrow range)

B. Safety injection system actuation on low primary system pressure (wide range).

C. Reactor trip on a low Departure from Nucleate Boiling Ratio (DNBR) (narrow range).

D. Reactor trip on low primary system pressure (wide range).

E. Containtment Cooling System Actuation (wide range).

In addition, four non Class 1E pressure channels are provided as inputs to the DSS to initiate a reactor trip upon high pressurizer pressure due to an ATWS event.

5.6.2.2 Control

Two independent pressure channels provide wide range pressure signals for controlling the pressurizer heaters and spray valves. The output of one of these channels is manually selected to perform the control function. During normal operation, two small groups of heaters are proportionally controlled to offset heat losses. If the pressure falls below a low pressure setpoint, all of the heaters are energized. If the pressure increases above a high pressure setpoint, the spray valves are proportionally opened to increase the spray flow rate as pressure rises. The two channels are displayed and recorded in the main control room and are provided with high and low pressure alarms.

5.6.2.3 Startup and Shutdown

Two diverse restricted-range pressure measurement channels provide a control room indication of RCS pressure during plant startup and shutdown in the control room. They also provide pressure signals to the shutdown cooling suction isolation valves (that prevents opening above a selected setpoint) and the safety injection tank isolation valves (to ensure they are open).

5.6.2.4 Quench Tank Pressure

Quench tank pressure is indicated in the control room. A high pressure alarm is provided.

5.6.3 LEVEL

5.6.3.1 Control

Two temperature compensated pressurizer level channels (red and green) are used to provide two independent level signals for control of the pressurizer liquid level. These signals are used to de-energize the pressurizer heaters on low-low pressurizer level to prevent heater burnout, provide input to one pen of a two pen recorder in the control room (the other pen records level setpoint), and actuate high, low and low-low pressurizer level alarms in the control room. The temperature input for compensation of both channels is provided from one dual element RTD. Both channels are indicated in the control room.

The liquid level in the pressurizer is programmed to vary as a function of average reactor coolant temperature and is computed by the reactor regulating system. If the level indication differs from the computed program level, the control system adjusts the Chemical and Volume Control System (CVCS) charging or letdown flow rates to correct the deviation.

5.6.3.2 <u>Startup and Shutdown</u>

Two safety-related, wide range temperature compensated pressurizer level channels are provided for main control room indication of pressurizer level during plant startup and shutdown. In addition, a black non-safety-related channel (also temperature compensated) is provided in the control room.

5.6.3.3 <u>Quench Tank Level</u>

Quench tank level is indicated in the control room. High and low level alarms are provided.

5.6.4 REACTOR COOLANT LOOP FLOW

Reactor coolant flow measurement is described in Chapter 7.

5.6.5 REACTOR COOLANT PUMP INSTRUMENTATION

The reactor coolant pumps and motors are equipped with the instrumentation necessary for proper operation and to warn of incipient failures. A description of the major instrumentation follows.

5.6.5.1 <u>Temperature</u>

5.6.5.1.1 <u>Pump Seal Temperatures</u>

The reactor coolant temperature in the lower seal cavity is fed to the plant computer. The pump seal temperature is also alarmed to alert the operators to a high temperature condition. A high temperature condition is an indication that the integral heat exchanger is not performing satisfactorily or is a backup indication that the component cooling water flow has decreased or supply temperature increased.

5.6.5.1.2 <u>Motor Stator Temperatures</u>

Each reactor coolant pump motor is provided with six RTDs embedded in the stator windings. The two highest reading RTDs chosen during pump testing are selected for input to the control room. One is connected to the plant computer and one is indicated and alarmed on a control panel. Should stator temperature exceed a predetermined limit, a high temperature alarm will be sounded in the control room. High temperature is detrimental to motor winding insulation life, and may be caused by high ambient temperature, reduction in the cooling airflow to the stator or inadequate time delay between successive starts of the motor.

5.6.5.1.3 <u>Motor Bearing Temperature</u>

Temperatures of the motor lower thrust, upper thrust, upper radial, and lower radial bearings are fed to the plant computer. The upper and lower motor thrust bearings are also displayed in the control room and annunciated if either thrust bearing temperature exceeds a safe value.

5.6.5.2 Pressure

5.6.5.2.1 Pump Seal Pressures

The middle, upper, and vapor pump seal cavities in each pump are provided with pressure elements which generate a signal proportional to the pressure within the cavity. The pressure in the seals is displayed in the control room. Abnormally high pressure in the upper and middle seal cavities indicates a failed or failing lower or middle seal. A low pressure condition in the middle seal cavity indicates a failed or failing upper seal.

5.6.5.2.2 Motor Oil Lift Pump Discharge Pressure

This pressure measurement channel provides a local indication of oil lift pump discharge pressure.

5.6.5.3 Motor Oil Reservoir Level

Differential pressure transmitters are used to produce signals proportioned to the oil levels in the upper and lower motor oil reservoirs. These signals are used to annunciate low level alarms in the control room.

5.6.5.4 Reverse Rotation Switch

Reverse rotation of a reactor coolant pump is sensed by a reverse rotation switch. This switch actuates an alarm in the control room. Reverse rotation indicates failure of the mechanical anti-rotation device.

5.6.5.5 RCP Pump/Motor Vibration Monitoring

The vibration of the RCP motor shaft is monitored at the upper and lower guide bearings. The vibration of the pump shaft is monitored at the pump-half coupling hub. In addition, shaft axial position and vibration phase angle are monitored by probes placed in the pump coupling area. All HI and HI-HI alarms for each pump are reflashed to drive a common annunciator. The plant computer is utilized to provide a control room indication of the amplitude of each channel.

5.6.5.6 Motor Current SPDS Inputs

Each RCP motor feeder is furnished with a current transducer providing an analog value of pump motor current to the Safety Parameter Display System Computer. The magnitude of the current is related to pump/motor integrity, and pump load can indicate a saturated condition.

ORIGINAL DESIGN PARAMETERS OF REACTOR COOLANT SYSTEM*
(See Table 5.1-1a for revised best estimate design parameters)

Design Thermal Power, Mwt (Includes Net Heat Addition from Pumps)	2825
Btu/hr	9.644×10^9
Design Pressure (except Steam Generator), psia	2500
Design Temperature (Except Pressurizer), °F[(1)]	650
Pressurizer Design Temperature, °F	700
Coolant Flow Rate, lb/hr	120.4×10^6
Cold Leg Temperature, °F[(2)]	553.5
Average Temperature, °F[(2)]	583
Hot Leg Temperature, °F[(2)]	612.5
Normal Operating Pressure, psia[(2)]	2250
System Water Volume, ft^3 (Without Pressurizer)	8860
Pressurizer Water Volume, ft^3	600
Pressurizer Steam Volume, ft^3	600
Initial Hydrostatic Test Pressure of RCS Components at 100 °F (Except Reactor Coolant Pump), psia	3125
Initial Reactor Coolant Pump Hydrostatic Test Pressures, psia	
Casing and Cover	3342
Heat Exchanger Inner Coil - High Pressure	3750
Seal Flange	3750
Upper & Middle Seal Pressure Breakdown Device	4080

* See Chapter 3 for a description of the seismic analysis of reactor coolant system components. Seismic design loads for RCS components are presented in Table 3.7-8.

(1) Miscellaneous RCS piping associated with the pressurizer has a design temperature of 658 °F, and the pressurizer surge line has a design temperature of 700 °F.

(2) The values listed represent historical operating conditions. The latest pressure-temperature analyses shall be utilized for determination of pressure-temperature design inputs.

Table 5.1-1A

DESIGN PARAMETERS (BEST ESTIMATE) OF REACTOR COOLANT SYSTEM*

Design Thermal Power, MWt (Includes Net Heat Addition from Pumps)	3044
Btu/hr	10.389×10^9
Normal Operating Pressure, psia (in Pressurizer)	2200
Coolant Flow Rate, gpm (at full power)	351,800
Temperature	
Cold Leg (coolant inlet), °F	551.0
Average Temperature, °F	580.0
Hot Leg (coolant outlet), °F	609.4
Maximum System Water Volume, ft^3 (Without Pressurizer)	9334
Pressurizer	
Normal Operating Temperature, °F	653
Water Volume, ft^3	680
Steam Volume, ft^3	520

[1] Valves may be open or shut during normal operation or post-accident.
[2] Component may be excluded from RCPB based on SAR definition 5.2A.

Table 5.2-3

REACTOR COOLANT SYSTEM MATERIALS

Reactor Vessel	
Shell	SA-533 Grade B, Class 1 Steel (8-5/8 in. minimum thickness)
Forgings	SA-508 Class 2
*Cladding	Weld Deposited Austenitic Stainless Steel (Type 304) or NiCrFe Alloy (equivalent to SB-168), 1/8 in. minimum
*Vessel Internals	Type 304 Austenitic Stainless Steel and NiCrFe Alloy
*Fuel Cladding	Zircaloy-4
*Control Element Drive Mechanism	
Housings	SA-182 Special Code Case 1337
Nozzles	Type 316 Stainless Steel
Pressurizer	
Shell	SA-508 Grade 3, Class 1
*Cladding	Austenitic Stainless Steel or NiCrFe Alloy (equivalent to SB-168, Alloy 690)
Steam Generator	
Primary Head	SA-508, Class 3a (forging)
*Primary Head Cladding	Weld Deposited Stainless Steel, Type 309L/308L
Tube Sheet	SA-508, Class 3a (forging)
*Tube Sheet Cladding	Weld Deposited NiCrFe Alloy (UNS N06052/W86152)
*Tubes	SB-163 Alloy UNS N06690 (thermally treated)
Shell	SA-508, Class 3a (forgings)
Reactor Coolant Pumps	
*Casing	ASME-SA-351 GR CF8M
*Internals	ASTM-A-351-69, Gr CF8
Wear Ring	CF8

* Indicates material exposed to reactor coolant.

Table 5.2-3 (continued)

Reactor Coolant Piping	
*Pipe	SA-516 Grade 70
*Cladding	Austenitic Stainless Steel (Type 304), 3/16 in. nominal
*Surge Line	Austenitic Stainless Steel (Type 304)
*Valves	Stainless Steel ***
Weld Materials for Reactor Coolant Pressure Boundary	
Base Material	Weld Material
SA-533 Grade B, Class 1	SFA-5.5 E-8018**,C3; MIL-18193, B4
SA-508 Class 2 to SA-533 Grade B, Class 1	SFA-5.5 E-8018, C3
SA-508 Class 3a to SA-516 Grade 70	SFA-5.18 ER70S-6
NiCrFe Alloy	SFA-5.11 E-NiCreFe-3;SFA-5.14 ER-NiCrFe-3, ENICrFe-7
Austenitic Stainless Steel Cladding	SFA-5.9 ER-308, ER-309, ER-312 SFA-5.4 ER-308L, ER309L
SA-516 Grade 70	SFA-5.1 E-7018
SA-182 FI to SA-516 Grade 70	SFA-5.1 E-7018
Alloy 690 Weld Overlays	SFA-5.14 ERNiCrFe-7A

---

* Indicates material exposed to Reactor Coolant. Hot leg piping is exposed locally to Reactor Coolant fluid at the replacement RTD nozzles.

** Special weld wire with low residual elements of copper and phosphorous was used for the reactor vessel core belt line region.

*** Bodies and bonnets of valves in systems exposed to reactor coolant will be constructed of corrosion resistant austenitic stainless castings or wrought steels. Typical grades used are SA-182 F316 and SA351-CF8M materials. Valve stems are typically corrosion resistant precipitation-hardened stainless steels such as 17-4PH. Discs and wedges are typically austenitic wrought or cast stainless steels and may be hard surfaced. Some valve discs and seats are constructed entirely of hard surfacing material. Non-pressure retaining valve components in contact with the RCS fluid may be constructed of other corrosion resistant materials such as Inconel. Non-pressure retaining valve parts that are not exposed to the RCS fluid may be constructed of various materials. Hard surfacing materials are typically Stellite or approved low cobalt equivalents such as Norem, Deloro, Everit 50, EB5150, or Colmonoy.

Table 5.2-12

CAPSULE REMOVAL SCHEDULE

(Reference 21 with CEN-15 (A))

At the nearest scheduled refueling outage, reactor surveillance capsules shall be removed and surveillance specimens tested in accordance with the following schedule:

Capsule Number	Capsule Location Code	Capsule Identification	Vessel Location	Removal Interval (EFPY) (Withdrawal Time)
1	1	W-83	83°	Standby[a]
2	2	W-97	97°	1.69 (actual, EOC 2)
3	3	W-104	104°	15.7 (actual, EOC 14)
4	6	W-284	284°	30
5	4	W-263	263°	Standby[a]
6	5	W-277	277°	Standby[a]

Prior to changing removal intervals, NRC approval is required per 10 CFR 50, Appendix H, "Reactor Vessel Surveillance Specimen Withdrawal Schedules." Withdrawal schedules may be modified to coincide with those refueling outages or plant shutdowns most closely approaching the withdrawal schedule.

[a] If required, Capsules designated as "Standby" under Removal Interval, will be repositioned to ensure that peak fluence is obtained prior to 60 years (48 EFPY). Upon issuance of the renewed license, the ANO-2 specimen capsule withdrawal schedule will be revised to withdraw and test a standby capsule to cover the peak fluence expected through the end of the period of extended operation (Reference 2CAN100302, 2CAN010401, and NUREG 1828).

Table 5.2-13

CONFORMANCE OF RCS/LOW PRESSURE SYSTEM INTERFACES WITH GENERAL DESIGN CRITERIA 14 AND 55

Point of Interface	Degree or Conformance
Loop A Safety Injection & Shutdown Cooling	ECCS. The system meets the requirements on an “other defined basis” as it serves an engineered safeguards function and automatic isolation is inappropriate. A class CC check valve provides the first boundary; it is the first of two valves which are in series. From this point on the piping branches. The first branch is at the leakage relief line where valve 2SV-5001, a class CC normally closed solenoid valve, completes the RCS pressure boundary. The second branch is the S. I. Tank line where a class CC check valve completes the RCS pressure boundary. The third branch is the line from the H.P. headers where a class CC check valve completes the code boundary. The reactor coolant pressure boundary extends to the outboard containment isolation valves. The fourth branch is the line from the LP header where a class CC check valve completes the code boundary. The reactor coolant pressure boundary extends to the outboard containment isloation valve.
Loop B Safety Injection & Shutdown Cooling	ECCS. The system meets the requirements in the same manner as Loop A.
Loop C Safety Injection & Shutdown Cooling	ECCS. The system meets the requirements in the same manner as Loop A.
Loop D Safety Injection & Shutdown Cooling	ECCS. The system meets the requirements in the same manner as Loop A.
HPSI to Shutdown Cooling Suction (Hot Leg Injection)	GDC 55 requirements are met on an “other defined basis.” Each line has a check valve inside containment and a remote manually controlled valve outside containment. Penetration 2P13 also has an exterior manual gate valve which is locked closed. The exterior remote manually controlled isolation valves are normally closed and stay closed immediately following an accident. The reactor coolant pressure boundary extends to the outside containment isolation valves.

Table 5.2-13 (continued)

Point of Interface	Degree or Conformance
Charging Lines to RCS Lines 2CCA-8-30" ID and 2CCA-6-30" ID; auxiliary spray line to 2CCA-15-4" in series	Complete conformance. GDC 55 requirements are met on an “other defined basis” as this penetration supports an engineered safeguards function. Check valves are located in each charging line and the auxiliary spray line (2CCA-26-2", 2CCA-27-2" and 2CCA-16-2" respectively) and are the first of two valves in series. These three lines converge to a single charging line which contains a remote manually controlled isolation valve outside containment. The RCPB extends to this valve.
Letdown line from RCS line 2CCA-3-30" ID	Complete conformance. Although the reactor coolant pressure boundary ends at the second isolation valve inside containment, this is considered a GDC 55 penetration based on the 10CFR50.2 definition of the RCPB. GDC 55 requirements are met with an automatically actuated isolation valve located outside containment as well as the inside isolation valves. Pressure rating is derated after the isolation valves immediately downstream of flow control valves 2SV4816 and 2SV4817; however, this section of piping is protected from overpressure by relief valve 2PSV-4822.
Shutdown Cooling Suction	Complete conformance. Although the reactor coolant pressure boundary ends at the second isolation valve inside containment, this is considered a GDC 55 penetration based on the 10CFR50.2 definition of the RCPB. The containment isolation valves are locked closed. The low pressure piping downstream of the second inside isolation valve is protected from overpressure by a relief valve which is an acceptable automatic isolation device in this configuration.
Reactor Drain Line from Line 2CCA-1-42″ ID	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Two Pressurizer Spray Line Drains from RCS Line 2CCA-15-1″	Complete conformance. Two hand-operated normally-closed valves in series are provided.

Table 5.2-13 (continued)

Point of Interface	Degree or Conformance
Reactor Drain Line from Letdown Line 2CCA-12-2″	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Reactor Drain Line from RCS Line 2CCA-5-30″ ID	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Reactor Drain Line from RCS Line 2CCA-7-30″ ID	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Reactor Drain Line from RCS Line 2CCA-9-30″ ID	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Refueling Level Indicator Connection from RCS Line 2CCA-1-42″ ID	Complete conformance. Two hand-operated normally-closed valves in series are provided.
Code Safety Relief Valves	Complete conformance. Two parallel safety valves, 2PSV-4633 and 2PSV-4634 complete the RCS pressure boundary.
Reactor head vent line	Complete conformance. Two normally closed SOV isolation valves in series. 2SV-4668-1, 2SV-4668-2, 2SV-4669-1, 2SV-4670-2.
RCPs 2P32A, 2P32B, 2P32C and 2P32D	Complete conformance. Although the pump seals comprise the pressure boundary, the seal water return line meets GDC 55 requirements with an automatically actuated MOV inside containment and an automatically actuated AOV outside containment.
LTOP Isolation Valves and ECCS Vent Valve	Complete Conformance. Two normally closed MOV isolation valves in series. 2CV-4730-1 and 2CV-4731-2, 2CV-4740-2 and 2CV-4741-1, 2CV-4740-2 and 2CV-4698-1.

Table 5.2-19

This table is historical. For current safety valve parameters, see Tables 5.5-10 and 5.5-11.

EQUIPMENT PROTECTED BY SAFETY VALVES

Name	Design Pressure	Design Temp.
Pressurizer	2500	700
Reactor Vessel	2500	650
Primary Side of Steam Generators	2500	650
Reactor Coolant Pump	2500	650
Reactor Piping[(1)]	2500	650
Steam Generators	1100	560
Main Steam Piping	1100	560

PRIMARY SAFETY VALVE (PRESSURIZER SAFETY VALVE) SPECIFICATIONS

	Pressure	Temperature
Normal Operating:	2235 psig	653 °F
Maximum Operating:	2260 psig	653 °F
Safety Valve Set Pressure:	2485 psig, +1%/-3%	
Min. Operating Press. Margin:	200 psi	
Accumulation:	3% set pressure	
Pressure Blowdown:	4% set pressure	
Pressure Sources:	Loss of Turbine Load	
Design Capacity/Rated Valve Capacity	395,000/419,000 lb/hr	
Basis of Design Capacity:	Loss of turbine load without reactor trip.	
Assumptions and Restrictions:	The only other pressure relieving devices which function are the main steam safety valves.	

Safety Valve Inlet Line Conditions		Safety Valve Outlet Line Conditions	
Press. Loss at Design Cap.:	50 psi	Normal Superimposed Backpress.:	100 Max
Flowing Fluid:	Saturated Steam	Normal Fluid Conditions:	Gas

Valve Data

Manufacturer:	Crosby Valve and Gage Co.			
Catalog No.:	Special			
Connections:	Inlet	Outlet		
Size	6″ w/4″ nozzle	6″		
Type	Flanged	Flanged		
Maximum Backpressure:	700 psig	Totally Enclosed Bonnet:	Yes	
Backpress. Compensation:	Yes	Orifice Size:	3.60 inches effective	
Valve Press. Rating:	2485 psig	Gagging Device:	Yes	
Valve Temp. Rating:	700 °F	Flowing Fluid:	Wet steam	

(1) Miscellaneous RCS piping associated with the pressurizer has a design temperature of 658 °F, and the pressurizer surge line has a design temperature of 700 °F.

Table 5.2-19 (continued)

This information is historical (see previous page). For current information, see Table 5.5-11.

SECONDARY SAFETY VALVE (MAIN STEAM SAFETY VALVE) SPECIFICATIONS

	Pressure	Temperature
Normal Operating:	900 psia	532
Maximum Operating:	1000 psia	556

Safety Valve Set Pressure:	See note.
Accumulation:	3% of set pressure
Blowdown:	5% of set pressure
Min. Operating Press. Margin:	72 psi

Pressure Sources	Loss of Turbine Load
Design Capacity	1,551,847 lb/hr each @ 1200 psia
Basis of Design Capacity:	Loss of turbine load without simultaneous reactor trip. Reactor trip on high pressurizer pressure.
Assumptions and Restrictions:	The only other pressure relieving devices which function are the pressurizer safety valves.

Safety Valve Inlet Line Conditions		Safety Valve Outlet Line Conditions	
Press. Loss at Design Cap.:	7 psi	Normal Superimposed Backpress.:	0 psig
Flowing Fluid:	Saturated Steam	Normal Fluid Conditions:	Air
		Maximum Backpressure:	225 psig

Valve Data

Manufacturer:	J.E. Lonergan Co.

	C-8010-3	0.080	0.653

NOTE: The RTNDT values in Table 5.2-20 were not changed by the revised copper and nickel estimates.

Table 5.2-21

Estimates for RPV beltline material C_VUSE unirradiated/initial values for the Transverse (weak) direction (ref SAR Section 5.2.4.3.3)

RPV Beltline Material	Material I.D.	Unirradiated/Initial C_VUSE Value (Transverse) (ft-lbs)	Comments
Intermediate Shell Plate	C-8009-1	94.9	Based on reduction to 65% of the C_VUSE (longitudinal) value in SAR Table 5.2-5 and CEP-FTP-ANO2, Revision 0, Appendix E - RPV Beltline Materials in accordance with MTEB No. 5-2, Section B.1.2. * Tranverse value from SAR Table 5.2-16 for baseline surveillance material (plate C-8009-3) specimen.
	C-8009-2	92.3	
	C-8009-3	87.1	
	C-8009-3 *	125.5 *	
Lower Shell Plate	C-8010-1	89.7	
	C-8010-2	93.6	
	C-8010-3	97.5	
Intermediate Shell Longitudinal Weld	2-203 A, B, & C	70.9	Based on 65% reduction of the unirradiated/initial C_VUSE longitudinal value of the 109 ft-lb value obtained firom ANO Engineering Report 92-R-2019-01 in accordance with MTEB No. 5-2, Section B.1.2.
Lower Shell Longitudinal Weld	3-203 A, B, & C	79.3	Based on 65% reduction of the unirradiated/initial C_VUSE longitudinal value of the 122 ft-lb value obtained from ANO Engineering Report 92-R-2019-01 in accordance with MTEB No. 5-2, Section B.1.2.
Intermediate to Lower Shell Horizontal (Girth) Weld	9-203	94.9	Based on 65% reduction of the baseline surveillance material specimen unirradiated/initial C_VUSE longitudinal value of the 146 ft-lb value obtained from ANO Engineering Report 92-R-2019-01 and SAR Table 5.2-16 (ref. TR-MCD-002 Report contained in CEP-FTP-ANO2, Revision 0, Appendix C – Evaluation of Baseline Specimens) in accordance with MTEB No. 5-2, Section B.1.2.
Weld Heat-Affected Zone (HAZ of Girth Weld)	HAZ of 9-203 at C-8009-3 side	98.5	Based on 65% reduction of the baseline surveillance material specimen unirradiated/initial C_VUSE longitudinal value of the 151.5 ft-lb value obtained from SAR Table 5.2-16 (ref. TR-MCD-002 Report contained in CEP-FTP-ANO2, Revision 0, Appendix C - Evaluation of Baseline Specimens) in accordance with MTEB No. 5-2, Section B.1.2.

Table 5.2-22

Predictions of Minimum Charpy Upper Shelf Energy (CvUSE) for RPV Beltline Materials to 48 EFPY (Reference SAR Section 5.2.4.3.4)

RPV Beltline Material	Material I.D.	% C_U (Note 1)	48 EFPY 1/4t Fluence (n/cm^2) (Note 1)	Unirrdiated C_VUSE Value (ft-lbs) (Note 1)	% Decrease Predicted in C_VUSE (Notes 1, 2)	Predicted 48 EFPY C_VUSE Value (ft-lbs) (Notes 1, 2, 3)
Intermediate Shell Plate	C-8009-1	0.098	3.188E+19	95	24.7	71
	C-8009-2	0.085	3.188E+19	92	23.0	71
	C-8009-3	0.096	3.188E+19	87	32.0*	59*
Lower Shell Plate	C-8010-1	0.085	3.192E+19	90	23.0	69
	C-8010-2	0.083	3.192E+19	94	22.8	72
	C-8010-3	0.080	3.192E+19	98	22.4	76
Intermediate Shell Longitudinal Weld	2-203 A	0.046	3.015E+19	71	24.2	54
	2-203 B	0.046	2.327E+19	71	22.7	55
	2-203 C	0.046	2.327E+19	71	22.7	55
Lower Shell Longitudinal Weld	3-203 A	0.046	3.020E+19	79	24.2	60
	3-203 B	0.046	2.331E+19	79	22.7	61
	3-203 C	0.046	2.331E+19	79	22.7	61
Intermediate to Lower Shell Horizontal (Girth) Weld	9-203	0.045	3.187E+19	95	24.3	72

Notes:

1. From Framatome-ANP Calculation 32-5024494-02, “Charpy Upper-Shelf Energy for ANO-2,” May 2005.
2. The measured percent decrease in CvUSE for the surveillance base metal plate and weld metal are within reasonable agreement with the values predicted using Regulatory Guide 1.99, Revision 2.
3. Predicted C_VUSE values independently confirmed in Section 4.2.1.2 of NUREG 1828 to be above the required 50 ft-lb minimum at 48 EFPY.

* Value predicted using Position 2.2 of Regulatory Guide 1.99, Revision 2.

Table 5.3-2

ORIGINAL THERMAL AND HYDRAULIC DATA
(Design Full Power Conditions)

I. Reactor Vessel (See Table 5.1-1a for latest values)

a. Rated core thermal power (Mwt)	2815
b. Design pressure (psia)	2500
c. Operating pressure at outlet (psia)	2250
d. Coolant outlet temperature (°F)	612.5
e. Coolant inlet temperature (°F)	553.5
f. Coolant outlet state	Subcooled
g. Total coolant flow (10^6 lb/hr)	120.4
h. Core average coolant enthalpy	
1. Inlet (Btu/lb)	551.5
2. Outlet (Btu/lb)	631.6
i. Average coolant density	
1. Inlet (lb/ft^3)	46.6
2. Outlet (lb/ft^3)	42.02

II. Steam Generators

a. Number of Units	2
b. Primary Side (or tube side)	
1. Design pressure/temperature (psia/°F)	2500/650
2. Operating pressure (psia)	2250
3. Inlet temperature (°F)	612.5
4. Outlet temperature (°F)	553.5

Table 5.3-2 (continued)

c.	Secondary (or Shell Side)	
	1. Design pressure/temperature (psia/°F)	1110/560
	2. Full load steam pressure/temperature (psia/°F)	900/531.95
	3. Zero load steam pressure (psia)	1000
	4. Total steam flow per gen. (lb/hr)	6.32×10^6
	5. Full load steam quality (%)	99.8
	6. Feedwater temperature, full power (°F)	452
III.	Replacement Pressurizer	
a.	Design pressure (psia)	2500
b.	Design temperature (°F)	700
c.	Operating pressure (psia)	2250
d.	Operating temperature (°F)	653
e.	Internal volume (ft^3)	1200
f.	Heaters (maximum)	96
	1. Type and Rating of Heaters (kw)	Immersion/13.16 ± 5%
	2. Maximum heater capacity (kw) (96 Heaters)	1326
IV.	Reactor Coolant Pumps	
a.	Number of units	4
b.	Type	Vert.-Cent.
c.	Design capacity (gpm)	80,500
d.	Design pressure/temperature (psia/°F)	2500/650
e.	Operating pressure (psia)	2250
f.	Type drive induction mot.	Squirrel cage
g.	Total dynamic head (ft)	275
h.	Rating, cold (hp)	6750 (nominal)
i.	Rating, hot (hp) (nominal)	4800
j.	Pump speed, rpm	900
V.	Reactor Coolant Piping (original design values)	
a.	Flow per loop (10^6 lb/hr)	60.2
b.	Pipe size (inside dia./wall thickness) (in.)	
	1. Hot leg	42/4-5/16
	2. Cold leg	30/3-1/4
c.	Pipe design press./temp. (psia/°F)(1)	2500/650

(1) Miscellaneous RCS piping associated with the pressurizer has a design temperature of 658 °F, and the pressurizer surge line has a design temperature of 700 °F.

U-Bend Handholes (2 ea.)	6
Tube Support Plate Inspection Ports (14 ea.)	3
Bottom Blowdown (2 ea.), nominal, in.	2[(1)]
Sample Nozzle (1 ea.), nominal, in.	2
Reactor Coolant Side	
Design Pressure, psia	2514.7
Design Temperature, °F	650
Inlet Temperature, maximum (°F)	614.3
Outlet Temperature, maximum (°F)	554.7
Design Thermal Power (NSSS including RCP contribution), Mwt	3044
Coolant Flow-best estimate (ea.), lb/hr	66×10^6
Normal Operating Pressure, psia	2200
Coolant Volume, each, ft^3	1838
Secondary Side	
Design Pressure, psia	1114.7
Design Temperature, °F	560
Normal Operating Steam Pressure, Full Load-best estimate, psia	939
Normal Operating Steam Temperature, Full Load-best estimate, °F	536.8
Design Blowdown Flow, Continuous, ea., lb/hr	80,000
Steam Flow, Each-best estimate, lb/hr	6.83×10^6
Steam Moisture Content, Maximum, percent	0.10
Feedwater Temperature, °F (best estimate for design)	453
Number of Steam Separators, each	240
Number of Steam Dryers, each	8 Banks
Tube Sheet Design Differential Pressure, psi	1600

Table 5.5-2 (continued)

Dimensions	
Overall Height, Including Support Skirt, in.	742 (2)
Upper Shell Outside Diameter, in.	240.69
Lower Shell Outside Diameter, in.	169.75 (3)/ 171.07 (4)
Weights	
Dry, lb	1,167,000
Flooded, lb	1,789,600
Operating, lb	1,415,300

Notes:

(1) Each nozzle may be machined to a 3.5 inch ID. One blowdown nozzle on each steam generator is capped.
(2) Includes 1 inch allowance for field prep machining
(3) Tubesheet, A barrel and lower B barrel
(4) Upper B barrel and lower part of cone
(5) Normal operating values based on full power T_{cold} = 551 °F

Table 5.6-1 (continued)

System Parameter & Location	Indication		Alarm[1]		Rec[1]	Control Function	Inst. Range	Normal Operating Value
	Local	Control Room	High	Low				
Quench Tank Level		*	*	*			0-100%[3]	> 75%
Reactor Coolant Pump Differential Pressure		*				COLSS	0-130psid	95 psid
Reactor Coolant Pump Speed						CPC[5], PMS[6]	0-920 rpm	900 rpm

[1] All alarms and recorders are in the control room unless otherwise indicated.

[2] Sensor Range 3-95%

[3] Sensor Range 5-95%

[4] This parameter is actually displayed and trended on the Plant Computer.

[5] See Table 7.2-14

[6] COLSS runs as an application on the PMS platform and cooperatively supports this range. PMS displays speeds beyond 920 rpm, but indicates bad quality since such speeds are beyond the capability of the equipment.

6 ENGINEERED SAFETY FEATURES

6.1 GENERAL

The design, fabrication, testing and inspection of the core, Reactor Coolant Pressure Boundary (RCPB) and their protection systems give assurance of safe and reliable operation under all anticipated normal, transient, and accident conditions. Redundant systems have been provided as an Engineered Safety Feature (ESF) for additional protection. These ESFs have been designed to provide protection during:

A. Any size pipe break up to and including the circumferential rupture of a reactor coolant pipe (assuming unobstructed discharge from both ends); and

B. Any steam or feedwater line break.

The simultaneous occurrence of these two events is not postulated.

The release of fission products from the containment is limited in three ways.

A. Blocking the potential leakage paths from the containment is accomplished by:

   1. A steel lined concrete containment with welded piping penetrations which forms a virtually leaktight barrier preventing the escape of fission products should a Loss of Coolant Accident (LOCA) occur; and,

   2. Isolation of process lines by the Containment Isolation System (CIS) which imposes double barriers for each line which penetrates the containment.

B. Reducing the fission product concentration in the containment atmosphere is accomplished by a chemically treated spray which removes elemental iodine and coolant particulates from the containment atmosphere by a scrubbing action.

C. Reducing the containment temperature and pressure, thereby limiting the driving potential for fission product leakage, is accomplished with the Containment Spray System (CSS) and with the Containment Cooling System (CCS).

The following discusses the ESF's which accomplish the preset goals and give assurance of safe and reliable operation.

6.1.1 CONTAINMENT SYSTEM

The general purpose of the containment system is to provide a barrier confining potential releases of radioactivity from severe accidents. This is accomplished by maintaining leaktightness within specified bounds. As a design feature, the containment system is provided primarily for the protection of public health and safety.

The system consists of the containment structure, containment heat removal systems, containment air purification and cleanup systems, CIS, and the containment combustible gas control systems. Details of the containment system are given in Section 6.2.

6.1.2 SAFETY INJECTION SYSTEM

The principal design basis for the Safety Injection System (SIS), as described in General Design Criterion 35, is met. Protection for the entire spectrum of Reactor Coolant System (RCS) break sizes is provided. Separate and independent flow paths are provided (with the exception of the LPSI header) and redundancy in active components ensures that the required functions will be performed even if a single failure occurs. Separate emergency power sources are supplied to the redundant active components and separate instrument channels are used to actuate the systems.

Pumps which must operate following the Design Basis Accident (DBA) include the safety injection, containment spray, and service water pumps. The performance of the system is discussed in Section 6.3 and Chapter 15.

6.1.3 HABITABILITY SYSTEM

Environmental protection systems for the control room are designed in accordance with General Design Criterion 19 as discussed in Section 6.4. Shielding is discussed in detail in Section 12.1. Ventilation is discussed in Section 9.4.1. Fire protection is discussed in Section 9.5.1.

6.1.4 PENETRATION ROOMS VENTILATION SYSTEM

Experience has shown that containment leakage is much more likely at penetrations than through the welded liner plate. A separate ventilation system for the penetration rooms has been provided to collect any post-LOCA leakage and exhaust it through filters and radiation monitors. A detailed description is provided in Section 6.5.

6.1.5 MAIN STEAM LINE ISOLATION SYSTEM

The main steam line isolation system is designed to protect the reactor and the containment in the event of a main steam line rupture at any point inside or outside of containment. A detailed description is given in Sections 7.3.1.1.11.4 and 10.3.3.

6.2 CONTAINMENT SYSTEMS

6.2.1 CONTAINMENT FUNCTIONAL DESIGN

6.2.1.1 Containment Structure

6.2.1.1.1 Design Basis

The containment is designed to limit the release of radioactive material to the environment as a result of normal Reactor Coolant System (RCS) leakage as well as gross leakage following a postulated accident.

The principal design criteria established for nuclear power plant licensing are given in the 10 CFR 50, Appendix A, General Design Criteria for Nuclear Power Plants. These criteria establish minimum requirements for the design and performance of reactor containment in Section V, Criteria 50 through 57. The basic criterion used for design with regard to containment functional design for pressure and temperature accommodation is Criterion 50.

In addition, the containment is designed to accommodate design basis events that result in a low pressure inside containment. The operating conditions of the containment atmosphere must be controlled so that the maximum external-to-internal pressure differential achieved during these design basis events is less than the design differential pressure.

6.2.1.1.1.1 Postulated Accidents

Limiting design basis events are postulated to determine bounding structural loads on the containment structure. The events that were evaluated which result in high pressure inside containment were loss of coolant accidents (LOCA), main steam line breaks (MSLB), and events that result in low pressure inside containment such as inadvertent actuation of the containment heat removal system.

For the containment maximum pressure analysis, it is assumed that each postulated accident is concurrent with the most limiting single active failure in systems required to mitigate the effects of the accident. Under postulated simultaneous occurrences, such as a seismic event or local pipe break, effects are not explicitly evaluated in these sections except as they might affect the mass and energy release to containment. Containment response analyses of RCS pipe ruptures assume the loss of off-site power. Containment response analyses of main steam line ruptures assume that off-site power is available. The postulated accidents considered in the design of the containment include a spectrum of RCS pipe ruptures and main steam system pipe ruptures. The postulated RCS pipe ruptures are evaluated from an initial power level of 102% since that condition results in the maximum mass and energy addition to the containment. Since the secondary side inventory varies inversely with power level, the postulated secondary side breaks are evaluated for a spectrum of initial powers to ensure that the limiting initial condition is considered. The most severe accident is defined as the containment Design Basis Accident (DBA) which will also be used to develop the Environment Qualification (EQ) profile.

The original containment pressure/temperature analyses were performed for a spectrum of RCS and main steam line breaks (MSLB) to determine which break produced the highest containment pressure. RCS hot leg, pump suction and pump discharge pipe breaks ranging in size from 19.24 ft^2 to 0.5 ft^2 were analyzed. Main steam line pipe breaks ranging in size from 6.3 ft^2 to 1.575 ft^2 with power levels from 0 MWt to 2900 MWt were also analyzed. The FSAR

presents the original spectrum of breaks considered. The break spectrum analysis demonstrated that the 9.82 ft^2 slot break in the RCS pump suction piping produced the highest containment pressure peak. This break was designated the containment design basis accident.

For the subsequent power uprate and replacement steam generator project the limiting accidents were again evaluated to determine the impact on peak containment pressure. For these evaluations the limiting events were evaluated for LOCA and MSLB events. For LOCA, a slot break with an area equivalent to a double-ended guillotine break was considered for the hot leg, pump suction, and pump discharge locations. For MSLB, the limiting break size for all cases except 0% power was a double-ended break of the main steam line. This limit is due to the design of the SG flow limiting venturi preventing entrainment at the higher power levels. For 0% power the break size was reduced until no entrainment occurred.

For the containment minimum pressure analysis, no systems are actuated to mitigate the event. The severity of the event is controlled by the allowed containment atmosphere conditions during plant operation and the performance of the containment heat removal system.

6.2.1.1.2 Acceptance Criteria

Analyses were performed to demonstrate that the plant configuration meets all applicable criteria.

For events that result in high pressure inside containment, the following criteria are used to judge the acceptability of these analyses:

- the maximum post-accident containment pressure shall be less than design pressure,

- the maximum post-accident containment liner temperature shall be less than design temperature, and

- the containment heat removal system shall reduce the post-accident containment pressure and temperature to an acceptably low level following an accident.

For events that result in low pressure inside containment, the maximum external-to-internal pressure difference shall be less than the design limit.

6.2.1.1.2.1 System Design

The design of the containment is based upon the mass and energy absorption capacity of the volume contained within the structure, the operation of the containment spray systems, and the containment heat removal systems (CHRS). Sections 3.8.1 and 3.8.3 describe the design of the steel-lined containment structure. The principal design parameters for the containment are given in Table 6.2-7.

6.2.1.1.3 Design Evaluation

The adequacy of the containment design is demonstrated in this section by determining the containment response to design basis events that result in high pressure inside containment and to design basis events that result in low pressure inside containment.

The following is a description of the general plant response to these events.

Events that Result in High Containment Pressure

The events that result in high containment pressure exert an outward pressure loading on the containment structure, as well as create an environment inside the containment that places a thermal load on the containment liner and challenges the environmental qualification of equipment inside the containment.

Analyses were also performed to determine the minimum post-LOCA containment pressure response. These analyses fulfill the 10CFR50.46 Appendix K requirement that the containment pressure used in the evaluation of ECCS performance not exceed a pressure calculated conservatively for that purpose. These analyses are summarized in Section 6.2.1.1.3.4.

Experience has shown that the conditions resulting from postulated LOCAs and MSLBs are limiting with regard to structural loading on the containment structure and environmental qualification of equipment inside containment. Additionally, previous analyses have shown that for LOCA the largest pipe breaks bound smaller breaks in the evaluation of maximum containment pressure. Historical information regarding previous design evaluations can be found in the FSAR.

Condensation of steam on the structures inside containment plays a major role in limiting the containment pressure increase. In addition, automatic reactor protective system (RPS) and engineered safety feature (ESF) actuations are taken in response to MSLBs and LOCAs inside containment. The following is an overview of these automatic actions:

When containment pressure exceeds the containment pressure high (CPH) setpoint, the following automatic signals are initiated:

- Reactor trip
- Safety Injection Actuation Signal (SIAS) – adds borated water to the reactor coolant system (RCS)
- Containment Isolation Actuation Signal (CIAS) – isolated non-essential lines penetrating the containment.
- Containment Cooling Actuation Signal (CCAS) – reduces containment pressure and temperature by means of containment atmosphere air coolers.

When containment pressure exceeds the Containment Pressure High-High (CPHH) setpoint, the following automatic actuation signal is initiated:

- Containment Spray Actuation Signal (CSAS) – reduces containment pressure and temperature by spraying cold borated water into the containment. Additionally, this signal initiates isolation of the Main Steam and Feedwater Systems allowing the affected steam generator to boil dry.

Safety injection systems and containment spray systems initially take suction from the refueling water tank (RWT). When the water level in the RWT reaches a certain elevation, the recirculation actuation signal (RAS) is generated and the source of water for the high-pressure safety injection (HPSI) pumps and the containment spray (CS) pumps transfers to the sump. In addition, service water flow is directed to the shutdown cooling heat exchangers to provide cooling to the containment spray water.

Events That Result in Low Containment Pressure

There are events that result in a sudden pressure reduction inside containment (e.g., inadvertent actuation of the containment spray system). These events result in an inward loading on the containment structure. The design basis event for containment external pressure design has been determined to be the inadvertent actuation of the containment spray system. This analysis is described in Section 6.2.1.1.3.3.

6.2.1.1.3.1 LOCA Maximum Pressure Containment Analysis

The LOCA containment analysis is performed in two parts. The CEFLASH-4A and FLOOD3 computer codes calculated the mass and energy discharged from the RCS into the containment. This information was then used to determine the containment response using the COPATTA computer code. This subsection provides an overview of the analyses and a summary of the important results.

6.2.1.1.3.1.1 Mass and Energy Analysis

6.2.1.1.3.1.1.1 Methodology

In order to predict the peak containment pressure following an accident, energy sources are determined by the reactor manufacturer in the calculations of energy and mass release during postulated pipe break events.

The analytical simulation of the LOCA event is initiated from 102% power and is characterized by four distinct phases: blowdown, reflood, post-reflood, and long term cooldown. These phases, and the methodology used to analyze them, are described below.

Blowdown Phase

In the blowdown analysis, the following energy sources were considered: reactor coolant, safety injection water, core power transient and decay energy, core-to-coolant, primary metal-to-coolant, and steam generator forward and reverse heat transfer.

The LOCA causes a rapid depressurization of the RCS, which quickly falls below the shut-off heads of the HPSI and LPSI pumps. The safety injection pumps are the primary source of core cooling for the majority of the event and will start in response to either an SIAS on CPH or low pressurizer pressure signal. Once RCS pressure decreases below the pressure in the Safety Injection Tanks (SITs), the SIT check valves will open and SIT water will be discharged into the RCS.

This phase of the LOCA is simulated with the CEFLASH-4A computer code, Reference 9. The following assumptions were made in selecting input data for the code:

1. The model for fuel clad swelling and rupture was not used. The lack of clad swelling and rupture results in more fuel stored energy being transferred to the RCS coolant.

2. RCS volume was conservatively calculated based on the expansion of the reactor loop from cold to hot operating conditions.

3. The time-dependent main feedwater addition was used to account for the hot feedwater added to the steam generators (SGs). This results in more energy on the secondary side of the SGs that must be transferred to the containment.

4. Since the containment mass and energy release does not require the radial detail to track the stored energy in the hot assembly, a core nodalization of 1 radial region and 5 axial regions is used. In solving the conduction equation, the fuel rod is divided into 9 sub-regions (7 for the fuel pellet, one for the pellet-cladding gap, and one for the cladding). The energy transfer regime at the rod surface conditions. All heat transfer regimes are permitted and are selected on a dynamic basis. Hence, the code varies the fuel/clad related properties as a function of localized conditions.

5. Core stored energy is based on average pellet and clad temperatures computed at core average linear heat rates combined with specific heat and summed for the core average stored energy component from the fuel rods.

6. FATES (Reference 10) information provided for input to CEFLASH-4A consists of maximum fuel centerline temperature as a function of linear heat rate (kw/ft) at up to 20 axial positions. The FATES related information is translated into five axial nodes for input to CEFLASH-4A.

7. The CEFLASH-4A code allows for only one wall per node in the metal-to-coolant heat transfer model. A lumped parameter wall heat model is employed which takes a weighted average of the thermal conductors in each node.

8. The CEFLASH-4A wall representation uses total heat capacitance of all the walls in the RCS which actually face the given node being modeled. This tends to keep the single-wall-model temperature elevated which conservatively maximizes the thermal driving force for wall-to-coolant heat transfer for all the walls actually in the RCS when they are represented by a single wall model.

9. The core-to-coolant heat transfer model considers extended nucleate boiling in the core. The Thom Nucleate Boiling correlation was used when the core surface is exposed to primary coolant. When nucleate boiling can no longer be supported, CEFLASH-4A considers a variety of transitional boiling or convective heat transfer correlation, depending on the localized conditions.

10. Heat Transfer across the steam generator tubes is modeled with the same heat transfer coefficient in both the forward and reverse directions.

11. Emergency feedwater flow is conservatively omitted since it would cool the secondary sides.

Reflood and Post-Reflood Phases for Cold Leg Breaks

Following the initial blowdown, the reactor is first refilled by the incoming safety injection flow, including SITs, and then reflooded as the core becomes quenched. The effect of the SGs on the mass and energy to containment is important for cold leg breaks after blowdown because the exiting steam passes through the SGs prior to exiting the RCS to the containment.

The next phase of the transient simulation is the reflood phase, which is defined as the time period during which the coolant accumulating in the reactor vessel increases from the bottom of the active core to two feet below the top of the active core. At this point, the core is considered to be quenched and the entrainment reduces significantly.

The reflood and post-reflood phases of the LOCA are simulated using the NRC-approved FLOODMOD2 methodology, Reference 84. The FLOOD3 computer code, Reference 86 is used to implement this methodology. The important features implemented by the FLOOD3 code for this analysis are summarized below.

1. Intact and broken loops were treated individually.
2. Specific volumes of the fluids in the primary loop were varied with time.
3. A uniform methodology for both Reflood and Post-Reflood time frames was used.
4. A rigorous heat transfer scheme was used for treating the transfer of energy from the loop and steam generator walls to the fluid in the primary loop.
5. Containment backpressure was bounded conservatively.
6. Safety injection flow rates were computed explicitly.
7. The fluid in the vessel was heated mechanistically.
8. SIT and safety injection enthalpies were input separately.
9. Frothing analysis was performed internally.
10. Nominal RCS pressure drops are used and corrected accordingly for two-phase flow.

The decay heat modeled in FLOOD3 was representative of the ANSI/ANS 5.1-1979 +2σ decay heat standard.

During the reflood and post-reflood phases, liquid entrainment in the exiting steam flow is calculated based on a carryout rate fraction (CRF), which is defined as the ratio of the mass flow rate out of the core to the mass flow rate into the core. The CRF varies as the coolant accumulates in the core during reflood. Specifically, the CRF is 0.05 until the core level reaches 1.5 ft. above the bottom of the active core. As the core level increases from 1.5 ft. to 2 ft., the CRF increases linearly from 0.05 to 0.80. The CRF is then held constant (0.80) until the core level increases to an elevation corresponding to 2 ft. below the top of the active core. Test data indicate that the CRF decreases significantly as the core level raises further to the top of the core. The methodology models a step decrease in the CRF to the value of 0.05 after the core level increases above the elevation corresponding to 2 ft. below the top of the active core.

Reflood steam release to the containment was considered to start immediately at the end of blowdown; that is, the reactor vessel lower plenum refill time was not considered. Full operation of the safety injection was considered; that is, all tanks and pumps were operable except for the EDG failure cases where only one safety injection train was considered operable. This maximizes the core flooding rate and hence the rate of steam release to the containment. For discharge leg breaks, one of the four safety injection legs was considered for spillage; for suction leg breaks no spillage was considered.

Although test data indicate that significant condensation of steam occurs at the safety injection location, the model accounts for only 50% condensation during the interval that the SITs are injecting and the annulus is predicted to be full. No credit was taken for condensation at the safety injection locations at other times.

During the post-reflood phase, the energy in the RCS and SGs was transferred to containment via the exiting break flow. The end of the post-reflood phase occurs when the RCS and SG inventory and heat structures have cooled to the point that the generation of steam is dominated by fission product decay heat.

Reflood and Post-Reflood Phases for Hot Leg Breaks

For the hot leg break, the mass and energy analysis ends at the end of the blowdown phase. Since there is no viable means for the exiting break flow to pass through the SGs prior to exiting the RCS to containment for a hot leg break, the reflood and post-reflood phases are not simulated.

Long-Term Cooling Phase

The long-term cooling phase of the LOCA completes the transient simulation of this event. In this phase, the analysis accounts for all residual energy in the primary and secondary systems and decay heat. This analysis is typically run until the containment temperature returns to its initial value.

Except as noted below, the mass and energy calculation and the containment response calculation are done in parallel using the COPATTA containment code.

The CONTRANS code, Reference 87, was used to calculate the heat addition from the reactor vessel, fuel, and internals. CONTRANS was also used to calculate the heat addition from the RCS loop and SGs starting from the primary fluid temperature at the end of post-reflood period for cold leg breaks. Residual energy was modeled as follows:

- Commencing with the end of blowdown, the residual energy associated with the pressurizer was added directly to the containment atmosphere.
- Commencing with the end of the post-reflood phase, the residual stored energy associated with the RCS loop and the SG was added directly to the containment atmosphere.
- Commencing with the end of the post-reflood phase, the residual energy associated with the reactor vessel upper head and its miscellaneous internal hardware was added directly to the containment atmosphere.

The resulting time dependent energy addition was used as an input to the COPATTA calculation and added to the reactor vessel or directly to the containment atmosphere. In this manner, all sources of energy were explicitly modeled.

The decay heat input to COPATTA during the long-term cooldown phase was based on Branch Technical Position (BTP) ASB 9-2. The normalized reactor power as a function of time for the entire transient is shown in Figure 6.2-11.

6.2.1.1.3.1.1.2 Limiting Mass and Energy Data

Mass and energy release data were determined for double-ended slot breaks in three locations (hot leg, reactor coolant pump suction, and reactor coolant pump discharge) and two types of single failures (failure of one EDG and failure of one of the containment heat removal systems). All six cases assumed loss of off-site power at the time of the event. Table 6.2-8A provides the major assumptions for the mass and energy analysis.

The SIS is assumed to operate in its maximum heat removal mode for all RCS breaks where an EDG failure is not considered. Under this condition, the CHRS is assumed to take the most restrictive single failure. The most restrictive failure in the CHRS has been determined to be the loss of one containment spray train. For cases where the failure of an EDG is considered, the SIS and CHRS operate with a single train (one containment air cooler train, one containment spray train, and one SIS train).

Table 6.2-8B provides the mass and energy data for the limiting event (a double-ended discharge leg break with failure of one EDG). Table 6.2-8C shows the mass and energy distribution at the end of blowdown and the end of post reflood. This table also verifies that the mass and energy released from the RCS equals the mass and energy transferred to the containment.

6.2.1.1.3.1.2 Containment Response Analysis

6.2.1.1.3.1.2.1 Methodology

The mass and energy release data was used by the COPATTA computer code, Reference 88, to calculate the containment pressure and temperature response.

The containment parameters such as the design pressure and temperature, the net free internal volume and the containment surface areas are given in Tables 6.2-7, 6.2-8D, and 6.2-8E. As an additional conservatism, the volume occupied by the reactor coolant prior to the LOCA was included as occupied volume rather than free volume.

The ESF performance parameters and initial conditions within the containment are provided in Table 6.2-8F. These parameters were used in the COPATTA analysis. An overview of the COPATTA methodology is provided below.

COPATTA modeled the containment as three regions – one region modeled the containment atmosphere, another region modeled the containment sump, and the third region modeled the reactor vessel. Conditions in the atmosphere and the sump were determined by solving the conservation of energy and mass equations for each region.

The mass added to the containment from the break separates into a steam phase, which was added to the atmosphere region, and a liquid phase, which was added to the sump region. The water phase was assumed to be at the saturation temperature corresponding to the total containment pressure, while the steam phase was assumed to be at the partial pressure of the steam in the containment atmosphere. Thermal equilibrium between the air and steam in the containment atmosphere was assumed.

Condensation of steam on the structural heat sinks occurred at the saturation temperature corresponding to the partial pressure of the steam phase. All condensate created in a particular time step was transferred immediately from the atmosphere to the sump, unless the steam in the atmosphere was superheated. During atmospheric superheat conditions, a maximum of 8% of the condensate was assumed to remain in the vapor region (i.e., be re-vaporized) rather than be transferred directly to the sump.

The various structures in the containment were modeled to interact with the containment atmosphere and the sump. The rate of heat transfer between the containment heat structures and the containment regions was determined by the surface area, the surface temperature, the heat transfer coefficient, the physical arrangement of the conducting masses, and the thermal properties of these masses. The heat transfer coefficient used during the turbulent blowdown phase of the event was determined using a modified Tagami correlation, References 74 and 75. After the blowdown phase, the heat transfer coefficient transitioned from the modified Tagami correlation to the Uchida correlation, Reference 76. With the exception of mass and energy transfer due to a boiling sump, heat transfer between the water in the sump and the containment atmosphere was not modeled.

The containment heat sink data specified for the heat transfer calculations during the LOCA are given in Tables 6.2-8D and 6.2-8E. Table 6.2-8D lists the geometric configuration of the heat sinks, including materials, thicknesses, and surface areas for concrete, steel, and steel-lined structures, and lengths for piping. The carbon steel surfaces are assumed to be covered with a mild thickness of appropriate protective coating. Conservatively determined thermodynamic properties and heat transfer coefficients used in the analyses are given in Table 6.2-8E. These data plus the geometric data completely specify the necessary heat sink parameters for the calculation of energy transfer to and within the structures of the containment during a LOCA.

An analysis has been performed to determine the effects of interface resistance at the containment liner to concrete interface on the heat transfer into the heat sinks. Experimental values of interface conductance vary from 100,000 Btu/hr-ft^2-°F for joints prepared under laboratory conditions to 10 Btu/hr-ft^2-°F for joints with extremely poor contact in a vacuum (References 12, 39, 40, 41, 44, 47, 48, and 68). Based on these data, a conductance of 100 Btu/hr-ft^2-°F represents a conservatively low value for an interface in poor contact in air and therefore is suitable for modeling the concrete containment liner interface. Analysis has shown that by introducing an interface conductance of 100 Btu/hr-ft^2-°F on all lined concrete heat sinks instead of assuming perfect contact, the peak containment pressure increases less than one percent. This is considered an unrealistic assumption because of the heat transfer to the concrete from the liner plate. The concrete is poured directly against the liner plate, so they should be bonded together over much of the surface. Liner plate anchors (continuous angles 15 inches on centers) will hold the plate in close contact, if it is not bonded, and prestressing the containment structure will put the liner plate in compression, further assuring intimate contact with the concrete. After a LOCA, the compression in the liner plate is further increased due to the elevated temperature in the plate. An interface conductance of 100 Btu/hr-ft^2-°F was assumed for the DBA pressure transient analysis.

The containment atmosphere air cooler units, which are cooled by service water, remove energy from the vapor region of the containment. COPATTA determined the heat removal due to air cooler unit operation as a function of containment saturation temperature. The relationship of containment temperature versus cooler capacity is consistent with the manufacturer's performance data, see Figure 6.2-3A.

The containment spray system removes energy from the atmosphere by injecting water into the atmosphere. The energy removed from the atmosphere is a function of the heatup of the spray droplets. COPATTA determined the heatup of the droplets from a spray efficiency relationship, which was a function of the ratio of steam mass to air mass. This relationship was developed in Reference 74 assuming a mean spray droplet diameter and fall distance of 1,000 microns and 20 ft. respectively (actual fall distance is more than 100 ft.). The heat removed from the atmosphere due to heating of the spray droplets and any condensate due to this cooling was added to the water in the sump.

COPATTA used the input from CONTRANS for the reactor vessel region to include the effects of heat transfer from the energy stored in the primary and secondary metal. This region was used only during the long-term cooldown phase – not during the initial mass and energy release phases (blowdown, reflood, and post-reflood) when the primary coolant system pressure is not in equilibrium with the containment atmosphere.

6.2.1.1.3.1.2.2 Analysis Results for Limiting Case

A series of cases were analyzed to determine the limiting break location and single failure combination. These analyses made use of the containment initial conditions and containment heat removal system performance described in Table 6.2-8F. Table 6.2-8G provides the results of those analyses. The limiting peak pressure was 57.6 psig, which occurred for a double-ended slot break at the discharge of the reactor coolant pump with the single failure of an emergency diesel generator. For the case above, the peak temperature was 285 °F. The maximum pressure is less than the maximum design pressure and the maximum temperature does not challenge the maximum design temperature of the containment structure. In addition to the limiting cases evaluated, runs were made to evaluate Limiting Conditions for Operation (LCO) action statements in the Technical Specifications. Table 6.2-8J documents the breaks evaluated.

Due to the limiting nature of a LOCA it is a more severe accident for design of containment than the MSLB. This is due to the larger release of mass and energy to the containment. Although the short term peak temperature is higher for MSLB the long term impact of the increased mass and energy release is a greater challenge to the containment. As such the DBA is defined as the most limiting LOCA, the Double Ended Discharge Leg Slot break (DEDLS).

Table 6.2-8H provides the sequence of events for the DBA and Figure 6.2-8E shows the transient pressure response. Figure 6.2-8F shows the transient atmosphere and sump temperatures for the DBA. Figures 6.2-8E and 6.2-8F also demonstrate that containment heat removal systems are sized adequately to reduce containment pressure and temperature to a low level following the accident and maintain this low level thereafter. The containment wall liner plate temperature peaks at 271 °F at 313 seconds. The containment wall temperature distribution is illustrated in Figure 6.2-8G.

6.2.1.1.3.2 Main Steam Line Break Maximum Pressure Containment Analysis

Similar to the LOCA, a MSLB inside containment is characterized by the rapid blowdown of steam into the containment due to the rupture in a main steam line. The location of this break is postulated to be at one of the SG outlet nozzles. The steam generator contains an integral flow restricting nozzle which effectively limits the break size to the venturi area or 1.9 ft^2. A full guillotine break was considered for all power levels except 0%, due to the venturi preventing entrainment from occurring for the higher power levels. For the limiting case at 0% power the

effective break size was reduced so that no entrainment occurred. The general response of the containment, the reactor protection system, and the engineered safety features to main steam line breaks is discussed in Section 6.2.1.1.3. The following discussion augments that discussion as it applies to MSLB events:

- Until the Main Steam Isolation Valves (MSIVs) close, the initial portion of the transient is characterized by the blowdown of both SGs. In this early phase of the event, steam continues to flow to the turbine. Following the reactor trip, which occurs on a CPH signal, the turbine stop valves close. During this portion of the transient, the main feedwater continues to feed the SGs with the main feedwater pumps and main feedwater water regulating valves at their initial speed and position.

- When the containment pressure exceeds the CPHH setpoint, CSAS occurs and initiates closure of the MSIVs, the Main Feedwater Isolation Valves (MFIVs), and the Backup MFIVs along with spray initiation. It also trips the main feedwater, condensate, and heater drain pumps.

- Following the closure of the MSIVs, the flow of steam to the containment from the intact SG and isolated steam line cease. Although the intact SG repressurizes due to heat transfer from the RCS and eventually becomes an energy source, its affect on the containment response is small after the MSIVs close.

- The contribution of main feedwater flow is reduced significantly when the pumps trip off on the CSAS signal.

- The 0% power cases assume that feedwater flow to the steam generators is from the AFW system at the initiation of the steam line break. Once the transient starts, flow to the intact steam generator is diverted to the ruptured steam generator.

Similar to the LOCA, the MSLB containment analysis is performed in two parts. The SGNIII computer code was used to determine the mass and energy discharged into containment. These data were used to determine the containment response using the COPATTA computer code. This subsection provides an overview of the analyses and a summary of the important results.

6.2.1.1.3.2.1 <u>Mass and Energy Analysis</u>

6.2.1.1.3.2.1.1 <u>Methodology</u>

The SGNIII computer code, Reference 90, was used to determine the mass and energy data. SGNIII is a coupled primary and secondary model that calculates a time dependent mass and energy release.

The RELAP5 MOD3 code, Reference 91, was used to calculate the contribution of main feedwater, including flashing, to the affected and intact SGs. The code simulated the main feedwater trains including the main feedwater, condensate, and heater drain pumps, various valves and feedwater heaters. No credit was taken for closure of the main feedwater regulating valves. The primary inputs to the RELAP5 MOD3 code were the transient pressures of the intact and affected SGs. The time dependent RELAP5 MOD3 outputs of feedwater flowrate and its associated enthalpy (to each SG) were input directly to SGNIII.

The backup valves were built to the same code class as the piping in which they are installed (B31.1) but they have seismically qualified, Class 1E operators. Material traceability was required for the valve bodies. The valve actuation time is 18.5 seconds or less and they are located immediately upstream of the MFIVs. This assures that their performance meets or exceeds that of the existing valves which close within 25 seconds. The backup valves were installed during the first refueling outage. Annunciator alarms were added to notify operations should either backup valves' breaker open. See the FSAR analysis for additional details with respect to the reason for adding these valves.

While the mass and energy release analysis was conducted separately from the containment response analysis, the COPATTA containment code was used to predict the times for the containment pressure to reach the CPH and CPHH setpoints.

6.2.1.1.3.2.1.2 Limiting Mass and Energy Data

Mass and energy data were generated for a number of initial power levels and single failure combinations to determine the limiting condition. Except for the cases initiated from 0% power, a single break size was analyzed (guillotine break downstream of the SG nozzle). Due to the flow-limiting device in the outlet nozzle, this break size produced a break flow with no entrainment, which is the limiting condition for containment analysis. For cases initiated from 0% power, it was necessary to reduce the break size to achieve no entrainment.

Off-site power was assumed to be available throughout the transient for all cases analyzed. Although the loss of off-site power delays the actuation of containment heat removal systems, the influence of running RCPs on transferring RCS energy to the affected steam generator is a more dominant effect. The FSAR analysis contains a comparison of a loss of off-site power to an off-site power available case.

There are several trade-offs in determining the limiting initial conditions with regard to the power level versus inventory and feedwater flow inputs. As initial power level increases, RCS temperature and core decay heat increase resulting in more primary to secondary energy being present to boil-off the SG inventory. Main feedwater flowrate and enthalpy increase accordingly. However, initial SG inventory decreases with increasing initial core power. Therefore, the MSLB analysis included an evaluation of multiple power levels. The mass and energy sensitivity study included six power levels (102%, 94.8%, 75%, 50%, 25%, and 0% power).

Active component failures in the main feedwater and CHR systems were considered. Single active failures include the MFW or condensate pumps resulting in a failure to trip, MFIV or Backup MFIV failure to isolate, or containment spray or containment cooler failures. The single failure modes of the main and emergency feedwater systems are described in Tables 10.3-4 and 10.4-11, respectively.

The limiting case was determined to be a containment spray train failure for a MSLB initiated at 0% power. Table 6.2-9A provides the assumptions for the mass and energy analysis.

Table 6.2-9B provides the mass and energy data for the limiting event (a slot rupture of the main steam line initiated at 0% power with the failure of one containment spray train).

6.2.1.1.3.2.2 Containment Response Analysis

6.2.1.1.3.2.2.1 Methodology

The mass and energy release data from SGNIII was used by the COPATTA computer code to calculate the containment pressure and temperature. The program model description and thermodynamic assumptions are nearly identical to that used for the LOCA maximum containment pressure analysis, which is described in Section 6.2.1.1.3.1.2.1. The primary differences between the LOCA and MSLB containment response analyses are:

- the reactor vessel region model is not employed in the MSLB analysis,
- the Uchida correlation is used for the heat transfer coefficient to the structural heat sinks in the MSLB, rather than the modified Tagami correlation, and
- ESF performance parameters (provided in Table 6.2-9A).

The containment parameters such as design pressure and temperature, the net free volume, and the containment surface areas are the same as those used for the LOCA maximum containment pressure analysis, which are described in Tables 6.2-7, 6.2-8D, and 6.2-8E. The containment initial conditions and containment heat removal system performance used are provided in Table 6.2-9A.

6.2.1.1.3.2.2.2 Analysis Results for Limiting Cases

Mass and energy data for various power levels and single failures were analyzed to determine the limiting case. Table 6.2-9C provides the summary of those cases and the maximum containment pressure and temperature. The limiting peak pressure was 57.4 psig for a slot break initiated from 0% power with the failure of one containment spray train with the corresponding peak containment temperature of 392 °F. The limiting peak pressure is less than the maximum design pressure of 59 psig. In addition to the limiting cases evaluated, an additional run was made to evaluate an allowable Limiting Condition for Operation in the Technical Specifications.

Table 6.2-9D provides a sequence of events and Figure 6.2-8H shows the transient pressure and temperature response for the limiting peak pressure case. Note that the containment atmosphere temperature is reduced very rapidly by the injection of containment spray. Since the containment structure is initially subcooled, steam will condense on its surface at a temperature that is governed by the partial pressure of the steam.

The condensing heat transfer correlation used in main steam line break analysis is the Uchida correlation described in References 88 and 76. For the time periods where condensing heat transfer is used, water is condensed on the heat sink and transferred directly to the sump at the temperature corresponding to the partial pressure of the steam phase, unless the steam in the atmosphere was superheated. During atmospheric superheat conditions, a maximum of 8% of the condensate was assumed to remain in the vapor region (i.e., be re-vaporized) rather than be transferred directly to the sump.

The design temperature for the containment liner is 300 °F. The qualification temperatures for safety-related equipment are provided in Section 3.11.

The COPATTA code predicts vapor temperatures in excess of 300 °F for the initial minutes following pipe breaks that result in accidents with high blowdown enthalpy and hence high containment vapor superheat. This is primarily due to the conservative COPATTA code assumption that most (92%) steam condensed from the atmosphere during any calculational time interval is added to the sump liquid immediately at the end of the interval, and is not available to absorb additional heat from the superheated steam in the containment atmosphere.

Since condensation is a much more efficient heat transfer process than free convection for these conditions, it dominates the heat transfer between the containment vapor and structures. For conditions when the containment vapor is highly superheated the surfaces of the containment structures rapidly heat up to the saturation temperature corresponding to the partial pressure of steam in the vapor and follow the containment saturation temperature through the balance of the steam line blowdown period. Following the end of blowdown or the actuation of sprays, whichever occurs first, the containment vapor region rapidly de-superheats to the saturation conditions.

This has been demonstrated in Reference 69 where typical safety-related equipment were modeled as heat sinks in the containment using the COPATTA code and a similar main steam line break was analyzed. Heat transfer coefficients and spray start times were varied to determine their effects on equipment surface temperature.

The results of this study demonstrated that the equipment surface temperatures remained at or near the containment saturation temperature for the cases considered. The peak vapor region temperature obtained in these studies was 425 °F while the peak equipment temperature obtained was 255 °F which corresponds to the containment saturation temperature. The conclusion of this study was that the case which provided the highest containment steam pressure and hence the highest saturation temperature provides the design basis for containment temperature qualification.

6.2.1.1.3.3 Maximum Containment External-to-Internal Pressure Differential

The maximum external pressure loading on the containment has been evaluated assuming that the containment is subjected to an inadvertent actuation of the containment spray system. The pressure differential from outside to inside of the containment has been calculated assuming an inadvertent initiation of the containment spray system with 40 °F water.

Initial pressure, temperature, and relative humidity were varied to determine the conditions which would produce a maximum pressure differential across the containment wall of 5.0 psi. The resulting limits on initial pressure and relative humidity are reflected in the Technical Specifications. As noted in Section 3.8.1.3.1, the containment was checked for an external to internal load of 5.0 psi.

6.2.1.1.3.4 Minimum Containment Pressure Analysis for ECCS Performance Analysis

6.2.1.1.3.4.1 Introduction and Summary

Appendix K to 10 CFR 50 (Reference 31) lists the required and acceptable features of Emergency Core Cooling System (ECCS) evaluation models. Included in the list is the requirement that the containment pressure used in the evaluation of ECCS performance not exceed a pressure calculated conservatively for that purpose. This section presents the analysis that determined the minimum containment pressure that is used in the ANO-2 large break LOCA ECCS performance analysis presented in Section 6.3.3.2.

6.2.1.1.3.4.2 Method of Calculation

The calculations reported in this section used the 1999 EM Version of Westinghouse's NRC-accepted large break LOCA evaluation model for Combustion Engineering-designed PWRs (Reference 6, Supplement 4-P-A). In the evaluation model, the CEFLASH-4A computer program (Reference 9) determines the mass and energy released to the containment during the blowdown phase of the postulated LOCA. The COMPERC-II computer program (Reference 11) determines both the mass and energy released to the containment during the refill\reflood phase of the LOCA and the minimum containment pressure response used in the ECCS performance analysis.

6.2.1.1.3.4.3 Input Parameters

The input for the minimum containment pressure analysis for ANO-2 presented herein is consistent with the input used in the large break LOCA ECCS performance analysis of Section 6.3.3.2 which used the results of this section.

6.2.1.1.3.4.4 Mass and Energy Release Data

The mass and energy released to the containment for the limiting large break LOCA, the 0.4 DEG/PD break (Double Ended Guillotine break in Pump Discharge), are listed as a function of time in Table 6.2-34. The quantity of safety injection fluid that spills from the break is discussed in Section 6.2.1.1.3.4.8.

6.2.1.1.3.4.5 Initial Containment Internal Conditions

The initial containment internal conditions used in the analysis are:

Temperature	60 °F (minimum)
Pressure	13.2 psia (minimum)
Relative Humidity	100% (maximum)

For each parameter, the conservative direction with respect to minimizing the containment pressure appears in parentheses.

6.2.1.1.3.4.6 Containment Volume

The net free containment volume used in the analysis is: 1,820,000 ft^3 (maximum).

6.2.1.1.3.4.7 Active Heat Sinks

In order to conservatively maximize the heat removal capacity of the containment active heat sinks, the containment sprays and fan coolers were modeled to actuate in the shortest possible time following the LOCA and to operate at their maximum capacity.

The operating parameters used for the containment sprays are as follows:

Number of Pumps	2
Flow Rate	2515.5 gpm/pump
Actuation Time	20 sec after LOCA
Temperature	38 °F

The operating parameters used for the fan coolers are as follows:

Number of Fan Coolers	4
Actuation Time	0 sec after LOCA
Heat Removal Capacity (per fan) vs. Containment Temperature	0 BTU/sec at 33 °F 28663 BTU/sec at 300 °F

6.2.1.1.3.4.8 Steam Water Mixing

The effect on containment pressure due to condensing containment steam with spilled ECCS water was calculated in the manner described in Section III.D.2 of Reference 6. The effective ECCS spillage rate is shown in Figure 6.2-30. The spillage rate was determined using the maximum flow rate from two high pressure and two low pressure safety injection pumps.

6.2.1.1.3.4.9 Passive Heat Sinks

The surface areas and thickness of all exposed containment passive heat sinks are listed in Table 6.2-35. The material properties used for the passive heat sinks are listed in Table 6.2-36.

For the analyses described in Section 6.2, performed to determine the peak containment pressure and temperature conditions which could be encountered under the various postulated accident conditions, a thorough review of the containment layout drawings was conducted to determine those components and structures which would serve as heat sinks, and calculations were performed to determine the exposed surface areas of these components and structures. However, since larger heat sink surface areas result in lower containment pressures and consequently, represent the more severe condition with regards to the ECCS performance analysis, the heat sink surface areas used in the ECCS performance analysis were conservatively higher than the calculated values. In determining the heat sink surface areas to be put into the ECCS performance analysis, the individual calculated areas were multiplied by a factor which ranged in value from approximately 1.1 to 1.7. For those heat sinks whose surface areas could be determined with a good deal of certainty, factors on the low end of this range were used. For example, the calculated concrete surface areas were multiplied by factors ranging from approximately 1.1 to 1.3. Due to the difficulty of assuring that all the steel sink surface areas have been accounted for, larger factors were used in determining these areas. For example, a factor of approximately 1.4 was used in determining the surface area of the polar crane, and a factor of approximately 1.6 was used in determining the surface areas of the refueling structure and restraint steel. The factors were selected to ensure that the heat sink parameters put into the ECCS performance model represent the worst case condition. Overall, the steel heat sink surface areas used in developing the ECCS performance analysis were approximately 50 percent higher than those used in developing the containment response model, and the concrete surface areas were approximately 15 percent higher.

6.2.1.1.3.4.10 Heat Transfer to Passive Heat Sinks

The condensing heat transfer coefficient between the containment atmosphere and the passive heat sinks was calculated in the manner described in Section III.D.2 and Figure III.D.2-2 of Reference 6. The variation on the condensing heat transfer coefficient used in the analysis is shown as a function of time in Figure 6.2-31. In addition, the following heat transfer coefficients were also used in the analysis:

Containment Atmosphere to Sump Liquid	500 BTU/hr-ft^2 °F
Sump Liquid to Base Slab	20 BTU/hr-ft^2 °F
Containment Structure to Atmosphere	10 BTU/hr-ft^2 °F

6.2.1.1.3.4.11 Results

For the limiting large break LOCA defined in Section 6.3.3.2.2.6, the 0.4 DEG/PD break, the minimum containment pressure response for use in the ECCS performance analysis is shown in Figure 6.3-16f. The responses of the containment atmosphere and containment sump temperatures are shown in Figures 6.2-33 and 6.2-34, respectively.

The containment response is used in the large break LOCA ECCS performance analysis presented in Section 6.3.3.2.

6.2.1.2 Containment Building Subcompartment Structures

6.2.1.2.1 Design Basis

The design basis for the containment subcompartments is provided in Section 3.6.

6.2.1.2.2 System Design

The design of the reactor and steam generator subcompartments considers applicable thermal, static, seismic, impingement force, and pressure loadings during a LOCA as described in Section 3.8.3. Subcompartment vents are provided to ensure that excessive pressure loadings are not placed upon compartment walls.

As a result of the reactor cavity seal plate modification described in Section 6.2.1.2.3.2.2, the subcompartment pressurization analyses credit the leak-before-break (LBB) methodology described in CEOG Topical Report CEN-367-A. The ability to reference the LBB topical report limits postulated ruptures of piping to branch line pipe breaks for protection against dynamic effects. The reactor cavity subcompartment does not contain any branch lines and no longer has to consider dynamic effects from such postulated ruptures. The steam generator subcompartment does contain branch lines that must be considered to rupture, but the previous analyses postulated larger pipe ruptures that remain bounding for consideration of dynamic effects. The following descriptions of subcompartment pressurization analyses for both the reactor cavity and steam generator cavities do not consider credit for the LBB methodology and are therefore bounding in light of the current licensing basis that allows the use of the LBB topical. Additional detailed analyses have not been performed for either the reactor cavity seal plate modification described in Section 6.2.1.2.3.2.3 based on the bounding nature of the following subcompartment pressurization analyses.

The consequences of pipe ruptures within containment subcompartments have been evaluated to size and select the compartment vents, design pressures, and necessary pipe restraints in order to maintain acceptable pressure transients inside the subcompartments.

Subcompartment pressure analyses were considered for the two steam generator compartments and the reactor cavity. The calculational techniques for these analyses are presented in detail in Section 6.2.1.2.3.2. The analysis described in Section 6.2.1.2.3.2 was used to establish the original design criteria for the primary and secondary shield walls that compose the reactor and steam generator cavities. A discussion of the mass and energy releases for short-term pressure analysis and the justification for selection of break location and break size are presented in Section 6.2.1.2.3.1.

The design pressures and the calculated transient differential pressure peaks of design significance and design pressures for each of the subcompartments analyzed are presented in Tables 6.2-17 and 6.2-17A respectively. Curves of pressure variation vs. time for hot and cold leg breaks in the reactor cavity, the biological shield pipe penetration, and the most restrictive steam generator cavity are given in Figures 6.2-16A through 6.2-16P. The design pressures of the biological shield pipe penetrations shown in Table 6.2-17 include the effects of localized jet impingement loads.

Subcompartments and compartment subdivisions were chosen as those larger containment volumes which are separated by significant constriction. The calculated gross vent areas were reduced by appropriate equipment blockage areas to accurately model the actual vent area. Moveable obstructions to flow such as insulation, ducts, plugs, etc., were conservatively assumed to remain intact, providing greatest flow restriction. Flow coefficients were chosen to provide conservative vent flow characteristics. In the case of significant flow restrictions, a flow coefficient representative of an orifice was used. Flow coefficients used are summarized in Table 6.2-17B.

For the reactor cavity work prior to LBB considerations, two sets of analyses were performed for each break case considered. Each of these sets is concerned with assumptions regarding the obstruction to cavity venting presented by the neutron shield. These assumptions are as follows:

1. The neutron shield remains intact throughout the transient, thereby precluding venting from the nozzle region to the middle region;

2. Portions of the neutron shield in the vicinity of the break (reference Table 6.2-17B for specific locations) are assumed to “blow-out” during the transient. The remainder of the neutron shield is assumed to stay intact throughout the transient.

Case I provides a conservative analysis for reactor vessel sideforce. Case II provides an analysis yielding conservative values for vessel overturning moments and uplift loads.

Break locations are chosen to render each case, i.e., Case I and Case II assumptions, conservative. Specifically, for the analyses employing Case I assumptions, the break location is postulated to occur in a location presenting the most restriction to vent flow out of the break compartments. Analyses employing Case II assumptions postulate the break location to be in an unsupported leg of the RCS. This provides the least restrictive path for vent flow from the break down to the middle region. Then, for each break case considered, the vessel sideforce obtained for Case I is combined with the vessel loads obtained from Case II to yield a loading combination. The results of one analysis are transported so that both sets of loads are applied to the vessel and support system as if they had been generated by a break in one location. This transportation is made so as to render the analyses performed for design of reactor vessel supports conservative.

Calculations of compartment vent areas and volumes made for all analyses presented herein take no credit for increases in these parameters due to the assumptions regarding removal of movable obstructions, e.g., insulation.

Schematic drawings showing the nodalization of the reactor cavity and steam generator compartment and nodal net free volumes are given in Figures 6.2-3C through 6.2-3L. Table 6.2-17B tabulates flow coefficients and interconnecting flow path areas. As indicated in Figure 6.2-3C, the reactor cavity is subdivided into a total of 16 nodes: 12 in the nozzle region, three in the middle region, and one in the lower region. The 12 nodes of the nozzle region are separated by either the reactor coolant piping or the neutron shield support beams. The three nodes used to represent the middle region are separated by the reactor vessel column supports. Finally, the one node of the lower region represents the remainder of the cavity volume.

Four analyses were performed for the two breaks postulated to occur in the reactor cavity prior to LBB considerations. As discussed previously in this section, each of these analyses employs either Case I or Case II assumptions to the model illustrated in Figure 6.2-3C, locating the break in a position which will render the analyses conservative. This results in the following break locations:

	Case I	Case II
200 in^2 Cold Leg Circumferential Break	Southeast Leg	Northeast Leg
100 in^2 Hot Leg Circumferential Break	South Leg	South Leg

The results of these analyses are presented in Figures 6.2-16A through 6.2-16F.

The calculated transient pressure responses for each significant subcompartment analyzed, as listed in Table 6.2-17A, are below the allowable pressure values which the subcompartment walls can withstand.

The differential pressure loadings on the reactor vessel and steam generators and surrounding primary and secondary shield walls resulting from the subcompartment differential pressure transients described above are given in Table 6.2-17A.

Results of a nodalization study performed for reactor cavity modeling have been reported in previous amendments to this docket. This study showed the relative insignificant effect of increased nodalization in the nozzle region on maximum subcompartment pressures (viz. four percent increase in maximum calculated differential pressures going from six node base-case model to 12 nodes).

Although the model has evolved slightly since that time (due to finalization of design of the neutron shield support structure), the same conclusions still apply. Increasing the nodalization of the middle and lower regions is also of little consequence as these regions experience essentially the same pressure transient. (See Figures 6.2-16C and 6.2-16F.) This discussion, coupled with the discussion above pertaining to the choice of node locations, verifies the efficacy of the model described herein for calculating compartmental pressure responses.

6.2.1.2.3 Design Evaluation

6.2.1.2.3.1 Subcompartment Differential Pressure Considerations

Differential pressure analyses were performed for the reactor cavity and the steam generator compartment prior to LBB considerations. The following spectrum of RCS pipe ruptures were considered for the reactor cavity analyses. Pipe ruptures for Unit 2 were postulated using the criteria and methods described in the Combustion Engineering topical report on pipe breaks, CENPD-168, Revision 1. The calculations described in CENPD-168, Revision 1, were performed utilizing the support and restraint characteristics of Unit 2.

A. 100 sq. in. Hot Leg Circumferential Break

B. 200 sq. in. Cold Leg Circumferential Break

The steam generator subcompartment analyses consider the following breaks:

A. 5.90 sq. ft. Hot Leg Circumferential Break

B. 5.77 sq. ft. Hot Leg Slot Break (Side)

C. 9.82 sq. ft. Cold Leg Pump Suction Circumferential Break

D. 3.93 sq. ft. Cold Leg Pump Suction Slot Break (Side-East Orientation)

E. 3.93 sq. ft. Cold Leg Pump Suction Slot Break (Side-West Orientation)

F. 9.82 sq. ft. Cold Leg Pump Discharge Circumferential Break

Mass and energy release rates for these breaks are presented in Table 6.2-17D.

For the biological shield pipe penetration compartment, the design basis pressure transients are calculated using the cold leg pump discharge and hot leg slot breaks, assuming that all of the blowdown mass and energy are released into the penetration compartment.

The pressurizer is located in the south steam generator compartment on a concrete slab. It does not have a compartment per se and thus the limiting break for design conditions are the double ended hot leg rather than the pressurizer spray or surge lines. The main steam lines are located above the secondary shield wall and thus blow down into the containment rather than into an identifiable subcompartment. No other high energy lines contain sufficient energy to create subcompartment differential pressures which are more limiting than the lines already discussed.

The differential pressure analyses for the reactor and steam generator cavities are performed according to the analysis model described in Section 6.2.1.2.3.2. The analysis described in Section 6.2.1.2.3.2 was used to establish the original design criteria for the primary and secondary shield walls that compose the reactor and steam generator cavities. A subsequent analysis (to evaluate the permanent installation of floor grating) for the steam generator cavities has been performed according to the analysis model described in Section 6.2.1.2.3.2.1. The analysis of the LOCA establishes the requirements for the internal containment design, specifying the capability to withstand the postulated ruptures and release of the reactor coolant

and associated energy sources without exceeding the design conditions. Subcompartment venting and pressure communication is used to ensure that pressure differentials developed will remain below the structural capability of the compartment walls.

Design structural loads are established with the combination of subcompartment peak differential pressure loading and jet forces calculated in accordance with Bechtel Topical Report, BN-TOP-2, Revision 2.

The theoretical mass and energy release rates that establish the design of these internal containment subcompartments were supplied by Combustion Engineering. The blowdown code used to provide mass and energy release data for the subcompartment analysis was CEFLASH-4. The CEFLASH-4 code is described in Reference 17. In CEFLASH-4, the discharge mass and energy release rate through the reactor coolant pipe break was separately determined for the subcooled and saturated critical flow regimes. Subcooled critical flow was determined from an extrapolation of Moody's results (Reference 57). The Henry/Fauske correlation for subcooled flow was not used. Critical flow during saturated (2-phase) blowdown was determined from an interpolation of tabular values of flow vs. pressure and enthalpy as determined by Moody.

A comparison of predicted break mass flow rates using a CEFLASH-4 model of the LOFT semi-scale loop for Test 823 and actual experimental break mass flow rates for Test 823 is presented in Figure III-10 of Reference 17. This figure shows that CEFLASH-4 slightly over predicted the mass and energy release rate at the break when a discharge coefficient of 0.6 was employed in the model. In order to ensure that the mass and energy release data for the Unit 2 subcompartment analysis would be conservative, a break discharge coefficient of 1.0 was used in the CEFLASH-4 model of the Unit 2 RCS.

Evaluation of the reactor vessel supports is based on a method for developing mass and energy release rates which differs from that described in the previous paragraphs. The release rates were generated from a modified version of the CEFLASH-4 computer code. One modification was made: The combination Henry-Fauske/Moody critical flow subroutine of the CEFLASH-4A computer code, described in CESSAR Section 6.2.1.1-4 was incorporated. Release rates for the reactor vessel supports analysis were obtained from this critical flow subroutine. Subcooled and low quality fluid blowdown rates were predicted by the Henry-Fauske correlation while the remainder of the 2-phase region flows was obtained from Moody. A flow discharge coefficient of 1.0 was used throughout.

Subcompartment differential pressures were calculated using the COPDA code. COPDA is described in Section 6.2.1.2.3.2. Initial conditions for each compartment were assumed to be the same as those used in the containment peak pressure analysis (see Table 6.2-8). The mass and energy release data supplied by Combustion Engineering is provided in Table 6.2-17D.

Subcompartment differential pressures were calculated using the COMPARE code to evaluate the effects of leaving floor grating installed at the top of the steam generator cavities at elevation 426′ 6″. The initial pressure and temperature for each compartment is assumed to be the same as those used in the containment peak pressure analysis (see Table 6.2-8). The relative humidity value for each compartment that is used in the COMPARE code analysis is conservative when compared to the same value stated in Table 6.2-8. The mass and energy release data supplied by Combustion Engineering is provided in Table 6.2-17D.

6.2.1.2.3.2 Containment Subcompartment Pressure Transient Analysis Model

Generally, the occurrence of a LOCA is postulated to result from a rupture of the RCS piping within subcompartments of the containment. A pipe rupture of this type results in the expulsion of high enthalpy water out of the ruptured pipe, flashing partly to steam. As the pressure builds up within the compartment, the steam-air-water mixture flows through openings into the main volume of the containment. The maximum differential pressure achieved between the compartments determines the design strength requirements of walls and supports between the compartments, and the forces exerted upon the RCS and containment equipment. The maximum pressure differential developed depends on the number and shape of the openings between the compartment, the volume of each compartment, and the blowdown rate from the broken pipe.

The following multi-compartment analysis technique (i.e., COPDA code) was developed to study the pressure transients in cavities and/or compartments inside and outside of the containment resulting from the depressurization of the primary coolant, steam and feedwater systems. The analysis is based on the solution of the conservation equations for mass and energy, the continuity equation and the equation of state for water.

The analysis permits the selection of the control volume and flow path configuration that results in the best representation of the pressure transients in the compartments along the flow paths from the break to the containment of the atmosphere. During each calculation-time-increment the time dependent blowdown data is added to the compartment containing the rupture. The conservation equations and the state equations for water are solved to determine the stagnation properties in the compartment. The momentum equation is then solved for each flow path to each connected compartment. The conservation and state equations are again solved to determine the compartment state conditions for the beginning of the next time increment.

The reactor vessel cavity modeling geometry depicting the nodal volumes and their boundary relationships are given in Figure 6.2-3C and 6.2-3J. Figures 3.8-13, 3.8-13a, 3.5-15, and 5.5-12 provide structural and component support details of the reactor pressure vessel cavity. The flow areas and flow coefficients used in the reactor vessel cavity analysis are given in Table 6.2-17B.I. The steam generator cavity modeling geometry depicting the nodal volumes and their boundary relationships are given in Figures 6.2-3D through 6.2-3I. Figures 3.8-13, 3.8-13a, 5.5-13, and 6.2-3K provide structural and component support details of the steam generator cavities. The flow areas and flow coefficients used in the steam generator cavity analysis are given in Table 6.2-17B.II. The biological shield wall piping penetrations nodal volumes are given in Table 6.2-17C. The flow areas and flow coefficients used in the biological shield wall analysis are given in Table 6.2-17B.III.

The procedure is repeated in sequence for each compartment except that the flow from the upstream compartments replaces the blowdown.

A. Initial Compartment Conditions

The masses of air and water as steam in the compartments are determined using the initial conditions of temperature, pressure, relative humidity and compartment volumes. The compartment specific humidity is obtained by:

$$SH = (RH)(SSH) \qquad (6.2\text{-}11a)$$

where

SH = specific humidity of compartment air, lbm steam/lbm air

RH = relative humidity of compartment, air

SSH = specific humidity of saturated air at compartment temperature, lbm steam/lbm air

The vapor pressure of the water is determined by:

$$PW = \frac{(SH)(PT)}{0.623 + SH} \qquad (6.2\text{-}11b)$$

where

PW = vapor pressure of water at compartment temperature, psia

PT = total compartment pressure, psia.

The air pressure (PA) in the compartment is determined by:

$$PA = PT - PW \qquad (6.2\text{-}11c)$$

The mass of air (MA) in each compartment is evaluated using the perfect gas law equation:

$$MA = \frac{144(PA)(V)}{(R/n)(T)} \qquad (6.2\text{-}11d)$$

where

V = volume of compartment, cu. ft.

R = gas constant, 1545.3

T = compartment temperature, °F

n = molecular weight of air, 28.97 lbm/lb-mole

The mass of water (MS) in the compartment is:

$$MS = (MA)(SH) \qquad (6.2\text{-}11e)$$

The energy of the air (UA) in each compartment (I) is calculated, using 0 °F as a base, by the equation:

$$UA(I) = (CV)(MA(I))(TP)$$

where

CV = specific heat of air at constant volume, 0.171 Btu/lbm-°F

TP = compartment temperature, °F

The energy of the water vapor (US) in each compartment (I) is calculated by the equation:

$$US(I) = [MS(I)](UG) \qquad (6.2\text{-}11g)$$

where

UG = internal energy of the steam evaluated from the saturated steam tables at the compartment temperature.

B. Conservation of Mass and Energy in Compartments

The inventory of the total mass and energy in the compartments is maintained from the inlet and exit flows during each time increment by the following equations:

$$MA(I) = \sum^{N}|MAI| - \sum^{N}|MAO| + MA'(I)$$

$$MW(I) = \sum^{N}|MWI| - \sum^{N}|MWO| + MW'(I)$$

$$MS(I) = \sum^{N}|MSI| - \sum^{N}|MSO| + MS'(I)$$

$$MV(I) = MW(I) + MS(I) \qquad (6.2\text{-}11h)$$

$$MT(I) = MV(I) + MA(I)$$

$$UA(I) = \sum^{N}|UAI| - \sum^{N}|UAO| + UA'(I)$$

$$UW(I) = \sum^{N}(HI|MWI|) - \sum^{N}(HO|MWO|) + UW'(I)$$

$$US(I) = \sum^{N}(HGI|MSI|) - \sum^{N}(HGO|MSO|) + US'(I)$$

$$UV(I) = UW(I) + US(I)$$

$$UT(I) = UV(I) + UA(I)$$

where

MW(I) = mass of water in compartment (I), lbm

MV(I) = mass of water and steam in compartment (I), lbm

MT(I) = total mass in compartment (I), lbm

MAI = mass of air entering compartment, lbm

MAO = mass of air leaving compartment, lbm

MWI = mass of water entering compartment, lbm

MWO = mass of water leaving compartment, lbm

MSI = mass of steam entering compartment, lbm

MSO = mass of steam leaving compartment, lbm

UAI = total energy of air entering compartment, Btu

UAO = total energy of air leaving compartment, Btu

HI = enthalpy of water entering compartment (I), Btu/lbm

HO = enthalpy of water leaving compartment (I), Btu/lbm

HGI = enthalpy of steam entering compartment (I), Btu/lbm

HGO = enthalpy of steam leaving compartment (I), Btu/lbm

UA(I) = energy in air in compartment (I), Btu

UW(I) = energy in water in compartment (I), Btu

US(I) = energy in steam in compartment (I), Btu

UV(I) = energy in vapor in compartment (I), Btu

UT(I) = total energy in compartment (I), Btu

Primed (′) values refer to end of previous time step; all other values refer to current time step. N is equal to the total number of compartments used in the analysis. Essentially, an almost infinite number of compartments can be specified.

C. Compartment Pressure Calculations

The compartment pressure is calculated using the total mass and energy in the compartment after the flow from the upstream compartment and/or the blowdown has been added to the compartment inventory of mass and energy. A convergence procedure is used to arrive at the equilibrium thermodynamic conditions in the compartment using temperature as the search argument. The equilibrium thermodynamic state is considered to be determined when the search temperature provides properties such that the ratio of the difference between the trial energy balance and the energy inventory is less than 0.001. The state properties of the steam and water mixture at the search temperature are obtained from the saturation tables. The mass of steam is then determined by:

$$MS = [V-(MW)(VL)]/(VG) \qquad (6.2\text{-}11i)$$

where

V = volume of compartment, cu. ft.

VL = specific volume of water, cu. ft./lbm

VG = specific volume of steam, cu. ft./lbm.

The mass of water (MW) is determined by:

$$MW = MV - MS \qquad (6.2\text{-}11j)$$

A trial energy balance (ETRIAL) is calculated:

$$ETRIAL = (MS)(UG) + (MW)(UL) + (MA)(0.171)(TP) \qquad (6.2\text{-}11k)$$

The procedure is repeated varying the value of the compartment temperatures (TP) until the relation:

$$(UT - ETRIAL)/UT \leq 0.001$$

is satisfied.

If after establishing the thermodynamic equilibrium conditions MW $\leq$ 0, the compartment is considered to be superheated. The equilibrium conditions are recalculated by setting the steam mass equal to the vapor mass and calculating the steam pressure at the search temperature by:

$$PS = 0.5961(MS)(T/V) \qquad (6.2\text{-}11l)$$

where

PS = pressure of steam, psia

T = compartment search temperature, °F

V = compartment volume, cu. ft.

0.5961 = R/(mole weight)(144) = 1545.3/(18)(144)

The internal energy of the steam at the pressure and temperature is obtained from the superheat tables and a trial energy balance calculated by:

$$ETRIAL = (MS)(UG) + (MA)(0.171)(TP) \qquad (6.2\text{-}11m)$$

The procedure is repeated varying the value of TP until the relation:

$$(UT - ETRIAL)/UT \leq 0.001$$

is satisfied.

The total pressure in the compartment is the sum of the steam pressure and the air pressure (PA) with the latter being calculated by:

$$PA = (MA)(TP + 459.688)(0.37/V) \qquad (6.2\text{-}11n)$$

where

0.37 = R/(mole weight)(144) = 1545.3/(28.97)(144)

D. <u>Flow Calculation</u>

A compressible fluid flow equation is used for the analysis of compartment pressures.

In the application of the compressible fluid flow equation, the flow is considered to be critical if the ratio of the pressure in the downstream compartment (Compartment 2) to the pressure in the upstream compartment (Compartment 1) is less than RC as obtained by:

$$RC = \left[\frac{2}{1+K}\right]^{\frac{K}{K-1}} \qquad (6.2\text{-}11o)$$

where K is the isentropic exponent for the air, steam and water mixture leaving the compartment. K is calculated by:

$$K = (KGF)\frac{PS(I)}{PT(I)} + (KA)\frac{PA(I)}{PT(I)} \qquad (6.2\text{-}11p)$$

where

KA = isentropic value of K for air of 1.4

KGF = isentropic value of K for steam-water mixture

PS(I) = steam pressure in Compartment I, psia

PT(I) = total Compartment I pressure, psia

PA(I) = air pressure in Compartment I, psia

The form of the flow equation is:

$$G = \left\{(g_c)(K)(P1)(RHO1)\left(\frac{2}{K+1}\right)^{\frac{K+1}{K-1}}\right\}^{1/2} \qquad (6.2\text{-}11q)$$

where

RHO1 = MT(I)/VOL(I), lbm/cu. ft.

VOL(I) = volume of Compartment I

P1 = Compartment 1 pressure, psia

g_c = acceleration of gravity, 32.174 ft/sec^2

If the flow is subcritical, the form of the flow equation is:

$$G = \left\{\frac{2(g_c)(P1)(RHO1)(K)\left(R^{2/K} - R^{K+1/K}\right)}{K-1}\right\}^{1/2} \qquad (6.2\text{-}11r)$$

where

G = mass flow, lbm/sq. ft-sec.

R = P2/P1

P2 = Compartment 2 pressure, psia

The mass flow from Compartments 1 and 2 is calculated by:

total:	MF	=	(G)(A)(C)	(6.2-11s)
air:	MAF	=	(MF)[MA(I)/MT(I)]	
water:	MWF	=	(MF)[MW(I)/MT(I)]	
steam:	MSF	=	(MF[MS(I)/MT(I)]	

where

A	=	area of flow path, sq. ft.
C	=	coefficient calculated external to the code
MF	=	total flow mass, lbm/sec
MAF	=	air flow mass, lbm/sec
MWF	=	water flow mass, lbm/sec
MSF	=	steam flow mass, lbm/sec

The energy transferred by the flow (Btu) is calculated by:

air:	UAF	=	(MAF)(CP)[TC(I)]	(6.2-11t)
water:	UWF	=	(MWF)(HL)	
steam:	USF	=	(MSF)(HG)	

where

UAF	=	air flow energy, Btu
UWF	=	water flow energy, Btu
USF	=	steam flow energy, Btu
TC(I)	=	compartment temperature, °F
CP	=	specific heat of air at constant pressure, Btu/lbm °F
HL	=	enthalpy of water at compartment temperature, Btu/lbm
HG	=	enthalpy of steam at compartment temperature, Btu/lbm

The COPDA code has the Moody critical, 2-phase flow model as an optional vent flow calculation technique. This technique is discussed and justified in References 57 and 58. The Moody option was used for the biological shield penetration analysis discussed in Section 6.2.1.2.2.

E. Flow Coefficients

Two methods of determining flow coefficients were used in the subcompartment analyses described in Section 6.2.1.2.2. These are:

A. Incompressible flow theory coefficients; and,

B. Compressible orifice equations.

In general, incompressible flow theory is applicable when compressibility effects are unimportant (local Mach number, $M_L \leq .3$). For cases where flow is critical or near-critical at the exit of a subcompartment, compressibility effects become important and must be considered in determining flow coefficients.

The determination of loss factors from incompressible flow theory is well understood and documented. These loss factors have been determined by both analytical derivation (Reference 70) and by experiment (Reference 21). The factors are related to the pressure drop through a given flow region by $\Delta P = \Sigma_i 1/2\ K_i\ V^2$ where ΔP = pressure loss, $\Sigma_i\ K_i$ = sum of loss factors, and V = fluid velocity. This can be related to a flow coefficient by using the incompressible Bernoulli equation obtaining $C=1/(\Sigma_i\ K_i)^{1/2}$. The incompressible loss factors used in these subcompartment analyses were obtained from References 21 and 52.

As discussed above, the critical flow regime requires consideration of compressibility effects on flow coefficients. This is primarily manifested in the reduction of the vena contracta effect and corresponding increase in flow coefficients. This has been analytically and experimentally determined by a number of investigators including Buckingham (Reference 43), Cunningham (Reference 45), Perry (Reference 62), and Sozzi (Reference 71). The relations obtained by Cunningham (Reference 52) for critical and subcritical sharp edged orifices have been programmed into the COPDA computer code and are used for critical and near critical vent flows in these analyses. These equations yield a flow coefficient (c) in the range of 0.85 for paths experiencing critical flow and 0.61 for subcritical flow.

A basic COPDA assumption is that the fluid velocities in the compartment are small when compared with the fluid velocities in the vents. Under these circumstances the inertial effects are negligible in comparison with the other ″losses″ in the system. In general, inertial effects are not important when the ratio of the subcompartment cross-sectional area is four-to-one or greater. Also, these effects are negligible when differential pressures are 20 psid or greater. Where the exit losses are small and the flow is incompressible the COPDA type analysis must be modified to include inertial effects. Therefore, consistent with the basic COPDA assumptions, the inertial effects are not considered in this analysis.

6.2.1.2.3.2.1 Steam Generator Subcompartment Reanalysis

The steam generator cavities have the provision for installing grating at the top of the cavities on elevation 426′6″. The analysis described in Section 6.2.1.2.3.2 and associated results as shown in Tables 6.2-17A.II.a through 6.2-17A.II.f and Figures 6.2-16G through 6.2-16L did not account for the effects of having this grating installed. A subsequent analysis using the COMPARE computer code as the analysis tool was performed to determine the acceptability of having the grating installed on elevation 426′6″.

Generally, the occurrence of a LOCA is postulated to result from a rupture of the RCS piping within subcompartments of the containment prior to LBB considerations. A pipe rupture of this type results in the expulsion of high enthalpy water out of the ruptured pipe, flashing partly to steam. As the pressure builds up within the compartment, the steam-air mixture flows through openings into the main volume of the containment. The maximum differential pressure achieved between the compartments determines the design strength requirements of walls and supports between the compartments and the forces exerted upon the RCS and containment equipment. The maximum pressure differential developed depends on the number and shape of the openings (i.e., vents) between the compartments, the volume of each compartment, and the blowdown rate from the broken pipe.

The COMPARE computer code has provision for the transient calculation of conditions in a system of volumes connected by vents. Each volume is assumed to contain the stagnant homogeneous mixture of steam, air and water that will typically exist within a subcompartment during the course of a high energy line break (HELB) transient.

A quasisteady-state approximation, with a correction for fluid inertia effects, is used to represent the transient processes. Mass and energy inflow or outflow accounting, for each volume, is first accomplished for the particular time increment, assuming vent flows are constant.

Thermodynamic equilibrium is then assumed and state points determined. The resulting volume thermodynamic conditions are assumed to be constant and are used to calculate the new vent flows from or into volumes for the next time interval. This approach allows the transient to be calculated in an explicit manner without iteration or implicit matrix solution techniques.

6.2.1.2.3.2.1.1 <u>Method of Analysis</u>

A. Time Incrementation

The time increment is selected based on the rate change of a parameter (i.e., volumetric pressure). A rapidly changing pressure requires a smaller time increment so that a more adequate accounting for the effect of pressure (i.e., on vent flow) is obtained. The time increments utilized in the SG cavity COMPARE analysis are appropriate for the specified time intervals.

B. Volume Mass and Energy Changes

The COMPARE code accounts for mass and energy addition to a volume due to the blowdown from the postulated HELB. The code uses blowdown input data of water mass addition rate and water energy addition rate data points vs. time. The mass and energy addition rates vs. time are numerically integrated over the applicable time interval. The data used in the COMPARE analysis is found in Table 6.2-17D VIII.

C. Volume Thermodynamics

The COMPARE code treats each volume as though it were quasistatic which allows the volume mass and energy inventories, as affected by vent flow and blowdowns, to be taken. The thermodynamic state points, i.e., pressure and temperature, are then determined from the resulting specific internal energy and density of each volume.

6.2.1.2.3.2.1.2 Steam Generator Subcompartment Reanalysis Model

The steam generator cavity model used in the COMPARE analysis consists of 22 volumes with 52 junctions. Each steam generator cavity is divided into the following three regions:

Region	From Elevation	To Elevation	Description
Lower	336′6″	366′8″	This region is from the floor of the steam generator cavity to the top of the steam generator support pedestal.
Middle	366′8″	397′6″	This region is from the top of the steam generator support pedestal to the elevation where the SG cavity narrows.
Upper	397′6″	426′6″	This region is from the elevation where the SG cavity narrows to the top of the SG cavity wall.

The steam generator cavity modeling geometry showing the nodal volumes and their relationship is given in Figures 6.2-3L through 6.2-3N. The figures identify the physical obstructions which were used to determine the volume boundaries.

The subcompartment analysis for the SG cavities (Figure 6.2-3I) used in the original evaluation (SAR Section 6.2.1.2.3.2) only modeled volumes in the south SG cavity with containment being the remaining volume.

The major differences between the original COPDA model and the COMPARE model are as follows:

- The north SG cavity is modeled as volumes in the analysis. This is justified since there are passageways that provide a flow path between the north and south cavities thereby causing the north cavity to become pressurized during the HELB transient.

- The annular region around the SG cavities (i.e., between the outer SG cavity walls and the containment building) is modeled as a separate volume.

- The containment region above the top of the SG cavity walls (>elev. 426′6″) is modeled as a separate volume.

The 22 volume model is considered a more representative model for purposes of evaluating the pressure effects due to a HELB occurring in the south SG cavity.

6.2.1.2.3.2.1.3 Steam Generator Subcompartment Reanalysis Results

Steam Generator Cavity Wall Differential Pressure

The results of the steam generator cavity subcompartment pressure transient analysis using the COMPARE code and revised steam generator cavity models are that the original design criteria for the cavity walls (Table 6.2-17) is met with the grating installed on elevation 426′6″ of the cavity walls. The calculated differential pressures between the internal steam generator cavity

volumes and the surrounding containment building annulus is shown in Table 6.2-17A.IV. The peak pressures vs. time for the south steam generator cavity volumes are shown in Figure 6.2-16P. Since the maximum differential wall pressures are found in the south steam generator cavity, the peak pressures vs. time for the north cavity will not be depicted.

Steam Generator Cavity Grating

The pressure values calculated for the various volumes using the COMPARE code were converted to uplift forces that would be experienced by the cavity grating during a HELB. The grating at the top of the SG cavities (Elev. 426′6″) is restrained to prevent the grating from lifting and possibly causing damage to the containment liner or other equipment/structures during a HELB. This grating should be maintained in a restrained condition when the plant is at power operations or when the possibility of a HELB exists.

6.2.1.2.3.2.2 Reactor Vessel Cavity Permanent Seal Plate Modification

A modification to the reactor cavity seal plate was completed during 1996. This modification was completed without reanalyzing the effects of RCS pipe breaks within the reactor vessel cavity but was justified using approved leak before break (LBB) methodology as described in CEN-367-A. The ability to reference the LBB topical report precludes the need to protect against the dynamic effects associated with the postulated rupture of piping (i.e., subcompartment pressurization). Also, during normal operation, the hatch covers will be removed, providing ventilation for the region below the seal plate and there are no subcompartment pressurization concerns for the refueling conditions when the hatch covers are in place.

6.2.1.2.3.2.3 Steam Generator Replacement

Steam generator replacement took place during 2R15. This modification was completed without reanalyzing the effects of RCS pipe breaks within the steam generator cavities. This was justified using approved leak before break (LBB) methodology as described in CEN-367-A. For the SG compartments, the original energy releases used in the analyses were based on an assumed 9.82 ft^2 cold leg RCS pump discharge circumferential break. This release was associated with the worst case failure of RCS main coolant loop piping. LBB capability eliminates consideration of those pipe ruptures associated with catastrophic failure of RCS main coolant loop piping, however, piping attached to the RCS main coolant loop was considered. New mass and energy release calculations were performed for the steam generator replacement. Mass and energy releases used in the current SG compartment analysis based on RCS main coolant loop failure conservatively bound the mass and energy release calculated using LBB assumptions. Therefore, the original steam generator subcompartment pressurization analysis bounds the design condition after SG replacement and power uprate. The previous descriptions pertaining to the subcompartment analysis for the steam generator cavities describe the analysis completed prior to the aforementioned modifications.

6.2.1.3 Tests and Inspections

This section provides information about the program of testing and inspection of the containment systems with regard to preoperational and post steam generator replacement testing and inservice surveillance to ensure continued integrity.

6.2.1.3.1 Preoperational Testing

The ¼-inch steel liner plate forms the barrier to prevent leakage from the containment. All penetrations were continuously welded to the liner before the concrete was placed. Leak chase channels were installed on those liner plate seams where the liner plate is not readily accessible for inspection. The leak chase channels provide a means of leak testing inaccessible liner plate seams when access to the liner plate is blocked by interior concrete. No continuous leakage monitoring system is provided.

The steel liner plate is securely attached to the prestressed concrete containment and is an integral part of this structure. This containment is conservatively designed and rigorously analyzed for the extreme loading conditions of a DBA as well as for all other types of loading conditions that could be experienced. Thorough control was maintained over the quality of all material and workmanship during all stages of fabrication and erection of the liner plate and penetrations and during construction of the entire containment.

After the containment was completed, and all electrical and piping penetrations, equipment hatch, and personnel locks in place, the preoperational integrated leak test was performed. The containment was tested at 115 percent of the design pressure to prove structural integrity. The preoperational integrated leakage rate tests were conducted at design and reduced test pressures so that the reduced pressure test program can be used for subsequent periodic testing.

The design leak rate is not more than 0.1 percent by volume of the contained atmosphere in 24 hours at 54 psig. It has been demonstrated that, with good quality control during erection, this is a reasonable requirement.

All penetrations except the following are grouped in a few penetration areas:

A. Permanent equipment hatch

B. Personnel access lock

C. Main steam and feedwater lines

D. Emergency personnel lock

E. Containment purge lines

The following guidelines were in place during the test: Should there be any indications of abnormal leakage, the source of excessive leakage will be located and such corrective action as necessary will be taken. This will consist of repair or replacement. Appropriate action will also be taken to minimize the possibility of the recurrence of excessive leakage, including such redesign as might prove to be necessary to protect public health and safety. Leak testing will be continued until a satisfactory leak rate has again been demonstrated.

The integrated leakage rate test can be performed at design pressure any time during the plant life, if required, providing that the enclosed systems have been prepared for test.

A considerable background of operating experience is being accumulated on containments and penetrations. Full advantage of the knowledge was taken in all phases of design, fabrication, installation, inspection, testing, and operation. Practical improvements in design and details were incorporated as they were developed, where applicable.

For the foregoing reasons, it is concluded that a continuous leakage monitoring system is unnecessary. Since there is no such system provided, there can be no misoperation or malfunction which in itself might constitute a hazard. The steel-lined containment is self-sufficient, and, other than valves, locks and a hatch door, there are no operating parts. The containment boundary is extended only by penetrations that are further described and listed in Section 6.2.4.

Preoperational containment integrated leakage rate tests and local leakage rate tests were conducted in accordance with Appendix J to 10 CFR 50, ″Reactor Containment Leakage Testing for Water Cooled Power Reactors,″ and References 24 and 35.

6.2.1.3.2 Post Steam Generator Replacement Testing

Following completion of the repair of the containment construction opening after replacement of the original steam generators, the restored containment was subjected to a post-repair/pre-service structural integrity test (SIT) and an integrated leak rate test (ILRT).

6.2.1.3.3 Inservice Surveillance

Periodic containment integrated leakage rate tests and local leakage rate tests are conducted in accordance with Appendix J to 10 CFR 50, “Reactor Containment Leakage Testing for Water Cooled Power Reactors,” and ANSI/ANS-56.8-2002, “Containment System Leakage Testing Requirements.” The test frequency for integrated and local leakage rate tests, the test methods used including sensitivity analysis, the requirements for the acceptability of observed performance and the bases for them, and the action to be taken in the event acceptability requirements are not met are defined and are in accordance with the above listed references. Additionally, if at any time it is determined that the acceptance criteria defined in the Technical Specifications and in 10 CFR 50, Appendix J, are exceeded, repairs shall be initiated immediately.

Containment isolation systems are discussed in Section 6.2.4. All containment penetrations have been provided with test vents and test connections to permit periodic testing of the isolation valves. Where plant operation is not interfered with, local testing of the containment penetration is permitted. The methods of testing and the degree of conformance to Appendix J of 10 CFR 50 are discussed in Section 6.2.4.

6.2.1.4 Instrumentation Application

The containment atmospheric pressure is continuously monitored by four pressure transmitters located inside the containment. The ESF actuation design details and logics associated with these pressure transmitters are discussed in Chapter 7.

Instrumentation also monitors other parameters of the containment atmosphere to identify pressure boundary leakage in the RCS. The leakage detection system is discussed in Section 5.2.7.

Airborne radiation inside the containment is monitored by the containment monitoring system. This system is also discussed in Section 5.2.7.

Liquid level indication is provided in the containment recirculation sump and is discussed in Section 6.2.2.

6.2.1.5 Assurance of Operational Readiness

Established preoperational tests and inservice surveillance techniques are used to ensure that the containment systems will operate in the manner required if called upon. The containment leak rate tests and associated containment integrity test procedures are discussed in Section 6.2.1.3. The CHRS test and inspection procedures are discussed in Section 6.2.2.4. The operational integrity of the CISs is discussed in Section 6.2.4. In addition, each active containment system is composed of two or more trains, each of which is capable of meeting at least 100 percent of the required operational capacity for that system. The means by which a system achieves this functional redundancy is described in the system design for each ESF.

6.2.2 CONTAINMENT HEAT REMOVAL SYSTEMS

The functional performance objective of the CHRSs is to rapidly reduce the containment pressure and temperature after a postulated LOCA or Main Steam Line Break (MSLB) accident by removing thermal energy from the containment atmosphere. This function is performed by the Containment Spray System (CSS) and the Containment Cooling System (CCS). The CHRSs also assist in limiting off-site radiation levels by reducing the pressure differential between the containment atmosphere and the outside atmosphere, thereby reducing the driving force for leakage of fission products from the containment. These radiological evaluations are reported in Chapters 11 and 15. The CHRSs meet the requirements of GDC 38 as described in Section 3.1.4.

6.2.2.1 Design Bases

The CHRSs are designed to rapidly reduce the containment pressure and temperature following a LOCA or MSLB, and maintain these parameters at acceptably low levels as required by General Design Criterion 38. The sources and amounts of energy released to the containment which were used as the basis for the sizing of the CHRS are given in Section 6.2.1.

The CHRS are designed so that either of the following combinations of equipment will provide adequate heat removal to attenuate the post-accident pressure and temperature conditions imposed upon the containment following a LOCA or MSLB:

A. both trains of the CSS; or,

B. one train of CSS and one train of CCS.

The CSS also provides for iodine removal from the containment atmosphere by a combination of boric acid spray and a buffered pH solution. Therefore, at least one CSS must operate following a LOCA.

6.2.2.1.1 Containment Spray System

The CSS, shown in Figure 6.2-17, is designed to spray borated water into the containment in the event of a LOCA in order to suppress any resultant increase in containment pressure and temperature. The system is also designed to recirculate a buffered pH solution consisting of a combination of boric acid spray and Sodium Tetraborate (NaTB). The recirculation of this solution through the CSS is designed to reduce fission product iodine concentration in the containment atmosphere. This solution will retain the fission products in the containment sump water and thereby considerably reduce the potential of fission product leakage to the environs.

The heat removal capacity of the flow from the two pumps provided is adequate to keep the containment pressure and temperature below design conditions for any size break in the RCS piping up to and including a double ended slot break of the reactor coolant pump suction pipe. Adequate quantities of buffering agent are mixed with the boric acid spray creating a buffered pH solution. This solution is recirculated through the CSS to reduce the airborne concentrations of radioactive forms of iodine, and to retain these in the containment sump.

Additionally, the system is designed such that a single failure of any active component will not degrade the system's ability to fulfill these design objectives.

The CSS is designed to Seismic Category 1 requirements. System components as appropriate are designed to meet ASME Code Section III Class 2 requirements.

6.2.2.1.2 Containment Cooling System

The CCS, shown in Figure 9.4-4, is designed to support the operation of the CSS to remove sufficient heat energy from the containment atmosphere following a postulated LOCA or MSLB accident to maintain the containment atmosphere pressure below design pressure. Section 6.2.1, Containment Functional Design, provides the assumptions as to the sources and amounts of energy considered in the analyses of the containment pressure transient following a LOCA or MSLB inside containment.

The CCS consists of two redundant trains with two air cooler units per train. Each train is designed to meet and exceed the heat removal capacity assumed in the safety analysis. The safety analysis assumptions are presented in Table 6.2-8I.

The system is designed such that a single failure of any component will not degrade the CHRS containment heat removal capability. The remaining heat removal capacity would be fulfilled by the two operating CSS loops.

The system is designed to Seismic Category 1 requirements.

6.2.2.2 System Design

Individual descriptions of each CHRS follow.

6.2.2.2.1 Containment Spray System

A. General Description

A flow diagram of the CSS is shown in Figure 6.2-17.

The CSS consists of two separate loops of equal capacity and is independently capable of meeting CHRS requirements. Each loop consists of a containment spray pump, shutdown cooling heat exchanger, spray header, isolation valves, and the necessary piping, instrumentation and controls. The loops are supplied with borated water from a common Refueling Water Tank (RWT).

Upon system activation, the containment spray pumps are started and deliver boric acid to the respective spray headers. The spray headers are located at the highest possible level in the containment to maximize heat and iodine removal. Each header conforms to

the shape of the containment dome. Figures 6.2-18 and 6.2-19 show details of the spray headers. The headers are located outside of and above the movable missile shield, and contain 131 spray nozzles each. During normal plant operation CSS piping is maintained full of water from the RWT to Elevation 505 feet, 0 inches (minimum) in the 6-inch diameter risers within containment. When low level is reached in the RWT, the Recirculation Actuation Signal (RAS) automatically transfers the containment spray pump suction to the containment sump by opening the recirculation line valves and closing the RWT outlet and pump minimum flow recirculation valves.

During the injection mode, prior to the start of recirculation, each spray train will deliver a minimum flow of 1875 gpm. At the start of recirculation, with suction from the containment sump, minimum spray flow increases to the nominal design minimum of 2,000 gpm.

Following the switchover of suction to the containment sump, the sump solution will contain boric acid and buffering agent. This mixture of boric acid and buffering agent will continue to remove post-accident energy and remove and retain fission product iodine as it is recirculated through the CSS. The buffering agent is stored in three containers constructed with wire mesh sides which allow the sprayed fluid to permeate the containers. These containers will become submerged in the sprayed fluid accumulating in the building allowing the buffering agent to dissolve. The buffering agent is used to raise the pH of the sump fluid to an equilibrium pH of 7.0 or greater. A pH of 7.0 or greater will assure that the iodine washed out of the reactor building atmosphere by the spraying action will not re-evolve from the liquid as it is sprayed back into the building.

In the recirculation mode, the spray water is cooled by the shutdown cooling heat exchangers prior to discharge into the containment. The shutdown cooling heat exchangers are cooled by the SWS which is described in Section 9.2.1.

All components of the system which come in contact with the system fluid are made of stainless steel to minimize the corrosive effects of the acid and caustic solutions present.

B. Component Descriptions

1. Containment Spray Pumps (2P35A, B)

The two containment spray pumps are vertical centrifugal pumps driven by direct coupled induction motors. Each pump is rated for 2,200 gpm flow at a head of 525 feet. Each pump will provide the flow necessary to remove in excess of 120 million Btu/hr from the containment following a LOCA. The characteristics of the pumps are shown in Figure 6.2-20 and pump design data are summarized in Table 6.2-18. The pumps are located at an elevation of 317 feet, 0 inches in the auxiliary building.

System design ensures compliance with the pump Net Positive Suction Head (NPSH) requirements of Regulatory Guide 1.1.

The sump inventory is considered subcooled when sump temperature is below saturation temperature corresponding to the minimum Technical Specification (TS) allowed containment pressure. When sump temperature is above the saturation temperature corresponding to the minimum TS allowed containment pressure the

containment pressure is set equal to the liquid vapor pressure ($h_a - h_{vpa} = 0$). No credit is taken for increased containment pressure as a result of accident conditions.

$$NPSH_a = h_a - h_{vpa} + h_{st} - h_L$$

h_a = absolute pressure in feet of liquid on the surface of the liquid level

h_{vpa} = the head in feet corresponding to the vapor pressure of the liquid at the temperature being pumped.

h_{st} = static height in feet that the liquid supply level is above or below the pump centerline or impeller eye.

h_L = all suction line losses in feet including entrance losses and friction losses through pipe, valves and fittings, etc.

The pumps are driven by 450 HP motors rated 4,000 volts, 3-phase for use on a 4,160-volt, 3-phase, 60-Hz resistance grounded wye system. The motors have open drip-proof or weather protected enclosures and are provided with Class F insulation. The motors have a 1.15 service factor.

Power to these motors is supplied from the 4.16 kV buses which are part of the Class 1E electrical system. Power supply availability to these buses during all modes of station operation is discussed in Chapter 8.

The pumps are provided with minimum flow recirculation lines which permit a flow of 200 gpm from each pump to recirculate back to the RWT through a common line during the injection mode of operation. The RAS automatically closes two motor operated valves arranged in series in the common minimum flow line.

2. Buffering Agent Containers

Three buffering agent containers are placed in the base of containment. These containers function as a means of containing and measuring the amount of buffering agent in containment prior to any LOCA or MSLB. The containers are constructed with mesh wire sides which allow fluids collecting in the base of containment to permeate the containers and dissolve the buffering agent. The buffering agent is used to raise the pH of the sump fluid to an equilibrium pH of 7.0 or greater. A pH of 7.0 or greater will assure that the iodine washed out of the reactor building atmosphere by the spraying action will not re-evolve from the liquid as it is sprayed back into the building.

3. Sodium Hydroxide Tank (2T10)

The sodium hydroxide tank, located in the containment auxiliary building at elevation 355 feet, 4 inches, is a 10,000 gallon capacity stainless steel tank containing 30 w/o sodium hydroxide solution. The tank is designed to meet Seismic Category 1 requirements.

Note: The NaOH Addition System has been decommissioned. 2T10 has been abandoned in place.

A ladder and manway are provided for internal inspection. A recirculation pump is provided to recirculate the tank solution prior to sampling, and to provide a filling and draining capability. The tank is vented to atmosphere.

The tank is provided with electric heaters with capacity in excess of that necessary to maintain the tank solution temperature above 50 °F and to provide protection against freezing for the tank as well as the vents. Heat tracing is included for additional freeze protection for the NaOH vents (0CAN068004).

4. Refueling Water Tank (2T3)

The RWT, located west of the containment auxiliary building at elevation 355 feet, 4 inches, is a 500,500 gallon capacity stainless steel tank containing a boric acid solution between 2500 and 3000 ppm boron. The tank was built to meet Seismic Category 1 requirements. Tank design data are summarized in Table 6.2-20. Tank level, temperature, and alarm instrumentation are discussed in Section 6.2.2.5.1.

The tank capacity is based on the requirement for filling the refueling canal and is in excess of the 384,000 gallons required for containment spray and safety injection during any postulated LOCA or MSLB. The minimum allowable level is provided in the Technical Specifications.

The tank is vented to atmosphere. A ladder and manway are provided for internal inspection.

Five electric immersion heaters are provided to maintain the tank liquid inventory above a temperature of 40 °F to prevent the boric acid from crystallizing out of solution. Three of the five heaters are required to maintain the tank liquid above 40 °F during the coldest expected ambient temperatures, providing protection against freezing for the tank as well as the vacuum vent. The tank is the only component essential to safe shutdown of the plant that is not housed within temperature controlled areas. Heat tracing is included as additional freeze protection for the RWT vent. (0CAN068004).

The RWT is built to the 1971 Edition of the ASME Boiler and Pressure Vessel Code, Section III, Class 2, including the Summer 1973 Addenda. However, the radiography for the first and second ring vertical seams, and the 1-2 and 2-3 girth seams of the tank is per the Summer 1974 Addenda of the 1974 Edition of the ASME Code. All other tank welds are radiographed per the 1971 Edition of the ASME Code, Summer 1973 Addenda.

5. Shutdown Cooling Heat Exchangers (2E35A, B)

The two shutdown cooling heat exchangers are located at Elevation 317 feet, 0 inches in the auxiliary building. They are of shell and U-tube design, with the cooling fluid being service water. The shutdown cooling heat exchangers are further described in Section 9.3.6. Historical design data for the shutdown cooling heat exchangers are given in Table 6.2-21.

The basis for selection of the tube side and shell side inlet temperature during the recirculation mode is given in Sections 6.2.1.1.4 and 9.2.1.3.

6. Containment Spray Nozzles

Each containment spray header contains 131 hollow cone ramp bottom nozzles, each of which is capable of a design flow of 15.2 gpm (approximately 2000 gpm per train) with a 40 psi differential pressure. These nozzles have an approximately 3/8-inch spray orifice and will not be subject to clogging by particles that pass through the 1/16-inch sump strainer holes. The nozzles produce a mass equivalent drop size of approximately 880 microns at rated system conditions. During the injection mode, the reduced flow rate of 14.3 gpm per nozzle (1875 gpm per train) produces a slightly larger mass equivalent drop size of 925 microns. The spray solution will not interfere with nozzle performance at any temperature of interest in the containment. Each nozzle header is independently oriented to ensure full coverage of the containment volume outside the reactor cavity. Nozzle performance is shown in Figures 6.2-21 and 6.2-22.

7. Containment Sump

The containment sump is a small collection pit in the floor of the containment. The containment floor acts as a large collecting reservoir for the sump. The containment sump is designed to provide an adequate supply of water with a minimum amount of particulate matter to the CSS and the SIS. The bottom of the sump is at Elevation 331 feet, 6¼ inches in the containment. The minimum thickness of the concrete floor pad in the sump is 5 feet. An arrangement consisting of a series of strainer modules and a sump plenum that completely covers the sump is provided to prevent debris generated in a large break LOCA event from entering the sump without degrading ECCS and CSS pump performance. There are eight strainer modules connected to the west side of the plenum and fourteen modules connected to the east side of the plenum. The strainer modules are constructed from perforated plate with nominal opening size of 0.0625-inch diameter. The arrangement of the sump and plenum structure is shown in Figures 6.2-23A and 6.2-23B.

The plenum lower structural support channel is anchored to the containment floor and sealed with non-structural grout to prevent the entry of small, high density particles from entering the sump. The plenum has one small, screened opening at the containment floor level, on the east and west side of the plenum, to allow equipment leakage to drain into the sump. These two openings are provided with a fine mesh inner screen with a maximum diagonal opening size of 0.006 inches and a number 4 mesh (3/16 inch) outer screen which acts as an impingement barrier to protect the inner screen. The sump contains two box screens at the discharge of the floor drain lines that enter the sump. These box screens also utilize a fine mesh screen with a maximum diagonal opening size of 0.006 inches, and a number 4 mesh (3/16 inch) screen. The plenum is structurally designed to withstand the differential pressure developed within the plenum due to blowdown from subcompartment pressurization events described in Section 6.2.1. The strainers are designed for a differential pressure greater than the plenum.

The sump is divided into two compartments by a 3/8-inch thick steel plate with a 15 square foot screened opening which provides an interconnecting flow path between compartments. Debris that passes into the sump through the 0.0625-inch

strainer openings will be drawn into the suction piping for the CCS and SIS. Such debris will be of small enough dimension to pass through any restriction in either system, and will eventually be pumped back into the containment.

Information on containment sump flow characteristics is contained in the report entitled "Hydraulic Model Studies of Containment Sump Recirculation Intakes," Western Canada Hydraulic Laboratories, April 1978. These original tests included models with only the vortex suppression grating on the suction piping. Subsequent to these tests, the strainers were replaced to address GSI-191 issues. Analysis of the replacement strainer internal head losses have been performed and include loss coefficients for the vortex suppression grating as determined by the Western Canada Hydraulics Laboratories tests. The pump NPSH analysis, which includes the strainer and sump pit internal head losses, has determined that acceptable margin remains for the pumps taking suction form the sump.

It is recognized that the greatest potential source of debris in the containment is insulation. Fiberglass blanket and all-metal stainless steel reflective insulation is used on the reactor coolant pressure boundary piping and vessels. Calcium silicate insulation, which is covered with stainless steel jacketing, is used to insulate other hot piping within the steam generator (SG) cavities in containment. Stainless steel jacketed cellular glass insulation is used on chiller piping outside the SG cavities to prevent condensation, e.g., chilled water piping to the CEDM cooling units.

Insulation is permanently attached to piping and vessels except at welds where it is removable for inservice inspection, as required. Special fasteners are used to secure removable panels. A postulated high energy pipe rupture could break loose removable panels. Guillotine or slot breaks could blow or whip loose permanently installed panels. Insulation falling into the reactor vessel cavity would be of minimal consequence. Strainers are provided over the refueling canal drains as indicated in Figure 9.1-1 to prevent clogging in the unlikely event that any large object fell into the canal. The strainer modules are mounted on floor supports that raise the strainer inlets approximately eight inches above the containment floor. It is unlikely that insulation panels which have fallen to the floor of the containment would be washed into the strainer modules. The containment sump was evaluated in accordance with GSI-191 criteria to determine the affects upon the available Net Positive Suction Head (NPSH), strainer structural design, and other limitations on strainer head loss. In response to NRC Generic Safety Issue (GSI) -191 and Generic Letter (GL) 2004-02 issues, additional strainer surface area has been added to the sump.

Two 24-inch normally open, motor operated valves are located on the pump suction lines within the sump.

The containment sump analysis during post accident conditions complies with the requirements of Generic Letter 2004-02 for addressing Generic Safety Issue 191, as detailed in ANO’s compliance response to the Generic Letter. The updated design basis includes the following:

a. Debris quantities generated by a LOCA are determined by analysis that establishes the distance from a break at which various insulation, coatings, and other detrimental materials are released. A limiting break is determined from this analysis based on the debris mixture that produces the most detrimental strainer head loss.

b. Chemical effects associated with the precipitation of aluminum compounds are evaluated for their impact on sump strainer head loss and reactor fuel assemblies.

c. Strainer head loss due to debris and chemical precipitates was determined via scaled testing of strainer modules. The head loss test results were compared against available NPSH margin or strainer structural limits for acceptability.

d. The NPSH margin for the HPSI and Containment Spray pumps were revised to include available margins as sump temperatures become sub-cooled. This allows determination of the sump water temperature range at which NPSH becomes less limiting to strainer allowable head loss than the 6.1 feet containment sump strainer structural limitation.

e. Down Stream Effects are evaluated for components in the sump recirculation flow path to ensure the debris generated by a LOCA that can pass through the strainer's 0.0625-inch openings will not result in blockage or unacceptable wear.

f. The reactor vessel internals, including fuel assemblies, are evaluated for potential detrimental effects from the debris generated by a LOCA that can pass through the strainer.

Access is provided to allow valve maintenance and level indication is provided as stated in Section 7.5.2.5.

8. Piping

Historically, all system piping of 10-inch diameter and larger was welded SA-358, Grade TP-304, Class 1. Piping of 8-inch diameter and smaller whose primary rating is 150 lb. was welded SA-312 Grade TP-304. Piping of 8-inch diameter and smaller whose primary rating is 300 lb. was either seamless SA-376 or SA-312 Grade TP-304. All system piping joints were welded except the containment spray pumps, spray nozzles, flow orifices, and relief valves 2PSV-5653, 2PSV-5654, 2PSV-5696, and 2PSV-5697. Alternate materials and flanges may be used in accordance with approved design documents.

9. Valves

All CSS valves are stainless steel with suitable trim to be compatible with the borated water service, and are rated for the required pressures and temperatures.

Motor operated valves have remote position indication and hand switches in the control room.

C. System Operation

The CSS is automatically actuated by a Containment Spray Actuation Signal (CSAS) from the Engineered Safety Features Actuation System (ESFAS). The CSAS is initiated by a coincidence of 2-out-of-4 high-high containment pressure signals and a Safety Injection Actuation Signal (SIAS). CSAS may also be initiated manually by pushbutton from the control room. The following equipment is actuated by the CSAS:

1. Both containment spray pumps start (2P35A, B);

2. Both containment spray header isolation valves open (2CV-5612-1 and 2CV-5613-2);

3. Both trains of condensate (2P2A, B, C, D), heater drain (2P8A, B), and feedwater pumps (2P1A, B) stop.

4. Both main feedwater isolation (2CV1023-2, 2CV1073-2) and both backup valves (2CV-1024-1, 2CV-1074-1) close.

5. Both main steam isolation valves (2CV-1002, 2CV-1052) close.

All system components are lined up for emergency operation when the plant is at normal operating conditions.

A description of system operation after CSAS initiation is given in Section 6.2.2.2.1.A. When the level in the RWT reaches 6.0 ± 0.5% indicated level, the RAS is initiated automatically by two of four low level signals from tank mounted level switches.

The RAS automatically causes the following to occur:

1. Recirculation sump outlet valves open (2CV-5647-1, 2CV-5648-2, 2CV-5649-1, 2CV-5650-2);

2. CSS, High Pressure Safety Injection (HPSI) and Low Pressure Safety Injection (LPSI) pumps minimum flow line valves close (2CV-5628-2, 2CV-5672-1, 2CV-5673-1, 2CV-5123-1, 2CV-5124-1, 2CV-5126-1, 2CV-5127-1 and 2CV-5128-1);

3. LPSI pumps stop;

4. Service water flow to the shutdown cooling heat exchangers begins by opening of 2CV-1453-1 and 2CV-1456-2; and,

5. RWT outlet valves close (2CV-5630-1 and 2CV-5631-2).

During recirculation, water which has collected in the containment sump flows by gravity to the CSS pumps which return it to the containment spray headers via the shutdown cooling heat exchangers which reject containment spray fluid heat to the SWS. Provisions have been made to sample this fluid downstream of the shutdown cooling heat exchangers to monitor long-term fluid conditions, e.g., pH.

A break in the RCS, with the plant in the shutdown cooling mode (when CSS would not be immediately available), which would require initiation of the CSS for pressure, temperature, and activity control is not considered credible. However, design of the CSS will inherently accommodate this incredible event.

During shutdown cooling operations, CSS actuation would be achieved by manual initiation of CSAS by operator action after manually securing shutdown cooling. The time required for one operator to manually realign the CSS for spray operation of one train is conservatively estimated to be 20 minutes (three manual valves must be

repositioned). Since containment pressure will be well below design pressure and iodine release is expected to be small, iodine leakage from the containment is not expected to be significant during this time. Even if the iodine inventory was high, it would not preclude operator action with the appropriate protective equipment, and no significant containment leakage would be expected during the short time required for manual lineup of the CSS.

6.2.2.2.2 Containment Cooling System

A. General Description

A flow diagram of the CCS is shown in Figure 9.4-4. The system consists of two trains which function to reduce temperature and pressure following any postulated LOCA. Each system loop consists of two cooling units, each of which discharges into a separate distribution plenum. Intake during normal operation is through a duct network which is common to all four units. The two distribution plenums are also connected to a duct network which distributes the discharge of the cooling units to different areas in the containment.

The SWS, which supplies cooling water to the cooling units during post-accident operation, is described in Section 9.2.1.

The cooling units distribution plenums and supply ducts are designed to Seismic Category 1 requirements, and are designed to maintain functional integrity in the post-LOCA containment environment. The intake plenums for each loop are bypassed upon receipt of a Containment Cooling Actuation Signal (CCAS) by automatic operation of bypass dampers in each of the four cooling units. Operation of the bypass dampers permits air intake without use of the intake plenums, which are designed to Seismic Category 2 requirements.

B. Component Descriptions

1. Emergency Cooling Units

Data for the emergency cooling units is presented in Table 6.2-22. The units are located on two levels in the containment outside the secondary shield wall. One unit from each system loop is at Elevation 357 feet, 0 inches, and one unit from each system loop is at Elevation 376 feet, 6 inches. All cooling units are located in the northwest quadrant of the containment. The units are approximately 10 feet wide by 20 feet long by 10 feet high. Each unit consists of one set of chilled water cooling coils to be used for normal cooling, one set of service water coils to be used for emergency cooling, and a single speed axial fan. A bypass damper is provided on top of the unit between the chilled water coils and the service water coils. The unit housings are designed to withstand a differential pressure of 2 psi and are equipped with pressure relief valves which are sized to prevent a buildup of differential pressure over 2 psi on the housing during the worst anticipated pressure transient in accordance with Section 7.0 of American Air Filter's AAF-TR-7101, "Topical Report on Design and Testing of Fan Cooler/Filter Systems for Nuclear Applications." The cooling units are designed to Seismic Category 1 requirements in accordance with Section 2.0 of the same topical report. The fan is mounted on top of the unit. The fan motors are of the type that have been tested in accordance

with IEEE Report NSF/TCS/SC2-A, "Proposed Guide for Qualification Tests for Class IE Motors Installed Within the Containment of Nuclear Fueled Generating Stations" (now known as IEEE 334-1971).

The bypass damper opens automatically upon receipt of a CCAS or manually by handswitch from the control room.

The damper allows the saturated air in the containment to bypass the return air ducts and the chilled water cooling coils and to go through only the service water coils. The decrease in pressure drop due to the bypassing of the return air ducts and chilled water cooling coils permits the fan in the unit to handle the necessary quantity of air for emergency cooling purposes at the same speed as during normal operation.

Each fan has a back draft damper which prevents backflow through an idle unit.

2. Distribution Plenums and Ducts

Each distribution plenum receives air flow from two cooling units, one from each system loop. The plenums and the supply and recirculation ducts are designed to Seismic Category 1 requirements and to withstand a differential pressure of 2 psi. The plenums and the supply and recirculation ducts are equipped with the same type of pressure relief valves as the fan housings to prevent the buildup of pressure above 2 psid during the worst anticipated pressure transient in accordance with Section 7.0 of AAF-TR-7101. These plenums, supply, and recirculating ducts, will remain intact following a LOCA or steam line break accident to assure system operability. Analysis and tests have been performed in accordance with AAF-TR-7101, Section 7.0 to assure that the number, size, and location of the pressure relief vents is adequate to prevent pressure collapse of this ductwork.

C. System Operation

During normal operation, the cooling units will be operating with chilled water from the plant main chilled water system.

During emergency conditions, a CCAS will automatically place the system in operation.

A CCAS signal is caused by two of four low-low pressurizer pressure signals or two of four high containment pressure signals or manually by pushbutton in the main control room. A CCAS causes the following to occur:

1. Starts all four containment emergency cooling units;

2. Opens service water valves 2CV-1519-1, 2CV-1513-2, 2CV-1511-1 and 2CV-1510-2;

3. Opens bypass dampers on each cooling unit.

During emergency operation, air intake to the units is through the bypass dampers. Air is drawn through the service water cooling unit and fan and then discharged to the containment atmosphere via the distribution plenums and duct network.

6.2.2.3 Design Evaluation

The capability of the CHRS to maintain containment pressure below design values during the DBA has been confirmed by the containment transient pressure analysis discussed in Section 6.2.1. Detailed evaluations of the capability of each heat removal system to perform its intended function are given in the following sections.

6.2.2.3.1 Containment Spray System

Analysis has shown that each loop of the CSS is capable of removing in excess of 120 million Btu/hr from the containment atmosphere following the DBA.

The system design is based on the temperature of the spray water droplets reaching equilibrium with the temperature of the containment. This occurs with spray water falling through the steam-air mixture within the containment. The spray nozzles will deliver droplets with an equivalent diameter of approximately 925 microns during the injection mode and 880 microns during recirculation with the spray system operating at design conditions and the containment at design pressure.

A minimum of 68 feet is provided between the spray nozzles and the highest obstruction in the containment, with the exception of the containment polar crane, to insure that the droplets reach thermal equilibrium during their fall.

Curves describing CSS and containment response following a design basis LOCA are presented in Section 6.2.1.

The containment spray pumps were shop tested in accordance with the ASME Power Test Code PTC 8.2 - Centrifugal Pumps. Pump performance data is given in Figure 6.2-20.

A single failure analysis has been made on all components of the CSS to show that a single failure of any active component will not degrade the system's capability to fulfill its design objectives. This analysis is shown in Table 6.2-23. All of the active components of the CSS, with the exception of the containment sump motor operated valves, are located outside the containment and therefore are not required to operate in the steam-air environment resulting from the accident. Additionally, system arrangement minimizes the possibility of missile damage to any system component. The overlapping heat removal capability of the CSS and the CCS is discussed in Section 6.2.1.

Two isolation valves have been provided in each recirculation line, which provide redundant means of halting flow from the sump to areas outside containment in the event excessive leakage develops in the recirculation system due to component deterioration. The isolation valves located inside the containment sump are protected from clogging by the series of sump strainers and protected from missile damage by being totally enclosed by the sump plenum and support structure.

Leakage of the containment sump fluid to areas outside the containment due to component deterioration in the recirculation piping from the sump to the CSS pumps will be confined to one of the three watertight ESF pump rooms. Excessive leakage into the pump rooms will be detected by a multiple contact detector located in each pump room, which will cause alarms to sound in the control room at successively higher room water levels. Appropriate operator action will then be taken to detect and isolate the source of the leakage.

6.2.2.3.2 Containment Cooling System

Tests and analysis have confirmed that each train of the CCS is capable of removing in excess of 60 million Btu/hr from the containment atmosphere when operating at containment design conditions. A description of the analytical methods and models used to assess the performance of the CCS in post-DBA conditions is given in Section 6.2.1.

A single failure analysis for the CCS summarized in Table 6.2-24 shows that the system is designed to permit single failure of any active component without loss of the ability of the CHRS to fulfill its design function.

6.2.2.4 Testing and Inspections

The CHRSs were functionally tested in accordance with written procedures as outlined in Chapter 14 and are tested periodically as described in the following sections. These discussions lead to the surveillance Technical Specifications.

6.2.2.4.1 Containment Spray System

A. Spray Pumps - The spray pumps are run at full flow by recirculating refueling water through the shutdown cooling heat exchangers and refueling water return line to the RWT. Pump performance can be compared to the original shop test performance curve. This type of testing requires only an adjustment for specific gravity and volume flow to extrapolate the expected performance under accident conditions.

B. Buffering Agent (NaTB) – The concentration of the buffering agent is established at the time of initial container fill and is periodically checked by analysis of samples taken.

C. Motor Operated Valves - Valves operated by the CSAS are tested by manually inducing the CSAS with pump operation blocked. In addition, these and all other system motor operated valves can be operated individually by switches from the control room. Valve position indication on the same control room panel is used to verify valve operability.

D. Spray Header Nozzles - With the containment spray header inlet valves closed, low pressure air is blown through the test connection in each spray header. Air flow from each nozzle is indicated by the movement of a balloon held near the nozzle or by the movement of streamers attached to each nozzle prior to the test, or by use of thermography equipment. An alternative method which can be used is to introduce smoke into the spray header and observe each nozzle for flow.

E. Alarms - Provision is made in the circuitry of the various system alarms to test the proper operation of the alarm circuitry with a test input. These circuits include the containment high pressure alarms, and the containment high-high pressure alarms.

F. Integrated Functional Test - The entire system is functionally tested as a whole by means of the following procedure.

    1. Close the spray pump discharge stop check valve.

    2. Manually initiate service water flow to spray pump coolers.

    3. Manually initiate the corresponding CSAS and verify that all pumps and valves are operating as required.

G. Additive Concentrations - Periodic monitoring of the buffering agent is performed to ensure buffering of the spray water during recirculation mode can be accomplished. This provides assurance that the range of pH values given is not exceeded and prevention of re-evolution of iodine as stated in Section 6.2.3.3.1.2 is achieved.

The following verifications are performed to meet the requirements as stated and referenced above:

1. The RWT chemical concentrations are sampled (and adjusted when required) to assure that permissible concentrations are maintained.

2. The RWT temperatures are monitored and alarmed to ensure limits are not exceeded.

3. The containment atmosphere temperatures used in the analyses cannot be tested but are conservative for each given set of assumptions.

4. Since the minimum and maximum spray flow rates can not be tested by pumping fluid through the entire system, calculations have been performed to assure that actual flow rates will not exceed the limits assumed to determine the spray flow pH range.

5. The NaTB buffering agent is monitored to verify that the buffering agent containers hold the required amount of NaTB and that a sample from the buffering agent containers provides adequate pH adjustment of RWT water.

6.2.2.4.2 Containment Cooling System

The cooling units and distribution system were thoroughly tested prior to plant operation according to detailed preoperational test procedures.

Fan and coil performance under containment design conditions has been verified by actual tests of prototypes under simulated containment design conditions.

6.2.2.5 Instrumentation Requirements

The following sections provide descriptions of the instrumentation provided for the monitoring and actuation of each CHRS. Details of the design and logic of the instrumentation is discussed in Chapter 7.

6.2.2.5.1 Containment Spray System

Instrumentation required for the CSAS and the RAS is described in Section 7.3.

The CSS instrumentation has been designed to facilitate automatic operation, remote control, and continuous indication of system parameters.

All system motor operated valves are provided with position indication in, and are operable from the control room. This allows the operator to continuously monitor system status and remotely operate valves as necessary.

The RWT is equipped with a redundant level indication system.

Six level transmitters are mounted on the RWT, all of which provide separate level indication in the control room. Two of these transmitters provide input to a low level alarm in the control room. The remaining four transmitters provide the basis for the RAS signal as further discussed in Section 7.3.

Temperature indication and alarm instrumentation are provided for the RWT.

Level switches are provided on the RWT which automatically de-energize the tank heaters when the level drops to a point exposing the elements.

Local temperature indicators are provided at the inlet to the shutdown cooling heat exchangers. A local pressure indicator is located on the common 24-inch diameter supply line from the RWT.

Two level transmitters, two locally mounted level indicators and one control room mounted level indicating switch with associated low-high level alarm are provided on each spray header to monitor spray riser level and to facilitate riser fill operation.

6.2.2.5.2 <u>Containment Cooling System</u>

Flow switches are provided at the outlet of each cooling unit which, upon low flow, will sound an alarm in the control room.

Position switches provide bypass damper position indication in the control room.

6.2.3 CONTAINMENT AIR PURIFICATION AND CLEANUP SYSTEMS

There are three systems which provide for containment air purification and cleanup.

A. The CSS provides for fission product removal from the containment atmosphere following a postulated LOCA.

B. The hydrogen recombiner system provides for removal of hydrogen from the containment atmosphere following a postulated LOCA.

C. The Containment Purge System (CPS) provides for containment atmosphere purification for personnel access.

The CPS serves no safety function and is described in Section 9.4.5. The hydrogen recombiner system is discussed in Section 6.2.5. A description of the CSS and discussion of its function as a CHRS are presented in Section 6.2.2. This section describes and evaluates the fission product removal function of the CSS.

6.2.3.1 <u>Design Bases</u>

The design basis for the fission product cleanup capability of the CSS is to provide sufficient fission product removal and retention capability such that off-site radiation exposures resulting from a postulated LOCA are within the guidelines of 10 CFR 50.67. The Seismic Category I CSS provides heat removal capability as well as a scrubbing action on the containment atmosphere to remove airborne halogen and particulate fission products following a LOCA. The buffering agent is mixed with the boric acid spray as it fills the base of the building. This mixture of boric acid and buffering agent will continue to remove post-accident energy and remove

fission product iodine as it is recirculated through the CSS. Adequate amounts of buffering agent are added to raise the sump fluid pH to ensure removal of elemental iodine from the containment atmosphere and to retain the iodine in the containment sump fluid.

In order to achieve the above objective, the following system requirements must be met.

A. Sufficient TSP-C must be added to the sump solution before the recirculation of the sump solution occurs to assure that the iodine removed from the reactor building atmosphere by the spraying action will not re-evolve from the sump liquid as it is sprayed back into the building.

B. The containment spray header and spray nozzles must be designed to provide maximum coverage of the containment atmosphere.

The CSS is designed to withstand the Design Basis Earthquake (DBE) without rupture or loss of function. The system is designed to be redundant and capable of withstanding a single active failure as required by General Design Criterion 41. To ensure reliability of the system throughout its life, the system is designed to be inspectable and testable to the extent practicable as required by General Design Criteria 42 and 43.

6.2.3.2 System Design

6.2.3.2.1 System Description

The CSS is shown in Figure 6.2-17. Section 6.2.2 contains general system and individual component descriptions as well as discussion of the CSS heat removal capability. System design characteristics applicable to the CSS fission product removal capability follow.

Each CSS loop is designed to deliver borated water to its respective containment header at a minimum flow rate of 1875 gpm during the injection mode and 2,000 gpm during recirculation. Each of the spray headers is located at the highest possible elevation in the containment, conforming to the shape of the containment dome, and providing the maximum possible coverage of the containment atmosphere by the spray droplets. The location of the headers provides an area-averaged droplet fall height of 104 feet. The spray system directly sprays approximately 79 percent of the total containment free volume. This value is based on conservatively assuming that significant obstructions to the main spray will result from the polar crane and bridge, various platforms, pressurizer, steam generators, floors, missile shield, and refueling machine. The entire containment dome and all volumes under directly sprayed gratings are assumed to be directly sprayed.

Of the remaining 21 percent of the containment free volume not directly sprayed, approximately 14 percent have good communication with the main spray while seven percent have restricted communication with the main spray. Although not directly sprayed, volumes such as those under the refueling machine, polar crane and bridge, and the lower portions of the steam generator compartments, where the reactor coolant pumps are located, have good communication with the directly sprayed volumes and account for 14 percent of the containment free volume. The seven percent of the containment free volume having restricted communication with the sprayed volumes includes volumes such as the reactor vessel cavity and those portions of the annular region between the secondary shield walls and the primary containment wall which are covered by the operating floor or other floors. Table 6.2-24A provides a summary of all containment regions not directly sprayed and the volumes of these

regions. Additional mixing occurs between the directly sprayed region and the other volumes due to the recirculation provided by the containment fan cooling units described in Section 6.2.2. Air from the upper spaces is cooled and distributed to the lower regions where the spray access is obstructed.

The spray nozzles used are Sprayco model 1713A ramp bottom design, which deliver spray droplets of approximately 925 micron equivalent diameter with a 35 psi drop across the nozzles and 14.3 gpm per nozzle during injection and approximately 880 micron equivalent diameter at the system design condition of 40 psi drop across the nozzles and 15.2 gpm per nozzle during recirculation.

All CSS components which come in contact with the system fluid during storage or system operation are made of stainless steel to minimize the effect of corrosion. The material controls satisfy the recommendations of Regulatory Guide 1.44, "Control of the Use of Sensitized Stainless Steel," and Regulatory Guide 1.36, "Nonmetallic Thermal Insulation for Austenitic Stainless Steel."

A buffering agent is added to the spray fluid to adjust the pH of the spray fluid collected in the sump to an equilibrium pH of 7.0 or greater. A pH of 7.0 or greater will assure that the iodine removed from the reactor building atmosphere by the spraying action will not re-evolve from the sump liquid as it is sprayed back into the building. Also, the controls on the pH of the reactor containment spray are to ensure freedom from stress corrosion cracking of austenitic stainless steel components and welds of the containment spray system throughout the duration of a postulated accident to completion of cleanup.

6.2.3.2.2 System Operation

The CSS has two modes of operation which are initiated sequentially following system actuation. These are the injection mode and the recirculation mode.

6.2.3.2.2.1 Injection Mode

The CSS is actuated as described in Section 6.2.2. Upon system actuation, the containment spray pumps begin operation simultaneously with the opening of the valves to the spray headers. All other valves which must be opened or closed to assure proper system operation are in the proper (ESF) position as assured by administrative controls.

Each spray pump takes suction from the RWT through a header common to the associated train of SIS pumps. During injection with peak containment pressures, the minimum flow is 1875 gpm per header. The spray droplet size during injection is slightly larger than the nominal 880 microns.

6.2.3.2.2.2 Recirculation Mode

The injection mode will be terminated automatically by the RAS when low level in the RWT is reached. The RAS automatically opens the suction line valves from the containment sump, while closing the minimum flow line valves to the RWT and the RWT outlet valves. The RWT outlet valves closing and the sump outlet/isolation valves opening are coordinated so as to not adversely restrict the flow of water to the pumps while also providing enhanced margin against RWT vortexing. The RAS also opens service water system valves to allow service water flow through the shutdown cooling heat exchangers. The buffering agent is dissolved by the

sprayed fluid and collected in the containment sump. The containment sump water is made up of borated water from the RWT, safety injection tanks, RCS and boric acid makeup tanks and buffering agent. The total amount of buffering agent added when mixed with the total inventory of sump water will yield sump water with a minimum pH of 7.0 at containment temperatures.

6.2.3.2.2.3 System Response

The CSS will deliver full rated flow through the spray nozzles within 56 seconds after the containment design basis LOCA, assuming loss of off-site power. The length of the injection period depends upon the number of ECCS and containment spray pumps running, the size and location of the LOCA or MSLB, and the volume of water in the RWT.

6.2.3.3 Design Evaluation

The CSS is safety-related and is designed to operate following a postulated LOCA. A high degree of system reliability is maintained through system quality control, by general equipment arrangement to provide access for inspection and maintenance and by periodic testing. A failure analysis has been performed on all active components of the system to show that the failure of any single active component will not prevent fulfilling the system design function. This analysis is presented in Table 6.2-23.

Because of the large surface area interface between the spray droplets and the containment atmosphere, the spray system serves as a removal mechanism for fission products postulated to be dispersed in the containment atmosphere. Radioiodine in its various forms is the fission product of primary concern in the evaluation of a postulated LOCA. The major benefit of the containment spray is its capacity to absorb molecular iodine from the containment atmosphere and thus reduce its release to the environment. Off-site thyroid doses are a function of both the rate of removal and the final equilibrium decontamination factor.

6.2.3.3.1 Containment Spray System Performance Evaluation

The performance evaluation of the containment spray system for the removal of iodine from the containment atmosphere requires the determination of spray removal constants and associated decontamination factors (DF) for the various forms of iodine. The calculation of spray removal constants is treated separately for the injection and recirculation modes to account for the change in spray conditions. These removal constants and decontamination factors are then used to demonstrate acceptable results for the calculation of dose consequences for the design basis loss of coolant accident (see Section 15.1.13).

6.2.3.3.1.1 Injection Mode

The analysis of the spray iodine removal during the injection mode is based on the assumption that:

A. Only one out of two spray pumps is operating at a flow rate of 1875 gpm; and

B. Containment pressure and temperature are conservatively assumed to remain at 59 psig and 266 °F throughout the injection mode.

During the injection mode the pH of the spray water will be approximately 4.4, given the maximum RWT boron concentration of 3000 ppm. However, the fresh spray water from the RWT will contain no dissolved iodine and the spray removal constant, λ, for elemental iodine will not be dependent on pH. Based on the methodology of SRP 6.5.2 Rev. 2, the value of λ for elemental iodine during the injection mode is significantly larger than the value of 20 hr^{-1} permitted by the SRP. The spray removal constant for elemental iodine during the recirculation mode must be evaluated separately; see Section 6.2.3.3.1.2.

The removal of particulate forms of iodine by spray is primarily a mechanical rather than chemical process. The spray removal constant for particulate iodines is independent of pH. Based on the methodology of SRP 6.5.2 Rev. 2, the value of λ for particulate iodine is 3.97 hr^{-1} prior to recirculation, 4.24 hr^{-1} after recirculation up to a maximum decontamination factor (DF) of 50, after which the removal constant is reduced to 0.424 hr^{-1}. These values are applicable during both the injection and recirculation modes.

Organic forms of iodine are not assumed to be removed by the containment spray. A spray removal constant of 0 hr^{-1} is assumed for both the injection and recirculation modes.

6.2.3.3.1.2 Recirculation Mode

During the recirculation mode, the spray water will be buffered to a pH of more than 7.0 by the buffering agent. Because the sump water will contain dissolved iodine, the spray removal constant for elemental iodine will be dependent upon the spray pH during the recirculation mode.

Prior to the onset of recirculation while the sump is filling, the buffering agent in the three wire mesh baskets in the bottom on containment will be dissolving in the rising sump water. During this time and for a short period after the start of recirculation while additional mixing of the sump occurs, the pH of the sump water will continuously change, assuming different values which will be dependent upon the amount of buffering agent dissolved and the volume of water in the containment sump. The pH of the spray water drawn from the sump is expected to remain below 7.0 for only a short period following the start of sump recirculation. Once the spray pH reaches 7.0, it will continue to increase to less than 8, as water with higher than average buffering agent concentrations reaches the sump pit. As the higher concentration recirculation flow water returns to and mixes with the sump solution, the pH at the sump pit will fall to its final long term value. These transient conditions are expected to last only for a short time. The sump pH should exceed 7.0 within the first hour after the start of sump recirculation.

Calculations show that the Technical Specification minimum volume of buffering agent will ensure that after a LOCA, when all the water from the containment spray system and from the pipe break collects and mixes in the sump, its pH will be equal to or higher than 7.0. This minimum equilibrium sump pH calculation assumes maximum inventories of borated water at maximum boron concentrations consistent with the Technical Specifications. The maximum equilibrium sump pH is also calculated assuming the maximum possible buffering agent volume with the minimum inventories of borated water at minimum boron concentrations consistent with the Technical Specifications. The maximum equilibrium sump pH is approximately 8.0.

The final pH, with a minimum value greater than 7.0, will prevent the re-evolution of iodine during operation of the containment spray system in the recirculation mode. The short duration of spray at less than 7.0, just after the start of recirculation, does not significantly impact the long term cleanup of elemental iodine; consequently, the spray removal constant for the recirculation mode is calculated assuming a spray pH of 7.0.

Based on the methodology of SRP 6.5.2 Rev. 2, the spray removal constant, λ, for elemental iodine during the injection mode, is significantly larger than the value of 20 hr^{-1} permitted by the SRP. Therefore, the use of a spray removal constant value of 20 hr^{-1} during the injection and recirculation modes is conservative for LOCA dose calculations. A post-recirculation spray removal constant of 0.0 is conservatively used until the time that the projected pH reaches a value of 7.0.

The extent of cleanup of elemental iodine by the spray is limited by the decontamination factor. Using the methodology of SRP 6.5.2 Rev. 2, the DF for elemental iodine is significantly larger than the value of 200 permitted by the SRP.

6.2.3.4 Tests and Inspections

Tests and inspections for the CSS are described in Section 6.2.2.

These tests provide adequate proof that the buffering agent containers and CSS will deliver the proper mixture of boric acid and buffering agent under accident conditions.

6.2.3.5 Instrumentation Requirement

A description of the instrumentation requirements of the CSS is given in Section 6.2.2.

6.2.4 CONTAINMENT ISOLATION SYSTEMS

The containment isolation systems provide the means of isolating fluid systems that pass through containment penetrations so as to confine to the containment any radioactivity that may be released following a postulated accident. ANO-2 does not have a particular system for containment isolation; however, isolation is achieved by applying common criteria to penetrations in the various fluid systems and by using containment pressure and, in some cases, a safety injection signal to actuate the appropriate valves.

6.2.4.1 Design Bases

The design basis for the CIS is to minimize the release of radioactive material from the containment by closing all fluid penetrations not serving accident consequence limiting systems, so that the site boundary thyroid and whole body doses from radioactive material escaping through the containment penetrations plus the doses from other sources during any postulated accident are within the limits of 10 CFR 50.67.

The containment isolation systems are designed in accordance with 10 CFR 50 Appendix A, General Design Criteria 54, 55, 56 and 57, and meet the leak testing criteria of 10 CFR 50, Appendix J. The applicable criterion for each penetration is shown in Table 6.2-26.

The containment isolation systems are also designed to withstand the design basis earthquake and the credible failure of any single active or passive component without loss of isolating capability.

Information concerning the criteria applied with respect to the number and location of isolation valves is contained in Section 6.2.4.2 below.

Since no fluid instrument lines penetrate the containment, no special isolation criteria need be considered for this type of penetration on Arkansas Nuclear One - Unit 2.

6.2.4.2 System Design

The containment isolation systems are designed to provide at least a double barrier to the escape of radioactive material at each fluid penetration through the containment liner plate. The double barriers take the form of closed piping systems, both inside and outside containment, various types of isolation valves, and double resilient or compression seals.

Double barriers are provided to ensure that no single, credible failure or malfunction of an active or passive system component can result in loss of isolation or significant leakage.

A means of leak testing all barriers in fluid systems that serve a containment isolation function has been provided. The capability to periodically test the operability of all containment isolation valves which must operate to achieve isolation has also been provided.

Table 6.2-26 provides descriptive information concerning containment isolation barrier or valve arrangement and design for each containment fluid penetration, including the applicable General Design Criterion.

Schematic diagrams of each fluid penetration are shown on individual system diagrams as referenced in Table 6.2-26.

Containment isolation will be initiated by means of a Containment Isolation Actuation Signal (CIAS) and in some cases a Safety Injection Actuation Signal (SIAS). A CIAS occurs as a result of high containment pressure, or may be generated manually by pushbutton from the control room. A SIAS occurs as a result of low pressurizer pressure or high containment pressure. It may also be generated manually by pushbuttons from the control room. The instrumentation circuits that generate a CIAS and SIAS are described in Chapter 7.

A CIAS will cause all power operated containment isolation valves to close except those which are normally locked closed and those within the ESF systems and the CVCS charging system. Upon receipt of an SIAS, the CVCS charging system functions automatically to inject the contents of the boric acid makeup tanks into the RCS as described in Section 9.3.4.4.1. The outside containment isolation valve is located as close to containment as practical as required by General Design Criterion 55.

All automatic containment isolation valves that are activated by a CIAS or other ESF signal also have hand switches and position indication in the control room. All isolation valves and associated piping systems have been designed to operate under the expected dynamic forces resulting from intended or inadvertent closure under any operating condition.

Containment isolation valves that are located inside the containment are designed to function under the pressure-temperature conditions of both normal operation and the DBA. The expected pressure-temperature condition of normal operation is 14.7 psia and 110 °F. The pressure-temperature condition used for valve design inside the containment is 59 psig and 300 °F. Containment isolation valves located outside of containment are qualified to conditions specific to their location and application. The capability of valves designed to function in the post-DBA environment is discussed in Section 3.11.

6.2.4.3 Design Evaluation

The CIS is designed to present a double barrier to any flow path from the inside to the outside of the containment to meet the single failure criterion.

In all cases where two power operated isolation valves in series are used, channel separation is maintained. In all cases where check valves are used as automatic containment isolation valves, these valves are not used as the outermost isolation valve.

Adequate protection is provided for piping, valves, and vessels against dynamic effects and missiles which might result from plant equipment failures, including a postulated LOCA. Where system design permits, isolation valves inside the containment are located between the secondary shield and the inside containment wall. The secondary shield serves as the missile barrier. Containment isolation valves located outside containment are located as close to the containment as possible.

The containment purge system isolation valves need not be capable of closing against the flow and pressure inside the containment during a postulated DBA as they will remain closed until the plant is in operational Modes 5 and 6 as required by the Technical Specifications. These valves are qualified to remain closed against the DBA pressure. (2CAN047817, 2CAN047823)

6.2.4.4 Tests and Inspection

All components of the containment isolation systems were designed, fabricated, and tested under quality assurance requirements in accordance with 10 CFR 50, Appendix B. Nondestructive examination was performed on the components of the systems in accordance with the applicable codes described in Section 3.2.2.

The containment isolation systems are functionally tested under conditions of normal operation in accordance with the procedure outlined in Chapter 14.

The containment isolation systems are periodically tested to determine availability to perform the desired function.

Automatic isolation valves that receive a CIAS to close, where closure of the valve will not limit or restrict normal plant operation, are periodically functionally tested by the on-line testing capability described in Section 7.3. All other valves are periodically tested for CIAS electrical continuity.

All automatic isolation valves which are not tested during normal operation are functionally tested during each refueling shutdown.

Test connections and pressurizing means are provided to test each isolation valve or barrier for leak tightness. Either nitrogen or air is used as the pressurizing medium, depending on the physical location and service of each line. Testing frequencies are listed in the Technical Specifications.

Table 6.2-26 provides a list of containment penetrations, i.e., fluid system piping, instrument, electrical and equipment, and personnel access; and identifies the type of leak testing to be performed in accordance with 10 CFR 50, Appendix J.

6.2.5 COMBUSTIBLE GAS CONTROL IN CONTAINMENT

Three systems were originally provided for combustible gas control in containment. They are the hydrogen recombiner system, the containment air recirculation system, and the containment atmosphere monitoring system. Subsequent evaluation determined that the containment cooling units or containment spray system provide adequate atmosphere mixing and that the containment recirculation fans are not needed.

6.2.5.1 Design Bases

For pressurized water reactors, such as Arkansas Nuclear One - Unit 2, the only combustible gas of consequence inside containment is hydrogen. For the remainder of this section, combustible gas and hydrogen may be treated as synonymous.

The systems provided for hydrogen control in containment are designed to limit the hydrogen gas concentration to a maximum of 3.9 v/o following any postulated LOCA, and meet the design criteria of Regulatory Guide 1.7, by providing the following:

A. A redundant means of measuring the containment atmosphere hydrogen concentration using the containment atmosphere monitoring system.

B. A redundant means of mixing the containment atmosphere to prevent concentration of hydrogen in the containment dome using the containment cooling units and/or the containment spray system. (See Section 6.2.2)

C. A redundant means of controlling hydrogen gas concentrations without reliance on purging using the hydrogen recombiner system.

Sizing of the hydrogen recombiner system was based upon a hydrogen evolution rate consistent with the assumptions stated in Regulatory Guide 1.7 and as further discussed in Section 6.2.5.3.

Combustible gas control following a LOCA is accomplished by the recombiner system, manually started at a measured hydrogen concentration of approximately 2.0 v/o.

The systems used for hydrogen control in containment are designed to Seismic Category 1 requirements.

6.2.5.2 System Design

6.2.5.2.1 Containment Atmosphere Monitoring System

The containment atmosphere monitoring system consists of two redundant hydrogen gas analyzers, and two redundant radiation monitors. The function of the radiation monitors is discussed in Section 5.2.7.

The hydrogen analyzers are a flow-through type and provide, when placed in service, a continuous measurement of hydrogen concentration in containment.

The continuous sample for the monitoring system is drawn from a collection manifold.

6.2.5.2.2 Containment Air Recirculation System

The containment air recirculation system is described in Section 9.4. The system is not credited in any design basis accident or transient analysis. It is not credited in the ANO-2 probabilistic risk assessment for accomplishing the hydrogen mixing function.

6.2.5.2.3 Hydrogen Recombiner System

The hydrogen recombiner system consists of two Westinghouse thermal hydrogen recombiners located within containment at Elevation 426 feet, 6 inches. These are convection flow, 100 scfm electric units rated at 75 kW each. They are designed to operate at 95 percent efficiency and each unit is capable of maintaining the hydrogen concentration in the containment below 3.9 v/o following any postulated LOCA. Each unit is powered by a separate ESF bus, and is designed to withstand the DBE without loss of function. Data describing the units is provided in Table 6.2-27. The recombiner efficiency can be affected by the density of the air. To assure that a 4% hydrogen concentration is not reached prior to the time that containment post LOCA pressure drops to a value at which 95% recombiner efficiency can be assured, operational hydrogen concentration in containment that may develop over time as a result of leakage from the RCS is monitored and appropriately controlled.

6.2.5.3 Design Evaluation

This evaluation includes the following:

A. an evaluation demonstrating the functional requirements of the system; and,

B. an analysis of hydrogen generation following a LOCA.

Systems provided for hydrogen control in the containment meet the same design, quality assurance, redundancy, power source and instrumentation requirements as for an engineered safety feature system, and do not introduce any additional safety problems which may affect containment integrity.

No single failure in the hydrogen control systems can prevent the minimum necessary control of hydrogen concentration from occurring.

Sizing of the hydrogen removal equipment was based upon a hydrogen generation model as presented in Section 6.2.5.3.1.

6.2.5.3.1 Sources of Hydrogen

Following a postulated LOCA, hydrogen gas may accumulate within the containment as a result of:

A. the decomposition of water by radiolysis;

B. a metal water reaction involving the zirconium fuel rod cladding and the reactor coolant; and/or,

C. corrosion of metals within containment by the caustic containment spray solution.

The assumptions used in calculating the amount of hydrogen produced from each source are the same as, or more conservative than, those suggested in Regulatory Guide 1.7. In the current analysis, the COGAP computer program (NUREG/CR-2847, Ref. 80) was used to calculate the hydrogen generation and resulting concentration as a function of time.

The following sections provide more specific information about the assumptions and methods used to predict hydrogen gas accumulation.

6.2.5.3.1.1 Radiolytic Hydrogen Generation

Water is decomposed into hydrogen and oxygen by the absorption of energy emitted by nuclides contained in fuel and those intimately mixed with the LOCA water. The quantity of hydrogen that is produced by radiolysis is a function of both the energy of ionizing radiation absorbed by the LOCA water and the net hydrogen radiolysis yield, G (H_2), pertaining to the particular physical-chemical state of the irradiated water.

THE COGAP program utilizes a method that treats the sump water and core water separately to determine the total hydrogen radiolysis yield. Details of this methodology are found in Reference 80.

6.2.5.3.1.2 Chemical Hydrogen Generation

In addition to radiolysis, hydrogen is generated by chemical reactions occurring within the containment. The two primary sources of chemical hydrogen generation are (a) the zirconium-water reaction occurring at elevated fuel cladding temperatures and (b) the corrosion of metals in the alkaline environment of the post-DBA containment.

A. Zirconium - Water Reaction.

Zirconium reacts with steam according to the reaction

$$Zr + 2H_2O \rightarrow ZrO_2 + 2H_2 + \text{Energy}$$

The hydrogen gas evolved from this reaction is calculated to be:

$$\frac{2.01 \text{lbmole} H_2}{\text{lbmole} Zr} X \frac{386 \text{scf} H_2}{1 \text{bmole} H_2} X \frac{\text{lbmole} Zr}{91.22 \text{lb} Zr} = 8.505 \frac{\text{scf} H_2}{\text{lb} Zr} \qquad (6.2\text{-}25)$$

Where scf = Standard Cubic Feet at 70°F and 1 atm.

The ECCS, i.e., SIS, is designed to remove core heat at a rate that will prevent fuel rods from heating to the point where Zr-H_2O reactions will take place. The analysis of the LOCA shows that with the passive accumulators and the active elements of high pressure and low pressure safety injection, less than one percent of the zirconium cladding will react with water to generate hydrogen. In analyzing post-accident hydrogen generation, it has been conservatively assumed that five percent (more than 5 times the calculated rate) of the total mass of zirconium in Zircaloy-4 fuel cladding reacts. For a conservative estimate of 45,164 lb of Zircaloy-4 cladding which consists of 98.6 percent zirconium metal, this amounts to 2,227 lb of zirconium reacting. The total hydrogen generation from this source is then estimated to be 19,206 scf.

The hydrogen that is generated from the Zr-H_2O reaction exits from the core at a temperature approximating the temperature required for the reaction itself to take place, 3,365 °F (Reference 56). At this temperature, the hydrogen would instantaneously react with the oxygen in the containment air to produce water; in fact, this very assumption is made in determining the total exothermic heat of the Zr-H_2O reaction. In this analysis, however, none of the chemically produced hydrogen from the Zr-H_2O reaction is assumed to recombine.

B. Corrosion of Metals in Containment

Hydrogen is formed by corrosion of metals in the containment. The significant portion of this source of hydrogen is from the corrosion of zinc, copper and aluminum by the alkaline containment spray solution. Table 6.2-28 gives the quantity of each material in the containment. Zinc in the containment is in two forms: zinc base paint and galvanized metals such as ductwork and cable trays.

The corrosion rates for zinc base paint, galvanized surfaces, aluminum, and copper used for design purposes are given in Table 6.2-29. These corrosion rates are based on conservatively high pH and temperature conditions. The pH values assumed have been adjusted to room temperature for consistency with the industry methods for reporting pH/corrosion rate relationships.

6.2.5.3.1.3 Other Sources of Hydrogen

During normal operation of the plant, hydrogen is dissolved in the primary system water. The concentration of hydrogen in primary coolant ranges from 10 - 50 scc/kg of coolant. In addition hydrogen is also present in the pressurizer during normal operation. The total amount of hydrogen in the primary system is taken to be 500 scf.

6.2.5.3.1.4 Post-Accident Hydrogen Concentration in Containment

The time dependent quantity of hydrogen in the containment (assuming no pre-existing hydrogen concentration) is given in Figure 6.2-25. The amount of hydrogen contributed from each source as a function of time is presented in Figure 6.2-25A and the amount generated from spray induced corrosion of each metal is shown in Figure 6.2-25B. Note that the calculated hydrogen generation from spray induced corrosion assumed conservative pH conditions based on spray and sump water buffering by the former NaOH system. The lower long term pH values associated with NaTB will result in lower hydrogen production.

The addition of RCS vents will not change the total volume of hydrogen released to the containment and therefore compliance with 10CFR50.44 is not affected by RCS venting.

As shown in Figure 6.2-25, the effect of one hydrogen recombiner placed in operation at about 3.5 days after the accident is sufficient to maintain hydrogen concentrations below allowable limits if there is no pre-existing hydrogen concentration.

6.2.5.4 Tests and Inspection

Historical data removed - To review exact wording please refer to Section 6.2.5.4 of the FSAR.

All Seismic Category 1 components of the systems are designed, fabricated, installed and tested under quality assurance requirements in accordance with 10 CFR 50, Appendix B.

Hydrogen analyzers and radiation monitoring equipment are calibrated against known sources to verify their accuracy.

6.2.5.5 Instrumentation Requirements

Two hydrogen analyzers are provided for sampling of the containment atmosphere following beyond design basis events. Sample points are provided at various elevations inside the containment to ensure a representative sample. All containment isolation valves for this system provide position indication in and are operable from the control room. This allows the operator to continuously monitor system status and remotely operate valves as necessary.

The hydrogen recombiners are initiated manually from the control room.

6.3 EMERGENCY CORE COOLING SYSTEM

6.3.1 DESIGN BASES

The Emergency Core Cooling System (ECCS) or Safety Injection System (SIS) is designed to provide core cooling in the unlikely event of a Loss of Coolant Accident (LOCA). The cooling must prevent fuel melting or significant alteration of core geometry, limit the cladding metal-water reaction, and remove the energy generated in the core for an extended period of time following a LOCA. The SIS fluid must contain sufficient neutron absorber to maintain the core subcritical following a LOCA. In addition, the SIS functions to inject borated water into the Reactor Coolant System (RCS) to prevent fuel damage and to increase the shutdown margin of the core in the unlikely event of a steam line rupture. The system is actuated automatically.

6.3.1.1 Range of Coolant Ruptures

The SIS provides sufficient core cooling to accomplish the design requirements for all breaks in the RCS up to and including the double ended break in the largest reactor coolant pipe. A detailed discussion of the types of breaks is found in Section 6.3.3.

6.3.1.2 Fission Product Decay Heat

The fission product decay energy curve used in the design and accident analysis is the Proposed ANS Standard (Reference 16), with the addition of the uncertainties listed below. Included in the decay energy rate is the decay energy of the U-239 and Np-239 produced by neutron absorption in U-238. The standard decay energy rate for infinite reactor operation as a function of time after shutdown is shown in Figures 6.3-1A and 1B.

Cooling Time t_s (sec)	Uncertainty, used in ECCS Evaluation
$t_s < 10^3$	+ 20%, - 40%
$10^3 < t_s < 10^7$	+ 10%, - 20%
$t_s > 10^7$	+ 25%, - 50%

6.3.1.3 Reactivity Required for Cold Shutdown

The Refueling Water Tank (RWT) contains sufficient boric acid to provide shutdown margin for the reactor, cold, with all Control Element Assemblies (CEAs) out. Physics analytical methods are described in Section 4.3.3. Sampling of the system and RWT in accordance with the Technical Specifications ensures that the required boric acid content is present.

In addition to its emergency core cooling functions, the SIS functions to inject borated water into the RCS and increase shutdown margin following a rapid cooldown of the system as a result of a steam line rupture. Although there may be a brief return to criticality during this accident, critical heat flux conditions are not exceeded, and no core damage results. Refer to Section 15.1.4 for the analysis of the accident.

6.3.1.4 Capacity to Meet Functional Requirements

In addition to the requirements defined above, the following additional functional requirements are used for system design.

A. The safety functions defined in Section 6.3.1 are accomplished assuming the failure of a single active component during the injection mode of operation or the single failure of an active or passive component during the recirculation mode of operation. For failure analysis, all necessary supporting systems including the emergency electrical power system are considered.

B. The design of the SIS permits inspection and testing of components and subsystems to ensure their availability and proper operation.

C. All components of the system and associated critical instrumentation which must be operated following a LOCA are designed to operate in the environment to which they would be exposed.

D. The system is designated Seismic Category 1 and must be able to perform its function following an accident with combined LOCA and Design Basis Earthquake (DBE) loads.

E. The system is designed to meet the requirements of Section 6.3.1 for the duration of a LOCA condition. During the short period of time following blowdown, the core must be rapidly refilled with borated water to remove sensible heat. This requirement is met by the injection of borated water from the safety injection tanks and from the refueling water tank.

6.3.1.4.1 Capacity to Meet Short-Term Cooling Requirements

The safety injection tanks, containing borated water pressurized by a nitrogen cover gas, constitute a passive system which automatically discharged into the RCS to provide core cooling and re-cover the core when the pressure falls below the tank pressure. Adequate fluid is contained in the tanks to accomplish this function, assuming one tank discharging through a cold leg break.

The refueling water tank fluid is injected into the RCS by two sets of full capacity pumps. Each set consists of one High Pressure Safety Injection (HPSI) pump and one Low Pressure Safety Injection (LPSI) pump. Each set of pumps is capable of performing this function with one of the injection nozzles discharging through a cold leg break.

6.3.1.4.2 Capacity to Meet Long-Term Cooling Requirements

Long-term cooling is accomplished by recirculating the water in the containment sump using the HPSI pumps. The switch from injection to recirculation occurs automatically. The recirculated sump water is injected to the core and the mechanism for residual heat removal is boil-off of fluid in the reactor vessel. For certain break sizes and break locations, this may result in a long-term buildup of solids in the reactor vessel. Accordingly, manual realignment procedures have been developed which establish a circulation flow through the reactor vessel to flush dissolved solids from the core region. These procedures, which are implemented between two and four hours post-LOCA, insure the continued operability of the ECCS for extended periods of time following a LOCA.

6.3.1.4.3 Sequence of Events Diagram

The sequence of events diagram shown in Figure 6.3-12 identifies each safety system required to function to cool the core. The diagram begins with the initiating event, LOCA and branches out to show the sequence of events required to achieve each required safety function. The safety functions are reactivity control, containment temperature, pressure and iodine control, emergency core cooling, establish containment and combustible gas control.

The following systems and components are required to operate in support of the engineered safety features identified on the sequence of events diagram:

A. Engineered Safety Feature Actuation System (ESFAS)

B. Emergency Power System

C. Refueling Water System

D. Containment Sump

E. Service Water System

6.3.1.5 Safety Injection Component Arrangement

A. The safety injection pumps are located in the auxiliary building. During Recirculation mode, these pumps take suction from the containment sump. As a result of NRC Generic Safety Issue (GSI) -191 and Generic Letter (GL) 2004-02, the containment sump strainer surface area has been increased to accommodate the amount of debris transported to the sump screen. HPSI pump NPSH requirements have been evaluated for the head loss across the replacement strainers. The evaluation has concluded the NPSHA is greater than the NPSHR. The required NPSH for the HPSI pumps is 19.4 feet at a flow rate of 900 gpm. For this design calculation, the sump inventory is considered subcooled when containment sump pressure is below the saturation temperature corresponding to minimum Technical Specification allowed containment pressure. No credit is taken for increased containment pressure as a result of accident conditions. The available NPSH is calculated at the pump suction. The calculation is made assuming high pressure safety injection and containment spray pump operation.

   The NPSH required by the LPSI pumps is 25 feet at a flow rate of 5,000 gpm per pump during injection, when the pumps take suction from the refueling water tank. The calculation is made assuming HPSI and containment spray pump operation with RWT temperature of 110 °F. The LPSI pumps are not required during recirculation.

B. Three separate watertight rooms are provided for the Engineered Safety Feature (ESF) equipment. The safety injection and containment spray pumps, the shutdown cooling heat exchangers, and the piping are arranged so that the passive failure of one pipe will not flood more than one room or cause the failure of more than one pump of each type.

C. The four safety injection check valves are located as close as practical to the RCS cold leg piping. Each check valve leakage line is connected to the safety injection line immediately upstream of the safety injection check valve. The water in the safety injection piping is maintained at the refueling concentration by periodic circulation of refueling water through the safety injection piping.

D. The safety injection tanks are located inside the containment area and are protected from missiles.

6.3.2 SYSTEM DESIGN

6.3.2.1 System Schematic

A simplified diagram of the safety injection system is shown in Figure 6.3-2. The major components of this system are the refueling water tank, three HPSI pumps, two LPSI pumps, four safety injection tanks, eight High Pressure Safety Injection (HPSI) valves, and four Low Pressure Safety Injection (LPSI) valves.

6.3.2.2 Component Description

The design parameters and codes for the major components are listed in Table 6.3-1. The components required to provide core protection for the complete spectrum of reactor coolant pipe breaks are defined in Section 6.3.3.

6.3.2.2.1 Refueling Water Tank

The RWT is an atmospheric tank containing borated water at greater than 40 °F to maintain the boric acid concentration in solution. The tank is vented through the overflow and the atmospheric vent. The vent is sized for tank integrity during all thermal and pumping transients.

The RWT is normally used to fill the refueling canal and transfer tube for refueling operations. Approximately 384,000 gallons are required to fill the refueling cavity to a depth of about 24 feet above the reactor vessel flange joint.

The volume of water required by the safety injection and containment spray systems is approximately 384,000 gallons. This provides sufficient water so that the ESF pumps can take suction from the RWT for a minimum of 30 minutes after initiation of emergency core cooling and provides adequate water for long-term recirculation. This requirement of 384,000 gallons is based upon all seven ESF pumps operating at their rated flows.

The water level in the containment after this water (384,000 gallons) has been introduced and excluding that in the reactor vessel cavity is approximately seven feet above the 336-foot, 6-inch containment floor. The safety injection tank contents of 5,920 ft^3 is included in the inventory available for recirculation. For long-term core cooling, a continuous source of borated water is provided by recirculating water from the containment sump. This height of water will provide adequate NPSH for the ESF pumps even under boiling sump conditions.

6.3.2.2.2 Safety Injection Tanks

The four safety injection tanks are used to flood the core with borated water following a depressurization as a result of LOCA. The tank gas/water fractions, gas pressure, and outlet pipe size were the subject of a parametric study performed to determine the improvement in ECCS performance which could be effectively obtained over the results reported in the PSAR and were selected with NRC and ACRS review and approval.

The tanks contain borated water and are pressurized with nitrogen. The tank liquid level, boron concentration, and nitrogen cover pressure maintained in the tanks are as specified in the Technical Specifications.

Redundant and diverse level and pressure instrumentation is provided to monitor the tanks during plant operation, as discussed in Section 6.3.5. Provisions have been made for sampling, filling, draining, venting, and correcting boron concentration. The data summary for the safety injection tanks is given in Table 6.3-1.

In addition to the administrative controls placed on safety injection tank discharge valves, the motor operated isolation valves are provided with interlocks with the pressurizer pressure measurement channels to open the valves automatically prior to RCS pressure increasing above 700 psia, and to prevent inadvertent closure prior to or during an accident. Visual indication of valve position is provided in the control room.

When the RCS pressure increases above the safety injection tank pressure, but prior to the automatic opening of the safety injection tank discharge valves, the valves are opened by the operator, and power supply breakers to the discharge valves are open under administrative control.

6.3.2.2.3 Low Pressure Safety Injection Pumps

The LPSI pumps serve two functions. The first is to inject large quantities of borated water into the RCS during an emergency involving a large reactor coolant pipe rupture. Sufficient flow is delivered under these conditions to satisfy functional requirements described in Section 6.3.1.1. The second is to provide flow through the reactor core and shutdown cooling heat exchangers for shutdown cooling and residual heat removal during cold shutdown. The pump characteristics curve is presented in Figure 6.3-3.

The LPSI pumps are sized to provide adequate shutdown cooling flow. The flow available with a single LPSI pump is sufficient to maintain a core ΔT less than the full power ΔT, about 60 °F, at the initiation of shutdown cooling 3.5 hours after shutdown. Maintenance of the core at less than full power Delta T results in a lesser demand on the core structural design than does normal plant operation.

The design temperature for the LPSI pumps is derived from the temperature of the reactor coolant at the initiation of shutdown cooling, about 300 °F nominal plus the 60 °F Delta mentioned above. The design pressure for the low pressure pumps is based upon the sum of the maximum pump suction pressure, which occurs at the initiation of shutdown cooling, and the pump shutoff head.

The LPSI pumps are single stage centrifugal units equipped with mechanical face seals backed up by a bushing and with leakoff provisions. To prolong seal life, a portion of the pump discharge is cooled by service water and is recirculated to the seals. The pumps are provided with drain and flushing connections to permit reduction of radiation levels before maintenance. The pressure containing parts are fabricated from stainless steel; the internals are selected for compatibility with boric acid solutions.

The pumps are provided with minimum flow protection to prevent damage when starting against a closed system. The pumps are protected from run-out damage by appropriate system valve adjustments and/or orifice sizing during the test program. The flow restricting orifice (2F0-5090) in the main header is sized as required to provide system resistance suitable for precluding excessive pump run-out.

The low pressure pump data are summarized in Table 6.3-1.

6.3.2.2.4 High Pressure Safety Injection Pumps

The HPSI pumps function to inject borated water into the RCS if a break occurs in the RCS boundary. For small breaks, RCS pressure remains high for long periods of time following the break. In this event, the HPSI pumps will provide sufficient flow to meet the criteria given in Section 6.3.1. The HPSI pumps are also used during recirculation to maintain a water circulation through the core for extended periods of time following a LOCA.

The HPSI pumps are sized such that one pump will deliver saturated water at a rate sufficient to maintain level in the reactor vessel, matching boiloffs from decay heat at the time the safety injection system switches to the recirculation mode, not less than 20 minutes after the accident. The historical pump characteristic curve is shown in Figure 6.3-4. Current pump performance data is maintained in ANO testing documentation and calculations.

Mechanical seals are used and are provided with leakoffs. The seals are externally cooled. The pumps are provided with drain and flushing connections to permit reduction of the radiation level before maintenance. The pressure containing parts of the pump are stainless steel with internals selected for compatibility with boric acid solutions. The materials selected are analyzed to ensure that differential expansion during the design transients can be accommodated.

The pumps are provided with minimum flow protection to prevent damage which could result from operation against a closed discharge. The HPSI pumps have been evaluated and are maintained to operate while recirculating through the minimum recirculation flow path following an accident without experiencing significant degradation. The pumps are protected from run-out damage by appropriate system valve adjustments and/or orifice sizing during the test program. The header isolation valves (2CV-5015-1, 2CV-5035-1, 2CV-5055-1, 2CV-5075-1 for high pressure header Number 1 and 2CV-5016-2, 2CV-5036-2, 2CV-5056-2, 2CV-5076-2 for high pressure header Number 2) can be used to throttle HPSI flow to each RCS cold leg. There is a manual globe valve upstream of each isolation valve that is throttled to balance flow among the injection headers. The flow restricting orifices in the main headers (2F0-5101 for Number 1 and 2FO-5102 for Number 2) are sized as required to provide system resistance suitable for precluding excessive pump run-out.

The design temperature for the HPSI pumps is based upon the saturation temperature of the reactor coolant at the containment design pressure, about 300 °F, plus a tolerance of 100 °F. This provides the design temperature of 400 °F. The design pressure for the high pressure pumps is based upon the sum of the containment spray pump shutoff head and the shutoff head of the high pressure pump.

The high pressure pump data are shown in Table 6.3-1.

6.3.2.2.5 Piping

The following piping is provided to deliver borated safety injection water from the safety injection tanks and from the RWT to the safety injection nozzles in the RCS cold legs:

A. From each safety injection tank to its respective RCS cold leg safety injection nozzle;

B. Redundant piping from the RWT and containment sump to the suction of the HPSI, LPSI and containment spray pumps;

C. Redundant piping from the HPSI pump discharge to the HPI headers, each of the four safety injection nozzles; and,

D. Piping from the LPSI pump discharge to the LPI header which feeds the four injection nozzles.

The safety injection system piping is fabricated of austenitic stainless steel and is designed to ASME Code Section III. Flexibility and seismic loading analyses are performed to confirm the structural adequacy of the system piping.

6.3.2.2.6 Valves

The location, type, and size of the valves, type of operator, and position of the valve (during the normal operating mode of the plant) are shown on P&ID M-2232. Pressure rating and code design classification are also shown. Relief valves are discussed in Section 6.3.2.10.

A. Actuator Operated Throttling and Stop Valves

The position of each valve on loss of actuating signal or power supply (failure position) is selected to ensure safe operation of any given valve. Valve position indication is provided in the control room as indicated on M-2232. A locking-type control switch in the control room and/or a manual override handwheel is provided where necessary for efficient and safe plant operation.

B. Manually Operated Valves

All manually operated valves with nominal sizes larger than two inches are provided with a double packed stem with an intermediate lantern ring with a leakoff connection.

Globe valves are installed with flow entering the valve under the seat where this arrangement will reduce stem leakage during normal operation. Globe valves are installed with flow entering the valve above the valve seat in the following cases:

1. Normally open globe valves used for equipment isolation (pumps, control valve, etc.) where the pressure gradient is opposite to the normal flow direction when the valve is closed; and,

2. Normally open valves between the SIS and any other system if the flow is normally into the SIS and if the valve is to be closed during recirculation.

C. Check Valves

All check valves are the totally enclosed type. Low pressure drop check valves with flow resistance characteristics equal to or less than a clearway swing check valve of the same size as the connecting pipe are used in the pump suction lines.

6.3.2.3 Applicable Codes and Classifications

See Table 6.3-1.

6.3.2.4 Materials Specifications and Compatability

The materials used in the construction of the SIS components are given in Table 6.3-1. Pressure boundary materials in contact with radioactive coolant are austenitic stainless steel, with stellite or equivalent material being used for valve seats or discs. The materials of construction used in both the active and passive components have been evaluated and in each case it has been concluded that the materials selected are both compatible with the most severe environmental condition they will be exposed to and in accord with all code requirements.

Material controls satisfy the recommendations of Regulatory Guide 1.44, "Control of Use of Sensitized Stainless Steel," and Regulatory Guide 1.36, "Nonmetallic Thermal Insulation for Austenitic Stainless Steel."

6.3.2.5 Design Pressure and Temperatures

The design temperatures and pressures of each component are given in Table 6.3-1. The basis for these values is discussed in Section 6.3.2.2.

6.3.2.6 Coolant Quantity

The safety injection tanks contain sufficient water to recover the core even if the entire contents of one tank is discharged through a pipe break and if all water injected prior to the end of RCS blowdown is assumed lost. The safety injection tank water volume is given in Table 6.3-1.

The RWT is the source for the safety injection pumps. The volume of water in the refueling tank is determined by the quantity necessary to fill the refueling canal during refueling. This volume exceeds the quantity of water which must be injected after a pipe rupture to ensure recirculation from the containment sump and that pump NPSH requirements are met. The RWT volume is given in Table 6.3-1.

6.3.2.7 Pump Characteristics

LPSI and HPSI pump characteristic curves are provided in Figures 6.3-3 and 6.3-4.

6.3.2.8 Heat Exchanger Characteristics

The shutdown cooling heat exchanger is described in the Containment Spray System (CSS) (Section 6.2.2) and shutdown cooling system (Section 9.3.6).

6.3.2.9 ECCS Flow Diagram

Figure 6.3-2 shows the flow paths for the SIS.

Historical data removed - to review the exact wording please refer to Section 6.3.2.9 of the FSAR.

6.3.2.10 Relief Valves and Vents

Protection against overpressurization of components within the SIS is provided by conservative design of the system piping, appropriate valving between high pressure sources and low pressure piping, and by relief valves. All lines within the high and low pressure systems from

the RCS up to and including the safety injection valves are designed for full RCS pressure. In addition, the high pressure header to which the charging pumps discharge is designed for full RCS pressure up to and including the header check valve. Relief valves are provided as required by applicable codes.

All relief valves are of the totally enclosed, pressure tight type with suitable provisions for gagging.

A tabulation of relief valves is provided below:

A. Safety Injection Tank Relief Valves

The relief valves on the safety injection tanks are sized to protect the tanks against the maximum fill rate of liquid or gas into the safety injection tanks. They discharged into the containment. The set pressure is 700 psig with a capacity of 150 gpm.

B. Check Valve Leakage Relief Valve

A backpressure compensated relief valve is provided on the safety injection test and leakage return line. This relief valve is sized to protect against overpressure of the line when filling a safety injection tank. It discharges into the reactor drain tank. The set pressure is 500 psig with a capacity of 40 gpm.

C. LPSI Relief Valve

This backpressure compensated valve protects the LPSI line against the pressure developed due to a sudden temperature increase. It discharges into the holdup tank. The set pressure is 500 psig with a capacity of 5 gpm.

D. HPSI Relief Valve

These valves are sized to protect the HPSI lines against the pressure developed due to a sudden temperature increase. They are backpressure compensated and discharge into the holdup tank. The set pressure is 1,950 psig with a capacity of 5 gpm.

E. HPSI Header Relief Valve

The HPSI header to which the charging pumps discharge is protected from the charging pump discharge pressure by this valve. It discharges into the holdup tank. The set pressure is 2,485 psig with a capacity of 160 gpm.

F. LPSI Header Relief Valve

The LPSI header downstream of the Shutdown Cooling Water Heat Exchangers is protected from potential overpressurization, originating from CVCS system via the LPSI purification cross-tie, by this valve. It discharges into the Boron Management System collection header. The valve set pressure is 500 psig with a capacity of approximately 42 gpm.

6.3.2.11 System Reliability

6.3.2.11.1 Safety Injection Tanks

The safety injection tanks containing borated water pressurized by a nitrogen cover constitute a passive injection system; that is, no outside operator action or electrical signal is required for operation. Each tank is connected to one reactor coolant cold leg by a separate line. Two check valves isolate the tank from the RCS during normal operation. When the RCS pressure falls below the tank pressure, the check valves open discharging the contents of the tank into the system. Adequate borated water is supplied to rapidly cover the core, with one tank assumed to be discharging through the break. The evaluation in Section 6.3.3 demonstrates the adequacy of the quantity of coolant supplied.

Controls and interlocks for the motor operated isolation valves on the safety injection tank discharge are discussed in Section 6.3.2.15.

6.3.2.11.2 High Pressure and Low Pressure Safety Injection Subsystems

Two redundant HPSI systems are provided. One pump and the associated four injection valves operate from one emergency diesel generator; the other pump and injection valves operate from the second emergency diesel generator. This ensures the automatic operation of one complete, full capacity system in the unlikely event of simultaneous loss of offsite power and the failure of any active component, including an emergency diesel generator.

Active components necessary for LPSI are sized and arranged to provide two subsystems each capable of providing the required flow. Two motor operated injection valves and one LPSI pump operate from each diesel generator. Therefore, LPSI flow will be available for injection even though an emergency diesel generator should fail simultaneously with the loss of offsite power.

Since the LPSI system is not required to operate during the recirculation mode of core cooling, passive components (piping) are not redundant. Administrative controls ensure that the shutdown cooling flow control valve, common to both subsystems, is locked open at all times when the plant is operating. In addition, a locked open, manual bypass valve in parallel with the air-operated valve is provided to ensure flow in the event of accidental closure of that valve.

6.3.2.11.3 Power Sources

Two independent electrical buses supply power to the SIS equipment. Each bus may receive power from:

A. Plant turbine generator (normal power source);

B. Plant startup power source (off-site power);

C. Emergency diesel generators.

The initiation sensors, electrical controls, and electrical indication equipment normally receive power from four 120-volt AC buses. Two 125-volt ESF station batteries and six inverters are provided as a backup upon loss of all other sources of power.

Each plant transmission line has the capacity to supply sufficient power for all the ESF loads. Each of the two diesel generators has the capacity to supply power for one set of ESF equipment.

System reliability is achieved with the following:

A. Two electrical buses, with each bus supplying power to a 100 percent capacity low pressure pump, a 100 percent capacity high pressure pump, associated valves and support systems. (Each support system contains two full capacity subsystems);

B. Two sources of power, normal and standby to both buses, with automatic backup from the emergency diesel-generators; and,

C. Two emergency diesel-generators, each capable of supplying power for the minimum ESF loads.

A detailed description of the power sources is given in Chapter 8.

6.3.2.11.4 Capacity to Maintain Cooling Following a Single Failure

The SIS is designed to meet its functional requirements even with the failure of a single active component during the injection mode of operation or with the single failure of an active or passive component during the recirculation mode of operation. By providing proper redundancy of equipment, even with the single failure noted above, the minimum required safety injection equipment is always available.

The following design features are provided in the system in order to meet the single failure criterion:

A. Redundant HPSI and LPSI pumps.

B. Redundant piping between containment sump and safety injection pump suction.

C. Redundant HPSI headers.

D. Four injection discharge points into the RCS.

E. Three watertight rooms in the auxiliary building. Two rooms contain one HPSI pump, one LPSI, one containment spray pump and one shutdown cooling heat exchanger. The third room contains the common or shared HPSI pump.

A single failure analysis is given in Table 6.3-3.

6.3.2.12 Protection Provisions

The SIS is provided with protection from damage that could result from a LOCA by designing components to withstand the accident environment including missiles, coolant chemistry, high temperature and high pressure resulting from the accident and to withstand concurrent DBE and LOCA loadings.

6.3.2.12.1 Capability to Withstand Accident Environment

All SIS components and associated electrical equipment have been designed to withstand accident environmental conditions. The design of each component encompasses the most severe condition the equipment will encounter. A complete description of the equipment environmental qualification program is presented in Chapter 7.

6.3.2.12.2 Seismic Design

Since operation of the SIS, is essential following a LOCA, it is classified Seismic Category 1. The general design basis for Category 1 equipment is that it must be able to withstand the appropriate seismic loads plus other applicable loads without loss of design functions which are required to protect the public.

For the SIS, the components are designed to withstand the loads resulting from emergency operation following a LOCA, plus the stresses resulting from the DBE without loss of function.

Vessels which are connected to the ESF systems are supported and restrained to allow controlled movement during this load condition, and piping is designed to accept the imposed movements. Engineering calculations of the flexibility of the systems are performed to verify that the piping can accept these additional vessel movements and still remain within code allowable limits of stress.

Refer to Section 3.7 for details on seismic design and analysis methods.

6.3.2.13 Provisions for Performance Testing

The SIS is provided with the necessary connections such that proper operation of each active component can be determined. Recirculation lines are provided on each pump such that the pumps can be started during normal operation and pump performance determined. Provision for testing all check valves is provided either by pump operation or by the charging pump connection to the high pressure header. Additionally, the motor operated valves have position indication for testing.

The safety injection tanks and RWT are provided with sample connections to determine the boron content of each. This assures that fluid containing the proper boron content would be injected in the unlikely event of a LOCA.

6.3.2.14 Net Positive Suction Head

The HPSI and LPSI pumps are located in rooms in the lowest level of the auxiliary building. This location maximizes the available NPSH for the safety injection pumps.

The method of calculating NPSH is in agreement with the intent of NRC Regulatory Guide 1.1 in that no credit is taken for containment pressure increases due to accident conditions. Since the guide assumes no containment pressure increase above that present prior to a LOCA, boiling of water would occur at the peak temperatures predicted by the accident analysis, thus equilibrium between containment pressure and sump water at saturation conditions is modeled. Therefore, in determining available NPSH, the sump inventory is considered subcooled when sump temperature is below the saturation temperature corresponding to the minimum Technical Specification allowed containment pressure.

The NPSH available to the HPSI pumps during recirculation has been calculated based on piping drawings and on the following:

A. Pipe and fitting losses;

B. Total flow on one suction header of 3532.5 gpm, consisting of 2632.5 gpm for one containment spray pump and 900 gpm for one HPSI pump. However, due to differences in the suction pipe routing, the most limiting pump suction loss occurs when HPSI Pump C (2P-89C), with a lower maximum flow of 870 gpm, is aligned to the A train header.

C. Assuming the single active failure of the B Train LPSI failing to trip after RAS

- Impact to A Train NPSH is evaluated, since it will provide the needed safety function, even if the B Train pumps do not have adequate NPSH
- Maximum flow through the sump strainer is 12,735 gpm
- A Train Suction header flow is 3505.2 gpm consisting of CSS Pump A (2632.5 gpm) and HPSI Pump C (870 gpm)
- Maximum pump suction loss is 4.296 feet for the C HPSI Pump when aligned to the A Train;

D. The calculation of piping pressure drop and the conversion from psi to feet of water is a dynamic value which varies with sump temperature;

E. Containment sump water level at Elevation 343.66 feet;

F. HPSI pump inlet nozzles are located at an elevation of 319 feet, 7 inches;

G. Containment pressure is equal to minimum TS allowed pressure prior to the accident. Elevated pressures resulting from the accident are not credited. When sump temperature exceeds the saturation temperature corresponding to the pre-accident containment pressure, the containment pressure is set equal to the saturation pressure of the containment sump water at the elevated temperature.

The calculation determines NPSH margin considering only the clean strainer head loss. Debris-related head loss is then compared to this margin to ensure positive margin exists. The NPSH required, as determined by the pump test curves furnished by the manufacturer, is 19.4 feet at 900 gpm and 18.8 feet at 870 gpm.

The limiting NPSH margin for the single failure of the B Train LPSI failure-to-stop following RAS is 0.984 feet for HPSI Pump C operating at maximum flow of 870 gpm aligned to the A Train.

The limiting NPSH margin for two train flow with both LPSI pumps secured is 1.8 feet for HPSI Pump C operating at maximum flow of 870 gpm aligned to the A Train.

6.3.2.15 Control for Motor Operated Safety Injection Tank Isolation Valves

Since it is essential that the isolation valves on the safety injection tanks be open whenever the RCS is at pressure, administrative control is provided to assure that these valves are open with power to the motor operators removed after RCS pressure exceeds safety injection tank

pressure. Additionally, interlocks are provided such that these valves, if left powered, will automatically open prior to RCS pressure increasing above 700 psia. Power is applied to the valve motor operators as necessary to complete valve travel. During a cooldown/ depressurization of the RCS, after the valves are closed, power is removed from the operators and the breakers are opened and administratively controlled to prevent inadvertent opening and possible overpressurization of the RCS at low temperatures. A further description of valve control is found in Section 7.6.1.2.

Position indication in the control room is provided through sensors mounted on the valves. The circuit breakers associated with the safety injection tank isolation valves will be locked open during normal operation. These tank features ensure the availability of a flow path from the safety injection tanks. The valve controls and interlocks are designed to meet the intent of IEEE 279.

6.3.2.16 Motor Operated Valves and Controls (General)

In addition to the safety injection tank isolation valves, the following motor operated valves are included as part of the SIS or are present in the flow path:

HPSI injection valves	(8)
LPSI injection valves	(4)
HPSI pumps recirculation line valves	(3)
LPSI pumps recirculation line valves	(2)
Recirculation header isolation valve	(1)
RWT isolation valves	(2)
Containment sump isolation valves	(4)
Hot leg injection valves	(2)
HPSI header orifice bypass valves	(2)
Shutdown cooling isolation valves	(3)

The HPSI and LPSI injection valves are opened on receipt of an SIAS, as described in Section 6.3.2.20. The SIAS is described in Section 7.3, and the logic is designed to ensure that the minimum ESF required to meet the design bases given in Section 6.3.1 will be met.

The five isolation valves in the safety injection recirculation (mini-flow) lines and the recirculation header isolation valve are normally open and remain open during injection. The valves are automatically shut on receipt of a Recirculation Actuation Signal (RAS) to avoid returning the recirculating water from the containment sump to the refueling water tank. The RAS is described in Section 7.3.

The RWT isolation valves are normally open, fail-as-is valves. They receive an open signal on SIAS. These valves are closed automatically by the RAS.

The containment sump isolation valves are opened by the RAS, permitting the operating ESF pumps to take suction from the containment sump.

The hot leg injection valves are normally closed valves which are manually opened post-LOCA to accomplish core flushing. When the injection valves are opened, the normally open orifice bypass valves are manually closed to balance the injection flow between the hot leg and the cold leg. Section 6.3.3.15 discusses long-term ECCS performance.

The shutdown cooling isolation valves are described in Section 9.3.6. The controls for those valves are described in Section 7.6.

6.3.2.16.1 Other Power Operated Valves

Solenoid operated valves are installed in safety injection tank fill, drain, vent, and nitrogen supply lines as shown in Figure 6.3-2.

Finally, the air operated shutdown cooling flow control valve in the common LPSI line is a normally open, locked open, valve. The LPSI flow control valve fails open on loss of air. The associated air accumulator functions to maintain the valve in the open position if instrument air is degraded. Since inadvertent closure of this valve during injection would interrupt flow from the LPSI pumps, a second locked open manual valve is arranged in parallel with the first to ensure continuity of LPSI flow.

6.3.2.17 Required Manual Actions

No manual actions are required for the SIS to operate properly. The two modes of operation: injection and recirculation, are automatically initiated by SIAS and RAS signals, respectively, as outlined in Sections 6.3.2.20 and 7.3.

6.3.2.18 Process Instrumentation

The process instrumentation available to the operator in the control room to assist in assessing post-LOCA conditions is listed in Table 6.3-4. The type of instrument, parameter measured, instrument range and accuracy are listed in the table. Process instrumentation for monitoring SIS components is discussed in Section 6.3.5.2.

6.3.2.19 Materials

As discussed in Section 6.3.2.2, the pressure boundary components of the SIS are fabricated of austenitic stainless steel, and valve seats or discs are stellite or equivalent material. These materials are not subject to significant radiolytic or pyrolytic decomposition.

The only active components in the SIS exposed to the activity in recirculating fluid are the HPSI pumps. The pump and motor are designed for the anticipated heat and radiation field predicted for the recirculation mode of operation. Materials, such as the motor lubricating oil which may degrade, can be changed. As described in Section 6.3.2.2, the pumps can be isolated and flushed to allow maintenance while the system is operating, assuring continued safe operation.

6.3.2.20 System Operation

6.3.2.20.1 System Standby Condition

During normal plant operation, the SIS is maintained in standby, aligned for emergency operation. The status of the system is as shown in Figure 6.3-2.

6.3.2.20.2 Initiation of Safety Injection

Safety injection is automatically initiated upon a coincidence of 2-out-of-4 low-low pressurizer signals or 2-out-of-4 high containment pressure signals. Low pressurizer and high containment pressure conditions imply a LOCA. (See Section 7.3)

The reactor will be tripped by the Reactor Protective System (RPS). (See Section 7.3)

A. System Operation With Off-Site AC Power

The SIAS is accompanied by a reactor trip resulting in a turbine trip and generator trip. The power distribution system automatically transfers to the selected startup transformer. (See Chapter 8) Safety loads are sequenced onto the startup transformer in the same sequence as, and using the same circuitry as, loading on the diesel generators. The following equipment is simultaneously activated:

1. Two high-pressure safety injection pumps start,

2. Both low-pressure safety injection pumps start,

3. All eight high-pressure and all four low-pressure injection valves open,

4. The four safety injection check valve leakage pressure control valves close.

SIS components not listed above are lined up for emergency safety injection when the plant is at normal operating conditions, thus no signal input or operation is required for these components. Once the RCS pressure drops below safety injection tank pressure the safety injection tanks discharge their contents into the reactor coolant cold legs. The SIAS also isolates the letdown flow path.

B. System Operation Without Off-Site AC Power

The SIAS automatically starts the emergency diesel generators. If the transfer to the startup transformer is unsuccessful, all loads except for the first block in the loading sequence are disconnected automatically. Automatic loading commences as soon as operating voltage is available at the 4.16 kV ESF switchgear buses. The load sequencing for the emergency power supply is shown in Table 8.3-1.

Once one of the 4.16 kV ESF buses is energized from the emergency AC power supply, two LPI valves and the four high pressure injection valves are opened. Ten seconds later one high-pressure safety injection pump is started, with a LPSI pump started in approximately another five seconds. The starting sequence of the other diesel generator follows the same time sequence in operating safety injection system equipment. They also start the other HPSI and LPSI pumps.

6.3.2.20.3 Injection Mode of Operation

The safety injection pumps take suction from the suction headers, initially lined up to the RWT. The HPSI pumps deliver borated water to the HPSI headers, then into the RCS via the safety injection nozzles in the cold legs. The LPSI pumps discharge into the LPSI header and through the safety injection nozzles when reactor coolant pressure has decreased sufficiently. The coolant passes from the cold leg piping into the reactor vessel to cover and remove heat from the core.

For large pipe breaks, the RCS is depressurized and emptied rapidly. The safety injection tanks are a passive device in that they require no outside power or actuation signal. The driving head for injection is provided by the nitrogen gas pressure.

As coolant pressure falls below the sum of the tank pressure plus elevation head, the check valves in the lines connecting each tank to its associated cold leg open. Large quantities of borated water are rapidly injected into the RCS. The water rapidly covers and cools the core, limiting fuel cladding temperature and metal-water reaction.

Before the safety injection tanks have emptied, the safety injection pumps have started and provide sufficient flow to keep the core covered.

For smaller pipe breaks the RCS pressure falls less rapidly and the safety injection tanks do not come into play immediately. The HPSI pumps provide core cooling flow while pressure remains high. The LPSI pumps do not deliver coolant until system pressure has decreased below their shutoff head.

6.3.2.20.4 Recirculation Mode Initiation

Transfer to the recirculation mode of operation is initiated by low water level in the RWT, derived from the four independent level indicators on the RWT. The RAS shuts down the LPSI pumps, opens both containment sump recirculation line isolation valves, closes the minimum flow recirculation line isolation valves, and closes the refueling water tank discharge valves.

There is no single failure which would result in both LPSI pumps continuing to run following a RAS. Should one LPSI pump continue to run, it could experience inadequate NPSH and be damaged. The control room operator would be informed of the status of the LPSI pumps by Class 1E indication and thus would take action to manually secure an LPSI pump which had failed to trip following the RAS. Due to increased flow losses through the strainer and the common portion of that train’s suction pipe, the HPSI pump on the train with a LPSI pump that continues to run after a RAS could also experience inadequate NPSH. Since no single failure would result in both LPSI pumps continuing to run following a RAS, the HPSI pump on the train opposite of the running LPSI pump would perform the required safety function.

The transfer to the recirculation mode can also be accomplished manually.

6.3.2.20.5 Recirculation Mode Operation

During recirculation, the HPSI pumps continue to operate taking suction directly from the containment sump. The shutoff head of the HPSI pumps is greater than the saturation pressure of the reactor coolant following any break for which system operation is required. The pumps are designed so that one pump provides sufficient flow to match decay heat boiloff at the time recirculation is initiated, assuming 25 percent spill through the break.

As RCS pressure permits, and the RAS signal is cleared, Shutdown Cooling System (SDCS) operation may be initiated to speed RCS cooldown. Alignment of the SDCS valves, termination of the corresponding containment sump pump operation, and closure of the corresponding containment sump train containment isolation valve would be required prior to starting a LPSI pump. The LPSI pump would then be aligned to take suction from the RCS shutdown cooling nozzle and return the fluid through a shutdown cooling heat exchanger to the RCS cold legs.

6.3.2.20.6 Safety Injection Operation During Shutdown Cooling

With the LTOPs in service, the Safety Injection Tank outlet valves may be open when their associated Safety Injection Tank pressure is less than 280 psig. When a SIT is pressurized greater than 280 psig, the associated outlet valve is closed and the outlet valve breaker is open.

In the unlikely event of a LOCA at this time, the operator would be alerted by a combination of the following alarms and/or indicators:

Low pressurizer level alarm
High containment pressure alarm
Containment activity alarm
Containment temperature alarm
Containment sump level alarm
Low volume control tank level alarm
Shutdown cooling flow
Shutdown cooling temperature
Low RCS pressure

For large breaks, most of the above alarms and indications will be present. As break size decreases, so will the number of indications and alarms. For a break equal to or less than the capacity of one charging pump, sump level, containment activity, and containment temperature would increase, and volume control tank level would decrease.

When the operator is alerted to a loss of coolant condition, he will verify that the following functions have been performed as required.

A. Safety injection tank isolation valves opened.

B. HPSI and LPSI pumps started.

C. HPSI and LPSI valves opened.

D. Emergency diesels are started.

E. Containment isolation has taken place.

These actions may be manually initiated from the control room.

If the break is very small, the HPSI pumps may increase RCS pressure. The operator will then throttle the HPSI valves to limit pressure rise, monitoring pressurizer pressure. In the case of a small break and as RCS pressure permits, the SDCS can be used for decay heat removal, with the safety injection pumps used for pressure control

6.3.2.21 Interconnections With Other Systems

The safety injection flow path to the reactor vessel is through a safety injection nozzle on each of the four RCS cold leg pipes. This provides four separate flow paths from the SIS to the reactor core. During shutdown cooling, the LPSI pumps take suction from the RCS through a nozzle on the hot leg pipe in loop 2P32 C/D. Two motor operated valves in this line are interlocked with two pressurizer pressure measurement channels, to preclude their being opened when RCS pressure is above the design pressure rating of the downstream piping. Refer to Section 7.6.1.1 for further description of the interlocks.

A connection is provided from the discharge side of the Chemical and Volume Control System (CVCS) charging pumps to one of the high pressure headers. Its primary purpose is to test the operation of the four safety injection check valves at the RCS when the RCS is pressurized.

The connection can be used to adjust boron concentration in the safety injection tanks and it also provides an alternate injection path for the charging pumps. Connections from the RWT to the CVCS are provided. These connections have three functions:

A. to supply refueling water to the suction of the charging pumps;

B. to permit borated water at refueling concentration to be added to the RWT from the CVCS; and,

C. to permit small quantities of concentrated boric acid to be added to RWT for correction of the refueling water boron concentration.

Sample connections are provided on selected piping and on the RWT. Provisions are made for local sampling on readily accessible piping and for direct connection to the sampling system for piping that may be inaccessible after an accident or may contain high temperature or radioactive water. Sample connections are provided at the RWT and the safety injection tanks. (The safety injection tank drain header may be sampled from a drain line in the containment building. This sample can be used to check the boric acid concentration at any of the four safety injection check valves.)

Samples of water pumped through the safety injection pumps are available through the sampling system. A direct connection from the pump minimum flow lines to the sampling system is provided for this purpose. A connection to the sampling system is also provided on the shutdown cooling suction line.

A connection is provided from the safety injection tank drain header to the boron management system. Leakage through the four check valves in the safety injection lines adjacent to the reactor coolant loops can be bled to the boron management system through this connection.

A regulated nitrogen supply is provided to the safety injection tanks to maintain tank pressure during normal plant operation.

Drains are provided for radioactive liquids. Typical sources are valve and equipment leakoffs, pump drains and relief valve discharges.

6.3.2.22 System Leakage

During recirculation, the safety injection pumps take suction from the containment sump and return water to the RCS and hence to the core. Following a major LOCA, any system leakage may be radioactive and special care is taken to limit leakage outside the containment building.

Leakage to the ESF room will normally drain to the room. Should a gross gasket failure or equipment failure occur which cannot be directly isolated, the spillage will flow to the room.

6.3.3 PERFORMANCE EVALUATION

The performance evaluation of the ECCS during postulated LOCAs is discussed in this section.

6.3.3.1 Evaluation Model

The 1999 EM version of the Westinghouse large break LOCA evaluation model for Combustion Engineering designed PWRs, as described in Section 6.3.3.2.2 and its references, was used in performing the ECCS performance evaluation for a spectrum of large reactor coolant pipe breaks.

The S2M version of the Westinghouse CE small break LOCA evaluation model for Combustion Engineering designed PWRs, as described in Section 6.3.3.2.3 and its references, was used in performing the ECCS performance evaluation for a spectrum of small reactor coolant pipe breaks.

6.3.3.2 ECCS Performance

The results for the large break LOCA and small break LOCA ECCS performance evaluations are provided in this section. The methods and the technical justification are also discussed in this section.

6.3.3.2.1 Introduction and Summary

10 CFR 50.46 (Reference 1) provides the acceptance criteria for Emergency Core Cooling Systems (ECCS) for light water nuclear power reactors. The ECCS performance analysis presented in this section demonstrates that the ANO-2 ECCS design satisfies these criteria.

The analysis was performed for a spectrum of break sizes in the reactor coolant pump discharge leg. The limiting break size, that which results in highest peak cladding temperature, was identified as the 0.4 DEG/PD break (Double Ended Guillotine break in Pump Discharge). The results of the analysis demonstrate that, for a peak linear heat generation rate (PLHGR) of 13.7 kw/ft, the ANO-2 ECCS design meets the 10 CFR 50.46 Acceptance Criteria. Conformance is as follows:

Criterion (1) Peak Cladding Temperature. "The calculated maximum fuel element cladding temperature shall not exceed 2200 °F."

The ECCS performance analysis yielded a peak cladding temperature of 2144 °F for the 0.4 DEG/PD break described in Section 6.3.3.2.2.6.

Criterion (2) Maximum Cladding Oxidation. "The calculated total oxidation of the cladding shall nowhere exceed 0.17 times the total cladding thickness before oxidation."

The ECCS performance analysis yielded a maximum cladding oxidation of 0.1677 times the total cladding thickness before oxidation for the 0.04 ft^2/PD break described in Section 6.3.3.2.3.6.

Criterion (3) Maximum Hydrogen Generation. "The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam shall not exceed 0.01 times the hypothetical amount that would be generated if all of the metal in the cladding cylinders surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react."

The ECCS performance analysis yielded a maximum hydrogen generation of less than 0.01 times the hypothetical amount for the 0.4 DEG/PD break described in Section 6.3.3.2.2.6.

Criterion (4) Coolable Geometry. "Calculated changes in core geometry shall be such that the core remains amenable to cooling."

The cladding swelling and rupture models which are part of the Westinghouse evaluation models for Combustion Engineering PWRs account for the effects of changes in core geometry if such changes are predicted to occur. Adequate core cooling was demonstrated with the predicted core geometry changes. The analysis was performed to the point where cladding temperatures were decreasing and the RCS was depressurized, thereby precluding any further cladding deformation. Therefore, a coolable geometry was demonstrated.

Criterion (5) Long Term Cooling. "After any calculated successful initial operation of the ECCS, the calculated core temperature shall be maintained at an acceptably low value and decay heat shall be removed for the extended period of time required by the long-lived radioactivity remaining in the core."

The ECCS performance analysis showed that the rapid insertion of borated water from the safety injection tanks (SITs) and the safety injection pumps suitably limited the peak cladding temperature and cooled the core within a short period of time. Subsequently, the safety injection pumps would continue to supply cooling water from the refueling water tank (RWT) to remove heat from the long-lived radioactivity remaining in the core. When the RWT is nearly empty, the safety injection pumps would be lined up to recirculate water from the containment sump. See Section 6.3.1.4.2 for additional information on long term cooling.

6.3.3.2.2 Large Break Analysis

6.3.3.2.2.1 Evaluation Model

The large break LOCA ECCS performance analysis used the 1999 EM version of Westinghouse's NRC-accepted large break LOCA evaluation model for Combustion Engineering-designed PWRs (Reference 6, Supplement 4-P-A). The methodology for modeling the Next Generation Fuel (NGF) assembly design in ECCS Performance analyses using the 1999 EM is described in the CE 16 x 16 NGF Core Reference Report (Reference 93). Reference 94 denotes the topical report relevant to the 1999 EM for modeling the Optimized ZIRLO^{TM} cladding. The following computer codes are used in the 1999 EM and are described in the references cited with additional descriptive information provided in Supplement 4-P-A of Reference 6: The CEFLASH-4A computer code (Reference 9) is used to perform the blowdown hydraulic analysis of the reactor coolant system (RCS) and the COMPERC-II computer code (Reference 11) is used to perform the RCS refill/reflood hydraulic analysis and to calculate the containment pressure. It is also used in conjunction with the methodology described in Reference 28 to calculate the FLECHT-based reflood heat transfer coefficients used in the hot rod heatup analysis. The HCROSS (Reference 81) and PARCH (References 81 and 27) computer codes are used to calculate steam cooling heat transfer coefficients. The hot rod heatup analysis, which calculates the peak cladding temperature and maximum cladding oxidation, is performed with the STRIKIN-II computer code (Reference 30). Core-wide cladding oxidation is calculated using the COMZIRC computer code (Appendix C of Supplement 1 of Reference 11). The initial steady state fuel rod conditions used in the analysis are determined using the FATES3B computer code (Reference 10).

6.3.3.2.2.2 Safety Injection System Parameters

As described in Section 6.3.2, the ANO-2 ECCS consists of three high pressure safety injection (HPSI) pumps, two low pressure safety injection (LPSI) pumps and four SITs. Each HPSI pump injects to one of two high pressure injection headers which feed each cold leg. The LPSI pumps inject to a common header which feeds each cold leg. Each SIT injects to a single cold leg. Two of the HPSI pumps and the LPSI pumps are automatically actuated by a safety injection actuation signal that is generated by either low pressurizer pressure or high containment pressure. The SITs automatically discharge when the RCS pressure decreases below the SIT pressure.

The large break LOCA analysis conservatively represents both the spillage of safety injection flow into the containment and the most limiting single failure of the ECCS. In the analysis, all the safety injection flow to the broken discharge leg was assumed to spill into the containment.

A study was performed to determine the most limiting single failure of ECCS equipment. The study analyzed no failure, failure of an emergency diesel generator, failure of a LPSI pump, and failure of a HPSI pump. Maximum safety injection pump flow rates were used in the no failure case; minimum safety injection pump flow rates were used in the emergency diesel generator, LPSI pump and HPSI pump failure cases. The most limiting single failure, i.e., the failure that resulted in the highest calculated peak cladding temperature, was determined to be no failure of ECCS equipment. No failure is the worst condition because it maximizes the amount of safety injection that spills into the containment. This acts to minimize containment pressure which, in turn, minimizes the rate at which the core is reflooded. The failure of either an emergency diesel generator or a LPSI pump is not the most limiting failure because, in both cases, there is sufficient safety injection pump flow to keep the reactor vessel downcomer filled to the cold leg nozzles. This maintains the same driving force for reflooding the core as for no failure, but results in less spillage into the containment.

Based on the design of the ANO-2 ECCS, the most limiting single failure and spillage considerations, the following safety injection flows into the RCS were used in the analysis for a discharge leg break: 75% of the flow from two HPSI pumps, 75% of the flow from two LPSI pumps, and 100% of the flow from three SITs. Consistent with the fact that no failure is the worst condition, maximum HPSI and LPSI pump flow rates were used in the analysis.

6.3.3.2.2.3 Core and System Parameters

The significant core and system parameters used in the large break LOCA analysis are presented in Table 6.3-9. The analysis accounts for up to 10% steam generator tube plugging per steam generator.

The fuel rod conditions that are listed in Table 6.3-9 are for the hot rod burnup that produced the highest calculated peak cladding temperature. These limiting initial fuel rod conditions were determined by performing burnup dependent calculations with STRIKIN-II using initial fuel rod conditions calculated by FATES3B. The calculations included the analysis of (1) UO_2 fuel with (a) ZIRLO™ cladding and no integral fuel burnable absorber (IFBA), and (b) ZIRLO™ cladding and zirconium diboride (ZrB_2) IFBA, and (2) Next Generation Fuel with (a) Optimized ZIRLO™ cladding and no IFBA, and (b) Optimized ZIRLO™ cladding and ZrB_2 IFBA.

6.3.3.2.2.4 Containment Parameters

Section 6.2.1.1.3.4 presents the minimum containment pressure analysis that was performed as part of the large break LOCA analysis. It identifies the containment parameters used in the analysis. The values for these parameters were chosen to minimize containment pressure in order to minimize the core reflood rate.

6.3.3.2.2.5 Break Spectrum

The break spectrum consisted of five guillotine breaks in the reactor coolant pump discharge leg ranging in size from a full double-ended break to a 0.3 double-ended break. Table 6.3-11 lists the specific break sizes that were analyzed.

As described in Reference 6, the reactor coolant pump discharge leg is the most limiting break location. The pump discharge leg break is limiting because both the core flow rate during blowdown and the core reflood rate are minimized for this location.

6.3.3.2.2.6 Results and Conclusions

The important results of this analysis are summarized in Table 6.3-15. Table 6.3-14 lists times of interest for the breaks analyzed. As noted in Table 6.3-11, results for each break are presented in Figures 6.3-13 through 6.3-17. For each break, the variables listed in Table 6.3-12 are plotted as a function of time. For the break with the highest peak cladding temperature (the 0.4 DEG/PD break), the additional variables listed in Table 6.3-13 are plotted. Peak cladding temperature versus break size is shown in Figure 6.3-20.

Based on the results of this analysis, it is concluded the ANO-2 ECCS design satisfies the Acceptance Criteria of 10CFR50.46 for a spectrum of large break LOCAs.

6.3.3.2.3 Small Break Analysis

6.3.3.2.3.1 Evaluation Model

The small break LOCA ECCS performance analysis used the S2M (Supplement 2 Evaluation Model) version of Westinghouse's NRC-accepted small break LOCA evaluation model for Combustion Engineering-designed PWRs (Reference 8, Supplement 2-P-A). The methodology for modeling the NGF assembly design in ECCS Performance analyses using the S2M EM is described in the CE 16 x 16 NGF Core Reference Report (Reference 93). Reference 94 denotes the topical report relevant to the S2M EM for modeling the Optimized ZIRLO™ cladding. In the S2M evaluation model, the CEFLASH-4AS computer program (Reference 83) is used to perform the hydraulic analysis of the RCS until the time the Safety Injection Tanks (SITs) begin to inject. After injection from the SITs begins, the COMPERC-II computer program (Reference 11) is used to perform the hydraulic analysis. However, COMPERC-II was not run in this analysis because the breaks sizes analyzed were too small for the SITs to begin injecting until after the peak cladding temperature was calculated to occur. The hot rod cladding temperature and maximum cladding oxidation are calculated by the STRIKIN-II computer program (Reference 30) during the initial period of forced convection heat transfer and by the PARCH computer program (Reference 27) during the subsequent period of pool boiling heat transfer. Core-wide cladding oxidation is conservatively represented as the rod-average cladding oxidation of the hot rod. The initial steady state fuel rod conditions used in the analysis are determined using the FATES3B computer program (Reference 10).

6.3.3.2.3.2 Safety Injection System Parameters

As described in Section 6.3.2, the ANO-2 ECCS consists of three HPSI pumps, two LPSI pumps, and four SITs. Each HPSI pump injects to one of two high pressure injection headers which feed each cold leg. The LPSI pumps inject to a common header which feeds each cold leg. Each SIT injects to a single cold leg. Two HPSI pumps and the LPSI pumps are automatically actuated by a safety injection actuation signal that is generated by either low pressurizer pressure or high containment pressure. The SITs automatically discharge when the RCS pressure decreases below the SIT pressure.

In the small break LOCA analysis it is assumed that offsite power is lost coincident with reactor trip and, therefore, the HPSI and LPSI pumps must await emergency diesel generator startup and load sequencing before they start. The total delay time assumed is 40 seconds from the time the pressurizer pressure reaches the SIAS setpoint to the time that the HPSI pumps are at speed and aligned to the RCS. For breaks in the reactor coolant pump discharge leg all safety injection flow delivered to the broken discharge leg is modeled to spill out the break.

An analysis of the possible single failures that can occur within the ECCS has shown that the most limiting single failure of ECCS equipment is the failure of an emergency diesel generator to start (Reference 8). This failure causes the loss of both a HPSI and LPSI pump and results in a minimum of safety injection water being available to cool the core.

Based on the above, credit for the following safety injection flows are taken in the small break LOCA analysis for a break in the reactor coolant pump discharge leg: 75% of the flow from one HPSI pump, 50% of the flow from one LPSI pump and 100% of the flow from three SITs. Table 6.3-16 presents the HPSI pump flow rate versus RCS pressure used in the small break LOCA analysis. Injection from the LPSI pump is not credited in the small break LOCA analysis since the RCS pressure did not decrease to the LPSI pressure range for the break spectrum analyzed. Likewise, injection from the SITs is not credited in the analysis for the break spectrum analyzed even though the RCS pressure decreased below the SIT pressure for the 0.05 ft^2/PD break, which is the largest break size analyzed.

6.3.3.2.3.3 Core and System Parameters

The significant core and system parameters used in the small break LOCA analysis are presented in Table 6.3-17. The analysis accounts for up to 10% steam generator tube plugging per steam generator.

The fuel rod conditions that are listed in Table 6.3-17 are for the hot rod burnup that produced the maximum initial fuel stored energy. UO_2 fuel rods with (a) ZIRLO^{TM} cladding and no integral fuel burnable absorber (IFBA), and (b) ZIRLO^{TM} cladding and zirconium diboride (ZrB_2) IFBA, and Next Generation Fuel with (a) Optimized ZIRLO^{TM} cladding and no IFBA and (b) Optimized ZIRLO^{TM} cladding and ZrB_2 IFBA, were analyzed in determining the limiting fuel rod conditions.

6.3.3.2.3.4 Containment Parameters

The small break LOCA analysis does not use a detailed containment model. Therefore, other than the containment volume and the initial containment pressure, which are assumed to be 1,820,000 ft^3 and 14.7 psia, respectively, no containment parameters are employed in the analysis.

6.3.3.2.3.5 Break Spectrum

The break spectrum consisted of three reactor coolant pump discharge leg break sizes, namely, 0.03, 0.04, and 0.05 ft^2/PD breaks. Table 6.3-18 lists the specific break sizes that were analyzed.

The reactor coolant pump discharge leg was previously determined to be the limiting break location (Reference 8). It is limiting because it maximizes the amount of spillage from the safety injection system.

The 0.03 ft^2 to 0.05 ft^2 breaks are in the range of break sizes for which hot rod cladding heatup is terminated solely by injection from the HPSI pump. It is within this range that the limiting small break LOCA resides. Smaller breaks are non-limiting because the decreased break flow rate associated with the smaller break area results in later and less core uncovery than for these breaks. Larger breaks are non-limiting because injection from the SITs will recover the core and terminate cladding heatup before the cladding temperature approaches the peak cladding temperature calculated for the limiting small break LOCA.

6.3.3.2.3.6 Results and Conclusion

The peak cladding temperatures and cladding oxidation percentages for the small break LOCA analysis are summarized in Table 6.3-19. Table 6.3-20 lists times of interest for the breaks analyzed. As noted in Table 6.3-18, results for the variables listed in Table 6.3-23 are plotted as a function of time in Figures 6.3-23a through 6.3-25h for the breaks analyzed. Peak cladding temperature versus break size is presented in Figure 6.3-26. Table 6.3-21 compares the LBLOCA results to the SBLOCA results.

Based on the results of the analysis, it is concluded that the ANO-2 ECCS design satisfies the Acceptance Criteria of 10 CFR 50.46 for a spectrum of small break LOCAs.

6.3.3.3 Intentionally Left Blank

6.3.3.4 Fuel Rod Perforations

Fuel rod cladding performance for the spectrum of breaks analyzed is discussed in Section 6.3.3.2.

6.3.3.5 Evaluation Model

This sections refers to a Boiling Water Reactor (BWR) and is not applicable.

6.3.3.6 Fuel Clad Effects

This section refers to a BWR and is not applicable.

6.3.3.7 ECCS Performance

This section refers to a BWR and is not applicable.

6.3.3.8 Peaking Factors

This section refers to a BWR and is not applicable.

6.3.3.9 Conformance With Acceptance Criteria

The analysis in Section 6.3.3.2 demonstrates compliance with 10 CFR 50.46.

6.3.3.10 Effects of ECCS Operation on the Core

Reference 50 describes testing of the chemical behavior of boric acid in austenitic stainless steels. Testing and analysis of the effect of initiation of safety injection on reactor vessel integrity are summarized in Section 6.3.3.13 and in the response to General Design Criterion 31 (see Section 3.1). Finally, the effect of safety injection on the reactor core has been studied extensively.

6.3.3.11 Use of Dual Function Components

The SIS consists of components utilized for the safety injection function only as well as components which are used in other systems. Those components which perform a safety injection function only are the safety injection tanks, the HPSI pumps, and associated piping, valves, and instrumentation. Components which serve a dual function are described below.

6.3.3.11.1 Refueling Water Tank

During refueling, borated water from this tank is used to fill the refueling pool and the transfer tube. During plant operation, the tank is aligned to the suction side of the HPSI, CS, and LPSI pumps. The volume in the tank is maintained in excess of that required for safety injection and containment spray system operation defined in Section 6.3.2.2.1.

6.3.3.11.2 LPSI Pumps

These pumps are used to circulate reactor coolant through the shutdown cooling heat exchangers for reactor cooldown and for decay heat removal during shutdown. During normal operation of the plant, the pumps are aligned for safety injection.

6.3.3.11.3 Shutdown Cooling Heat Exchangers

These heat exchangers provided cooling during reactor cooldown and for decay heat removal during shutdown. At all other times the heat exchangers are lined up for containment spray cooling.

Operating procedures and design features are provided so that the normal safety injection system lineup is not altered except under reduced RCS pressure conditions. Valve interlocks on the shutdown cooling suction line preclude initiation of shutdown cooling until reactor coolant pressure has been reduced to an appropriately low value. (See Section 9.3.6)

Thus, the utilization of shared components in the SIS does not jeopardize system operating availability and reliability.

6.3.3.12 Lag Times

The safety injection tanks automatically inject coolant when RCS pressure falls below safety injection tank pressure. With large breaks, rapid depressurization results in injection flow from the tanks before the safety injection pumps start.

For operation of actuator operated valves and pumps, there is a time delay following the rupture consisting of the time for the appropriate plant parameters to attain the SIAS setpoint, plus the time required for actuation or startup of the active component itself. The longest delay occurs when off-site power is lost. In this case, the emergency diesel generator starts automatically on SIAS or loss of the off-site power, reaching normal voltage in less than 15 seconds. ESF loads and supporting equipment loads are automatically sequenced at the times listed in Table 8.3-1. Motor operated valves receive power as soon as the diesel generators are up to speed. HPSI pumps receive power 10 seconds after diesel generators are up to speed. LPSI pumps receive power 15 seconds after diesel generators are up to speed. The operating time is <15 seconds for the high pressure header valves and < 20 seconds for the low pressure header valves. The HPSI and LPSI pumps attain full speed within five seconds when automatically load sequenced. Table 6.3-8 shows the times that each component starts and becomes operational and the time at which credit is taken for component operation in LOCA analyses. The safety injection tanks are passive devices requiring no actuation signal or electrical power. The safety injection tanks automatically discharge coolant into the RCS when the RCS pressure drops below 600 psig (minimum tank pressure) + elevation head of tanks.

6.3.3.13 Thermal Shock Considerations

6.3.3.13.1 Reactor Vessel

In order to evaluate possible effects of ECCS operation, a detailed analysis of a reactor vessel response to thermal shock was performed (Reference 36). The analysis concluded that the CE reactor vessels are capable of sustaining the thermal shock imposed by ECCS operation without gross failure.

Further work was performed to refine the surface heat transfer coefficient (Reference 18) and the brittle fracture model (Reference 19) used in the evaluation.

In 1973, the AEC established guidelines on thermal shock. A detailed analysis of a crack arrest under thermal shock was submitted to the AEC in September, 1973 as a Topical Report, CENPD-116, "Analysis of the Structural Integrity of C-E Reactor Vessel Subject to Emergency Core Cooling Conditions."

6.3.3.13.2 Safety Injection Nozzles

All the ECCS injection connections to the RCS piping are thermally sleeved. These sleeved ECCS nozzles are designed to meet the following requirements:

A. Large Reactor Coolant System Pipe Break

   One injection of 40 °F water goes into the reactor coolant cold leg piping initially at the full power cold leg temperature and a system pressure of 200 psia or less with an initial flow rate of 20,000 gpm per nozzle. The initial flow rate decreases linearly over 30 seconds to 2,500 gpm per nozzle. Flow is then assumed to remain at 2,500 gpm per nozzle until an equilibrium temperature is reached.

B. Small Reactor Coolant System Pipe Break

   Five injections of 40 °F water goes into the reactor coolant cold leg piping initially at the full power cold leg temperature and a system pressure of 1,240 psia. An initial rate of 350 gpm per nozzle for 90 seconds is assumed followed by the injection of 40 °F water at 60 psia at a rate of 2,500 gpm.

6.3.3.13.3 Safety Injection Components

The HPSI pumps are designed to withstand 10 cycles of thermal transients from 300 °F to 40 °F and from 40 °F to 300 °F in 5 to 10 seconds. The LPSI pumps are designed to withstand 10 cycles of an increase in temperature from 40 °F to 300 °F in 5 to 10 seconds. Designing for these transients provides protection against adverse effects arising from the initiation of flow through the SIS of water from the RWT at start of injection and switchover to recirculation from the containment sump following a LOCA.

6.3.3.14 Limits on System Parameters

Boron concentration in the RWT must be at least 2,500 ppm during power operation to ensure adequate cold shutdown margin. The required quantity is discussed in Section 6.3.2.2.1. Safety injection tank pressure must be at least 600 psig, and the tanks must contain sufficient water so that three of the four tanks will fill the reactor vessel to the top of the core. The water volume is given in Table 6.3-1.

6.3.3.15 Long-Term ECCS Performance

Long-term post-LOCA residual heat removal is accomplished by continuous boil-off of fluid in the reactor vessel until the fuel decay heat is sufficiently reduced to prevent boil-off. As borated water is delivered to the core region via safety injection and virtually pure water escapes as steam, unacceptably high concentrations of boric acid and other solution additives may accumulate in the reactor vessel unless a flush path is provided.

For a hot leg break, safety injection flow introduced via the cold legs will travel down the annulus, through the core, and out the break. Thus, a flushing path is established through the reactor vessel, precluding the buildup of solids in the core region. However, for a cold leg break, only that amount of injected water required for decay heat removal actually makes it to the core, because the remainder spills out the break. Therefore, because of the geometry of the RCS, there is no flushing through the core for a cold leg break until an alternate flow path is established.

A large cold leg break has been found to be the worst case for boric acid buildup. The differences in RCS pressure between large and small break LOCA result in several competing factors which affect the time that precipitation begins to occur. A high system pressure and temperature (small break) causes a higher rate of boil-off, resulting in a somewhat faster buildup of boric acid. However, this faster buildup rate at high pressure is more than offset by a substantial increase in boric acid solubility at the associated higher temperature. The net result is that the large break is the worst case.

A post-LOCA boric acid precipitation analysis was performed for a large cold leg break. The analysis used Westinghouse's NRC-accepted Post-LOCA Long Term Cooling Evaluation Model for Combustion Engineering-designed PWRs (Reference 92). In the evaluation model, the BORON computer program (Appendix C of Reference 92) is used to calculate the boric acid concentration in the core as a function of time following the large break LOCA. The Safety Evaluation Report documenting NRC acceptance of the post-LOCA long term cooling evaluation model, including the BORON computer program, is contained in Reference 92.

The analysis used a boric acid concentration of 27.6 wt% as the solubility limit of boric acid in the core. This is the solubility limit of boric acid in saturated water at atmospheric pressure. Atmospheric pressure is a conservative minimum value for the core pressure following a large break LOCA.

Important plant design data used in the post-LOCA boric acid precipitation analysis are listed in Table 6.3-28.

The post-LOCA boric acid precipitation analysis determined that a minimum flow rate of 250 gpm from a HPSI pump to both the hot and cold sides of the RCS, initiated between two and four hours post-LOCA, maintains the boric acid concentration in the core below the solubility limit of 27.6 wt% for the limiting large cold leg break. The analysis also determined that the potential for entrainment of the hot side injection by the steam flowing in the hot legs is terminated prior to two hours post-LOCA.

Figure 6.3-52 compares the core boil off rate with the minimum simultaneous hot and cold side injection flow rate of 250 gpm. It shows that the initiation of 250 gpm of hot and cold side injection at 5 hours post-LOCA provides a substantial and time-increasing flushing flow through the core. (Flushing flow is the difference between the HPSI pump flow rate to the side of the RCS opposite the break and the core boil off rate.) Figure 6.3-53 presents the core boric acid concentration as a function of time for the large cold leg break. It shows that, without simultaneous hot and cold side injection, the boric acid concentration in the core exceeds the solubility limit at approximately 7.3 hours post-LOCA. When 250 gpm of simultaneous hot and cold side injection is initiated at 5 hours post-LOCA, the maximum boric acid concentration in the core is 23.3 wt% at 5.9 hours post-LOCA, as compared to the solubility limit of 27.6 wt%. Figure 6.3-53 also shows that a flushing flow rate of 20 gpm started by 5 hours post-LOCA is sufficient to prevent the core boric acid concentration from reaching the solubility limit.

The long-term performance of the ECCS system was very conservatively designed to provide the required simultaneous hot and cold side injection flow rate. This design meets the following criteria:

A. Provides redundant, safeguard-grade ability to initiate simultaneous hot and cold leg HPSI within four hours post-LOCA.

B. Precludes inadvertent hot leg injection before two hours post-LOCA so that core reflood and steam venting are not impaired (this is done by removing power from 2CV-5102-2 and 2CV-5101-1 during normal operation).

C. Ensures that a core through-flow is established independent of break location by balancing HPSI flow equally between the hot leg and cold legs.

D. Provides the testing capability to verify integrity of the reactor coolant pressure boundary and demonstrate the availability of each hot leg injection flow path.

E. Contains hardware and instrumentation qualified for post-LOCA environment.

The design consists of high resistance orifice bypass lines with isolation valves for cold leg HPSI injection and modulating valves in lines to the shutdown cooling suction line from the RCS to the HPSI discharge headers. This design was balanced during post-installation testing such that 50 percent of the HPSI flow is diverted to the hot leg and 50 percent to the cold legs.

Between two and four hours post-LOCA, the motor-operated valves on the hot leg injection lines are energized and opened while the motor-operated orifice bypass valves on each HPSI header are closed. This accomplished complete core flushing following a break at any location in the RCS piping. No determination of break location is needed since the flow path will satisfy cooling and flushing requirements under all break location conditions.

If the accident is a very small break requiring HPSI as an RCS inventory source, the RCS will have to be depressurized in order to allow the HPSI to operate. This will be accomplished by using the normal or Auxiliary Pressurizer Spray Systems or Pressurizer venting.

Any passive failure of HPSI piping inside the auxiliary building will be determined by the flow indicators on the HPSI discharge piping (2FI-5101-1 and 2FI-5102-2). Operator action can then be taken to isolate the failed HPSI train to prevent loss of recirculation fluid from containment. Any passive failures inside the reactor building do not require operator action since no fluid will be lost from containment and the redundant flow path will provide sufficient core through-flow for flushing.

The above described design provides more than adequate core flushing to prevent any boron precipitation and requires minimum operator action that can be implemented in minutes, although up to four hours is acceptable.

Table 6.3-22 provides a list of valves required for long-term cooling and includes the position of each valve during power operation, shutdown cooling, initial ECCS, recirculation ECCS, and long-term ECCS.

6.3.4 TESTS AND INSPECTIONS

During fabrication of the SIS components, tests and inspections were performed and documented in accordance with code requirements to assure high quality construction. As necessary, performance tests of components were performed in the vendor's facility. The SIS is designed and installed to permit inservice inspections and tests. Prior to initial plant startup, a comprehensive system of flow tests was performed to verify that the design performance of the system and individual components is attained. Periodic tests and inspections of the SIS components and subsystems are performed to ensure proper operation in the event of an accident. The scheduled tests and inspections are necessary to verify system operation since, during normal plant operation, SIS components are aligned for emergency operation and serve no other function. The tests defined permit a complete checkout on the subsystem and component level during normal plant operation. Satisfactory operability of the complete system may be verified during normal scheduled refueling shutdowns. Details of the planned pre-operational testing is presented in Chapter 14.

6.3.4.1 <u>System Testing</u>

The objective of this testing is to verify that the SIS will respond as required to perform its intended function. The tests are performed during each scheduled refueling shutdown. A test SIAS is applied to initiate operation of the system. The safety injection pump motors may be de-energized for this test. Circuit tests and pump starting and operation may be demonstrated at any time. The system test is considered satisfactory if control board indication and visual observations indicate that all components have received the test safety injection actuation signal in the proper sequence and timing. This verifies that the appropriate pump breakers have opened and closed, and that all valves have completed their travel. During reactor operation, the instrumentation channels used to initiate safety injection are checked during each shift while SIAS logic circuitry will be tested periodically as listed in the Technical Specification. The provisions of Regulatory Guide 1.22 are met.

6.3.4.2 Component Testing

In addition to the system level tests described in Section 6.3.4.1, tests to verify proper operation of the SIS components are also conducted. These tests supplement the system level tests by verifying acceptable performance of each active component in the SIS. The tests include cycling of all check valves to ensure proper operation and the checking of RWT level and the safety injection tank pressure and level instrumentation channels.

The safety injection pumps and valves are tested in accordance with the Edition and Addenda of the ASME Operation and Maintenance Code specified by 10 CFR 50 Section 50.55a(f).

6.3.5 INSTRUMENTATION REQUIREMENTS

6.3.5.1 Actuation Signal Generation

6.3.5.1.1 Safety Injection Actuation Signal

Initiation of safety injection is derived from four independent pressurizer pressure sensors and four independent containment pressure sensors. Coincident trip signals from 2-out-of-4 sensors for either parameter will automatically initiate safety injection. The operation of the SIS may be blocked only when RCS pressure is below the bypass permissive, which is less than 400 psia. Blocking of SIAS must be accomplished manually. The block is removed automatically before pressurizer pressure increases to 500 psia. The SIAS block and block removal design allows normal RCS cooldown without initiation of safety injection, at the same time prohibiting blocking of SIAS when the RCS is at operating pressure. (See Section 7.2.1.1.1.6)

6.3.5.1.2 Recirculation Actuation Signal

Four independent refueling water tank level transmitters provide signals for the RAS. Coincidence of 2-out-of-4 low water level signals or manual initiation in the control room will provide an RAS. The operation of RAS may be blocked below Mode 4 when RCS pressure is below the bypass permissive, which is less than 400 psia. Blocking of RAS must be accomplished manually and can only be accomplished concurrently with the blocking of SIAS. As with SIAS, the block is removed automatically before pressurizer pressure increases to 500 psia. The RAS block and block removal design requires RAS to be functional when SIAS is functional, at the same time providing a means to prevent inadvertent actuation of RAS.

6.3.5.2 System Instrumentation

The instrumentation provided for monitoring SIS components during normal plant operation and during SIS operation is discussed in this section. Instrumentation and indications providing information to the operator when system pressure is reduced is discussed in Section 6.3.2.20.

6.3.5.2.1 Pressure

A. LPSI Header Pressure

A pressure transmitter is located in the safety injection header. This pressure is indicated in the control room and provides confirmation of pump operation.

B. HPSI Header Pressure

Pressure transmitters are located in each HPSI header. These pressures are indicated in the control room and provide confirmation of pump operation.

C. Safety Injection Tank Pressure - Wide Range

A wide range pressure transmitter mounted on each safety injection tank permits readings of each tank's pressure in control room.

D. Safety Injection Tank Pressure - Narrow Range

Two narrow range pressure transmitters on each tank permit more accurate tank pressure measurement than the wide range. One transmitter alarms on high and low pressure and the other alarms on high-high and low-low pressure.

E. Safety Injection Check Valve Leakage Pressure

Pressure transmitters are located on each of four safety injection lines just upstream of the safety injection check valve adjacent to the reactor coolant loops. Leakage past these valves during plant operation will be indicated by an increase in pressure.

6.3.5.2.2 <u>Level</u>

A. Refueling Water Tank Level

Two instrument channels give control room indication of the water level in the RWT. Each indicator actuates an alarm on low water level in the tank.

B. Refueling Water Tank Level

Four additional level transmitters provide input to the RAS logic. The signal is initiated when any two of the four inputs indicate low tank water level. An operating bypass is provided to block RAS actuation in modes 4, 5, and 6 with pressurizer pressure below the bypass permissive, which is less than 400 psia.

C. Safety Injection Tank Level - Wide Range

Water level for each safety injection tank is indicated in the control room on the vertical display panel throughout the complete tank volume except for water above the upper tank tangent or below the lower tank tangent. Signal input for this indication is provided by a differential pressure transmitter. (Regulatory Guide 1.97, post-accident monitoring variable). Refer to Section 7.5.2.5 for analysis of post-accident monitoring instrumentation.

D. Safety Injection Tank Level - Narrow Range

Two narrow range level transmitters on each tank permit more accurate tank level than wide range. One transmitter alarms on high and low level and the other alarms on high-high and low-low level. Since operating water level must be maintained within a range which ensures proper operation of the tanks, alarms will be actuated if the tank water level falls below the minimum value or rises above the maximum value corresponding to the volumes listed in Table 6.3-1.

6.3.5.2.3 <u>Valve Position</u>

A. Safety Injection Tank Isolation Valve Position

Valve position is indicated in the control room by redundant indications. Indicator lights verify either the fully open or fully closed position. In addition, a separate valve position limit switch will sound an alarm in the control room if the valves are not fully open when pressurizer pressure is over 700 psia.

6.4 HABITABILITY SYSTEMS

The control room habitability systems include radiation shielding, redundant emergency air filtering and emergency air conditioning systems, radiation monitoring, lighting and fire protection equipment. These systems are described in detail in the applicable sections of this safety analysis report as referenced below. Fire protection and lighting systems are discussed fully in Sections 9.5.1 and 9.5.3 and are not further mentioned in this section.

6.4.1 HABITABILITY SYSTEMS FUNCTIONAL DESIGN

6.4.1.1 Design Bases

A. The radiation exposure of control room personnel during any one of the postulated Design Basis Accidents (DBAs) discussed in Chapter 15 does not exceed the guidelines in 10 CFR 50, Appendix A, General Design Criterion 19 and 10 CFR 50.67.

B. During any one of the postulated DBAs discussed in Chapter 15, the control room emergency air conditioning and emergency air filtering systems maintain the control room atmosphere at temperatures and humidities suitable for prolonged occupancy.

C. Control room personnel are protected from prolonged exposure to smoke and/or noxious vapors.

D. The control room is automatically isolated from outside air on high radiation.

E. The control room emergency air conditioning and emergency air filtering systems meet design bases A, B, C and D assuming a loss of off-site power and the failure of a single active component.

F. The control room and the control room emergency air conditioning and emergency air filtering systems are designed to withstand the Design Basis Earthquake (DBE).

6.4.1.2 System Description

The control room emergency air conditioning and emergency air filtering systems are discussed in Section 9.4.1.2.2, including a description of the operating modes, filters and components. Control room shielding is described in Section 12.1.2.7 and ventilation parameters are given in Section 12.2.2.3.

The Unit 2 control room is adjacent to and interconnected with the Unit 1 control room. Non-seismic Category 1 kitchen and sanitary facilities are part of the Unit 1 control room, but outside of the emergency ventilation system envelope, and are available to the Unit 2 operators. Food, potable water and portable sanitary facilities can be brought to the control room, as needed, by each shift.

6.4.1.3 Design Evaluation

The evaluation of the control room emergency air conditioning and emergency air filtering systems is presented in Sections 9.4.1.3 and 12.2.2. The evaluation of the control room shielding given in Section 15.1.13 shows that the dose received by any operator during the 30 days following a postulated LOCA, including ingress and egress, is less than the limits of 10 CFR 50 General Design Criterion 19.

6.4.1.4 Testing and Inspection

Testing and inspection of the control room emergency air conditioning and emergency air filtering systems and their associated fans and filters is discussed in Section 9.4.1.4. The Technical Specifications prescribe inservice testing and acceptance criteria as well as the bases for the tests.

6.4.1.5 Instrumentation Requirement

Instrumentation for the control room emergency air conditioning and emergency air filtering systems is described in Section 9.4.1. Radiation monitoring is discussed in Sections 12.2 and 11.4.

6.5 PENETRATION ROOMS VENTILATION SYSTEM

6.5.1 DESIGN BASES

This system is designed to collect, monitor and process potential leakage in the penetration rooms and the Engineered Safety Features (ESF) pump rooms to minimize environmental activity levels resulting from post-Loss of Coolant Accident (post-LOCA) containment leaks. Experience has shown the containment leakage is more likely to occur at penetrations than through the liner plate or weld joints.

The design basis for the charcoal adsorber is to have a capability of removing 25 percent of the core iodine inventory. The 25 percent was derived using the standard assumption that during a DBA 50 percent of the halogens are released from the core and that 50 percent of this iodine that is released plates out within the containment. Although these assumptions were part of the design basis of the Penetration Room Ventilation System, it is not credited for iodine removal in the accident analyses.

Table 9.4-3 contains an analysis of each ESF air filtration system with respect to Regulatory Guide 1.52.

6.5.2 SYSTEM DESIGN

For the air flow control diagram, see Figure 6.5-1.

The penetration rooms ventilation system is designed to meet the following criteria:

A. Seismic Category 1.

B. A single failure will not cause a loss of function.

C. Sufficient remote instrumentation and control are available to permit the operator to monitor and control equipment operation from the control room.

D. Power is from the ESF buses in case of loss of off-site or onsite power.

The penetration rooms are formed adjacent to the outside surface of the containment by enclosing the area around the majority of the penetrations. The only penetrations which do not pass through this area are:

A. both main steam lines;

B. the containment equipment hatch (which contains a double gasketed closure);

C. the containment escape lock;

D. the fuel transfer tube;

E. the containment purge lines;

F. the containment sump penetration; and,

G. the reactor drain tank discharge line.

The containment purge lines and containment sump penetrations are not considered a source of significant leakage because they are welded to the liner plate. The Reactor Drain Tank discharge line is not considered to be a source of significant leakage because it is embedded in the base slab. The main steam lines are not considered a source of significant leakage because they are connected to the liner plate by welding through flued heads. The containment escape lock can be tested during normal operation and the containment equipment hatch is tested prior to containment closure. There are double seals at each access opening. The fuel transfer tube opening is covered with a gasketed blind flange which is removed only during plant shutdown for transfer of fuel to the spent fuel pool. Also, the Reactor Drain Tank Discharge Line and Containment Sump Penetrations are located in HPSI pump rooms that are isolated by Safety Injection Actuation Signal (SIAS). See Section 3.8 for additional information.

Leakage into each of the penetration rooms is discharged to the containment flue (vent – see Figure 11.2-2) through a pair of filter assemblies (one standby) each consisting of a roughing filter, a High Efficiency Particulate Air (HEPA) filter, and a charcoal adsorber. The entire system is designed to operate under negative pressure up to the fan discharge which is downstream of the filters.

The design flow rate from the penetration rooms far exceeds the maximum anticipated containment leakage. The maximum anticipated leak rate of 0.1 percent per day amounts to approximately 1.25 scfm compared to a design evacuation rate of 2,000 scfm for the system.

The fan operating status and the radiation level of filter effluent are displayed in the control room and high radiation is annunciated. Filter differential pressure is displayed locally. The filter flow rate is displayed in the control room and a low flow rate is annunciated. The system may be actuated by an operator for testing during normal plant operation. A containment isolation signal actuates the system following a postulated accident.

Particulate filtration is achieved by a roughing filter and a HEPA filter. Adsorption filtration is accomplished by an activated charcoal adsorber.

Filters and adsorbers are designed to withstand a rough handling test in accordance with MIL-STD-282 without visible damage or decrease in filtration efficiency.

A check valve is provided at the discharge of each fan to prevent recirculation. Filter cross-connect valves were provided in the original design for the purpose of maintaining adequate cooling air from the operating fan through the idle filter train to prevent it from reaching an ignition temperature. Subsequent calculations have confirmed that a significant margin to ignition temperature will be maintained for 30 days post-LOCA with no convective (neither fans nor natural circulation) or conductive heat transfer from the charcoal adsorbers.

A description of the filters and adsorber is given in the following paragraphs:

<u>Roughing Filter</u> - The function of this filter is to remove relatively large granular or fibrous material which may be originally in the system or contained space or may be introduced during maintenance activity, and prevent this material from lodging in the HEPA filters, thus extending the useful life of the HEPA filters.

The roughing filters are designed to meet the following criteria.

A. Roughing Filter - Unit Type

1. The roughing filter is of sufficient capacity to handle the rated air flow at a face velocity not exceeding 300 feet/minute.

2. Media are two inches thick replaceable glass pads coated with suitable oil.

3. The pressure drop of these filters with clean pads under rated conditions, standard air, does not exceed 0.2-inch water gauge (W.G.).

4. This unit is used in conjunction with a medium efficiency filter in potentially radioactive service.

B. Roughing Filters - Medium Efficiency

1. The filter cells are of the throwaway cartridge type labeled Class 1 UL 900, of medium efficiency (80-85 percent by the dust spot method of testing).

2. Each unit has a capacity of not less than 1000 cfm with a face area of 24 x 24 inches. The depth does not exceed 11½ inches. The initial resistance at rated air flow does not exceed: 0.3-inch W.G. when clean, and 1-inch W.G. when dirty.

3. This unit is used in all potentially radioactive areas.

<u>HEPA Filter</u> - These cells serve to remove effectively all particulates from the airstream. They also prevent dirt reaching the charcoal cells which follow.

The HEPA filters are designed to meet the following criteria.

A. Each filter cell is of the throwaway extended medium, open-faced, rectangular, water repellant, dry type, suitable for radioactive service, and is in compliance with Underwriter's Laboratories Standard UL 586 high efficiency air filter units, and AEC-HSB-306. The filters are satisfactory for operation up to 250 °F.

B. The filters are of either glass fiber or glass fiber and asbestos paper, 0.015 inch minimum thickness, having a minimum base weight of 48 pounds per 3,000 square feet. The filter medium contains no more than five percent combustible or organic material, in accordance with MIL-F-51079A.

C. The basic design criteria for this filter is set forth in Health and Safety Bulletin 306 (3-31-71) which incorporates U.S. Military Specification MIL-F-51068D captioned "Filter, Particulate, High Efficiency, Fire Resistant." The dust holding capacity to 2-inch W.G. final pressure drop is at least six pounds of NBS (96 percent Cottrell – four percent lint) precipitate fed in accordance with NBS Procedure on a 24 x 24 x 12-inch filter.

<u>Charcoal Adsorber</u> - These are designed to remove gaseous contaminants only. The charcoal is retained between perforated metal plates with 0.045 diameter holes spaced closely together. The effective open area is about 35 percent.

The charcoal adsorbers are designed to meet the following criteria.

A. Each adsorber cell is of the unit tray or drawer type with a layer of charcoal, activated for trapping elemental iodine and radioiodine in the form of organic compounds.

B. The adsorbers are constructed so the airflow through the adsorption bed is essentially in a vertical direction. The minimum depth of each bed is two inches. The effective face area of the filter is of such dimensions that the average velocity through the bed does not exceed 45 feet per minute at standard conditions for a gas charcoal "contact" or "dwell" time of approximately 0.25 second per 2-inch depth.

The description of major system components is given below:

Penetration Rooms Ventilation System

Fans

Type	Centrifugal
Capacity, CFM	2000

Motors

Type	Induction
Horsepower rating, hp	10
Voltage, V	460
Phase	3
Enclosure	Open drip-proof
Insulation class	B

Roughing Filters

Quantity per assembly	2
Rated flow per filter cell, CFM	1000
Type	Replaceable
Media	Glass fiber
Average Efficiency	80 percent
Rating basis	ASHRAE Std. 52-68 Test Method original, current revision for replacements
Rated pressure drop, unloaded, inches W.G.	0.54

HEPA Filters

Quantity per assembly	2
Rated flow per filter cell, cfm	1000
Type	High efficiency, dry
Media	Glass fiber (waterproof, fire retardant)
Frame	Chromized steel

Face guards	4 x 4 mesh galvanized hardware cloth
Separator	Aluminum
Seal	Polyurethane
Efficiency, percent	99.97 percent with 0.3 micron diameter DOP
Rating basis	MIL-STD-282
Rated pressure drop, unloaded, inches W.G.	1.0
Codes or Standards	Health and Safety Bulletin 306 UL-586 MIL-F-51079A MIL-F-51068D MIL-STD-282 ANSI-101.1-1972

Charcoal Adsorbers

Quantity per assembly	6 (2-inch trays)
Rated flow per filter cell, cfm	333.3
Type	Activated coconut shell, impregnated
Granular Size	10-14 mesh
Ignition temperature, °C	360
Charcoal per cell, ft^3	1.47
Maximum moisture content, percent	3
Gasketing material	ASTM-D-1056, GR SCE-43
Casting material	304 stainless steel
Efficiency, percent	99.9 percent elemental iodine at 25 ºC, 70 percent relative humidity 99.5 percent methyl iodide at 25 ºC, 70 percent relative humidity 99.9 percent Freon 112
Rating basis	RDT-M16-1T, June 1972
Retention time, sec	0.25
Rated pressure drop, inches W.G.	1.0
Codes	AEC-DP-1082, July 1967 RTD-M16-1T, June 1972 AEC-DP-1075

6.5.3 DESIGN EVALUATION

The system is provided with two fans and two filter assemblies. Both fans, discharging to the containment flue (vent), are controlled from the control room.

During normal plant operation, this system is held on standby with each fan aligned with a multi-filter assembly. A Containment Isolation Actuation Signal (CIAS) will actuate the fans. Control room instrumentation monitors operation. The system can be tested during normal operation.

6.5.4 TESTS AND INSPECTIONS

The system was given a preoperational test before the station produced power as described in Section 14.1.

Periodic performance tests, during normal plant operation, will consist of performance tests on exhaust fan flow rates, motor operation, valve operation, and filter testing as described below.

The HEPA filter and charcoal adsorber systems field acceptance test and retest frequency are shown in Table 1 of ANSI N45.8.3-1973.

A visual inspection of filters, adsorbers and mounting frames for obvious damage and defects preceeds any test so that necessary repairs or corrections are made. This inspection is performed according to Appendix A of ANSI N45.8.3-1973.

A filter housing leakage rate test is conducted on each housing section after completion of all welding, but before weld touch up, and has to pass an internal air pressure test of 1.5 psi and an external air pressure test of 20-inch W.G. for a 5-minute period. All leaks shall be repaired and the section retested.

Testing of the HEPA filters and filter bank follows the recommended methods as specified in ANSI N-101.1-1972.

Each HEPA filter is tested with thermally generated DOP of uniform 0.3 micron droplet size in accordance with Edgewood Arsenal Manual Documents No. 136-300 - 195A and No. 136-300 - 175A. System efficiency is to be within tolerance of 99.97 percent when measured by means of a portable photometer upstream and downstream of the filter. A downstream concentration of greater than 0.03 percent (99.97 percent efficient) indicates that the integrated penetration reading is unsatisfactory and the individual cells and their gaskets must be tested to locate any leaks. Corrective action shall then be taken and the procedure repeated until the bank tests satisfactorily.

Testing of the charcoal adsorbers will follow the recommended methods as specified in Oak Ridge National Lab Manual, Nuclear Safety Information Center ORNL-NSIC-65 Design, Construction and Testing, of High Efficiency Air Filtration Systems for Nuclear Application by C.A. Burchstead and A.B. Fuller.

The charcoal adsorbers are tested by the use of Refrigerant-11 (R-11) introduced on the upstream side of the filters.

Instrumentation will provide for measuring the relative upstream and downstream concentrations of R-11. Leakage greater than 0.05 % across the adsorber banks will require corrective action.

6.5.5 INSTRUMENTATION REQUIREMENTS

On receipt of a CIAS, the 3-way electrically-operated solenoid valves mounted in the air lines to the pneumatic operators on the duct isolation dampers will be automatically de-energized, closing off the air supply to the operators. These isolation dampers are designed to fail-closed on loss of air pressure, providing sealed penetration rooms. Indicating lights in the control room show their position.

Both exhaust fans receive a CIAS. The power operated butterfly valve at the discharge of each filter opens when its respective fan starts. Since only one fan is required, one of the fans may be aligned as a standby. High temperature detectors set well below the charcoal ignition temperature are provided for alarms in the control room.

The discharge flow of each fan is monitored, and an alarm is provided if a low flow (less than 1,500 scfm) condition exists for 20 seconds after the fan is started. On receipt of the alarm, the operator will stop the fan and start the other fan.

PRINCIPAL CONTAINMENT DESIGN PARAMETERS

Characteristics	Data
Containment maximum design pressure, psig	59
Containment maximum design temperature, °F	300
Internal dimension	
Cyclindrical wall diamter, ft.	116
Cylindrical wall height, ft.	171.5
Curved dome height, ft.	37
Total height, ft.	208.5
Volume	
Gross internal volume, ft^3	2,042,000
Net free internal volume (minimum), ft^3	1,778,000
Containment design leak rate	
First 24 hr, % of containment free volume	0.1
After first day, % per day	0.05

Table 6.2-8

INITIAL CONDITIONS FOR PRESSURE ANALYSIS
(Information Maintained for Sub-compartment Pressurization Analysis)

Characteristics	Data
Reactor Coolant System	
NSSS Power Level, Mwt	2908
Coolant Pressure, psia	2250
Average Coolant Temperature, °F	586
Mass of Reactor Coolant System liquid, lbm	427,706
Mass of Reactor Coolant System steam, lbm	3551
Liquid plus steam energy, Btu (a)	254×10^6
Internal liquid coolant volume, cu. ft.	9740
Internal steam volume, cu. ft.	555
Containment System	
Pressure, psia	14.7
Relative humidity, %	53
Inside temperature, °F	120
Outside temperature, °F	88
Refueling Water Tank (RWT) water temperature, °F	120
Safety injection tank water temperature, °F	120
Service Water temperature, °F	120
Stored Water	
Refueling Water Tank, cu. ft.	5,652
Four safety injection tanks, cu. ft.	

(a) All energies are relative to 32°F

Table 6.2-8A

ESF PERFORMANCE PARAMETERS AND NSSS ASSUMPTIONS FOR MASS AND ENERGY ANALYSIS (LOCA)

PARAMETER	DATA
Initial NSSS Parameters	
Reactor Power, MWt	3087
RCS Pressure, psia	2300
RCS Inlet Temperature, °F	556.7
RCS Flow Rate, gpm	322,000
SG Pressure, psia	1001.1
ESF Performance Parameters	
SIS (Loss of an Emergency Diesel Generator)	1 HPSI / 1 LPSI
SIS (Loss of One CHR System)	2 HPSI / 2 LPSI
SIT Pressure, psia	650
SIT Temperature, °F	140
RWT Temperature, °F	120
RWT Inventory, gal.	384,000

Table 6.2-8B

Miscellaneous Stored Energy Release

Source of Energy	Energy (BTU)
Steam Generator	3.64E+07
RCS Loop	1.58E+07
Upper Head & Other Internals	1.13E+07
Pressurizer	1.15E+07

Table 6.2-8C

DOUBLE-ENDED DISCHARGE LEG BREAK MASS AND ENERGY BALANCE

	Initial	Mass Balance End of Blowdown	End of Post Reflood
RCS Coolant Inventory (lb)	457,272	38,809	104,953[1]
Change in RCS Inventory (lb)	0	- 418,464	- 352,320
Mass Added by 3 SITs (lb)	0	59,409	272,118
Mass Added by SI Pumps (lb)	0	0	99,290
Break Flow to Atmosphere (lb)[2]	0	477,864	573,682
Break Flow to Sump (lb)[2]	0	0	150,215
Error (% Break Flow)		0.002	-0.023

	Initial	Energy Balance End of Blowdown	End of Post Reflood
RCS Coolant Inventory (Btu)	274,764,348	9,240,063	25,325,924[3]
Change in RCS Inventory (Btu)	0	- 265,524,285	- 249,438,423
Energy Added by 3 SITs (Btu)	0	6,512,712	25,239,601
Energy Added by SI Pumps (Btu)	0	0	8,741,500
Energy Added from Fuel (Btu)	0	13,761,000	36,316,542
Energy Added from RCS Walls (Btu)	0	8,460,860	16,060,463
Energy Added from SGs (Btu)	0	- 751,650	85,233,165
Break Flow to Atmosphere (Btu)[2]	0	288,488,400	404,685,351
Break Flow to Sump (Btu)[2]	0	0	13,224,949
Error (% Break Flow)		1.7	0.7

The mass balance and energy balance errors are defined in terms of percent of break flow.

---

[1] Value includes the mass remaining at the end of blowdown.

[2] EOPR values were taken from FLOOD3 output and do not reflect the redistribution of mass and energy to account for 50% condensation of steam flow when the SITs are injecting and the annulus is full.

[3] Value includes the energy remaining at the end of blowdown.

[1] Areas shown are those in contact with the containment atmosphere
[2] Thickness is effective as a result of combining similar thickness walls
[3] One side of wall is exposed to containment atmosphere, one side is insulated
[4] Water filled pipe exposed to containment atmosphere, dimensions are radial from center of pipe

Table 6.2-8E

HEAT SINK THERMODYNAMIC DATA AND MATERIAL PROPERTIES

Thermal Properties for Heat Sinks

Material	Heat Capacity (Btu/ft^3-°F)	Thermal Conductivity (Btu/hr-ft-°F)
Type A Coating	N/A	N/A
Type B Coating	30	0.9
Type C Coating	33	0.1
Type D Coating	30	7.4
Concrete	30	0.8
Carbon Steel	54	25
Stainless Steel	54	10
Air	0.017	1.0
Conduit	42	62
Water	0.376	61

Heat Transfer Coefficients

Region	Heat Transfer Coefficient (Btu/hr-ft^2-°F)
Sump Liquid to Containment Atmosphere	0.0
Containment Sump and Floor to Sump Liquid	0.4
Heat Sink Surfaces Exposed to Outside Air	2.0
Sink Surfaces Exposed to Containment Atmosphere	Modified Tagami

Table 6.2-8F

ESF PERFORMANCE PARAMETERS AND CONTAINMENT INITIAL CONDITIONS FOR CONTAINMENT PRESSURE RESPONSE ANALYSIS (LOCA)

ESF SYSTEM	PERFORMANCE DATA
Containment Air Coolers	
Actuation (CPH), psia	20.7
Actuation Delay Time, sec.[1]	52.0
Heat Removal per Train	See Table 6.2-81
Service Water Temperature, °F	See Figure 6.2-3B
Containment Spray	
Actuation Signal (CPHH)	25.7
Actuation Delay Time, sec.[1]	60.0[2]
Flow Rate (pre-RAS) per pump, gpm	1875
Flow Rate (post-RAS) per pump, gpm	2000
Temperature (pre-RAS), °F	120
Shutdown Cooling Heat Exchangers	
Heat Transfer Area, ft^2	5220 per unit
Overall Heat Transfer Coef., Btu/hr-ft^2-°F	155.5
Service Water Flow Rate (post-RAS), gpm	3350
Service Water Temperature, °F	See Figure 6.2-3B

INITIAL CONTAINMENT CONDITIONS	DATA
Pressure, psia	15.5
Temperature, °F	140
Relative Humidity, %	0
Leakage	None
Outside Temperature, °F	90

[1] Assumes a loss of offsite power
[2] This includes 17.4 seconds fill time for spray header

Table 6.2-8G

MAXIMUM CONTAINMENT PRESSURE AND TEMPERATURE RESULTS (LOCA)

Break Location	Break Size (ft^2)	Single Failure	Pressure (psig)	Time of Peak Pressure (sec)	Temperature (°F)
RCP Discharge	9.82	1 Containment Spray Train	56.9	143.8	284
RCP Discharge	9.82	1 EDG	57.6	148.6	285
RCP Suction	9.82	1 Containment Spray Train	53.1	61.4	285
RCP Suction	9.82	1 EDG	53.2	61.4	285
Hot Leg	19.24	1 Containment Spray Train	55.7	11.0	283
Hot Leg	19.24	1 EDG	55.7	10.8	283

Note: all breaks were double-ended slot

Table 6.2-8H

SEQUENCE OF EVENTS DESIGN BASIS ACCIDENT

Time (sec)	Event Description
0.0	Pipe rupture (9.82 ft^2 DEDLS), reactor coolant system (RCS) depressurization begins.
0.6	Containment Air Cooling Actuation Setpoint (CPH)
1.1	Containment Spray Actuation Setpoint (CPHH)
8.0	Safety injection tanks begin injection into the RCS.
14.9	End of Blowdown.
14.9	Safety injection (HPSI) and (LPSI) pumps begin injection into the RCS.
52.6	Containment air coolers begin operation.
61.1	Containment sprays begin operation.
73.6	Safety injection tanks empty.
148.6	Containment reaches peak pressure (57.6 psig).
148.8	Containment reaches peak temperature (285 °F)
2707.62	Switchover to sump recirculation as RWT reaches low level.
2600000	End of Analysis

Table 6.2-8I

CONTAINMENT AIR COOLER PERFORMANCE DATA, PER TRAIN

120 °F Service Water		110 °F Service Water		95 °F Service Water	
Inlet Temp (°F)	Performance (Btu/hr)	Inlet Temp (°F)	Performance (Btu/hr)	Inlet Temp (°F)	Performance (Btu/hr)

Table 6.2-8J

LOCA MAXIMUM CONTAINMENT PRESSURE AND TEMPERATURE RESULTS SUPPORTING TECHNICAL SPECIFICATION LIMITING CONDITIONS FOR OPERATION

Case[1,2,3,4]	Break Location	CS	CAC	Pressure (psia)	Temperature (°F)
1	RCP Suction	1	1	53.2	284
2	RCP Discharge	1	1	57.4	285
3	RCP Suction	2	1	53.2	284
4	RCP Discharge	2	1	56.4	283
5	RCP Suction	2	0	53.2	285
6	RCP Discharge	2	0	56.9	284

Notes:
1 Loss of offsite power is considered.
2 No additional single failure is considered.
3 Both Emergency Diesel Generators are considered to operate.
4 Full Flow of both Safety Injection Trains Considered.

Table 6.2-9C

MAXIMUM CONTAINMENT PRESSURE AND TEMPERATURE RESULTS (MSLB)

		Peak Pressure		Peak Temperature	
Power[1]	Failure	(psig)	(sec)	(°F)	(sec)
102%	Main feedwater pump to trip	55.1	141.8	402	49.8
94.9%	Main feedwater pump to trip	54.7	150.0	401	49.7
75%	Condensate pump to trip	53.7	158.0	399	49.5
50%	Main feedwater pump to trip	55.2	182.4	397	49.1
25%	Condensate pump to trip	55.2	228.2	395	48.9
0%	Containment Spray Train	57.4	196.0	392	52.4
0%[2]	1 Train of Containment Sprays and 1 Train of Containment Air Coolers (Tech. Spec. LCO case)	58.1	196.4	392	52.4

Note:

[1] All cases were double-ended guillotine breaks except the 0% Power case which was a slot break of 1.94 ft^2.

[2] This case does not represent the DBA. This case, however, does represent the limiting case for the Technical Specification (TS) Limiting Condition for Operation (LCO). In addition to the typical single failure peak containment pressure cases presented in the original FSAR, other cases have been assessed to determine the results of peak pressure conditions under the bounding TS LCO action statements (One CSS and one CCS available bounds two CSS available and two CCS out of service) for containment heat removal systems. The results of these additional analyses demonstrate that peak pressures are bounded by the containment design pressure of 59 psig.

Table 6.2-9D

SEQUENCE OF EVENTS
LIMITING CONTAINMENT PEAK PRESSURE ANALYSIS (MSLB)
(Slot break initiated from 0% power with failure of one containment spray train)

Time (sec)	Event Description
0.0	Start of Event
3.6	Containment Air Cooler Actuation Signal (CPH)
7.4	Containment Spray Actuation Signal (CPHH)
12.5	MSIV shuts
27.5	Backup MFIVs shut
33.6	Containment Air Coolers Start
52.4	Containment Spray Starts (time of peak containment temperature)
196.0	Time of Peak Containment Pressure
400.0	End of Analysis

15-16	39	Orifice Flow

Table 6.2-17B (continued)

b. Flow Paths Sensitivity to Break Location (See Figure 6.2-3C)

	Flow Area (1) (ft^2)			
	200 in^2 Cold Leg Circumferential Break		100 in^2 Hot Leg Circumferential Break	
Flow Path	Case I - Neutron Shield Intact(2)	Case II - Neutron Shield Partially "Blown-Out"(3)	Case I - Neutron Case Shield Intact(4)	Case II-Neutron Shield Partially "Blown-Out"(5)
1-13	Blocked	1.5	Blocked	Blocked
2-14	Blocked	5.5	Blocked	1
3-14	Blocked	Blocked	Blocked	8
4-14	Blocked	Blocked	Blocked	7.5
5-14	Blocked	Blocked	Blocked	1.5
6-15	Blocked	Blocked	Blocked	Blocked
7-15	Blocked	Blocked	Blocked	Blocked
8-15	Blocked	Blocked	Blocked	Blocked
9-15	Blocked	Blocked	Blocked	Blocked
10-13	Blocked	Blocked	Blocked	Blocked
11-13	Blocked	8	Blocked	Blocked
12-13	Blocked	9	Blocked	Blocked

NOTES:

(1) Orifice flow coefficients are used for the unblocked flow paths.

(2) Break is postulated in the Southeast cold leg (see Figure 6.2-16A).

(3) Break is postulated in the Northeast cold leg (see Figure 6.2-16B).

(4) Break is postulated in the South hot leg (see Figure 6.2-16D).

(5) Break is postulated in the South hot leg (see Figure 6.2-16E).

Table 6.2-17B (continued)

II. Steam Generator Compartment Models

a. Cold Leg Pump Suction Circumferential Breaks (See Figure 6.2-31)

Flow From-To	Flow Area (Ft^2)	Flow Coefficient
1-2	170.0	0.74 - Contraction & Expansion
1-3	115.0	0.71 - Contraction & Expansion
1-4	115.0	0.71 - Contraction & Expansion
1-5	170.0	0.74 - Contraction & Expansion

9-10	265.0	1.00

Note: Subsequent analyses have updated some of the flow areas and flow coefficients to reflect changing and current configurations of structures and equipment (grating, etc.). The results demonstrate that peak pressure remains below design pressure for the cavities. The original model is retained here for historical purposes. The analyses are on file in the ANO Calculation Room.

III. Biological Shield Pipe Penetration Model

Flow From-To	Flow Area (Ft²)	Flow Coefficient
1-2	19	0.69 - Free Expansion & 90° Turn
1-3	19	1.00 - Free Expansion
2-5	160	1.00 - Free Expansion
3-4	575	0.61 - Orifice
4-5	1250	1.00 - Free Expansion

Table 6.2-17C

**BIOLOGICAL SHIELD PIPE PENETRATION MODEL
NODAL VOLUMES**

I. Hot Leg Penetration Model (Ft^3)

V1 = 107 - Hot Leg Penetration
V2 = 7,600 - RPV Cavity
V3 = 50,000 - Lower South S. G. Compartment
V4 = 50,000 - Upper South S. G. Compartment
V5 = 1.23×10^6 - Containment Atmosphere

II. Cold Leg Penetration Model (Ft^3)

V1 = 193 - Cold Leg Penetration
V2 = 7,600 - RPV Cavity
V3 = 50,000 - Lower South S. G. Compartment
V4 = 50,000 - Upper South S. G. Compartment
V5 = 1.23×10^6 - Containment Atmosphere

Table 6.2-18

CSS PUMP DATA

Characteristics	Data
Equipment numbers	2P35 A&B
Quantity	2
Type	Vertical, single stage centrifugal
Pumped fluid[3]	Borated water containing sodium hydroxide (pH 4.5 - 10.9)
Design pressure, psig (internal)	400
Design temperature, °F	350
Design flow rate, gpm	2200
Design head, ft.	525
NPSH required at design flow rate, ft.	10
Maximum operating flow rate, gpm	2632.5[1]
Head at maximum operating flow rate, ft.	493
NPSH required at maximum operating flow rate, ft.	12.5
Minimum available NPSH, ft.	18.88[2]
Shutoff head, ft.	610
Materials of construction	
Casing	Austenitic stainless steel
Impeller	Martensitic stainless steel
Shaft	Martensitic stainless steel
Driver	
Type	Induction motor
Service factor	1.15
Nameplate rating, HP	450
Voltage	4000
RPM	1780
Phase	3

(1) Maximum flow of 3200 gpm is credited following start of pumps during header fill phase. Maximum flow of 2632.5 gpm applies to sump recirculation condition.
(2) Minimum available NPSH occurs during recirculation mode for two train alignment combined with a single failure of a LPSI pump failure-to-trip on RAS with NPSHa listed for the opposite train and the most limiting NPSH margin.
(3) Sodium Hydroxide was the specification for the pumps, but has since been replaced with Sodium Tetraborate (NaTB) buffering agent.

REFUELING WATER TANK DATA

Characteristics	Data
Equipment Number	2T3
Quantity	One
Type	Vertical
Stored Material	Boric Acid 2500 ppm B (min) 3000 ppm B (max)
Design Pressure, psig	(Note 1)
Normal Operating Pressure, psig	0
Design Temperature, °F	150
Normal Operating Temperature, °F	40 - 110
Capacity, gal.	500,500
Material of Construction	Stainless Steel
Number of Heaters	5
Type of Heater	Electric Immersion

Note 1: Tank is designed to withstand an internal pressure equal to a column of water 10 ft. above the liquid level of the tank when full, and an internal vacuum of one ounce per square inch below atmospheric pressure.

Table 6.2-21

HISTORICAL SHUTDOWN COOLING HEAT EXCHANGER DATA

Characteristics	Data
Equipment Numbers	2E35A, B
Quantity	Two
Type	Shell & U-Tube
Design Duty, Btu/Hr	28×10^6
Overall Heat Transfer Coefficient, Btu/Hr-°F	1.08×10^6
Shell Side	
Fluid	Service Water
Design Temperature, °F	250
Design Operating Temperature Inlet, °F	100
Design Operating Temperature Outlet, °F	111.9
Design Pressure, psig	150
Design Operating Flow, gpm	4,850
Pressure Loss at Design Flow, psi	10
Design Fouling Factor, (Hr-/Ft^2-°F)/Btu	0.002
Tube Side	
Fluid	Reactor or Sump Water
Design Temperature, °F	400
Design Operating Temperature, Inlet °F	144
Design Operating Temperature, Outlet °F	124.8
Design Pressure, psig	650
Design Operating Flow, gpm	3,000
Pressure Loss at Design Flow, psi	8
Design Fouling Factor, (Hr-Ft^2-°F)/Btu	0.0006
Materials of Construction	
Shell	Carbon Steel
Tubes	Ebrite 26-1
Tubesheets	316L (Clad)

Table 6.2-22

CCS AIR COOLER DATA

Characteristics	Data
Equipment Number	2VSF1A, B, C, D
Quantity	four
Design heat removal rate, BTU/hr (per train) at design service water flow rate of 1250 gpm	See Table 6.2-44
Cooling fluid design temperature, °F	120
Cooling fluid	Service water
Emergency cooling coils:(1)	
number	eight per unit
tubes per coil	192
tube type	finned
tube material	90-10 cupronickel
Fans:	
number per unit	one
type	vaneaxial
blade material	steel
Fan motor:	
type	squirrel cage induction
service factor	1.0
nameplate rating, hp.	75
voltage	460
RPM	1180
Unit casing, material	steel
Design operating pressure, psig	59
Design operating temperature, °F	300
Design operating relative humidity, %	100

(1) For normal cooling coil data, see Section 9.4.2.

Table 6.2-23

CONTAINMENT SPRAY SYSTEM SINGLE FAILURE ANALYSIS

Component	Malfunction	Comments and Consequences
Refueling Water Tank Outlet Valve	Fails to open on SIAS Fails to close on RAS	Only one of two valves is required to open Only one of two valves is required to close
Refueling Water Tank Supply to CVCS Isolation Valve	Fails open	CVCS pressure boundary integrity is still maintained and RWT drains through charging pumps in addition to CSS, HPSI, and LPSI pumps
Containment Sump Isolation Valve	Fails to open on RAS	Both valves on either suction header are required to open
Spray Pump	Fails to start on CSAS	Only one of two pumps is required to start
Spray Pump Minimum Flow Isolation Valve	Fails to close on RAS	Only one of two valves in series is required to close to terminate minimum flow from each pump
	Premature RAS (partial)	A) Common valve (2CV-5628-2) - no single failure or partial RAS can close this valve B) Individual pump valves (2CV-5672-1, 2CV-5673-1) no single failure or partial RAS can close both valves
Spray Header Isolation Valve	Fails to open on CSAS	Only one of two valves is required to open

Note: For containment pressure protection considering MSLB in containment, single failure analysis Tables 6.2-23, 6.2-24, and 10.3-4 are combined with no more than one active single failure except for the Limiting Condition of Operation Action Statement cases as defined in SAR Tables 6.2-8J and 6.2-9C.

Table 6.2-23 applies to mitigation of LOCA. For main steam line or main feedwater line breaks both trains are required to mitigate.

Table 6.2-24

CONTAINMENT COOLING SYSTEM SINGLE FAILURE ANALYSIS

COMPONENT	FAILURE	COMMENTS AND CONSEQUENCES
Bypass damper	One damper fails to open after CCAS	CHRS heat removal requirements will be satisfied by the two trains of containment spray.
Vaneaxial fan	One fan fails to operate	CHRS heat removal requirements will be satisfied by the two trains of containment spray.
Distribution ducts	Duct collapse or flow is blocked by missile damage at one point in the distribution system.	CHRS heat removal requirements will be satisfied by the two trains of containment spray.

Note: For containment pressure protection considering MSLB in containment, single failure analysis Tables 6.2-23, 6.2-24, and 10.3-4 are combined with no more than one active single failure except for the Limiting Condition for Operation Action Statement cases as defined in SAR Tables 6.2-8J and 6.2-9C.

Table 6.2-24 applies to mitigation of LOCA. For main steam line or main feedwater line breaks both trains are required to mitigate.

Table 6.2-24A

SUMMARY OF CONTAINMENT REGIONS NOT DIRECTLY SPRAYED

Total Containment Volume Not Directly Sprayed		365,000 ft³
I.	Volumes having good communication with directly sprayed volumes:	
A.	Under polar crane from El. 496' to first concrete (varies El. 357' to El. 428')	102,000 ft³
B.	Elevator El. 455' to El. 336'-6" (sides are open)	14,000 ft³
C.	Under missile shield from El. 426'-6" to el. 377'-6"	36,000 ft³
D.	Under reactor head laydown slab El. 405'-6" to operating floor, El. 357'-0"	34,000 ft³
E.	Under refueling machine, El. 403' to refueling canal floor, El. 362'-0"	7,000 ft³
F.	Lower portion of steam generator compartments from El. 366'-6" to El. 336'-6"	55,000 ft³
	SUBTOTAL	248,000 ft³
II.	Volumes having restricted communication with directly sprayed volumes:	
A.	Annular volumes between the secondary shield walls and the primary containment wall which are covered by concrete slabs (El. 357' and El. 374'-6")	79,000 ft³
B.	Under refueling canal floor, El. 361'-6" and 358' to El. 336'-6"	31,000 ft³
C.	Reactor vessel cavity and volume below the pressurizer base slab	7,000 ft³
	SUBTOTAL	117,000 ft³

Table 6.2-25

EXPOSED COATINGS WITHIN CONTAINMENT

Category	Item Description	Surface Area, ft^2	Type of Coating[a]
Liner Plate	Prime Total Liner Plate	79,000	Inorganic Zinc
	Finish Wainscot and Penetrations	19,034	Modified Phenolic or Epoxy
Structural Steel	Prime Structural Steel	22,000	Inorganic Zinc
	Finish Structural Steel	22,000	Modified Phenolic or Epoxy
Miscellaneous Metal	Prime Misc. Metal	37,000	Inorganic Zinc
	Finish Misc. Metal	37,000	Modified Phenolic or Epoxy
Concrete Walls	Prime Concrete, if required	1,000	Clear Primer for Concrete
	Surfacing Material	1,000	Modified Phenolic or Epoxy
	Special Coating for Surfacing Material	1,000	Modified Phenolic or Epoxy
Concrete Floors	Prime Concrete, if required	12,200	Clear Primer for Concrete
	Surfacing Material	12,200	Modified Phenolic or Epoxy
	Special Coating for Surfacing material	12,200	Modified Phenolic or Epoxy
Piping 3″ and Larger	Prime Total 3″ and Larger Carbon Steel Pipe and Fittings	9,780	Inorganic Zinc
Mechanical Equipment	Prime Polar Crane	47,551	Epoxy Primer
	Finish Polar Crane	47,551	Epoxy Enamel
	Prime RCP Motors	2,000	Inorganic Zinc
	Finish RCP Motors	2,000	Modified Phenolic or Epoxy
Electrical	Motor Control Centers	560	Electrostatic Plating
Piping 2″ and Smaller	Prime Total 2″ and Smaller Pipe and Fittings		Inorganic Zinc
	Finish 2″ and Smaller Pipe and Fittings		
H&V Equipment	Containment Cooler Fans with Coils	2,400	Modified Phenolic or Epoxy
	Electric Fans	60	Modified Phenolic or Epoxy
	Reactor Cavity Supply Fans	110	Modified Phenolic or Epoxy
	CEDM Cooling Unit Fans	600	Baked-on Epoxy Primer
Mechanical Equipment	Prime the following: Safety Injection Tanks Refueling Machine and Motor Reactor Vessel Head Lift Rig Fuel Transfer Machine & Motor	3557	Inorganic zinc

[a] Coatings installed during construction. Repairs of damaged coatings may use reformulated replacement coatings that contain materials different than the previous coatings, may not require a primer, and may not be the same type (e.g., inorganic). Although replacement coatings can decrease the zinc mass in the containment, analyses for post-accident conditions using previous zinc mass estimates are conservative. Coatings and repairs are governed by Specification ANO-A-2437.

CODES AND SYMBOLS		NOTES
(1) Valve Type The following codes are used to identify valve type: CHK - Check GAT - Gate GLB - Globe BTY - Butterfly BAL - Ball REL - Relief SCHK - Stop Check BCK - Ball Check (2) Actuator Type The following codes are used to identify valve actuator types: AO - Air Operator SO - Solenoid Operator MO - Motor Operator M - Manual SA - Self Actuated	(3) Valve Position The following codes are used to identify different valve positions: O - Open LC - Locked Closed C - Closed FAI - Fail As Is (4) Design Criteria This column references the appropriate General Design Criteria of 10 CFR 50, Appendix A. ODB – Other Defined Basis * - Penetration is GDC 55 based on 10 CFR 50.2. Based on the definition in SAR Section 5.2, the reactor coolant pressure boundary ends before the penetration.	(5) Valves fail open in order to ensure the capability to sample the containment atmosphere for hydrogen in the event power to either ESF bus is lost. (6) These penetrations are in use during the Type A test. Type B or C tests will be conducted and applied to the Type A test results. (7) The valve positions represent conditions immediately following automatic actuation/isolation signals from the Engineering Safety Features Actuation System. These valves will/may be overridden and opened by the operator prior to or after the isolation signals. (8) These valves may not be opened during power operations, therefore, manual adjustments may be made prior to as-left Type C Appendix J tests. (9) Vents, drains and other similar connections that are not connected to another process system are not included as isolation barriers although they are a part of the isolation boundary. Where closed systems are identified as a barrier, the individual valves that form part of the closed system boundary are not listed separately. (10) All containment isolation valves were originally designed and tested by the manufacturer to close in a maximum of 20 seconds. Actual closing times are controlled by the Inservice Testing Program and Technical Specifications.

Table 6.2-26 (continued)

NOTES
(11) **<u>If</u>** control, or solenoid valves are added to this table; **<u>Then</u>** notify Unit 2 Planning and Maintenance that an addition has been made to SAR Table 6.2-26, which will require: a. The following note to be inserted into the controlling plant database (such as equipment database/component database) Maintenance Notes for the newly added control valve, its actuator, and power and control circuit components, which states: Planner – If maintenance, repair, or replacement work is performed on this valve, it's actuator, it's control circuit, or it's power circuit, a full stroke test of the valve is required and stroke times verified to be within limits pursuant to TS 4.6.3.1.1, SAR Table 6.2-26, and the Inservice Testing Program. Ref. CR-2-98-0409. b. A review of any active work document which exists for the newly added control valve, its actuator, and power and control circuit components to ensure that they contain Post Maintenance Testing that complies with the requirements stated in the Maintenance Note referenced in requirement 1 above. c. A review of any active CM activity which exists for the newly added control valve, its actuator, and power and control circuit components, to ensure that the Post Maintenance Testing complies with the requirements stated in the Maintenance Note referenced in requirement 1 above. **<u>If</u>** control or solenoid valves are deleted from this table; **<u>Then</u>** notify Unit 2 Planning, Unit 2 Maintenance, and Unit 2 Systems Engineering, that a deletion has occurred in SAR Table 6.2-26, which will require: a. The following note to be removed from the controlling plant database (such as equipment database/component database) Maintenance Notes for the deleted valve, its actuator, and power and control circuit components. Planner – If maintenance, repair, or replacement work is performed on this valve, it's actuator, it's control circuit, or it's power circuit, a full stroke test of the valve is required and stroke times verified to be within limits pursuant to TS 4.6.3.1.1, SAR Table 6.2-26, and the Inservice Testing Program. Ref. CR-2-98-0409. b. A review of any active work document which exists for the deleted control valve, its actuator, and power and control circuit components, to ensure the Post Maintenance Testing requirements are appropriate. c. A review of any active CM activity which exists for the deleted control valve, its actuator, and power and control circuit components, to ensure the Post Maintenance Testing requirements are appropriate.
(12) This penetration meets the requirements of GDC-57 with the exception of 2MS-55 and 2MS-74, which are maintained in the open position during power operations. These valves are steam trap isolations for the A SG steam supply to the EFW turbine and the ADV. Closing these valves during operation potentially challenges the operability of the steam driven EFW pump and ADV. The NRC has approved this configuration per 0CNA040508.

Table 6.2-27

HYDROGEN RECOMBINER CHARACTERISTICS

Parameter	Value
Equipment number	2M55A,B
Quantity	Two
Type	Thermal hydrogen recombiner
Design pressure, psig	75[(1)]
Design temperature, °F	1400[(2)]
Design capacity, SCFM	100
Design codes	IEEE Standard 279-1971 IEEE Standard 308-1971 IEEE Standard 344-1971
Hydrogen removal efficiency, percent	95
Heater Characteristics:	
Number of heaters	5 Banks
Capacity of heater, KW	15 (Max.)
Type of heater	Electric resistance

(1) The recombiners have been environmentally qualified to 85 psig and 316 °F.
(2) This is the maximum operating temperature of the recombiner heaters.

Table 6.2-28

QUANTITIES OF ZINC, COPPER AND ALUMINUM IN CONTAINMENT

Material	Surface Area (ft.²)	Thickness (in)
Aluminum	2,000	0.1
Copper	58,960	0.007
Zinc	115,000	0.004
Zinc Based Paint	210,000	0.003
Cupro-Nickel	132,440	0.007

The surface areas listed are conservative estimates of the total exposed surface areas of the material and include some margins for possible future additions.

The thickness values used as input to COGAP (Ref. 80) are larger than the thickness of material that will corrode to produce hydrogen during the 30 day time period of the analysis. This assures the maximum calculated hydrogen production.

Repairs of damaged coatings may use reformulated replacement coatings that contain materials different than the previous coatings, may not require a primer, and may not be the same type (e.g., inorganic). Although replacement coatings can decrease the zinc mass in the containment, analyses for post-accident conditions using previous zinc mass estimates are conservative. Coatings and repairs are governed by Specification ANO-A-2437

Table 6.2-29

METAL CORROSION RATES ASSUMED FOR POST-ACCIDENT HYDROGEN GENERATION

Time	Corrosion Rate in mils/year

5	Sheet Metal and Pipes[1,2]	Galvanized Coating Steel	0.00008 0.0049	110,500
6	Concrete Walls and Floors[1,2]	Type C Coating Concrete	0.0063 1.38	28,000
7	Structural Steel[1,2]	Type A Coating Steel	0.0004 0.0349	119,300
8	Crane Girders[1,2]	Type D Coating Steel	0.0005 0.0098	67,000
9	Concrete[1,2]	Concrete	2.70	68,000
10	Stainless Steel [1,2]	Stainless Steel	0.0179	7,000
11.	Containment Sump Strainers	Stainless Steel	0.0063	12,900
12.	Containment Sump Plenum	Stainless Steel	0.0332	1,705
13.	Refueling Canal Deep End Strainers[1]	Stainless Steel	0.0223	19

Notes:

(1) Thickness is effective thickness as a result of combining similar thickness walls.

(2) One side of wall is exposed to containment atmosphere, one side is insulated.

Table 6.3-1

SAFETY INJECTION SYSTEM COMPONENT PARAMETERS

Refueling Water Tank

Quantity	1
Recommended Design Pressure, ft	10
Recommended Design Temperature, °F	150
Material	SA-240 -Gr 304 Stainless
Nominal Capacity, gal	500,500
Contained Liquid	Borated water 3000 ppm, max.
Liquid Temperature, °F, min.	40
Code	ASME III, Class 2
Seismic Category	I

Low Pressure Safety Injection Pumps

Quantity	2
Type	Single Stage, Centrifugal
Safety Classification	2
Code	Draft ASME Pump and Valve Code, Class 2
Design Pressure, psig	650
Design Temperature, °F	400
Design Flow Rate, gpm	3100
Design Head, ft	350
Maximum Flow Rate, gpm	5700
Head at Maximum Flow Rate, ft.	265
Materials	Stainless Steel ASTM-A-351 Gr CF8M
Seals	Mechanical
Motor Horsepower	* 450 (2PM60A); 500 (2PM60B)

* One 450 hp pump motor burned up and the only replacement was a 500 hp motor.

Table 6.3-1 (continued)

High Pressure Safety Injection Pumps

Quantity	3
Type	Multistage, Centrifugal
Safety Classification	2
Code	Draft ASME Pump and Valve Code, Class 2
Design Pressure, psig	1950
Design Temperature, °F	400
Design Flow Rate, gpm	320
Design Head, ft.	2900
Maximum Flow Rate, gpm	900*
Head at Maximum Flow Rate, ft	1300*
Materials	Stainless Steel ASTM-A-351 Gr CF8M
Shaft Seal	Mechanical
Motor Horsepower	650

* These values are for HPSI pumps 2P-89A/B. The maximum flow rate for HPSI pump 2P-89C is 870 gpm with a corresponding head (at maximum flow rate) of 1250 ft.

Safety Injection Tanks

Quantity	4
Safety Classification	2
Code	ASME III, Class 2
Design Pressure, Internal/External, psig	700/0
Design Temperature, °F	200
Operating Temperature, °F	120
Normal Operating Pressure, psig	610
Minimum Operating Pressure, psig	600
Volume, Total, ft^3	1855
Volume, Liquid, ft^3	1480
Fluid	Borated Water, 3000 ppm Boron, max.
Material	Stainless Clad Carbon Steel

DELETED

(Historical Information)

Table 6.3-3

FAILURE MODE ANALYSIS

HIGH PRESSURE SAFETY INJECTION
(Injection Mode)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
HPSI Loop Flow Indicator - 4	Malfunction	None	Comparison of Flow to other Flow Indicators and Valve Position Indicators.	CRI	
HPSI Valve - 8	Fails to open	Valve in ruptured loop--no effect Valve in non- ruptured loop partial flow loss but flow to core still greater than minimum required.	Flow Indication Pressure Indication Valve Position Indication.	CRI	
Pump Discharge Isolation Valve - 3	None	None, "Locked Open" valve	NA*		NA*
Pump Minimum Flow Recirculation Stop Valve - 3	None	None, "Locked Open" valve.	NA*		NA*
HPSI Pump - 3	a. Fails to Start	Loss of HPSI flow from 1 pump	Pump Motor Lights, Header Pressure	CRI	Flow from at least one pump available.
	b. Stops	Loss of HPSI flow 1 pump	Pump Motor Lights, Header Pressure	CRI	Flow from at least one pump available.
Pump Suction Isolation Valve - 2	None	None, "Locked Open" valve.	NA*	NA*	

* Not applicable where no failure mode is indicated.

Table 6.3-3 (continued)

HIGH PRESSURE SAFETY INJECTION
(Recirculation Mode)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
HPSI Lines Connecting to RCS - 4	Rupture	1. Break in ruptured loop--no effect. 2. Break not in ruptured loop--up to 50% of total flow may not reach the core	Sump level alarms if outside containment. Nothing if inside.	CRI	2 HPSI pumps supplying coolant through two loops is sufficient to maintain core cooling.
HPSI Discharge Check Valve - 4	Fails Closed	1. Valve in ruptured loop--no effect. 2. Valve in non-ruptured loop--at least 67% of HPSI flow from 2 pumps reaches core.	Flow Indication, Pressure Indication.	CRI	Flow is sufficient to cool core
HPSI Loop Flow Indicator - 4	Malfunction	None	Comparison to flow other flow indicator and Valve Position Indicator.	CRI	Balancing of flow is not essential during long-term cooling. Flow is balanced during short term and not normally altered.
Check Valve Associated with HPSI Valves - 4	Fails Closed	1. Valve in ruptured loop--no effect 2. Valve in non-ruptured loop--at least 67% of HPSI flow from 2 pumps reaches core.	Flow Indication, Pressure Indication.	CRI	Flow is sufficient to cool core.

Table 6.3-3 (continued)

**HIGH PRESSURE SAFETY INJECTION
(Recirculation Mode) (continued)**

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
HPSI Valve - 8	Fails Closed	Valve in ruptured loop--no effect Valve in non-ruptured loop--partial flow loss but flow to core still greater than minimum required.	Flow Indication, Pressure Indication, Valve Position Indication	CRI	
HPSI Pump Discharge Relief Valve - 3	Fails Open	ırtial loss of HPSI flow.	None	CRI	Loss of flow will be insignificant
HPSI Line between Pump Discharge Isolation Valves and Safety Injection Valves	Rupture	Loss of HPSI flow from one pump.	Room Vent Radiation Monitor, Level Indication, Level Alarm, Sump Pump Operation, Flow Indication.	CRI	Affected HPSI pump must be stopped and header isolated. Backup HPSI is restarted.
Pump Discharge Isolation Valve - 3	Fails Closed	Loss of HPSI flow from 1 pump	Flow Indication, Pressure Indication.	CRI	At least 1 HPSI pump is available. Each pump is full capacity.
Pump Minimum Flow Recirculation Stop Valve - 3	Fails Closed	None, valve is not necessary after RAS.	None		
Pump Discharge Check Valve - 3	Fails Closed	Loss of HPSI flow from 1 pump	Flow Indication, Pressure Indication.	CRI	At least 1 HPSI pump is available.

Table 6.3-3 (continued)

HIGH PRESSURE SAFETY INJECTION
(Recirculation Mode) (continued)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
HPSI Pump - 3	a. Stops	Loss of HPSI flow from 1 pump.	Pump Motor Lights	CRI	At least 1 HPSI pump is available.
	b. Seal Failure	Slight reduction in output from affected pump.	None		
	c. Loss of seal coolant	Loss of HPSI flow from 1 pump.	None		Effect is not expected, but conservatively postulated.
Pump Suction Isolation - 2	Fails Closed	Loss of suction to1 HP pump	Pressure Indication. Possible Flow Indication.	Local CRI	At least 1 HPSI pump is available.
Pump Suction Line Prior to Pump Isolation Valves	Rupture	Loss of suction to all pumps on header. Spillage into pump room until break is isolated.	Flow Indication, Pressure Indication, Room Vent Radiation Monitor, Level Indicator, Level Alarm, Sump Pump Operation.	CRI	RWT has been isolated at RAS. Requires isolation at containment sump. All pumps on the other header are available.
Safety Injection Pump Minimum Flow Recirc Stop Valve - 2	Fails Open	None	Valve Position	CRI	2 valves are in series
LPSI Valve - 4	Fails Closed	Valve in ruptured loop--no effect. Valve not in ruptured loop--at least 50% of LPSI flow reached core.	Valve Position, Flow Indication, Pressure Indication	CRI	Flow from 50% on LPSI pump is adequate.

Table 6.3-3 (continued)

LOW PRESSURE SAFETY INJECTION
(Injection Mode)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
LPSI Segment to Shutdown Cooling Heat Exchange Isolation Valve - 1	None	None	NA	NA	
Flow Indicator Controller Stop Valve - 1	None	None	NA	NA	Fail open valve.
CVCS Crosstie to SDC/LPSI Line	Rupture	Loss of Heat Exchanger	Flooding, Aux. Sump Level, Penetration Vent Radiation Monitor.	Local CRI CRI	Protected by 2PSV-5082
Pump Discharge Isolation Valve - 2	None	None	NA	NA	
Pump Minimum Recirculation Stop Valve - 2	None	None	NA	NA	
Pump - 2	a. Fails to start	Loss of LPSI flow from one pump.	Pump Indication lights.	CRI	Other pump starts.
	b. Stops	Loss of LPSI flow from one pump.	Flow Indication.	CRI	Other pump starts simultaneously. Each pump is full capacity.
	c. Fails to stop with the RAS	Pumps may cavitate unless flow is reduced.	Flow Indicator fluctuations	CRI	Operator may stop pumps.
Pump Suction Isolation Valve - 2	None	None	NA	NA	

Table 6.3-3 (continued)

SAFETY INJECTION TANK SEGMENT
(Injection Mode)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
SI Tank Isolation Valve - 4	None	None, valve is Normally Open, Locked Open "Fail As Is" valve.	NA	NA	
Drain and Fill Isolation and Valve - 4	None	None, valve is "Fail Closed" valve.	NA	NA	
Check Valve Leakage Control Valve - 4	None	None, valve is "Fail Closed" valve.	NA	NA	
SI Tank Purge Valve - 4	None	None, valve is "Fail Closed" valve.	NA	NA	
N. Supply Line Stop Valve	None	Valve is "Fail Closed" valve.	NA	NA	
SUCTION SEGMENT FOR SAFETY INJECTION (Injection Mode)					
Refueling Water Tank Isolation Valve - 2	Inadvertently closed during use of tank.	Loss of suction to affected pumps.	Valve Position, Flow Indication.	CRI	
	Inadvertently opened during use of sump	None-Check valve restricts flow to RWT during recirculation.	Valve Position	CRI	Operator Error. Operator should detect abnormal valve position by indicator lights.

Table 6.3-3 (continued)

SUCTION SEGMENT FOR SAFETY INJECTION (Injection Mode) (continued)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
Sump Isolation Valve - 2	a. Inadvertently opened during use of refueling water tank	None-RWT flows to sump until RAS if building pressure is low. None-Check valve restricts flow to RWT if building pressure is high. Potential flow from sump to RWT through mini-recirc line.	Valve Position, Possible loss of flow	CRI	Operator error. Operator should detect abnormal valve position by indicator lights and take action to terminate mini-recirc.
	b. Inadvertently closed during use of sump.	Loss of suction to one pump header.	Valve Position, Flow Indication.	CRI	

SUCTION SEGMENT FOR SAFETY INJECTION (Recirculation Mode)

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
Suction Line - 2	Rupture	Leakage until break is isolated--full flow is available through the parallel leg.	Pump room sump pump operation	CRI	Require isolation of rupture at sump valves.
RWT Check Valve - 2	a. Fails Closed	None during long-term cooling	None	None	
	b. Fails Open	None--Isolation valve in series stops flow to RWT.			

Table 6.3-3 (continued)

**SUCTION SEGMENT FOR SAFETY INJECTION
(Recirculation Mode) (continued)**

Component Identification and Quantity	Failure Mode	Effect on System	Method of Detection	Monitor	Remarks
RWT Isolation Valve - 2	Inadvertently open during recirculation cooling	None--Check valve restricts flow to RWT.	Valve Position	CRI	Operator error. Operator should detect position indicator light and close valve.
Sump Isolation Valve - 2	Inadvertently closed during recirculation cooling	Loss of suction to 1 pump header.	Valve Position	CRI	Operator error. Full flow is available through parallel leg. Operator should detect position indicator light and open valve.
Suction Line Between Containment Wall and Isolation Valve - 2	Rupture	None-Isolation inside containment available	None	None	

Abbreviations used in Table 6.3-3 are:

CRI - Control Room Indication

HPSI - High-Pressure Safety Injection

LPSI - Low-Pressure Safety Injection

SIAS - Safety Injection Actuation Signal

RAS - Recriculation Actuation Signal

RW - Refueling Water

Refueling Water Tank

Reactor Coolant System

Safety Injection System

Table 6.3-9

**SYSTEM PARAMETERS AND INITIAL CONDITIONS
FOR THE LARGE BREAK LOCA ECCS PERFORMANCE EVALUATION**

Quantity	Value	Units
Reactor power level (102% of rated power)	3087	Mwt
Peak linear heat generation rate (PLHGR) of the hot rod	13.7	kw/ft
PLHGR of the average rod in assembly with the hot rod	12.91	kw/ft
Gap conductance at the PLHGR(1)	2474	Btu/hr-ft^2-°F
Fuel centerline temperature at the PLHGR(1)	3172.9	°F
Fuel average temperature at the PLHGR(1)	1967.2	°F
Hot rod gas pressure(1)	401.79	psia
Moderator temperature coefficient at initial density	+ 0.5×10^{-4}	$\Delta\rho$/°F
RCS flow rate	118.0×10^{6}	lbm/hr
Core flow rate	113.86×10^{6}	lbm/hr
RCS pressure	2200	psia
Cold leg temperature	540.0	°F
Hot leg temperature	607.1	°F
Plugged tubes per steam generator	10	%
Low pressurizer pressure SIAS setpoint	1400	psia
Safety injection tank pressure (min/max)	550/650	psia
Safety injection tank water volume (min/max)	1000/1600	ft^3
LPSI pump flow rate (min, 1 pump at 40 psia)	3544.2	gpm
HPSI pump flow rate (min, 1 pump at 40 psia)	767.28	gpm

(1) These quantities correspond to the rod average burnup of the hot rod that yields the highest peak cladding temperature.

**TIMES OF INTEREST
FOR THE LARGE BREAK LOCA ECCS PERFORMANCE EVALUATION
(Seconds after Break)**

Break	SI Tanks On	End of Bypass	Start of Reflood	SI Tanks Empty	Hot Rod Rupture
1.0 DEG/PD	9.4	16.6	27.6	78.8	60.1
0.8 DEG/PD	10.3	17.5	28.4	79.7	52.8
0.6 DEG/PD	12.0	19.2	30.1	81.4	47.8
0.4 DEG/PD	15.1	22.8	33.5	85.1	76.7
0.3 DEG/PD	18.6	27.0	37.6	89.4	127.7

Table 6.3-15

**PEAK CLADDING TEMPERATURES AND OXIDATION PERCENTAGES
FOR THE LARGE BREAK LOCA ECCS PERFORMANCE EVALUATION**

Break	Peak Cladding Temperature (°F)	Maximum Cladding Oxidation (%)	Maximum Core-Wide Oxidation (%)
1.0 DEG/PD	2034	7.3	< 1
0.8 DEG/PD	2085	9.2	< 1
0.6 DEG/PD	2107	9.2	< 1
0.4 DEG/PD	2144	12.6	< 1
0.3 DEG/PD	1987	5.9	< 1

Note: These results reflect the Analysis of Record and do not include errors as reported annually in accordance with 10 CFR 50.46.

Table 6.3-16

**HIGH PRESSURE SAFETY INJECTION PUMP
MINIMUM DELIVERED FLOW TO RCS
(ASSUMING ONE EMERGENCY DIESEL GENERATOR FAILED)**

RCS Pressure, psia	Flow Rate, gpm
14.7	738.7
22	736.6
31	733.3
35	732.2
46	729.0
191	680.4
327	631.8
456	583.2
577	534.6
692	486.0
800	437.4
899	388.8
990	340.2
1071	291.6
1142	237.6
1201	172.8
1248	102.6
1269	54.0
1281	0.0

Notes:
1. The flow is assumed to be split equally to each of the four discharge legs.
2. The flow to the broken discharge leg is assumed to spill out the break.

Table 6.3-17

**SYSTEM PARAMETERS AND INITIAL CONDITIONS
FOR THE SMALL BREAK LOCA ECCS PERFORMANCE EVALUATION**

Quantity	Value	Units
Reactor power level (102% of rated power)	3087	MWt
Peak linear heat generation rate (PLHGR)	13.7	kW/ft
Axial shape index	-0.3	
Gap conductance at PLHGR[(1)]	1853	BTU/hr-ft^2-°F
Fuel centerline temperature at PLHGR[(1)]	3303	°F
Fuel average temperature at PLHGR[(1)]	2070	°F
Hot rod gas pressure [(1)]	710	psia
Moderator temperature coefficient at initial density	0.0×10^{-4}	$\Delta\rho$/°F
RCS flow rate	117.4×10^{6}	lbm/hr
Core flow rate	113.3×10^{6}	lbm/hr
RCS pressure	2200	psia
Cold leg temperature	556.7	°F
Hot leg temperature	621.1	°F
Plugged tubes per steam generator	10	%
MSSV first bank opening pressure	1130.9	psia
Low pressurizer pressure reactor trip setpoint	1400	psia
Low pressurizer pressure SIAS setpoint	1400	psia
HPSI Flow Rate	Table 6.3-16	gpm
Safety injection tank pressure	500	psia

Note (1) These quantities correspond to the rod average burnup of the hot rod that yields the maximum initial stored energy.

Table 6.3-18

**BREAK SPECTRUM
FOR THE SMALL BREAK LOCA ECCS PERFORMANCE EVALUATION**

Break Size and Location	Abbreviation	Figure No.
0.05 ft^2 Break in Pump Discharge Leg	0.05 ft^2/PD	6.3-23
0.04 ft^2 Break in Pump Discharge Leg	0.04 ft^2/PD	6.3-24
0.03 ft^2 Break in Pump Discharge Leg	0.03 ft^2/PD	6.3-25

Table 6.3-19

**PEAK CLADDING TEMPERATURES AND OXIDATION PERCENTAGES
FOR THE SMALL BREAK LOCA ECCS PERFORMANCE EVALUATION**

Break	Peak Cladding Temperature (°F)[(a)]	Maximum Cladding Oxidation (%)[(b)]	Hot Rod Oxidation (%)[(c)]
0.05 ft^2/PD	1992	13.18	< 0.73
0.04 ft^2/PD	2111	16.77	< 0.88
0.03 ft^2/PD	1971	12.42	< 0.69

(a) Acceptance criterion is 2200 °F.
(b) Acceptance criterion is 17%.
(c) Acceptance criterion is 1.0% core-wide cladding oxidation. Rod-average oxidation of the hot rod is given as a conservative representation of the core-wide cladding oxidation.

Note: These results reflect the analysis of record and do not include errors as reported annually in accordance with 10 CFR 50.46.

Table 6.3-20

**TIMES OF INTEREST
FOR THE SMALL BREAK LOCA ECCS PERFORMANCE EVALUATION
(Seconds after Break)**

Break	HPSI Flow Delivered to RCS	LPSI Flow Delivered to RCS	SIT Flow Delivered to RCS	Peak Cladding Temperature Occurs
0.05 ft^2/PD	190	(a)	1755	1625
0.04 ft^2/PD	224	(a)	(b)	1852
0.03 ft^2/PD	280	(a)	(b)	2273

(a) Calculation completed before LPSI flow delivery to RCS begins.
(b) Calculation completed before SIT injection begins.

Table 6.3-21

**LARGE AND SMALL BREAK LOCA
COMPARISON OF RESULTS**

	Discharge Leg Break	
	Small	Large
	0.04 ft^2/PD	0.4 DEG/PD*
Peak Cladding Temperature, °F	2111	2144
Maximum Cladding Oxidation, %	16.77	12.6
Maximum Core Wide Oxidation, %	< 0.88	< 1
Peak Linear Heat Generation Rate, kw/ft	13.7	13.7

* 0.4 DEG/PD = 0.4 Double Ended Guillotine at Pump Discharge.

CHAPTER 7 (CONT.)	

7 INSTRUMENTATION AND CONTROLS

7.1 INTRODUCTION

The instrumentation and control systems which monitor and perform safety-related functions are discussed in Chapter 7. Complete descriptions and analyses of these systems are provided in Sections 7.2 through 7.6.

7.1.1 IDENTIFICATION OF SAFETY-RELATED SYSTEMS

The safety-related instrumentation and controls, including supporting systems, are identified below. The responsibility for design and supply of each system is identified as follows:

Combustion Engineering, Inc.	(CE)
Bechtel	(B)

7.1.1.1 Plant Protection System (PPS)

The PPS includes the electrical and mechanical devices and circuitry (from sensors to actuation device input terminals) involved in generating signals associated with the two protective functions defined below.

A. Reactor Protective System (Reactor Trip System) (CE)

The Reactor Protective System (RPS) is that portion of the PPS which generates signals that actuate reactor trip. A description of the RPS, detailing the functions of the system modules is found in Section 7.2.

B. Engineered Safety Features Actuation System (CE)

The Engineered Safety Features Actuation System (ESFAS) is that portion of the PPS which generates signals that actuate Engineered Safety Features (ESF). This system is a part of the ESF systems. Details of the actuation system modules are found in Section 7.3.

The ESF systems actuated by the ESFAS are listed below:

1.	Containment Isolation System (CIS)	(B)
2.	Containment Spray System (CSS)	(B)
3.	Containment Cooling System (CCS)	(B)
4.	Safety Injection System (SIS)	(CE)
5.	Penetration Room Ventilation System (PRVS)	(B)
6.	Main Steam Isolation (MSI)	(CE)
7.	Emergency Feedwater (EFW)	(CE)

The instrumentation and controls for ESF systems are described in Section 7.3. Supporting systems are discussed in Section 7.4.

7.1.1.2 Systems Required for Safe Shutdown

The systems required for safe shutdown include those systems which may be required to secure and maintain the reactor in a hot shutdown condition.

The systems are listed below:

A. Emergency Power Systems (B)

  1. Emergency Diesel Generator (B)

  2. Fuel Oil Storage Transfer System (B)

  3. Emergency Power Distribution System (B)

B. Emergency Feedwater System (B)

C. Chemical and Volume Control System (CVCS) (Boron Addition Portion) (CE)

D. Service Water System (SWS) (B)

Note: A and B are required in the event normal power sources are unavailable.

The instrumentation and controls for the systems required for safe shutdown are described in Section 7.4.

Auxiliary systems vital to the proper functioning of safety-related systems are designed to the same criteria as those for the safety-related systems that they support, including compliance with applicable portions of IEEE 279-1971 and IEEE 308-1971. This compliance is shown in Section 7.4 and other applicable sections in the auxiliary systems description.

7.1.1.3 Safety-Related Display Instrumentation

The safety-related display instrumentation provides information to the operator to allow him to adequately monitor plant operating conditions and to perform any required manual safety functions.

Most of this instrumentation is supplied by CE. This instrumentation is described in Section 7.5.

7.1.1.4 Other Systems Required for Safety

Other systems required for safety include the interlocks required to prevent overpressurization of the Shutdown Cooling System and to assure safety injection is available. These are provided as listed below.

A. Shutdown Cooling Interlocks (CE, B)

B. Safety Injection Tank Isolation Valve Interlocks (CE, B)

C. Refueling Interlocks (CE)

These systems are described in Section 7.6.

7.1.1.5 Comparison - Reactor Protective System

Historical data removed - To review the exact wording please refer to Section 7.1.1.5 through 7.1.1.8 of the FSAR.

7.1.2 IDENTIFICATION OF SAFETY CRITERIA

The design bases, criteria, regulatory guides, standards and other documents that are implemented in the design of the systems listed in Section 7.1.1 are included in each of the subsections describing the system (See Sections 7.2 through 7.6).

7.1.2.1 Design Bases

The design bases for the safety-related instrumentation and control of each safety-related system are presented in the section of this chapter that discusses the system to which the information applies. The criteria for systems required for safe shutdown are described in Chapters 8, 9, and 10 as appropriate.

In particular, the instrumentation and controls for the RPS and ESF systems conform to the following:

A. Actuation systems conform to the IEEE Criteria for Nuclear Power Plant Protection Systems (IEEE 279-1971);

B. Actuation systems are designed using the IEEE Trial - Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems (IEEE 338-1971) as a guide;

C. Systems are designed using the IEEE 336-1971, "Installation, Inspection and Testing Requirements for Instrumentation, and Electric Equipment during the Construction of Nuclear Power Generating Systems" as a guide;

D. Design bases as described in Sections 7.2.1 and 7.3.1.2;

E. Quality assurance procedures as described in the Quality Assurance Program Manual (QAPM);

F. "General Design Criteria for Nuclear Power Plants," Appendix A to 10 CFR 50, July 7, 1971, as described in Sections 7.2.2 and 7.3.2.

7.1.2.2 Independence of Redundant Safety-Related Systems

Channels that provide signals for the same protective function are designed to meet the independence and separation requirements of Section 4.6 of IEEE 279-1971.

The cabling which is associated with redundant channels of vital circuits for the RPS and the ESFAS are physically separated to preserve the redundancy and to prevent a single event from causing multiple channel malfunction or interactions between channels.

Separation between redundant channels begins with the physical separation of the sensors. Separation of the wiring is discussed in Section 8.3.1.4.

Separation within the PPS cabinet is provided by barriers within the panel. These barriers within the cabinet run the full depth and full vertical dimension. All cabling entering each barriered section of the panel is separated as it enters the cabinet.

The reactor trip switchgear, which interrupts power to the coils of the Control Element Drive Mechanisms (CEDMs), is contained in a single cabinet which is separated into four sections to ensure separation of protection signals.

The ESFAS is provided with two independent and separate relay cabinets which maintain separation between the two actuation trains.

7.1.2.3 Physical Identification of Safety-Related Equipment

Physical identification is provided to enable plant personnel to recognize that RPS and ESF system equipment are safety-related.

The PPS cabinet is identified by a nameplate. A color coding scheme is used for identification of physically separated channels within the cabinet and channel wiring. The channel identification plates on each section of the PPS cabinet, front and back, shall be color coded as follows:

Channel 1:	Red
Channel 2:	Green
Channel 3:	Yellow
Channel 4:	Blue

Wiring bringing signal inputs into the PPS cabinet is color coded as listed above. Intercabinet wiring ducts or conduits will also be color coded. Identification of cables is made at the terminal points.

All nonpanel mounted protective components are identified with a name tag which provides the channel number and the suffix 1, 2, 3 and 4 to specifically identify the protective channel with which the component is identified.

For additional information concerning physical identification of safety equipment, see Section 8.3.1.5.

7.1.2.4 Conformance to IEEE 317

Conformance to IEEE 317 is discussed in Sections 8.3.1.1.13 and 8.3.1.2.

7.1.2.5 Conformance to IEEE 323

All RPS and ESFAS equipment is qualified for use using the intent of IEEE 323-1971 as a guide. Descriptions of the seismic and environmental qualification of Class 1E equipment are provided in Sections 3.10 and 3.11.

7.1.2.6 Conformance to IEEE 336 (Regulatory Guide 1.30, Revision 0 August 1972)

Information is provided throughout this report concerning installation, inspection and testing of equipment.

IEEE 336-1971, "Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During the Construction of Nuclear Power Generating Stations," is discussed in Section 8.3.1.3.

7.1.2.7 Conformance to IEEE 338

The RPS and ESFAS are periodically tested, using criteria described in IEEE 338-1971, "Periodic Testing of Nuclear Power Generating Station Protection Systems," as a guide. The response time test (Section 4.1 of IEEE 338) is checked during preoperational testing and as required by the Technical Specifications.

7.1.2.8 Conformance to Regulatory Guide 1.22

The RPS and ESFAS can both be fully tested during reactor operation. Conformance of the RPS and the ESFAS to the recommendations contained in Regulatory Guide 1.22, "Periodic Testing of Protection System Actuator Functions," is discussed in Sections 7.2.1.1.9 and 7.3.1.1.9, respectively.

7.1.2.9 Conformance to Regulatory Guide 1.47

7.1.2.9.1 Reactor Protective System and Engineered Safety Features Actuation System

The RPS and the ESFAS as described in Section 7.1.1.1 conform to the requirements of Regulatory Guide 1.47, "Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems." This conformance is described below.

Bypasses can be classified into two groups: operating bypasses and trip channel bypasses.

Operating bypasses include the RPS/ESFAS pressurizer pressure bypass, the RPS/ESFAS high/low steam generator level bypass, the ESFAS RWT level bypass, the high log power bypass and the DNBR/LPD trip bypass. The trip channel bypasses are those bypasses used for maintenance and testing. The trip channel bypasses are also provided to remove a trip channel from service for an extended period without affecting plant safety or availability in the event of an equipment failure not readily repairable or accessible. Both types of bypasses have the following features:

A. All means of bypassing the PPS are expected to occur as frequently as once per year.

B. Bypass indicators are located adjacent to or near the initiating switch. In addition, contacts are provided from each bypass logic circuit to the plant annunciator system for audible alarm.

C. The bypass indicators are designed to meet safety system criteria such as: testability by varying input signals (using the PPS testing system) and observing the indicators and bistables; redundancy by supplying bypass and normal indicators in addition to plant annunciators; and channel separation by keeping the indicators within the channel boundaries.

D. Credible failures occurring within the plant annunciation system are isolated at the switch or relay contact level in order to prevent them from affecting a bypass. In addition, permissives must also be in effect before the bypass can occur. Credible failures occurring at the bypass indicators will only affect one channel due to separation of channels.

E. All bypass indicators and plant annunciators are capable of being tested during normal system operation.

F. A single failure within a bypass channel can cause one of the following erroneous bypass indications:

   1. Operating Bypasses

      Burned out bypass indicator lights. When the operator bypasses a channel, both normal and bypass indicators will be extinguished, but control room annunciators will function.

   2. Trip Channel Bypasses

      Shorted bypass indicator contact. This will indicate a bypass condition, but the bypass will not be in effect. The operator can initiate and remove the bypass. Plant annunciator will still function.

      Open circuit to bypass indicator or burned out indicator. The operator can still initiate and remove the bypass. It will be annunciated in the control room.

<u>Operating Bypasses</u>

The operating bypasses are used during routine startup and shutdown. These bypasses must be manually inserted. The RPS/ESFAS pressurizer pressure bypass and the RWT low level bypass utilize a permissive contact input generated by pressurizer pressure to insure the bypass is removed if plant conditions deviate from the point where the bypass is no longer safe. The RPS/ESFAS high/low steam generator level bypass utilizes a permissive contact input generated by RCS temperature to insure removal of the bypass prior to entering Mode 3. Once the bypasses are automatically removed, they will not be reinstated until the permissive conditions return and the bypass switch is returned to the bypass position. Indicator lamps are provided in the bypass circuit to monitor directly the application of the bypass. Indicator lamps are also provided to display the presence of the permissive signals. These indicator lamps are located on the PPS Remote operator's modules. Annunciation is provided on the main control boards if a bypass in any channel is instated.

Operating bypasses on the remote operator's modules include the RPS/ESFAS pressurizer pressure bypass, RPS/ESFAS high/low steam generator level bypass, ESFAS RWT level bypass, and the high logarithmic power bypass.

<u>Trip Channel Bypasses</u>

These bypasses are utilized to individually bypass channel trip inputs to the protection system logic for maintenance or testing. The trip channel bypasses are also provided to remove a trip channel from service for an extended period without affecting plant safety or availability in the event of an equipment failure not readily repairable or accessible. The trip logic is converted

from a 2-out-of-4 to a 2-out-of-3 logic for the parameters being bypassed. Only one channel for any one parameter may be bypassed at any one time. This is accomplished by electrically interlocking the manual bypass switches. These bypasses must be manually initiated and removed. Individual bypass indicator lights are provided locally at the PPS cabinet and at the remote operator's modules located in the control room. The wiring for these indicators is run within their respective channels so that faults in any one module will not affect the other channel bypass indication or bypass. A separate signal is provided to the plant annunciator when any trip channel bypass is present.

7.1.2.9.2 Auxiliary and Supporting Systems

In addition to the RPS and the ESFAS which conform to the requirements of Regulatory Guide 1.47, systems actuated or controlled by the protection system and auxiliary or supporting systems that must be operable to support the protection system have been designed to comply with Regulatory Guide 1.47, "Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems," as supplemented by the following statement:

Positions 2, 3(b) and 3(c) of Regulatory Guide 1.47 are supplemented as follows:

A. The design criteria for the indication system (Position 2) reflects the importance of both providing accurate information for the operator and reducing the possibility for the indicating equipment to adversely affect the monitored safety systems. In developing the design criteria, the following were considered:

1. The bypass indicators have been arranged to enable the operator to readily assess the operating status of each safety system and determine whether continued reactor operation is permissible.

2. When a protective function of a shared system can be bypassed, indication of that bypass condition should be provided in the control room of each affected unit. No shared systems have protective functions for Arkansas Nuclear One - Unit 2.

3. Means by which the operator can cancel erroneous bypass indications, if provided, should be justified by demonstrating that the postulated causes of erroneous indication cannot be eliminated by another practical design. No means have been provided by which the operator could cancel a bypass indication until the condition which initiated the bypass has been corrected.

4. The indication system has not been designed in conformance with criteria established for safety systems. Administrative procedures will not require immediate operator action based solely on the bypass indications.

5. The indication system has been designed and will be installed in a manner which precludes the possibility of adverse effects on the plant's safety systems. Failure or bypass of a protection function will not be a credible consequence of failure occurring in the indication equipment and the bypass indication will not reduce the required independence between redundant safety systems.

6. The indication system has the capability of assuring its operable status to the extent that the indicating and/or annunciating function can be verified. Administrative controls will be employed to ensure that the availability of the safety-related systems is not significantly degraded by the conduct of tests during plant operation.

Additional information on conformance to Regulatory Guide 1.47 is contained in Section 8.3.1.2.

7.1.2.10 Conformance to IEEE 379-1972

The instrumentation and processing electronics associated with the RPS and the ESFAS conform to the requirements of IEEE 379-1972, "IEEE Trial Use Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protective Systems." A discussion of the single failure criterion is provided in Sections 7.2.2.3.2 and 7.3.2.2.2.

7.1.2.11 Conformance to Regulatory Guide 1.62

Manual initiation of the RPS and ESFAS is in conformance with the requirements of Regulatory Guide 1.62, "Manual Initiation of Protective Actions." Manual initiation of the RPS is described in Sections 7.2.1.1.1.12 and 7.2.2.3.2. Manual initiation of the ESFAS is described in Section 7.3.2.2.2.

7.1.2.12 Conformance to Regulatory Position on the Application of the Single Failure Criterion to Manually Controlled Electrically Operated Valves

Fluid systems have been examined to identify all manually controlled electrically operated valves for which a single failure, including the failure of any active or passive electrical component, could result in a loss of system safety function. There are no such valves.

7.2 REACTOR PROTECTIVE SYSTEM (REACTOR TRIP SYSTEM)

7.2.1 DESCRIPTION

7.2.1.1 System Description

The Reactor Protective System (RPS) consists of sensors calculators, logic, switchgear and other equipment necessary to monitor selected Nuclear Steam Supply System (NSSS) conditions and to effect reliable and rapid reactor shutdown (reactor trip) if any one or a combination of the monitored conditions reach a limiting safety system setting. The system functions are to protect the core (fuel design limits) and Reactor Coolant System (RCS) pressure boundary for anticipated operational occurrences.

Four measurement channels, with electrical and physical separation, are provided for each parameter used in the generation of trip signals, with the exception of CEA positions. (See Sections 7.2.1.1.2.2 and 7.2.1.1.2.5) A 2-out-of-4 coincidence of like trip signals is required to generate a reactor trip signal.

These same features include the capability of the RPS to operate, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criteria. The only operating restriction while in this condition (effectively one-out-of-two logic) is that no provision is made to bypass another channel for periodic maintenance. The system logic must be restored to at least a two-out-of-three condition prior to removing another channel for maintenance.

A reactor trip signal serves to de-energize the Control Element Drive Mechanism (CEDM) coils, allowing the shutdown and regulating CEAs to drop into the core. Undervoltage relays in the Control Element Drive Mechanism Control System (CEDMCS) provide a simultaneous trip signal to the turbine and Feedwater Control System (FWCS). Since this trip is equipment protective only, it is not designed in accordance with criteria established for safety-related equipment.

A manual reactor trip is also provided.

Comparison of the trip setpoints and instrument ranges presented in Table 7.2-4 indicates that the RPS setpoints do not fall within the upper or lower 10 percent of the instrument range.

The Core Protection Calculator (CPC) System process inputs are monitored over their entire range of operation to compute the core DNBR and local power density. The acceptability of the CPC system input monitoring ranges is discussed in Section 7.2.1.1.2.5.

A discussion of the RPS seismic and environmental qualification is found in Sections 3.10.2 and 3.11.2, respectively.

A discussion of the RPS testability is found in Section 7.2.1.1.9.

7.2.1.1.1 Trips

7.2.1.1.1.1 High Linear Power Level

The high linear power level trip is provided to trip the reactor when indicated neutron flux power reaches a preset value. The flux signal used is the average of the three linear subchannel flux signals originating in the nuclear instrument safety channel. The allowable trip setpoint is shown in Table 7.2-4.

Pre-trip alarms are initiated below the trip value to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.2 High Logarithmic Power Level

The high logarithmic power level trip is provided to trip the reactor when indicated neutron flux power reaches a preset value. The flux signal used is the logarithmic power signal originating in each nuclear instrument safety channel. The allowable trip setpoint is shown in Table 7.2-4. The trip may be manually bypassed by the operator as shown in Table 7.2-1.

Pre-trip alarms are initiated below the trip value to provide audible and visual indication of approach to a trip condition. The trip bypass also bypasses the pre-trip alarms.

7.2.1.1.1.3 High Local Power Density

The high Local Power Density (LPD) trip is provided to trip the reactor when calculated core peak LPD reaches a preset value. The calculation of the peak LPD is performed by the CPCs, which compensate the calculated peak LPD to account for the thermal capacity of the fuel. A trip results if the compensated peak LPD reaches the preset value. The calculated trip assures a core peak LPD below the safety limit for peak fuel centerline temperature (°F). The allowable trip setpoint is given in Table 7.2-4. The effects of core burnup are considered in the determination of the LPD trip.

Pre-trip alarms are initiated below the trip value to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.4 Low DNBR

The low DNBR trip is provided to trip the reactor when the calculated Departure from Nucleate Boiling Ratio (DNBR) approaches the preset value. The calculation of DNBR is performed by the CPC based on core average power, reactor coolant pressure, reactor inlet temperature, reactor coolant flow, and the core power distribution. The calculated trip setpoint includes allowances for sensor and processing time delays and inaccuracies. These allowances ensure that a trip is generated within the CPC before the minimum DNBR is exceeded in the limiting coolant channel in the core during an anticipated operational occurrence.

Pre-trip alarms are initiated above the trip value to provide audible and visual indication of approach to a trip condition. The trip setpoint is listed in Table 7.2-4.

7.2.1.1.1.5 High Pressurizer Pressure

The high pressurizer pressure trip is provided to trip the reactor when measured pressurizer pressure reaches a preset value. The allowable trip setpoint is shown in Table 7.2-4.

Pre-trip alarms are initiated below the trip setpoint to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.6 Low Pressurizer Pressure

The low pressurizer pressure trip is provided to trip the reactor when the measured pressurizer pressure falls to a preset value. The allowable trip setpoint is shown in Table 7.2-4 for normal operation. At pressures within 200 psia above the trip setpoint, this trip setpoint can be manually decreased to 200 psia below the existing pressurizer pressure, to a minimum value of

100 psia. This ensures the capability of a trip when required during plant cooldown. The trip setpoint can be manually bypassed as shown in Table 7.2-1. The bypass is automatically removed as pressure is increased above a fixed value and the low pressure setpoint automatically increases, maintaining the fixed increment between the plant pressure and the setpoint. These values are shown in Table 7.2-4.

Pre-trip alarms are initiated above the trip setpoint.

7.2.1.1.1.7 Low Steam Generator Water Level

The low steam generator water level trip is provided to trip the reactor when measured steam generator water level falls to a preset value. Separate trips are provided from each steam generator. The allowable trip setpoint is shown in Table 7.2-4.

To assure that the accuracy of the level instrumentation is sufficient to initiate a timely trip during a steam generator blowdown such as during a steam or feedwater line break, an investigation was made of the effect on level sensing accuracy from rapid depressurization of the secondary side of the steam generator and the possible subsequent flashing of water in the reference leg of the level instrumentation.

Two cases were considered, the first being a change in secondary pressure representative of the range evaluated for the main steam line break accident from full power pressure to the low pressure trip. The second case involves a change in secondary pressure from an assumed zero power pressure to the same trip pressure. These represent the maximum change in pressure which could occur prior to another trip being generated, i.e. low pressure.

The level reference legs are connected to the steam generator via a small diameter pipe and a condensation pot. The pipe, the condensation pot and the level reference legs are un-insulated to enhance heat transfer to the surrounding environment. The initial temperature profile in the reference leg was conservatively calculated assuming that all of the liquid in the condensation pot and the liquid at the top of the level reference leg were at the saturation temperature for the initial steam generator pressure.

Additional assumptions in calculation of the temperature profile were that the containment atmosphere surrounding the reference leg is at 120 °F and that heat transfer to atmosphere was by natural convection with a conservatively low film heat transfer coefficient. With these assumptions temperature profiles were calculated for the full load and no load cases, respectively.

The effects of varying fluid pressure and flashing of the reference leg to steam have been considered. The effects of flashing in the reference leg were negligible. Ambient temperature effects on the reference leg were considered in the development of setpoints.

The trip setpoint can be manually bypassed as shown in Table 7.2-1. The bypass is automatically removed as reactor coolant temperature rises above a fixed value.

Pre-trip alarms are initiated above the trip setpoint.

7.2.1.1.1.8 Low Steam Generator Pressure

The low steam generator pressure trip is provided to trip the reactor when the measured steam generator pressure falls to a preset value. Separate trips are provided from each steam generator. The allowable trip setpoint during normal operation is shown in Table 7.2-4. At steam generator pressures within 200 psi above this setpoint, the operator has the ability of

manually decreasing the setpoint to 200 psia below the existing system pressure to permit plant cooldown. During any plant operations which cause an increase in steam generator pressure, the setpoint is automatically increased to 200 psia below steam generator pressure, until the setpoint reaches the normal operating setting.

Pre-trip alarms are initiated to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.9 High Containment Pressure

The high containment pressure trip is provided to trip the reactor when measured containment pressure reaches a preset value below the allowable limit shown in Table 7.2-4.

Pre-trip alarms are initiated to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.10 Loss of Load

The loss of load trip has been deleted from the RPS design.

7.2.1.1.1.11 High Steam Generator Level

A high steam generator water level trip is provided to trip the reactor when measured steam generator water level rises to a high preset value. Separate trips are provided from each steam generator. The design criterion for this trip is that a reactor trip will be initiated upon reaching the high water level trip setpoint to ensure that excessive moisture carryover will not occur. The high steam generator level allowable trip setpoint is shown in Table 7.2-4. The trip is an equipment protective trip only and is not required for plant safety.

Since credit is not taken for equipment protective trips in the safety analysis of the plant, they do not fall within the scope of IEEE 279-1971. However, in order to preserve uniformity of function and design, the high steam generator level trip function meets the design bases listed in Section 7.2.1.2. The high steam generator level trip is incorporated in the same manner as any other trip function, i.e., four separated, redundant, testable channels, and meets all the requirements of IEEE 279-1971.

The trip setpoint can be manually bypassed as shown in Table 7.2-1. The bypass is automatically removed as reactor coolant temperature rises above a fixed value.

Pre-trip alarms are initiated to provide audible and visual indication of approach to a trip condition.

7.2.1.1.1.12 Manual Trip

A manual reactor trip is provided to permit the operator to trip the reactor. Actuation of two adjacent pushbutton switches in the control room will cause interruption of the AC power to the CEDM power supplies. Two sets of trip pushbuttons are provided. These switches actuate the required sets of trip circuit breakers which directly interrupt power to the CEDMs. The pairs of switches AD and BC are located in the main control room on different panels. Actuation of either pair will effect a full reactor trip at the system level. This RPS manual trip initiation feature is in complete conformance with Regulatory Guide 1.62, "Manual Initiation of Protective Actions."

7.2.1.1.2 Initiation Circuits

7.2.1.1.2.1 Process Measurements

Various pressures, levels and temperatures associated with the NSSS and the containment building are continuously monitored to provide signals to the RPS trip bistables. All protective parameters are measured with four independent and isolated process instrument channels.

A typical protective channel, as shown in Figure 7.2-1, consists of a sensor and transmitter, instrument power supply and current loop resistors, indicating meter and/or recorder, and trip bistable/calculator inputs.

The piping, wiring, and components of each channel are physically and electrically separated from that of other like protective channels to provide independence. The output of each transmitter is typically an ungrounded current loop which has a live zero. The nuclear instruments provide a pulsed and current signal. The RCP speed sensors provide a pulsed signal. Signal isolation is provided for computer inputs and control board indicators. Each channel is powered from a separate vital bus.

7.2.1.1.2.2 Control Element Assembly Position Measurements

The position of each CEA is an input to the RPS. These positions are measured by means of two reed switch assemblies on each CEA.

Each reed switch assembly consists of a series of magnetically actuated reed switches spaced at intervals along the CEA housing and wired with precision resistors in a voltage divider network. A magnet attached to the CEA extension actuates the adjacent reed switches, causing voltages proportional to position to be transmitted for each assembly. The two reed switch assemblies and associated cables of each CEA are physically and electrically isolated from each other. Each reed switch position cable is enclosed in a flexible stainless steel sheath between the CEA and the connector bulkhead.

The position signals are used as inputs to the CPC system. (See Section 7.2.1.1.2.5 for further details.) Either set of reed switch assemblies on each CEA can be selected for monitoring in the control room through a selector switch.

The CEA position reed switch system is designed, manufactured, tested and installed to the identical design, quality assurance and testing criteria as the remainder of the signal generation and processing equipment for signals utilized by the RPS. The reliability of the CEA position signal is assured in two ways, by proper design and manufacture, as detailed above, and by proper utilization within the RPS.

Each CEA is instrumented by redundant CEA reed switch position transmitters.

The CEA Reed Switch Position Transmitter Assemblies (RSPTs) contain circuits which provide analog CEA position information to the CPCs and the CEA Calculators (CEACs) as described in Section 7.2.1.1.2.5. The RSPTs also contain three discrete CEA position switches which provide signals (contact closure) to the CEDMCS. The discrete CEA position switches provide information that the CEA has reached either its Upper Electrical Limit of Travel (UEL), its Lower Electrical Limit of Travel (LEL) or has tripped to its fully inserted rod bottom (DR) position. The UEL and LEL circuits provide signals to terminate CEA motion when these limits are reached.

Failure of these circuits to perform is not a safety-related concern since mechanical stops are provided. The rod bottom switch serves only to indicate that the CEA has reached its lower mechanical limit of travel and is fully inserted. None of these circuits are used to initiate a control action. Therefore, the independence criterion of Section 4.7.3 of IEEE 279 does not apply. The CEA position indication system is further described in Section 7.5.1.4.

The three discrete reed switch position signals are contained within the same RSPT housing as the analog CEA position signals but the circuits are physically separated with separate power supplies, reed switches and electrical wiring. Due to physical constraints in the reactor vessel head area, both the analog and digital signals are transmitted in separate conductors within the same cable assembly from the reactor vessel head to a point outside of containment. The discrete position information cable is then separated from the safety-related cable which goes to the CPCs. From this point to the CEDMCS the discrete position information cable is maintained separated from high voltage sources. The cables which provide the discrete position information signals originate from either Channel C or D. A total of 61 cables originate from Channel C. The remaining 20 cables originate from Channel D. (These two groups of cables are maintained separated and are routed in separate raceways. Power and control cables are excluded from these raceways.) The cabling then enters the CEDMCS in an area which is separated from the power section of the CEDMCS cabinet.

The method of cabling of the RSPTs is considered acceptable due to three major design provisions.

A. The CEDMCS is decoupled from the reed switch cabling by means of relay isolation of the limit contacts and physical separation of the power portion of the CEDMCS from the limit switch interface.

B. The interconnecting cabling is kept separated from power and control cables.

C. The CPC system data acquisition equipment is designed to reject noise that might be coupled into signal lines.

The capability of the CPCs to reject noise was verified by suitable testing in an Electro Magnetic Interference (EMI) environment.

One set of the redundant signals for all CEAs is monitored by one CEAC and the other set of CEAs by the redundant CEAC.

The CEAs are arranged into control groups that consist of sets of CEAs that are symmetric about the core center. These groups are required to move together and should always indicate the same CEA position.

Each CEAC monitors the position of all CEAs within each control group. Should a CEA deviate from the group position, the CEACs will monitor the event, sound an annunciator and transmit appropriate "penalty" factors to the CPCs. This assures correct operation of the RPS as any credible failure of a CEA reed switch assembly will result in an immediate operator alarm.

The CEACs display the position of each regulating and shutdown CEA to the operator in a bar chart format on the Channel B or Channel C CPC operators module.

The CPCs utilize selected CEA position reed switch signals as a measure of subgroup and group CEA position. The CPCs assess CEA deviation information from each CEA calculator to modify calculation results in an appropriate manner should a deviating CEA be indicated by either CEAC.

The detailed signal paths of CEA position intelligence within the RPS are shown in Figure 7.2-32. Figure 7.2-14 details the overall signal paths of all CEA position information. As shown in Figure 7.2-14, a separate CEA position system, which counts the CEA motion demand pulses for each CEA, is utilized for the plant computer functions, including the Core Operating Limit Supervisory System (COLSS) function.

The plant computer calculates CEA group average positions. Individual and group positions are available for display on the plant computer.

7.2.1.1.2.3 Ex-Core Neutron Flux Measurements

The ex-core nuclear instrumentation includes neutron detectors located around the reactor core and signal conditioning equipment located in the auxiliary building. Neutron flux is monitored from source levels through full power and signal outputs are provided for reactor protection and for information display. There are six channels of instrumentation: two are startup channels and four are safety channels. See Figure 7.2-2.

The four safety channels provide neutron flux information from startup neutron flux levels to 200 percent of rated power covering a single range of approximately 10^{-8} to 200 percent power (10 decades). Each safety channel consists of three fission chambers, a preamplifier and a signal conditioning drawer containing power supplies, a logarithmic amplifier (including combination counting and mean square variation techniques), linear amplifiers, test circuitry and a rate-of-change of power circuit. These channels feed the RPS and provide information for rate of change of power display, DNBR, local power density, and overpower protection.

The detector assembly provided for each safety channel consists of three identical fission chambers stacked vertically along the length of the reactor core. The use of multiple subchannel detectors in this arrangement permits the measurement of axial power shape during power operation.

The fission chambers are mounted in holder assemblies which in turn are located in four dry instrument wells (thimbles) in the reactor cavity near the biological shield. The wells are spaced around the reactor vessel to provide optimum neutron flux information.

The preamplifiers for the fission chambers of safety channels "A", “B”, "C", and "D" are mounted outside the Reactor Building in the Upper South (Rm 2137) Electrical Penetration Room, Upper North (Rm 2133) Electrical Penetration Room, Lower South (Rm 2111) Electrical Penetration Room, and Lower North (Rm 2112) Electrical Penetration Room, respectively. Physical and electrical separation of the preamplifiers and cabling between channels is provided.

7.2.1.1.2.4 Reactor Coolant Flow Measurements

A fuel design limit on DNBR is specified to protect the fuel cladding as discussed in Sections 4.4 and the Technical Specifications.

The PPS provides a trip on low DNBR, as discussed in Section 7.2.1.1.1.4, which ensures that this specified fuel design limit is not exceeded for anticipated operational occurrences. Since DNBR cannot be directly measured, it is calculated as a function of several physical parameters. One of these physical parameters is core coolant mass flow rate.

The mass flow rate is obtained in the RPS using the pump speed inputs from the four Reactor Coolant Pumps (RCPs), and the core inlet and outlet temperatures. The flow rate through each reactor coolant pump is dependent upon the rotational speed of the pump and the pump head. This relationship is typically shown in pump characteristic curves. Flow changes resulting from changes in the loop flow resistance occur slowly due to core crud buildup, increase in steam generator resistance, etc. Calibration of the pump speed signal, relating pump rotational speed to flow, will be performed periodically.

Flow reductions associated with pump speed reductions are more rapid than those produced from loop flow resistance changes. The pump rotational speed signal is converted to a pump flow using mathematical relationships based on pump characteristics and periodic loop flow calibrations.

For those flow transients discussed in Chapter 15, these mathematical relationships are shown to produce a conservative value of flow relative to the flow calculated with the pump transient.

The speed of each RCP motor is measured to provide a basis for calculation of reactor coolant flow through each pump. Two metal discs, each with 44 uniformly spaced holes about its periphery, are scanned by proximity devices. The metal discs are attached to the pump motor shaft, one to the lower portion. Each scanning device produces a voltage pulse signal, the frequency of which is proportional to pump speed. One revolution of the RCP shaft results in the production of 44 distinct pulses. The expected pulse amplitude is 10 volts. The pulse width is a function of the RCP speed. The expected pulse width at an operating speed of 891 rpm is 0.57 millisecond; the time between successive pulses will be 1.52 milliseconds.

These signals are transmitted to the CPCs which compute the flow rate. Adequate separation between probes is provided. The redundant RCP speed sensor circuits have been routed in conformance with Section 8.3.1.4.3. Each channel is powered from a separate vital AC bus. This assures the independence of the redundant speed signals and RPS channels.

The RCP speed measurements are calibrated based on the average time between every "Nth" pulse at a given value of pump speed, where N is adjustable. Since this time is a function of only the pump speed and the number of holes in the disc, recalibration of the pump speed signals will not be required. Periodic observations of the calculated pump speed signals will be performed to assure satisfactory operation of the electronics associated with the speed sensing system.

The loop flow rates (normalized to design flow rates) calculated for each pump are summed to give a normalized core mass flow rate. Further details are provided in Section 7.2.1.1.2.5.

A low DNBR trip, Variable Overpower Trip (VOPT), or RCP low speed trip will be initiated in the event of flow reduction transients caused by pump speed changes such as the 4-pump loss of coolant flow and the single RCP shaft seizure. (See Section 15.1.5) Anticipated flow reductions due to changes in the coolant loop resistance or pump wear occur more slowly and are small in magnitude. These reductions are monitored using instrumentation which is not part of the RCP speed sensing system.

This method for measurement of coolant mass flow rate satisfies Section 4.8 of IEEE 279-1971. It also satisfies the below listed design bases for the anticipated transients and postulated accidents considered in Chapter 15.

A. A reactor trip will be initiated to ensure the minimum hot channel DNBR will not decrease below the DNBR SAFDL for any anticipated operational occurrence (see Section 15.1.5).

B. The consequences of the postulated RCP shaft seizure will be no more adverse than the consequences reported in the safety analyses.

The RCP speed measurement system is designed, manufactured, tested and installed to the identical design, quality assurance and testing criteria as the remainder of the signal generation and processing equipment for signals utilized by the RPS.

7.2.1.1.2.5 Core Protection Calculators

General

Four independent CPCs are provided, one in each protection channel. Calculation of DNBR and local power density is performed in each CPC, utilizing the input signals described below. The DNBR and local power density so calculated are compared with trip setpoints for initiation of low DNBR trip (See Section 7.2.1.1.1.4) and a high local power density trip (See Section 7.2.1.1.1.3).

Two independent CEACs are provided as part of the CPC system to calculate individual CEA deviations from the position of the other CEAs in their subgroup.

As shown in Figure 7.2-26, each CPC receives the following inputs: core inlet and outlet temperatures, pressurizer pressure, RCP speed, ex-core nuclear instrumentation flux power (each subchannel from the safety channels), selected CEA position, and single CEA deviation penalty factors from the CEACs. Input signals are conditioned and processed. The following calculations are performed in the CPC and the CEACs:

A. CEA group and subgroup deviations, single CEA deviations;

B. Correction of ex-core flux power for shape annealing and CEA shadowing;

C. Reactor coolant flow rate - from RCP speed;

D. ΔT power - from reactor coolant temperature and flow information;

E. Calibrated ex-core flux power - corrected ex-core flux power signals are summed and further compensated to agree with the ΔT power. Although the absolute value of ex-core power level is calibrated to ΔT power, the inherent fast time response of the ex-core signals to power transients is in no way modified;

F. Axial power distribution - from the corrected ex-core flux power signals;

G. Fuel rod and coolant channel planar radial peaking factors - selection of predetermined coefficients based on CEA positions;

H. DNBR;

I. Comparison of DNBR with a fixed trip setpoint;

J. Local power density - setpoint value of core average power, which for existing power distribution, corresponds to the acceptable fuel design limit on kW/ft;

K. Comparison of local power density with a fixed trip setpoint;

L. CEA deviation alarm;

M. Variable overpower and comparison of variable overpower with a Variable Overpower Trip (VOPT) setpoint;

N. Reactor Coolant Pump (RCP) speed and comparison of RCP speed with a minimum RCP speed trip setpoint; and,

O. Compensated cold leg temperature difference and comparison of the compensated cold leg temperature difference to a cold leg temperature difference trip setpoint.

Outputs of each CPC are:

A. DNBR trip and pre-trip;

B. DNBR margin (to control board indication);

C. Local power density trip and pre-trip;

D. Local power density margin (to control board indication);

E. Calibrated neutron flux power (to control board indication);

F. CEA Withdrawal Prohibit (CWP);

G. Sensor failure; and,

H. Core coolant mass flow rate.

Each calculator is mounted in specially designed cabinets with an operator's display and control module located on the main control board. From the four modules an operator can monitor all calculators, including specific inputs or calculated functions.

The design description presented herein makes a specific use of ex-core detectors for monitoring the axial power distribution and does not provide a means of monitoring the azimuthal tilt magnitude. However, the CPCs and associated hardware are designed with the capability of using specified in-core detectors for both axial power distribution and azimuthal tilt monitoring.

CPC DESIGN QUALIFICATION PROCESS

The CPCs are designed to initiate a reactor trip to insure that the DNBR and local power density fuel design limits are not exceeded for the design basis events specified in Section 7.2.2.1. The safety analysis in Chapter 15 provides analyses of the design basis events which require a low DNBR or high local power density trip. The design qualification process consists of a series of design analyses and tests. A description of the design qualification process is contained in the remainder of this section.

Chapter 15 Analyses

The assumptions made concerning the CPC characteristics in the Chapter 15 accident analyses are imposed upon the CPC design as functional requirements. These requirements include the capability of the CPC 1) to monitor conditions characteristic of the events which require a CPC trip in the accident analyses; 2) to conservatively calculate the minimum DNBR and maximum local power density which will occur during the events; and, 3) to initiate a low DNBR or high local power density trip consistent with the time response requirements of these events.

Chapter 7 Design Requirements

In addition to the requirements imposed by the Chapter 15 accident analysis, the CPC system functional requirements include all the RPS design requirements listed in Section 7.1.2.

CPC Functional Description

The CPC functional requirements consist of the requirements imposed by the Chapter 15 analysis and the requirements imposed by the Chapter 7 design requirements. The CPC software description, the CPC timing requirements, and the CPC hardware specification are generated from these functional requirements.

Reload Data Block

The Reload Data Block consists of a separate group of cycle-dependent parameters, most operating condition-dependent parameters, and CEA related parameters. Reload Data Block constants and disks were added in accordance with CEN-330-P-A and CEN-323-P-A. As part of each fuel cycle's design process, values for the Reload Data Block constants are evaluated for applicability, consistent with the cycle design, performance, and safety analyses. Any necessary changes to the RDB constants will be installed in compliance with CEN-323-P-A.

CPC Software Description

The CPC software description contains an algebraic representation of the calculations to be performed to calculate the low DNBR and high local power density. The CPC software description defines the algorithms and the CPC executive system, and the system time response requirements. Detailed software description of the CPC/CEAC system is provided in CEN-305-P and CEN-304-P respectively.

Software Design Qualification Procedure

The software design qualification procedure includes the following modules:

A. CPC Software Description

B. CPC Software Flow Charts and Code

C. Phase I Software Module Testing

D. Phase II Design Qualification Testing

The objective of the software design qualification procedure is to demonstrate that the specified calculations have been correctly implemented in the hardware system. Details of this procedure are discussed in CEN-39(A)-P-A.

7.2.1.1.2.5.1 System Description

7.2.1.1.2.5.1.1 General

There is a separate and independent calculator for each protective channel which provides two trip functions, DNBR and local power density, to a RPS logic channel.

The function of the CPC system is to monitor pertinent reactor core conditions and to provide an accurate, highly reliable means of initiating a reactor trip whenever the minimum core DNBR approaches the design limit or peak LPD approaches the fuel design limit, during reactor operation.

The DNBR and the local power density trip functions are calculated from monitored parameters by four redundant digital calculators. The digital calculators provide channel trip outputs when either the calculated DNBR or local power density reaches its respective trip setpoint. The calculator channel trip outputs are utilized by the RPS logic in the same manner as the direct parameter trips from the bistable comparators.

The entire RPS, of which the CPC system is a part, adheres to all applicable IEEE protection system design criteria as detailed in the design bases of Section 7.2.1.1.2.5.1.2.

The CPC system is similar in function to previously licensed analog calculator systems. Increased accuracy of calculation is provided with this system through the direct rather than inferred measurement of CEA position, by monitoring CEA deviation with redundant CEA calculators, and by the ability of a digital calculator to utilize more sophisticated correlations of measured data.

The functional integrity of the system is assured through the redundancy of the design combined with a comprehensive program of on-line monitoring of system performance through displays, operator readouts, and automatic monitoring features; and, a periodic test program that both verifies the functional integrity of each calculator and verifies the integrity of the stored programs in the calculator and the calculator memory, producing a hard copy printout of test results for logging and future reference.

7.2.1.1.2.5.1.2 Design Bases

The CPC system is designed to calculate core parameters and to initiate trip signals, when necessary.

The CPC system conforms to the criteria and requirements set forth in the following documents:

A. 10CFR50, "Licensing of Production and Utilization Facilities," Appendix A, "General Design Criteria for Nuclear Power Plants."

B. IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations."

C. IEEE 323-1971, "General Guide for Qualifying Class I Electric Equipment for Nuclear Power Generating Stations."

D. IEEE 344-1971, "IEEE Guide for Seismic Qualifications of Class I Electric Equipment for Nuclear Power Generating Stations."

7.2.1.1.2.5.1.3 Hardware Design

System Configuration

The CPC system configuration is shown on Figure 7.2-27. There are five major functional groupings of the system equipment:

A. Signal Generation and Processing Equipment

The signal generation and processing equipment converts process parameters, such as pressure, into signals compatible with the calculator input subsystem. Each redundant channel of the system has separate, independent signal processing equipment.

B. CEA Calculators

A CEAC monitors the position of CEAs within each control group. There are two independent and redundant CEACs located in Protection Channels B and C, respectively. Each CEAC monitors one of the two redundant measurements of individual CEA position for each CEA. A penalty factor, derived from CEA deviation information, is an isolated output utilized as an input to each CPC. The CPC monitors both CEACs, utilizing the most conservative deviation information of both CEACs.

C. Core Protection Calculators

A CPC monitors process parameters from the signal generation and processing equipment, CEA deviation information from the CEAC, and CEA group position information from "target CEA" position transmitters. The CPC calculates a conservative measure of DNBR and local power density and provides a channel trip signal to the RPS should the respective trip limits be exceeded.

D. Calculator Operator's Module

An operator's module is provided for each protection channel at the main control board. The operator's module monitors the status and operation of a calculator in each channel. Display functions, annunciator lamps, operator communication interface, and administrative control functions are consolidated on this module.

E. Permanent Mass Storage Units

A permanent mass storage unit is provided in a portable test/maintenance cart. Testing of the calculator is accomplished quickly and accurately through the use of the permanent mass storage unit.

The relationship of the subsystems relative to the CEAC is shown in Figure 7.2-33. A similar structure exists for the CPCs.

The interconnection of CEACs and CPCs is shown in Figure 7.2-32. The outputs of the CEACs are isolated with fiber optic data links whose design precludes any electrical connection between the CEAC output and the CPC input.

The input CEA position signals to the CEAC from other channels are isolated with fiber optic isolators.

The isolation criteria for all forms of isolation are:

A. No single credible failure at the isolator output shall affect the isolator input signal; and,

B. No single credible failure at the isolator input shall be allowed to affect the functional integrity of the module connected to the isolator output. At most, a failure at the isolator input shall cause an erroneous signal at the isolator output.

Signal Generation and Process Equipment

Primary Pressure

There are four redundant pressurizer pressure instrument channels.

The piping, wiring and components of each channel are separated from that of the other channels to provide independence.

The output of the pressure transmitter is an ungrounded current loop which has a live zero.

The input signal to the CPC system is derived from a loop dropping resistor which provides a low impedance voltage signal source with a one to five volt range.

Signal isolation is provided for inputs to the plant computer and control board indicators.

Each channel is powered from a separate vital bus.

Hot Leg Temperature

Hot leg temperature is measured with a pair of precision RTD sensors. The output of the resistance to current converter (R/I) is an ungrounded current loop which has a live zero.

The input signal to the CPC system is derived from a pair of loop dropping resistors which provides a low impedance voltage signal source with a one to five volt range.

The wiring and mounting of components of each channel are separated from the other channels to provide independence.

Signal isolation is provided for inputs to the plant computer and control board indicators. Each channel is powered from a separate vital bus.

Cold Leg Temperature

The measurement of cold leg temperature is functionally identical to the measurement of hot leg temperature with the exception that two precision RTD sensors/channels and no averaging circuitry is used. A single dropping resistor is used in lieu of the pair used in the hot legs.

Ex-Core Neutron Flux Power

A block diagram of the ex-core neutron flux power measurement system is shown on Figure 7.2-2.

The four safety channels provide signals to each of the four channels of the CPC system.

Each safety channel consists of three fission chambers located axially along the core.

The output of each fission chamber is processed by a signal conditioning unit that provides a linear power signal of 0 to 10 volts corresponding to 0 to 200 percent power.

Reactor Coolant Flow

There are four redundant channels of reactor coolant flow measurement.

Reactor coolant flow is determined from the measurement of the speed of the RCPs.

Each RCP has four independent, separate proximity sensors mounted in the RCP motor housing.

The rotational speed of the RCP is measured by locating the proximity sensor near a disc that is attached to the shaft of the RCP motor. The disc has holes drilled at equidistant locations about its circumference. As the disc rotates, the proximity pickup senses the absence of metal at the location of each hole.

The signal processing equipment associated with the proximity sensor channel converts the signals from the sensor to voltage levels that correspond to the presence and absence of metal.

Each voltage pulse that corresponds to a disc hole passing the probe is then conditioned to a standard pulse of fixed duration and voltage magnitude by the pulse shaping unit. The pulse output of the pulse shaping unit is conditioned by a "divide by N" circuit and is then utilized as an input to the CPC.

CEA Position

The CEAs in the reactor core are arranged such that there are 20 sets of four symmetrically located CEAs. These symmetrical sets of four CEAs are designated as subgroups and are controlled by the CEDMCS. The center CEA is allocated to one of the 20 symmetrical subgroups for control purposes.

Each CEA has two Reed Switch Position Transmitters (RSPTs) assigned to provide information on the position of the CEA in the core. CEA position information is provided directly to the core protection calculators for one CEA in each four CEA subgroup. One CEA RSPT in each subgroup sends CEA position information to the CPC with a corresponding channel assignment. This CEA subgroup position information is used to calculate planar radial peaking factors. CEA deviation information is obtained in Channel B by isolating the Channel A signals and then routing them to Channel B for comparison. A second (redundant) measure of CEA deviation is obtained in Channel C by a similar allocation and buffering process for the redundant CEA RSPTs in Channels C and D. A functional diagram of the CEAC interface with the CPC system is presented as Figure 7.2-32.

Core Protection Calculator

Each CPC is a 32-bit mini-computer which is comprised of the following major components:

A. Central Processing Unit (CPU)

The CPU controls programmed sequence and performs arithmetic functions.

B. Memory

The memory stores programmed sequence and calculation results.

C. Data Input/Output Subsystem

The data input/output subsystem directs information into and out of the calculator.

Central Processing Unit

The CPU manages the resources provided by the data input/output subsystem and memory. The programmed sequences are stored in memory. The logical flow of the sequences is directed by the CPU. Periodic sequences are requested by the scheduler, which is activated by a real time clock. The CPU is equipped to cope with malfunctions within itself, its memory, and its source of power.

The CPU performs control, arithmetic, and logical functions. The CPU accesses instructions from protected memory, decodes the instruction, and executes the required operation. In addition to the control section, the CPU contains working registers and hardware for both fixed point and floating point arithmetic operations. The CPU also controls data transfers to and from the data input/output subsystem.

Power loss is detected in a manner which insures sufficient time to execute an orderly shutdown.

Upon loss of power, the power fail detection circuitry causes the CPU to set the system outputs in a fail-safe condition. The CPU then initiates an orderly shutdown.

The CPC meets General Design Criterion 23 by tripping a channel on loss of power or disconnection of the system.

The CEAC meets General Design Criterion 23 by setting the output in a fail condition on loss of power. The fail condition corresponds to the signal that would occur on a complete loss of power to the CEAC. Each CPC will detect the failed CEAC output and initiate an annunciator.

Any single random failure is acceptable as long as the failure is detectable during test and the interval between tests is chosen on the basis of failure rate to give acceptable overall system reliability.

The actions, which occur upon loss and restoration of power, are similar to an analog signal, e.g. steam generator level, which is connected to a bistable relay card (one per channel) in the Plant Protection System (PPS). The CPC provides a contact opening for each trip function, i.e. low DNBR and high local power density to a bistable relay card in the PPS. Should the analog signal representing steam generator water level exceed a preset limit, the bistable relay card initiates a channel trip by de-energizing three trip relays. Likewise, the corresponding bistable relay cards for low DNBR and high local power density act in the same manner when the CPCs provide an open trip contact.

Within the PPS the contacts of the three trip relays on each bistable relay card form the 2/4 logic matrices. Four trip paths, which actuate the reactor trip switchgear, are constructed from the contacts of the matrix relays. The "lockout relay" which assures that a reactor trip goes to completion is placed in the final four trip paths of the RPS. The "lockout relay" must be manually energized to reset the reactor trip switchgear and allow the withdrawal of CEAs.

As a result, each analog process input or contact from the CPCs may return to its normal value or state when the corresponding normal conditions exist.

Memory

The calculator memory utilizes metallic oxide semiconductor (MOS) technology. The memory word length is 32 bits with an additional 5 bits utilized for error correction and detection. The memory is provided with battery backup and with a reload capability from Programmable Read Only Memory (PROM) for recovery from power interruptions. Memory integrity is monitored with hardware that monitors each memory read or write to allow detection and correction of single bit errors, detection of all double bit and some multiple bit errors. Memory protection is provided under the control of the software executive program. The memory protection hardware allows the establishment of predefined memory segments with predefined read, write or execute privileges by the various programs executing under the executive control. Violation of the established privileges will be detected and annunciated by the executive program.

Data Input/Output Subsystem

The data input/output subsystem controls the conversion and routing of data into and out of the CPU. The operation of the data input/output subsystem is controlled by the CPU and the executive program in protected memory.

Inputs

The input functions controlled by the data input/output subsystem controller are analog input conversion, digital input conversion, digital data link service, and pulse input conversion.

A. Analog Inputs

Analog inputs are converted to digital values by the analog input module. The analog input module utilizes electronic switches to select the appropriate signal for conversion and then utilizes an analog to digital converter to obtain conversion. The analog input module is designed to operate at a speed, accuracy and noise immunity that will meet the overall system response time and accuracy requirements. Reference voltage sources are provided for on-line calibration and diagnosis.

B. Digital Inputs

Digital inputs are handled as an input scan function by the data input/output subsystem. The contact inputs from the operator's modules, the CPU keyswitch, and the test switch input from the test panel are also periodically commanded to be read by the executive software. Contact input signals are converted to a logic level by an internal power supply and a contact bounce suppression circuit.

A detailed description of this function is provided in CEN-69(A)-P.

C. Pulse Inputs

The input signal from a reactor pump sensor is a voltage pulse whose frequency is proportional to the rotational speed of the RCP.

A pulse input module of the data input/output subsystem converts the frequency signal to a digital value by determining the time period that elapses between successive pulses.

D. CEA Calculator Data Links

The data links are isolated with fiber optic cable to assure that failures will not propagate in either direction across the data link.

The data link transfer is designed to allow functional independence of the CPC from the CEAC.

Outputs

A. Analog Outputs

Each redundant channel of the CPC system provides three continuous displays of calculated system outputs. The displays are DNBR margin, local power density margin, and calibrated neutron flux power.

B. Digital Outputs

Contact outputs are utilized for pretrip, trip and CWP, and annunciation and status indications.

C. Plant Computer Data Links

The data links are isolated with fiber optic cable to assure that no failures at the plant computer will affect the CPCs or the CEACs.

Both CEACs and CPCs respond in a similar manner during service of the plant computer data link, so that the CPC description is typical for a CEAC. However, each link is electrically isolated from the others and functions independently of the others.

Test/Maintenance Cart

A test/maintenance cart is utilized for off-line periodic testing. The test cart is not a portion of the on-line system and may be utilized for periodic testing or program loading only when the channel is bypassed. In the new system, the maintenance cart is not required for execution of the test programs, except memory verification.

In channels that have both a CEAC and a CPC, the calculator select switch on the PPS test panel enables the selected calculator, permitting only one calculator in a channel to have access to the test cart at one time.

A test maintenance cart is provided to facilitate software loading and testing. The test cart contains a disk on which is stored:

1. test data for the Maintenance Cart ‘Periodic Test’ Program execution;

2. expected results for the Maintenance Cart ‘Periodic Test’ cases;

3. a memory image for comparison to the on-line memory;

4. a memory file for reload of the calculator software;

5. off-line diagnostic programs.

The test cart also contains a terminal device for hard copy printout and keyboard interaction during testing.

Only one calculator may be tested at a time.

An interlock, with the channel bypass switch at the RPS logic, prevents initiation of a test unless the channel is bypassed.

CEA Calculator

There are two redundant CEACs that provide penalty factor information to each of the four CPCs.

The CEACs are separated and independent of each other and each receives CEA position information that is derived from separate position transmitters.

The CEACs interconnection is shown in Figure 7.2-32. The outputs of the CEACs are isolated with fiber optic cable whose design is such that there is no electrical connection between the CEAC output and the CPC input.

The input CEA position signals to the CEAC from other channels are isolated with fiber optic isolators.

The isolation criteria for all forms of isolation are:

A. No single credible failure at the isolator output shall affect the isolator input signal; and,

B. No single credible failure at the isolator input shall be allowed to affect the functional integrity of the system connected to the isolator output. At most, a failure at the isolator input shall cause an erroneous signal at the isolator output.

The hardware structure of the CEACs is similar to the structure of the CPCs.

Each CEAC is composed of the following subsystems: CPU, memory, and data input/output subsystem. The CEACs are 32-bit mini-computers.

Central Processing Unit

The CPU of the CEAC is identical to the CPU of the CPCs described in an earlier section also entitled, "Central Processing Unit," and supports all of the same features.

Memory

The memory system of the CEACs is identical to the memory of the CPCs, including protected memory for the application program.

Data Input/Output Subsystem

The data input/output subsystem controls the conversion and routing of input data to the CPU and the conversion and routing of output data from the CPU. The operation of the data input/output subsystem is under control of the CPU and the resident programs in memory.

Inputs

A. Analog

The analog input function of the CEAC is identical to that of the CPC.

B. Contacts

Contact input signals are converted to a logic level by an internal power supply and a contact bounce suppression circuit.

Outputs

A. Contact

Contact outputs are provided to the annunciators.

B. Data Link

A separate fiber optic isolated data-link is provided for each CPC and CEAC to the plant computer.

Operator's Module

An operator's module is provided for each protection channel. This module is mounted at the main control board.

The operator's module is designed to facilitate the monitoring of system status, the monitoring of all analog and digital plant signal values and key calculated variables, trip and pre-trip setpoints and the calibration of the system through the use of addressable constants.

The operator's module contains a Display Unit which has the capability of displaying alpha numeric data and character graphical data. The Display Unit is equipped with a touch sensitive screen which allows the operator to interact with the system for selection of displayed values, sets of values or graphs and for selection of data to be input for addressable constant changes.

Switches are mounted on the operator's module for the following functions:

1. enable data entry (keylock switch);

2. operating bypass of keylock switch less than the Log Power Bistable reset point;

3. selection of a CPC or CEAC for display or interaction (functions only in Channels B and C).

Specific operator's module displays are:

A. Menu

   A master menu display screen is provided to assist the operator in choosing the appropriate display.

B. Technical Specification Channel Check

   A display of six (6) point ID values to facilitate the operator's cross channel checking function is provided.

C. Point ID Display

   A display of the current values of selected Point IDs is provided.

D. CEA Position Display (CEAC Only)

   A series of character graphical displays of CEA position for all CEAs and CEA groups is provided.

E. Alarm/Status

   A display is provided of detected CPC/CEAC problems to assist in diagnosis and repair.

F. Addressable Constant Check

   A display of the addressable constant values to assist in verification of these values.

G. Interactive Displays

   1. A display is provided to support the modification of addressable constants.

   2. A display is provided to select specific groups of Point IDs for display.

Status lamps are provided on the operator's module to indicate the following conditions:

<u>CPC Trouble</u>

An indicator is illuminated when a CPC sensor goes out of range, when a failure is detected by the on-line diagnostic programs, when the watchdog timer is not reset, or when the CPC is placed in the test mode.

<u>CEAC Trouble</u>

An indicator is illuminated when a CEAC sensor goes out of range, when a CEA deviation is detected, when a failure is detected by the on-line diagnostic programs, when the watchdog timer is not reset, or when the CEAC is placed in the test mode.

Trip Bypass

An indicator is illuminated when the CPC is placed in an operating bypass when reactor power is less than the Log Power Bistable reset point.

CPU Unlock

If the CPC/CEAC consolette keylock switch is removed from the lock position, the CPU Unlock indicator illuminates and system software halts execution.

Function Enable Active

An indicator is illuminated when the CPC/CEAC operator's module touch screen (inputs) is enabled via the Function Enable Keylock Switch.

CPC/CEAC Calculator Select

A pushbutton indicator is illuminated to indicate selection of either the CPC or CEAC for Operator's Module Interaction (Channel B or C only).

CEAC INOP

An indicator is illuminated when a CEAC is set to an inoperative status in the CPC channel.

7.2.1.1.2.5.1.4 Software Structure

A. Executive Program

The executive program provides task scheduling and priority maintenance, interrupt service, startup service and input/output service:

1. Interrupt Service

The interrupt service module services the real-time clock interrupts that are counted to determine when a program should be scheduled. The interrupt service module notifies the task scheduler module of the occurrence of a real-time clock interrupt.

The interrupt service module also detects on-line internal interrupts that result from diagnostic traps in the CPU. Diagnostic traps include:

- AC power failure and restoration
- Integer arithmetic faults
- Floating point arithmetic faults
- Memory access violations
- Invalid instructions
- Certain misuse of the Commercial Instruction Set (not used in CPC)
- Memory system uncorrectable faults
- Privileged instruction execution violations

2. System Startup

The system startup module restarts the real-time program activity following the detection of an internal interrupt or fault condition. Upon the completion of periodic testing the reload process enables the initialization program which will cause the calculator outputs to remain in the fail safe state until the initialization process is complete.

3. Task Scheduler

The task scheduler module initiates the scheduled execution of periodic programs in a predefined priority order. The real-time clock interrupt is utilized as the real-time standard.

4. Input/Output Service

The input/output services modules request data input from a selected device, transfer the data to the appropriate memory locations and perform on-line diagnostic monitoring and annunciation on the external devices. The input/output services module responds to requests from other programs.

B. Applications Programs

The applications programs run under the supervision of the executive program. The applications programs are selected to run at rates consistent with the dynamic response criteria of the function it supports. The executive monitors this execution rate and annunciates when a program does not meet its scheduled frequency.

The applications programs are:

1. Operator Module Monitor

The operator module monitor program consists of two modules. A service module responsible for monitoring the operator module switch status, and a function module that performs the current function requested of the operators module. The operator module monitor communicates with the operator module by means of digital input/output service from the execution program and by means of data link service from the data link service program.

2. Initialization

The initialization program monitors key variables in the protection program data base and maintains the system outputs in a predetermined state following system startup until time dependent transients due to start up die out.

3. System Monitor

The system monitor programs the interface with the off-line test devices of the test cart during testing.

4. Data Link Service

The data link service program provides an interface between the serial, byte oriented asynchronous data links servicing the operator's module, CEACs and plant computer and the data base for the appropriate programs.

5. Idle

   The idle program computes a checksum of protected memory and annunciates when the checksum does not compare to a predetermined value.

6. Protection Algorithm Programs

   There are four protection algorithm programs. These programs and their functions are:

   a) Flow Program

      The flow program calculates the reactor coolant mass flow rate, performs trip and pre-trip comparisons and logic and performs the direct RCP speed trip comparison and logic.

   b) Update Program

      DNBR and power density values are updated. Neutron flux power is determined and calibrated to thermal power. The larger power is used in the calculation of hot channel heat flux distribution. A trip may be initiated if conditions are outside the wide band operating space. Dynamic updates on static DNBR and quality margin are performed. LPD margin, power density margin, and calibrated neutron flux power are sent to analog meters. Variable overpower trip is determined.

   c) Power Distribution

      Percent CEA subgroup withdrawals are calculated. Several penalty factors are determined, as is the CEA withdrawal prohibit flag.

      Corrected excore neutron flux values are determined, including shadowing effects. A spline fit is used to determine core average axial power distribution, and pseudo hot pin power distribution is calculated.

   d) Static DNBR Program

      Hot pin flux distribution, hot pin ASI, and integrated one pin radial peak are calculated.

      Fluid properties that are pressure dependent are calculated, and region dependent flow split and power corrections are determined.

      Linear heat and hot channel flux distributions are calculated. DNBR distribution is determined, and then minimum static DNBR is calculated.

<u>Plant Computer Data Link Task</u>

The plant computer data link task is executed at a low priority. When executed, this task checks the plant computer status to determine if the plant computer is ready to receive data. If the plant computer is ready, a pre-determined set of data is transferred across the data links. Otherwise the task completes immediately with no data transfer performed.

Input Data

During on-line performance of the calculations, the calculators will derive their input data from the channel input sensors through the data input/output subsystem.

Each process input shall be sampled at a rate consistent with the dynamic response of the sensor and the rate of response requirements of each parameter for each anticipated operational occurrence. The maximum input sampling rate capability of the system is greater than that needed to support the time response requirement of the protective functions. This sampling rate includes the analog to digital conversion time with the multiplexer operating in a random address mode.

The input sensors and signal processing equipment will be calibrated after installation based upon vendor calibration data and functional testing.

Input Data Processing

The input sensor signals to the CPC and CEAC are read, converted to a digital format, and limit checked. When sensor limits are detected as being exceeded, this condition is indicated on the Operator's Module.

The CPC also monitors the CEAC input data, comparing the two redundant channels and monitoring the operability of the data link. When a CPC detects that a CEAC data link is inoperable, it indicates and annunciates this condition. When the CPC detects a significant discrepancy between the information provided by the two data links it also indicates and annunciates this condition.

The operator's module provides the capability to read all input parameters for a calculator so that the operator can compare their values between channels.

Digital Conversion and Accuracy

The output of the signal processing equipment is connected to a multiplexer and analog to digital converter for analog signals. Each protective channel has a separate multiplexer and analog to digital converter.

The accuracy of the signal conversion and program data manipulation will be accommodated by combining all measurement errors, calculational uncertainties, and operating allowances in the algorithms.

The measurement errors applicable to the subject trips' design are the uncertainties in the monitored NSSS variables resulting from sensor location, calibration and dynamic characteristic.

The calculational uncertainties considered can be categorized as follows:

A. The uncertainties associated with the computational methods used to correlate monitored NSSS variables to NSSS parameters and to calculate trip parameters;

B. The accuracy associated with the manipulation of numerical values within the CPC.

The operating allowances considered include the following:

A. Allowances for maximum variation of unmonitored parameters that affect the margin to the fuel design limits;

B. Allowances for deadbands on monitored variables. These deadbands can be considered as threshold magnitudes on certain variables within which a variation is allowed without affecting the margin to the fuel design limits;

C. Allowances for the total trip response time associated with initiating a low DNBR and/or high LPD trip signal. The trip response time is the time from having a monitored variable change at the input side of a CPC to the time a trip signal is initiated;

D. Allowances for the RPS logic time delay. This delay encompasses the time from when the trip units receive a trip signal to the time the trip circuit breakers open;

E. Allowances for the time required to initiate CEA insertion;

F. Allowances for the time required to effectively terminate the transient resulting from an anticipated operational occurrence.

Measurement error corrections are applied to the monitored variables in order to correctly accommodate the relationships among the NSSS variables that affect the fuel design limits. Calculation uncertainties are applied to the result of the individual algorithms. The algorithms employed are the result of extensive analysis employing the most recent design methods and the resulting correlations are chosen to be conservative with respect to the results obtained using the design methods. Application of calculational uncertainties in this manner also assures that the relationship among the NSSS parameters that affect the fuel design limits is accommodated in a conservative manner. Operating allowances for parameters not monitored by the CPCs are treated by simulating the unmonitored parameters as additional inputs which are always at their worst case operating limits. Deadband allowances on monitored variables are treated by assuming that the affected variables are at their worst case deadband limits.

Treating the above operating allowances in this manner again assures that the interrelationship of NSSS parameters on fuel design limits is conservatively predicted. Allowances for time delays associated with system operation are accommodated by using methods which project the monitored NSSS variables as function of time based on current and past values. This projection technique predicts the magnitudes of NSSS variables ahead in time by an amount equal to or greater than the total system delay time. The prediction methods are based on extensive analyses which account for total sensor, system and reactor dynamics during anticipated operational occurrences and are conservative with respect to the results of these analyses. Calculational uncertainties are applied to the implementation of these techniques in the manner described previously.

The following security measures assure that the algorithm coefficients and system constants entered into the computer memory have been correctly stored in the pre-assigned memory location.

A. The change capability is restricted by a key switch controlled enable of the change value function on the operator's module with appropriate administrative controls.

B. The operator's module software is designed such that data may be entered only into pre-selected memory locations.

C. Following entry of the data, the operator may request verification by selecting the identification number of the constant on the operator's module. The data contained within that location and the number of the location will then be displayed. The data displayed may then be crosschecked against the data that was to be entered.

D. The Maintenance Cart 'Periodic Test' program is structured to verify memory contents in two ways:

   1. Data values are entered and the computed results are checked against a pre-computed result stored in permanent mass storage.

   2. Each protected memory location is checked on a location by location basis against a pre-entered value in permanent mass storage.

   Any deviation in the test results described in "1" or "2" above, will result in the affected channels being removed from service.

<u>Input Data Checks</u>

CEA position data is checked for sensor failure by the CEACs. The normal range of input signal is from +5 to +10 volts. Since the position signal is derived from a zero to +15 volt power supply, the majority of CEA sensor failures will result in an input signal that falls outside the normal signal range. When the CEAC detects an out-of-range sensor input value, an annunciator is initiated.

Penalty factors for out-of-sequence conditions and CEA deviation or subgroup deviation are applied within the DNBR and LPD algorithms to account for increase radial peaking resulting from CEA position misalignments. Each CPC receives CEA deviation penalty factors from both CEACs via optically isolated data links. Thus, each CPC has two common sets of CEA deviation data derived from two independent and isolated calculator channels.

When a CEA Calculator is brought off-line either due to a failure detected by on-line tests or by technician actions performed to periodically test, troubleshoot, diagnose and repair a CEAC, the CPC will detect that a CEAC data link is out of service and will annunciate that condition. The CPC will then utilize data from the redundant CEA Calculator. The Technical Specifications restrict the time period that a CEAC can remain out of service.

If a CEAC should be taken out of service coincident with its redundant counterpart, this condition will be recognized and indicated by the CPCs. In this situation, the CPCs will use a predetermined penalty factor.

All sensor values are checked against predetermined limits when read into the protection algorithms. If a sensor value approaches the limit of its usable range, the calculator will initiate an annunciator.

<u>Timing</u>

The CPC is designed to accommodate its design basis events including the consideration of sensor response times, integral CPC calculational delays and downstream RPS actuation delays.

Each calculator monitors the execution frequency of its internal functions and annunciates if these frequencies are not maintained. In addition, a watchdog timer on each calculator monitors the periodic operation of each calculator and provides annunciation and a channel trip if it is not reset within a predetermined fixed time period.

The CPC system's response time is verified consistent with the requirements of the Technical Specifications.

Initialization

The initialization of a CPC involves assurance of the integrity of the programs and constants stored in memory, loading the initialization data from Programmable Read Only Memory (PROM) or disk drive, and assuring that the calculator output assumes a trip condition and remains tripped for a time period that will allow the time history dependent data values to achieve a current status.

Program Modification

If program modification is required for the CPC system, the entire source program will be modified, reassembled and documented at offsite facilities. Assembler listings and source and object code of the program will be maintained as program documentation. Following program assembly, the new program will be loaded into a prototype calculator that is functionally identical to the field calculator. Static and dynamic testing will be performed on the prototype as described in CEN-39-(A)-P. Program performance during the prototype tests will be recorded, documented, and checked to assure that program performance meets the design bases requirements of function accuracy and response time. When the new program has successfully completed the prototype performance tests, a new Maintenance Cart 'Periodic Test' program will be written, assembled and loaded into the permanent mass storage device of the prototype calculator. Operation of the Maintenance Cart 'Periodic Test' program will be verified on the prototype calculator. Documentation of the test program and data will be maintained in an identical manner to the protection algorithms. The strict administrative procedures and documentation required for program modification are discussed further in CEN-39-(A)-P.

At the field, the following procedure will be used to load a new software version into a calculator.

A. The channel to be modified must be bypassed at the RPS logic, converting the DNBR/LPD trip function to a 2-out-of-3 coincidence.

B. Access to the calculator must be obtained through the use of key switch control at the PPS test panel. Actuation of this key switch will result in annunciation and a channel trip for a CPC; or, annunciation of a CEAC fail condition for a CEAC.

C. The calculator must be taken off-line and enabled for program loading.

D. The Executable image of the system that has been preassembled and verified at the prototype, will be loaded from the permanent mass storage unit.

E. The Maintenance Cart 'Periodic Test' program will then be executed to verify program integrity.

F. Following verification of the memory contents, a maintenance program may be executed to copy the verified memory contents into the EPROM loader. The EPROM loader and memory contents are then verified.

G. Following successful completion of the Maintenance Cart 'Periodic Test', the calculator can then be brought on-line in.

Assurance that data have been correctly stored in the pre-assigned memory locations and that no other memory locations have been altered is obtained by utilizing testing functions and procedures following each data load and periodically throughout the life of the plant.

Testing assures that the stored programs and data are correct by:

A. Verification that measured input data are stored in the correct location by addressing the data value through the operator's module and cross-checking this value with the other channels.

   Hardcopy results of this step are produced by the personnel performing the test, in accordance with pre-established procedures. This printed verification of the input data is comparable to verification of the direct analog trip functions and previously licensed designs of analog calculated trip functions.

B. Verification of the addressable constants by calling up the addressable constant by means of the operator's module and verifying the displayed value against the required value.

   Hardcopy results of this step are produced by the personnel performing the test, in accordance with pre-established procedures. The results are comparable to hardcopy produced as a result of the testing of previously licensed analog calculator trip functions.

C. All other data values are stored in or derived from data stored in memory.

   Constant data stored in memory is automatically verified by:

   1. A checksum calculation on the program file as it is loaded into the calculator.

   2. Checksums calculated by the idle task on a continual basis.

D. As an independent check on the memory values, each protection algorithm is run in a periodic testing environment. This test re-verifies memory. Hardcopy results are produced for each test of each protection algorithm.

7.2.1.1.2.5.1.5 <u>System Security</u>

<u>Core Memory and Data Entry</u>

The calculator utilizes on-line diagnostics to verify memory integrity.

Memory accesses by the programs are monitored by a hardware memory address translator (MAT). Memory is segmented into various functional elements and the calculator programs are assigned restricted access to the memory. Access privileges include:

- Write - the ability of a program to enter data into a given segment of memory.
- read - the ability of a program to retrieve data from a given segment of memory.
- execute - the ability of a program to read an instruction from a memory segment and execute it.

Access privileges are defined during the software design consistent with each program's function: for example, a protection algorithm input data area would have access privileges of read but not write or execute for that program. A protection program instruction storage area would have read and execute privileges but not write privileges. A protection program output data area would have write but not read or execute privileges. Note that the same memory area may have different accesses allowed for different programs.

The executive program contains the access privileges for each program. When a program is scheduled for execution, its access privileges are defined to the MAT hardware by the executive. If the access privileges are violated by the program during execution, the executive will be notified of that condition. The executive will annunciate this occurrence and provide a channel trip for a CPC or will annunciate this occurrence and provide an out of service condition for a CEAC.

This method of access monitoring has the advantages of annunciation of access violation and the advantage of being able to detect a broader range of access violations when compared to a simple hardware write only memory protect scheme.

Data Input/Output Subsystem

The input data base derives its data from the data input/output subsystem during normal operation. Under control of the protection program, the central processing unit of the calculator will command the data input/output subsystem to convert a specific input parameter to a digital value and cause this value to be stored in a predetermined location in the input data base.

The memory access translator will prevent the CPU from altering the program instructions. This will assure that data values acquired from the data input/output subsystem are stored in the proper memory location.

Operator's Module

There are four operator's modules for the CPC system located on the PPS section of the main control board. There is one operator's module for each protection channel. The cabling and location of the modules adhere to four channel separation criteria. The CEACs are located in protection Channels B and C. The operator's module for Channels B and C have the capability of addressing either a CPC or a CEAC.

Data entry capability requires the enablement of this function with a key switch on the operator's module.

Regardless of the status of the operator's module, data cannot be entered into incorrect memory segments due to the operation of the memory access translator.

The operator communication software is designed such the data entry from the operator is restricted to the addressable constants. The software is designed such that it is impossible for the operator to alter any protected memory location or any non-protected memory location other than addressable constants. An operator request to alter any memory location other than an addressable constant is treated as an invalid request by the operator communications software. This design feature is independent and redundant to the memory access translator.

Physical Access

Physical access to the Core Protection Calculators and CEA Calculators shall be under key lock administrative control.

Program Integrity

Integrity of the system software is assured by a combination of administrative procedures and tests. These procedures and tests start at the earliest stages of the design process and extend throughout the life of the nuclear power plant.

Administrative control of the software generation process will begin at the start of design. A design specification will be prepared for each program or group of programs. The design specification will include a general description of each program module or subroutine, inputs and outputs, timing requirements and the detailed algorithms or steps required of the program. Each design specification will also include flow charts of sufficient detail to describe the logic of the programs.

The programmer will use the design specifications to generate the code for each program. The programmer will also generate a series of test cases for each program to verify the correctness of the binary object code produced. These test cases will exercise the program over the full range of inputs and through every branch in the program. Final verification that the programs meet their specifications will take place during the software commissioning phase of the design qualification test. The procedures and tests to be followed during software commissioning are described in CEN-39-(A)-P.

When the correctness of each program has been verified by thorough testing, the programmer will complete the documentation package by preparing a written description. The complete documentation package will then consist of the program description, flow charts, source-language listings and test cases. From this point on, the documentation package will be subject to an administrative procedure which must be followed for every change to the program. A program change is defined as any alternation, no matter how slight, of any portion of any program with the exception of changes to the addressable constants. The procedure will require the following actions to be performed in the sequence given:

A. Change description and flow charts

B. Change program listings and source programs

C. Assemble or compile source programs

D. Generate new test cases and test changed programs

E. Update data for the periodic test program

F. Generate new media of protection programs and periodic test programs with changes installed.

Program changes at the binary level will not be permitted.

Completed and tested programs will be loaded. When memory has been loaded, the access enable switch will be activated and the auto-restart routine will be started. The auto-restart routine will load addressable constants, address locations and initial data base values from protected memory into the unprotected (live) data area. When the system has been initialized, the periodic test program will be run.

Up-to-date copies of the documentation, i.e., descriptions, flow charts and listing, will be maintained at the plant site to assist in maintenance of the system. However, the only changes that will be performed onsite will be adjustments to "addressable" constant.

Testing of the programs is discussed in detail in CEN-39-(A)-P.

7.2.1.1.2.5.1.6 Bypasses

Operating Bypasses

The Low DNBR and High LPD trip computations are performed continuously regardless of whether or not the reactor is at power.

A provision exists for bypassing the trip output contacts when reactor power is less than the Log Power Bistable reset point.

This bypass is designed in accordance with IEEE 279-1971, Section 4.12 criteria. The design incorporates the following features:

A. The bypass requires a key switch enable for each channel at the CPC operator's module. The bypass is manually initiated under administrative control.

B. The bypass is automatically removed from each protection channel when the nuclear flux instrumentation for the channel indicates that reactor power is greater than the Log Power Bistable setpoint.

Indication of the bypass is designed in accordance with IEEE 279-1971, Section 4.13 criteria. The design incorporates the following indication design features:

A. Indication of the bypass is given for each channel by a lamp on the CPC operator's module.

B. Annunciation of the bypass is provided at the main control board.

Channel Bypasses

A provision exists for bypassing a single channel of the four protection channels for maintenance or test. The bypass is also provided to remove a trip channel from service for an extended period without affecting plant safety or availability in the event of an equipment failure not readily repairable or accessible. Following the bypass, the PPS logic will be in a 2-out-of-3 configuration for the bypassed trip parameters.

This bypass is implemented at the PPS and is designed to IEEE 279-1971 criteria. The design incorporates the following features as described in detail in Section 7.2.1.1.5:

A. A hardware interlock prevents the plant operator from bypassing more than one of the four channels of any type of trip at one time.

B. A key is required to gain access to the means for manually bypassing the protective channel.

C. Indication of bypass or removal of any channel from service is given by lights and annunciation at the main control board.

7.2.1.1.2.5.1.7 <u>Testing</u>

The purpose of both the automatic and periodic testing of the CPC system is to contribute to high system reliability by means of failure detection and to call attention to system performance that is not within prescribed limits. The automatic and periodic tests provide a means of checking, with a high degree of confidence, the operational availability of system input sensors and all devices used to derive the final system output signal. The system tests are summarized in Table 7.2-17.

In compliance with Section 4.4 of IEEE 279-1971, a qualification program has been implemented to verify that the CPC system equipment meets the performance requirements, established to achieve system requirements, within all environmental constraints.

In addition, factory tests, design and performance qualification tests are implemented to assure that the installed protection system, with precision and reliability, performs its intended function.

<u>Automatic On-Line Testing</u>

The automatic on-line testing consists of three separate checks: (1) internal self-checking of the input data, (2) internal self-checking of the calculator, and (3) an external watchdog timer that monitors the execution of the cyclic scheduling mechanism. Although failures in the on-line system are expected infrequently, the automatic on-line testing is provided to assure high continuous system reliability beyond that provided in typical analog calculated trips.

The protection algorithms check the reasonability of input sensor data against predetermined maximum and minimum values.

The internal self-checking of the calculator consists of monitoring the calculator AC power supply, monitoring internal machine faults, monitoring memory error correction and detection, monitoring the memory access translator hardware and providing a "check-sum" comparison of protected memory. When the calculator detects a significant drop in the AC power supply voltage, the calculator will set its outputs in the fail-safe condition and initiate an annunciator. The calculator will then cause an orderly shutdown of its functions, placing the machine in the "wait" state. Restoration of power will cause the calculator to initiate execution of the auto-restart program followed by the initialization task.

As each calculator cycles through its programs the integrity of the memory is monitored by the error correction and detection hardware and the memory access translator hardware. Additional error detection and memory verification is accomplished on a time available basis. The Idle Time Loop task creates a checksum of the contents of consecutive memory locations and

compares the checksum against a pre-programmed constant. Detection of an error will initiate a CPC or CEAC failure annunciation. The Idle Loop Task runs when no higher priority task is enabled. If a checksum error occurs, the calcualtor sets the outputs in the fail-safe state and enters a non-interruptable wait state until the malfunction is repaired.

The software monitors the following internal machine faults:

A. Fixed-point divide fault (division by zero or quotient overflow);

B. Floating-point arithmetic fault (exponent overflow or underflow, division by zero);

C. Memory parity error;

D. Illegal instruction (non-existent operation code);

E. Failure to meet the timing requirements of program timing and input sampling rates;

F. Memory access protection violation/memory address translator violation; and,

G. Instruction alignment faults.

If any of the above faults occurs, the software will attempt to recover by entering the auto-restart and initialization routines and will also generate an annunciator. While in the initialization routine, the outputs will remain in the fail-safe condition. If a successful recovery is made, the outputs will be reset, and calculations will continue. Error codes for the last three fault conditions will be stored and printed at the start of the periodic test. If recovery is not successful, the calculator will cycle through the initialization routing until the malfunction is repaired.

To provide a check on the system software and to detect time frame overruns for each software task routine, an external "watchdog timer" is installed as part of the data input/output subsystem. Thus, if the internal cyclic scheduling mechanism fails or if the calculator hangs in a non-interruptable state, the "watchdog timer" will time out and will light the CPC or CEAC failure light at the operator's module directly. The indication will latch until it is manually reset. Timeout of the watchdog timer will set the calculator outputs in the fail-safe condition.

Further on-line testing capability is provided by continuous status indication and information read out from each CPC. Continuous displays of the following information are provided to the operator:

A. DNBR margin;

B. Local power density margin; and,

C. Calibrated neutron flux power.

Cross checking of the four channel displays can be made to assure the integrity of the calculator. The majority of the calculator failures will result in anomalous indications from the failed channel that can be readily detected by the operator during cross checking.

In addition, each protection channel is equipped with an operator's module which provides another level of assurance of the functional integrity of the calculator channels.

Periodic Testing

IEEE 338-1971, "Trial Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection System," provides the guidance for development of procedures, equipment, and documentation of periodic testing. The basis for and the scope and means of periodic testing are described in this section.

The CPC system is periodically and routinely tested to verify its operability. A complete channel can be individually tested without initiating a reactor trip, and without violating the single failure criterion. The system can be checked from the sensor signal through the bistable contacts for low DNBR and high local power density in the PPS. Overlap in the checking and testing is provided to assure that the entire channel is functional.

The analyses and tests that are performed to demonstrate the reliability of the hardware and software design initially are addressed subsections which follow, "Environmental Qualification Testing," "Factory Testing" and "Design and Performance Qualification Testing." The minimum frequencies for checks, calibration, and testing of the CPC system have been included in the Technical Specifications.

Periodic testing of the CPC system is divided into two major categories: (1) on-line system tests, and (2) off-line performance/diagnostic tests. Off-line testing is further subdivided into two categories: performance testing and diagnostic testing. Performance testing is used to check the numerical accuracy of the calculations. Diagnostic testing is used as an aid to troubleshooting whenever the performance tests or the on-line tests (interchannel comparisons) indicate the presence of a failure.

On-Line System Test

The on-line portion of the periodic testing consists of comparisons of like parameters among the four protective channels. Comparisons are made using the digital displays on the operator's module and the analog meters on the control board. Comparisons of like analog and digital inputs give assurance that the analog and digital multiplexers and the A/D converters are functioning properly. These comparisons also give assurance that data are being properly entered into and retrieved from the data base. Comparison of intermediate and final calculated parameters verifies the performance of the protection algorithms and the analog display meters on the control board.

Off-Line Performance Test

Before off-line testing is initiated, the channel to be tested is bypassed at the PPS and the trip logic is changed to 2/3 for the DNBR and local power density trips. Interlocks are incorporated in the PPS to prevent bypassing more than one channel at a time. To initiate off-line testing, a key is required.

The performance test uses the calculator data base to verify numerical accuracy of the calculations. The data base, depicted in Figure 7.2-43, is divided into three areas, namely, raw input data, filtered input data and calculated values. The raw data area contains the last samples of raw analog and digital data. The filtered data area contains averaged input data, filtered input data, past samples of input data needed for dynamic compensation, and dynamically compensated data. The calculated values area contains intermediate and final calculated values and calibration constants which are updated periodically.

During performance testing, the test inputs are loaded directly into the data base. For each set of test inputs, the expected calculated results are also loaded and compared with the values calculated by the protection algorithms. If a test fails, the test program prints the expected results and the actual results on the hard copy device on the test cart (when restarted it proceeds to the next set of test data) and halts at that point unless restarted by the operator. Dynamic effects in the calculations are tested by loading the filtered data area of the data base with test values representing past values of time varying inputs.

From the standpoint of the calculator software structure, the performance tests are virtually identical to the on-line functions. Only two differences exist from the normal functions of the calculators. First, the calculator outputs are in a fail-safe condition for the duration of the tests, and second, the algorithms use predetermined data instead of the data input/output subsystem. The algorithms are executing in the test mode, however, and do not distinguish between the data sources.

Off-Line Diagnostic Tests

After a given failure is detected by a performance test, on-line test, or on-line diagnostic, hardware diagnostic programs are provided to aid in locating and correcting malfunctions.

Two types of hardware diagnostic programs are provided. The first set of diagnostic programs runs under the supervision of the system monitor task. These diagnostics, adapted to the specific hardware configuration, are activated by the system monitor. Each diagnostic program is executed within the framework of the system monitor. The first set of diagnostics provides a means of testing:

A. Data Input/Output Subsystem - gives the ability to read the analog input reference voltage;

B. Memory Protect - verifies the memory address translator's protect feature; and,

C. Operator's Module - generates a test sequence.

The second set of diagnostics consists of independent stand-alone programs which provide a means of detecting and locating errors in the following system components:

A. Central Processing Unit, Arithmetic Logic Unit, floating point instructions and Memory tests, exhaustively test CPU, logic, and arithmetic instructions, floating point instructions and tests memory for all known worst case data patterns and also insure that an instruction can be fetched from every location in memory;

B. Real Time Clock - tests the interrupt functions;

C. RS-232 ports - verifies input and output functions;

D. Disc (Permanent Mass Storage) - verifies disc functional capability, I/O commands, and bulk storage integrity;

E. Data Input/Output Subsystem - provides a means of testing I/O services and commands;

F. Memory Address Translator - verifies memory access monitoring hardware;

G. Loader Storage Unit - verifies reboot capability; and,

H. EPROM Loader.

All diagnostics will be supplied so that they may be loaded via the disc.

Plant Computer Monitoring

No credit is taken for the operation of the plant computer in determining the reliability of the CPCs or in determination of the required interval for periodic testing.

The plant computer provides a backup monitoring capability (in addition to the plant operating personnel) by providing periodic comparisons of sensor channel inputs and checking of calculated results of the CPCs.

Failure of the plant computer will in no way affect the operation of the CPCs due to the following design provisions:

A. The data links to the plant computer are isolated such that any credible failure at the plant computer will not affect the operation of the CPCs.

B. All data transfers are controlled by the CPCs and data links allow only one way data transfer from the CPCs to the plant computer.

C. The reliability of the CPC hardware and the periodic testing interval shall be specified such that loss of the plant computer will not adversely affect the overall reliability of the PPS.

Environmental Qualification Testing

The CPC system will be qualified for service in its expected environment by comprehensive testing. These qualification tests during design basis environmental conditions were performed on a type-test basis in accordance with the guidance set forth in IEEE 323-1971. The design basis environmental conditions include the following:

A. Temperature and humidity; and,

B. Seismic.

The test carts are excluded from the seismic testing. The annunciator lights on the operator's modules are not required to operate during a seismic disturbance.

In addition to the environmental and seismic testing, design qualification testing will be performed on a type test basis to demonstrate the adequacy of the CEA optical isolators*. These optical isolators must prevent any credible failure or event at the output wiring from propagating to, or degrading the input signals to the device. The devices must be qualified for the following conditions:

A. Short circuit of signal leads: to each other, individually to ground and both to ground;

B. Open circuit of signal leads; and,

C. Application of the maximum credible potential to the output signal leads.

For Arkansas Nuclear One - Unit 2, isolated signal leads are connected to cabinets or equipment where the maximum available voltage is 120 volts AC or 125 volts DC.

The fiber optic data links will be qualified by analysis.

*Note: The paragraph above is historical information. CEA isolation amplifiers were removed by a hardware upgrade during refueling outage 2R7 and replaced with fiber optic isolators. See License Am-101.

Factory Testing

In addition to the equipment testing done in compliance with quality assurance requirements, the following tests are performed.

A. System Integration Test

The CPC system equipment will be operated for a predetermined period at the plant site to verify their reliability prior to being placed into service.

B. System Configuration

The CPC system will be configured at the factory. Acceptance tests are conducted on the configured system before system shipment.

Design and Performance Qualification Testing

The DNBR/LPD calculator system performance will be verified in accordance with CEN-39-(A)-P. Following installation at the plant site, preoperational tests are run to verify the installed integrity of the system and the correctness of the interconnecting wiring.

7.2.1.1.2.5.1.8 Analysis

Failure Mode and Effects Analysis

Analog voltage or contact openings indicate the status of each trip parameter for each channel of four channels. Separation and isolation is incorporated to assure independence of all redundant equipment.

The status of each trip parameter is checked at the bistable level of the RPS. When a parameter reaches its respective trip value, the bistable logic generates contact opening signals to the logic matrices.

Each input channel provides a contact opening signal to three of the six logic matrices. When two bistable channels indicate a trip condition for the same protection parameter, the logic matrix that is monitoring those channels will cause the four logic matrix relays to drop out, opening their respective contact in each of the four trip paths.

The trip circuit breaker control relay for each trip path responds to the contact opening signal by providing a contact opening and a contact closure signal to two reactor trip circuit breaker control circuits.

The actuation of the logic matrix relays for any one of the six logic matrices will result in the trip of all eight reactor trip circuit breakers. Only four reactor trip circuit breaker trips are required to generate a full reactor trip. This logic is arranged such that the trip path actuation logic is a selective 2-out-of-4 coincidence.

The reactor trip circuit breakers are arranged such that they will latch in the tripped state until they are manually reset. This design feature assures that all valid trip initiations will cause the reactor trip to proceed to completion.

Each of the four redundant CPCs provides a contact opening to the RPS at the bistable level.

A. A failure of one of the CPCs in the tripped condition will cause the reactor trip logic to revert to a 1-out-of-3 coincidence. Three intact calculators remain to monitor the input parameters of which only one is required to operate to effect a reactor trip. If the failed channel is bypassed, then the reactor trip logic becomes 2-out-of-3. In this instance, the system can tolerate another single failure and still initiate a valid reactor trip.

   A single failure of the CPC that results in a failure to initiate a reactor trip will not cause loss of functional capability since only two of the three remaining channels are required to effect a reactor trip.

   Failures in the CPCs can be detected by one or more of the following methods.

   1. Interchannel comparison of the continuous displays of DNBR margin, local power density margin and calibrated nuclear flux power from each of the operable CPCs.

   2. Interchannel comparison of intermediate calculated results from each of the operable CPC operator's modules.

   3. Through annunciators and/or trip signals generated as a result of the self test features or watchdog timer timeout.

   4. Through the performance of periodic testing of each CPC.

B. A process sensor channel failure to a CPC may produce a channel trip if the failure is in the direction of the trip condition, or the failure may produce erroneous results in the output of a single calculator.

   In either case, three intact channels remain. Only two channels are required to initiate a valid reactor trip.

   Failures in the NSSS process sensor channels can be detected by one or more of the following methods.

   1. Spurious trip or pre-trip of a CPC channel or by annunciators generated by sensor limit checking done by the on-line diagnostics.

   2. Interchannel comparison of the continuous displays of DNBR margin, local power density margin and calibrated neutron flux power from each of the operable CPCs.

3. Interchannel comparison of the intermediate calculated results from each of the operable CPC operator's modules.

4. Interchannel comparison of the input sensor values from the operator's module and control board mounted displays.

5. Through the performance of periodic sensor tests and calibrations.

C. A failure in a CEA reed switch position input to the CPCs will result in conditions identical to the results delineated in "B," for the calculator which utilizes this signal as an input.

In addition, the CEA position signal will be utilized by one of two redundant CEACs. The CEACs will detect the sensor failure in range as a CEA deviation. This deviation will result in penalizing all four CPC calculations in the conservative direction such that trip setpoints will be approached. This deviation will also be annunciated by the affected CEAC. The CEAC sensor failure lights are activated on detection of excessive CEA motion. Rate limits are different for up and down travel.

The optical isolator* is designed such that all credible single failures of the reed switch sensor channel input (including an open circuit, short circuit, or application of the maximum credible voltage of 120 volts AC) will result in, at most, an erroneous signal being processed by the isolated CEAC and passed on as a penalty factor that will result in more conservative calculations within the CPC.

Also, the optical isolator* output will not affect the accuracy of the input signal.

If the CEA reed switch position sensor fails in such a manner that the sensor signal is outside of the normal sensor range, the CEAC will annunciate the CEA sensor failure and process the CEA sensor value as if it was at its extreme limit of the normal range.

The normal range of the CEA reed switch sensor is fully inserted to fully withdrawn, corresponding to a signal range of +5 to +10 volts.

Major sensor failures will cause the sensor signal to indicate one extreme of the power supply voltage that powers it--either zero volts or +15 volts. An out-of-range sensor signal is defined as a signal that is greater than +10 volts or less than +5 volts.

*Note: The CEA isolation amplifiers were removed by a hardware upgrade during refueling outage 2R7 and replaced with fiber optic isolators. See License Am-101.

CEA reed switch position sensor channel failures can be detected by one or more of the following methods.

1. Comparison of the redundant sensor values between the two CEACs at the CPC operator's module. Each CEA has two redundant CEA reed switch position sensor channels that detect its position. One sensor channel is utilized as an input to one CEAC and the redundant sensor is utilized by the redundant calculator.

2. Comparison of CEA positions within a group as displayed to the operator as inches withdrawn or on a bar chart format on the operator's module displays.

3. Deviation annunciator from the CEAC.

4. Sensor fail annunciator from the CPC or CEAC.

5. Periodic tests and calibrations of the sensor channel.

D. A failure of a CEAC may result in a spurious indication of a deviation or penalty factor.

This failure will result in causing the CPCs to assume a more conservative calculation of DNBR and local power density.

The redundant CEAC remains intact and its output is still read by the CPCs.

The CPC programs are designed to utilize the more conservative penalty factors of both CEACs. This feature assures that for any failure of a CEAC, the redundant calculator will still provide protection should a CEA-related incident occur that is more severe than the penalty factor and deviation that resulted from the failure.

CEAC failure can be detected by one or more of the following means:

1. Interchannel comparison of the sensor inputs and intermediate results between the two redundant CEACs.

2. Annunciators generated as a result of on-line diagnostic.

3. Annunciators generated by the CPCs which compare the CEAC outputs and annunciate any significant discrepancy.

4. Malfunction of the CEAC operator's module.

5. The performance of periodic testing of each CEAC.

E. The eight data links between the two CEACs and the four CPCs utilize fiber optic coupling to provide the required isolation between calculators.

Each data link is designed such that any credible single failure including short circuit, open circuit, or application of the maximum credible voltage of 120 volts AC cannot affect the operational integrity of the CEAC. This feature is inherent in the operation of the isolator.

The operational integrity of the CPCs will not be compromised since the CPC utilizes the most conservative data of the two valid penalty factors from the two CEACs.

IEEE Criteria Analysis

IEEE 279 Criteria

The LDNBR trip and the HLPD trip as implemented in the CPCs meet the design criteria of IEEE 279-1971, "Criteria for Protective Systems for Nuclear Power Generating Stations."

The manners in which the design requirements are met are delineated below by a statement of the criteria, followed by a description of the pertinent design feature that assures conformance with the criteria.

IEEE 279-1971, Section 4.0

"4.1 General Functional Requirements"

"The nuclear power generating station protection system shall, with precision and reliability automatically initiate appropriate protective action whenever a condition monitored by the system reaches a preset level. This requirement applies for the full range of conditions and performance enumerated in Section 3(7), 3(8), and 3(9)."

The LDNBR trip and the HLPD trip meet the design requirements of IEEE 279-1971, Section 4.1, by monitoring NSSS parameters that can affect core heat flux and power density, by calculating current and projected values of DNBR and LPD, and by initiating a reactor trip within a sufficient time interval such that the minimum core DNBR shall be no less than its required value and the peak local power density shall not initiate centerline fuel melting for any anticipated operational occurrence.

"4.2 Single Failure Criterion"

"Any single failure within the protection system shall not prevent proper protective action at the system level when required."

The low DNBR trip and the high local power density trip meet the design requirement of Section 4.2 by utilizing the principle of redundancy as follows:

A. Pertinent NSSS variables are monitored by redundant sensors and signal processors.

B. The DNBR and local power density calculations are performed in redundant calculators.

C. The signal to initiate a reactor trip is generated and transmitted to the RPS logic redundantly.

D. The independence of each redundant channel from sensor to signal processor to the CPC to the PPS logic is assured by physical separation or barriering, separate redundant power sources for each channel, and by isolation devices at the channel outputs that prevent the propagation of credible failures from external systems into the channel.

E. The integrity of each redundant channel is assured by a comprehensive testing program consisting of:

    1. Internal self testing features of the calculators that alarm fault conditions:

        a. watchdog timers;

        b. primary power failure detection and on-line diagnostics; and,

        c. sensor range checking;

2. Periodic comparison between redundant channels of:

    a. addressable contents for calculations;

    b. calculational results; and,

    c. input display meters;

3. Periodic testing of each trip channel to the criteria of IEEE 338-1971, "Trial Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection System":

    a. input simulation with recording of computed results and comparison of results against known performance criteria;

    b. verification of sensor integrity by interchannel comparison of similar parameters.

"4.3 Quality of Components and Modules"

"Components and modules shall be of a quality that is consistent with minimum maintenance requirements and low failure rates. Quality levels shall be achieved through the specification of requirements known to promote high quality, such as requirements for design, for the derating of components, for manufacturing, quality control, inspection, calibration and test."

The requirements of Section 4.3 are met by the LDNBR trip and the HLPD trip in the following ways:

A. The calculators utilize digital integrated circuits of proven reliability. Digital devices are less sensitive to time and temperature effects than analog devices.

B. The use of discrete components, such as capacitors and resistors, in the calculators is minimized, improving reliability and accuracy.

C. All modules implementing the low DNBR trip and high local power density trip will be qualified for its specific design basis event environment to the design guide requirements of IEEE 323-1971, "General Guide for Qualifying Class I Electric Equipment for Nuclear Power Generating Stations."

D. The manufacturing quality control and inspection is controlled in accordance with C-E requirements for Class 1E electrical equipment.

E. Integrated system testing at the factory and in the field.

"4.4 Equipment Qualifications"

"Type test data or reasonable engineering extrapolation based on test data shall be available to verify that the protection system equipment shall meet, on a continuing basis, the performance requirements determined to be necessary for achieving system requirements."

The LDNBR trip and HLPD trip will meet the requirements of Section 4.4 by performance of type testing and analysis to the criteria of IEEE 323-1971, "General Guide for Qualifying Class I Electric Equipment for Nuclear Power Generating Stations." The type-test programs will include:

A. Seismic testing to the criteria of IEEE 344-1971, "Guide for Seismic Qualification of Class I Electric Equipment for Nuclear Power Generating Stations"; and,

B. Environmental testing simulating design basis temperature and humidity environment.

"4.5 Channel Integrity"

"All protection system channels shall be designed to maintain necessary functional capability under extremes of conditions (as applicable) relating to environment, energy supply, malfunctions, and accidents."

The CPCs LDNBR trip and HLPD trip meet the design requirements of Section 4.5 by assuring that:

A. All channel equipment is qualified for ANO-2 design basis environment to IEEE 323 Criteria;

B. Separated and independent power sources are provided for each channel. Each battery source is ungrounded and derived from a high reliability station battery through an invertor. Each calculator is provided with an AC fail detector that senses a low voltage condition, generates an alarm and initiates an orderly shutdown of the calculator. All calculator inputs to the RPS logic fail "safe" (in the tripped condition) on loss of power; and,

C. Sensor location, equipment location and interconnecting cable routing for each channel are maintained independent from every other redundant channel through physical separation or barriering. Isolation devices are utilized at the calculator outputs. These measures assure that proper protective system action will not be prevented by malfunctions or accidents that may occur, even if these events occurred in one of the redundant channels.

"4.6 Channel Independence"

"Channels that provide signals for the same protective function shall be independent and physically separated to accomplish decoupling of the effects of unsafe environmental factors, electric transients, and physical accident consequences documented in the design basis, and to reduce the likelihood of interactions between channels during maintenance operations or in the event of channel malfunctions."

The requirements of Section 4.6 are met by the CPCs low DNBR trip and the HLPD trip in the following ways:

A. CEA Position Information

Each CEA in the reactor core is monitored by two redundant CEA reed switch position transmitters. CEAs are generally controlled by subgroups of four CEAs due to core symmetry considerations. For this reason, one CEA reed switch position transmitter for each CEA in one core quadrant is utilized directly by one of four redundant CPCs

as representative of the position of that subgroup. The signal from this transmitter is also buffered through an optical isolator* and utilized by one CEAC to determine CEA deviation. The second reed switch transmitter for each CEA in that quadrant is utilized directly by the redundant CEAC. Following this allocation process through all four core quadrants will yield the system shown by Figure 7.2-32.

Each CEAC is physically and electrically separated from its redundant counterpart. Each CEAC transmits a set of CEA deviation data to each of the four CPCs through four fiber optically isolated data links.

The CEACs and the data links to the CPCs, including the use of deviation data by the CPCs, are designed so that no credible single failure can cause the CPC system to fail in an unsafe manner when both CEACs and two or more CPCs are initially in operation. Operability requirements for the system will be included in the Technical Specifications. The intent of Section 4.6 of IEEE 279-1971, which requires channel independence, is fulfilled as follows:

1. The physical independence required is achieved through the use of two separate measurements of each CEA position. These CEA positions are processed by two redundant CEACs which are located in two physically isolated channels of the CPC system.

2. Optical isolators* located in Channels A and D which transmit 20 CEA positions to the CEAC in Channels B and C, respectively, are designed such that open circuits, short circuits, or the application of the credible potential to the optical isolator output will not affect measurement Channel A or D and its CPC.

3. The electrical isolation required is achieved through the use of optical isolators in every signal line of the data links. Since there is no electrical connection across the fiber optic cable and since the dielectric breakdown voltage of the fiber optic cable far exceeds the maximum credible potential (120 volts a-c or 125 volts d-c), electrical transients cannot propagate from one channel to another. At most, electrical transients can produce only erroneous data within the confines of the isolated portion. Such erroneous data is provided for as described below.

*Note: The CEA isolation amplifiers were removed by a hardware upgrade during refueling outage 2R7 and replaced with fiber optic isolators. See License Am-101.

4. The CEACs and the data they transmit provide protection for the CEA-related anticipated operational occurrences defined in Section 7.2.2.1.1. The CEACs transmit data which is used to obtain a multiplier on the radial peaking factors stored in the CPCs. The CPCs limit this multiplier to a value greater than or equal to 1.0. A CEAC can only cause the CPCs to approach the trip setpoint; it can never cause a displacement in the unsafe direction. Erroneous data from a CEAC will cause either: (1) the trip setpoint to be approached if the erroneous penalty factor is greater than the existing penalty factor; (2) the utilization of the correct (higher) penalty factor from the other CEACs if the erroneous penalty factor is lower than the existing penalty factor.

5. Storage of the data from the CEACs in the CPC data base is under the control of the software in the CPCs. Therefore, a failure in one of the CEACs can never destroy all or part of the data base in any CPC.

Table 7.2-13 describes the actions taken for postulated single failures and demonstrates that the CPC system remains safe.

B. NSSS Process Information

All NSSS process information, including neutron flux measurements and RCP speed measurements utilize the following criteria to assure that no single event could negate a protective function:

1. Four (4) redundant physically separated sensors;

2. Physical separation or barriers between redundant cabling; and,

3. Physical separation or barriers between redundant signal processing equipment.

C. Plant Computer Data Links

Fiber optic isolated data links from each calculator to the plant computer are designed such that open circuits, short circuits or the application of the highest credible potential to the isolator output will not affect calculator performance and will not prevent any calculator from performing its intended function.

D. CEA Withdrawal Prohibit (CWP)

A CEA withdrawal prohibit (CWP) logic signal is transmitted to the CEDMCS when 2-out-of-4 coincidence conditions are met on high pressurizer pressure pre-trip, low DNBR pre-trip, or HLPD pre-trip. As shown in Figure 7.2-47, each CPC will send a single contact opening to the PPS when a pre-trip condition exists for LDNBR or HLPD. The PPS uses these four contacts from the four CPCs to control interposing or auxiliary logic relays which form a 2/4 logic matrix.

Channel independence is maintained as the CWP contact from the CPC in each redundant channel is directly wired to the auxiliary logic relay in the respective channel of the PPS. The contacts of the auxiliary logic relays are wired to form a 2-out-of-4 coincidence logic matrix.

A spare relay on the high pressurizer pressure bistable in each PPS channel is wired to form a similar 2/4 logic matrix. The two matrices, connected in series, form the required logical "OR" and provide an "open-contact" to the CEDMCS to initiate a CEA withdrawal prohibit interlock.

The CWP logic and relay/contact interfaces are manufactured and tested to meet all safety systems standards and design bases of the PPS. No single failure of CWP logic and interfaces will compromise the independence of the CPC channels or the PPS channels. Any credible failure at the CEDMS/PPS (Channel A) interface, including open/close circuit, application of 120 volts AC or 125 volts DC, cannot propagate the failure within the associated PPS and CPC channel and prevent any channel from performing its intended function. The CWP wiring is separated from the 240/139-volt AC power buses at the CEDMCS such that the application of this potential is not a credible event.

The CWP interlock prohibits the withdrawal of all regulating and shutdown CEAs in any group mode of control, regardless of any demand for motion by the operator. An unwarranted CWP initiation or a failure to initiate a CWP when required is not a control system action which requires protective action.

"4.7 Control and Protection System Interaction"

There are no interactions between the CPCs and CEACs and any control system. An interlock function for CWP is provided as discussed below. There are no interactions between the CPCs and CEACs and the plant computer including the CEA sequencing functions of the plant computer or the Core Operating Limit Supervisory System (COLSS).

Signals derived from the following protection system sensors are inputs to both the plant computer and the CPCs.

A. pressurizer pressure - 1 per channel
B. hot leg temperature - 2 per channel
C. cold leg temperature - 2 per channel

Process instrumentation signals listed above enter the plant computer as analog inputs. These signals are isolated at the protection system in accordance with the requirements of IEEE 279-1971, Section 4.7.2. Therefore, no credible failure at the plant computer can prevent these signals from performing their protective function. The plant computer only monitors these signals.

The plant computer, including COLSS and the CPC system has no elements of software which are the same.

The COLSS software runs in the plant computer.

The COLSS programs receive input signals from sensors separate from the CPC system. No data is transmitted from the CPCs or CEACs for use by COLSS. No data can be transmitted from the plant computer or COLSS for use by the CPCs or CEACs.

There is no equipment which is common to the CPC system and any automatic control function of the plant computer.

Protective functions and plant computer control functions derive their inputs from separate sensors. For example, process measurements (pressurizer pressure, hot leg temperature, cold leg temperature, etc.) are each measured by six separate sensors: four for protection and two for control.

The requirements of Section 4.7.2 of IEEE 279-1971 are met by fiber optic isolation of the data links to the plant computer. These isolators ensure that no credible failure at the plant computer can prevent the CPC system from performing its intended function.

There are no programs and calculations in the plant computer and COLSS which are essentially the same as those included in the CPC system. As stated in Section 7.7.1.3, COLSS calculates the core power operating limits based on margin to DNBR and peak linear heat rate. COLSS uses the DNBR peak linear heat rate and core power level calculations to provide an indication

that is available to inform the operator of the margin to core power operating limits. The CPC system calculates the minimum hot channel DNBR and the power level corresponding to the limit on Local Power Density (LPD). These calculations are based on many of the same physical principles as the COLSS calculation. There are many differences in the mathematical techniques used to model the physical principles. Moreover, COLSS and the CPCs use different computers and programming languages.

The CPCs use the calculations to initiate a reactor trip when safety limits are reached.

"4.7.1 Classification of Equipment"

No portion of the CPCs, including the CEACs and their sensors, is used for both control and protective functions. No portion of the CPCs including the CEACs and their sensors is used in the CEA sequencing or COLSS functions.

"4.7.2 Isolation Devices"

No signals are transmitted from the CPCs and CEACs for control system use or for use by the CEA sequencing or COLSS functions. Signals which are transmitted to the plant computer for monitoring only are isolated by devices meeting the requirements of this section.

"4.7.3 Single Random Failure"

The CPCs and CEACs use sensors and systems which are independent from all control systems and the plant computer and COLSS. Therefore, any single failure in the plant computer, or in any control system, will have no effect whatsoever on the CPCs or CEACs.

"4.7.4 Multiple Failure Resulting from a Credible Single Event"

The CPCs and CEACs use sensors and systems which are independent from all control systems and the plant computer and COLSS. Therefore, any combination of multiple failures in the plant computer, COLSS or control systems will have no affect whatsoever on the CPCs or CEACs.

"4.8 Derivation of System Inputs"

"To the extent feasible and practical, protection system inputs shall be derived from signals that are direct measures of the desired variables."

The LDNBR trip and the HLPD trip meet the requirements of Section 4.8 by monitoring the pertinent parameters for each calculation as detailed in Table 7.2-9.

"4.9 Capability for Sensor Checks"

"Means shall be provided for checking, with a high degree of confidence the operational availability of each input sensor during reactor operation...."

The integrity of the low DNBR trip and the high local power density trip sensors is verified by cross checking between channels. For each CPC, the calculator values of DNBR margin, LPD margin and calibrated neutron flux power are continuously displayed for immediate comparison. At each operator's module, the values of input data, intermediate calculated results, and final calculated results are available on demand for four channel comparison. Input, output and

status indications available to the CPC system are summarized in Tables 7.2-14, 7.2-15, and 7.2-16. These channels bear a known relationship to each other, and this method ensures the operability of each sensor during reactor operation.

Section 4.9 of IEEE 279-1971 requires that means be provided for checking sensor inputs during reactor operation. Section 4.9 suggests the following ways of accomplishing this function:

"(1) by perturbing the monitored variable; <u>or</u>

(2) within the constraints of paragraph 4.11, by introducing and varying, as appropriate, a substitute input to the <u>sensor</u> of the same nature as the measured variable; <u>or</u>

(3) by cross checking between channels that bear a known relationship to each other and that have readouts available."

The system design uses the method of (3) above for periodic testing of sensor inputs. Cross-checking like sensor inputs between channels not only verifies the integrity of the sensors, but also verifies proper operation of the input multiplexer, Analog-to-Digital (A/D) converter, I/O interface circuits and analog acquisition software.

A failure of the A/D converter which would produce errors (non-linearity) at other points in the range are detected by the cross-checking of sensor inputs. Sensor inputs normally provide enough points to cover the A/D converter range fully, e.g. process inputs - 1 to 5 volts, CEA positions - 5 to 10 volts, ex-core power - 0 to 10 volts.

Testing of the sensor inputs, in conjunction with the digital simulations and exercising of the trip output contacts, completely verifies the CPC system from input to output. Each test segment overlaps adjacent test segments to provide complete coverage. This overlap testing approach is the same one that is used in the testing of non-computed protective functions.

Cross channel checking provides the same level of confidence in the adequacy of the test as the other alternatives since:

A. All input multiplexing switches are tested and verified;

B. The A/D converter is verified over its entire range; and,

C. The data handling software is verified.

The use of a dummy power signal to initiate a trip output re-verifies the dynamic operation of the system.

<u>"4.10 Capability for Test and Calibration"</u>

"Capability shall be provided for testing and calibrating channels and the devices used to derive the final system output from the various channel signals. For those parts of the system where the required interval between testing will be less than the normal time interval between generating station shutdowns, there shall be capability for testing during power operation."

The CPC system utilizes overlap testing to assure compliance with Section 4.10 of IEEE 279-1971.

First, sensor integrity is verified through utilization of control room displays to cross check channels that bear a known relationship to each other.

Next, the sensor signals and the data acquisition hardware and software are verified by cross channel checks of the signal inputs by comparison of those stored values with the corresponding values indicated on the control room displays. This process involves utilization of the operator's module to display measured signal values with the system functioning on-line.

The calibration of the data acquisition equipment including A/D converters is also verified by displaying the fixed value precision reference voltage supplied for each channel.

This portion of the test has verified that the sensors, data acquisition and calculator hardware, and software responsible for data acquisition are functioning properly.

The next step in periodic testing involves the verification that the data verified as properly measured and displayed in the first step is utilized correctly by each calculator to synthesize the correct output result from the measure inputs. This step involves the off-line performance test.

These tests involve utilizing sets of pre-calculated inputs to the calculator data base. By executing each program with predetermined inputs, the performance tests simulate varied input conditions. The output of each performance test is compared against predetermined results to assure that the calculator hardware and software properly execute the code for each protection algorithm to synthesize an output from the input variables. The first test step assures that input signals were properly measured and stored in the correct memory location. The second step assures that the calculator hardware and software retrieved the measured values correctly and properly synthesized the desired output from the input of the several measured values which were indirectly related to the desired output.

The final step in the test involves assurance that the data acquisition software and hardware responsible for initiating a channel trip functions properly. As described below, a dummy power signal is inserted that initiates a trip condition. This test is performed with the calculator on-line, but with the channel bypassed. Proper actuation of the trip contact completes the channel verification from input sensors to final output result. As can be seen from the above discussion, each test step overlaps the preceding step so that the linkage between each step in the verification process is maintained.

A. Interchannel Comparisons

With the CPC on-line, interchannel comparisons of "like" quantities are performed to determine the integrity of the sensors, A/D converters, the corresponding multiplexer channels and the calculated results. The calculated variable of DNBR, local power density and calibrated neutron flux power are continuously displayed on the main control board and may be readily cross-checked by the operator. Major calculator failures will be detected by discrepancies between the four channel display indicators.

The CPC operator's modules may also be used to provide displays of inputs, outputs, and selected intermediate calculated values so that the operator may make channel comparisons of the operable channels.

B. Digital Simulations and Diagnostics

A series of digital simulations with known inputs are performed sequentially in each CPC to verify the operation of the CPC software. In the channel under test, the CPC is placed off-line after the channel DNBR and local power density trips are bypassed from the PPS, changing the 2/4 protection logic to 2/3. Interlocks are designed in the RPS to prevent the bypassing of the same trip function in more than one channel at any one time.

The test program containing input data and predetermined output values is then executed followed by a "go"/"no go" verification of the calculated results against the predetermined values. Similar digital simulations are performed in each CEAC. The simulations are created to verify the software operation of the CEAC.

Administrative procedures and hardwired interlocks prohibit the testing of bothCEACs simultaneously. For the brief time a CEAC is in test, the CPC in each safety channel ignores the input data from the CEAC under test by observing the status of information within the data format. Should a failure provide indications that both CEACs are in test, the CPCs will utilize the default CEA deviation penalty factor, which is stored as a value in protected memory.

The qualification tests prove that the CPC system performs all its intended functions including demonstration of correct action as a result of a combination of several parameters and verification of pre-trip and trip limits as required for periodic testing by IEEE 279-1971, Section 4.10. The intent of Section 4.10 of IEEE 279-1971 may be met by either verifying that the system software remains an exact duplicate of the one which passed qualification tests or by direct demonstration of multi-parameter effects and pre-trip and trip limits. The former is accomplished during software load by manually verifying checksums and by the idle task which continually verifies memory block checksums as the program executes. The latter is also done to provide redundant testing as described below.

The System Executive Task includes a sequence of software tests and a sequence of hardware tests as a part of the periodic channel test. Part of the software tests are designed to test the effect of sensor inputs on the protection programs, and to test the accuracy of the trip and pre-trip limits.

For each test, a definitive set of calculated variables and outputs will be compared to a stored set of constants which represent the correct results for the test. If an error occurs the expected and actual value of the affected variable will be printed on the Hard Copy Terminal/Device at the end of each test. In addition, erroneous results will be flagged. Since the same set of calculated variables will be checked and printed out for all tests run on a particular protection program, the effect of multiple parameters on a single output will be tested.

C. Dummy Power Signal Insertions

To exercise the CPC contact closure outputs, a dummy power signal from the ex-core nuclear instrumentation drawer is inserted using test potentiometers. The power signal is increased to trip the low DNBR and high local power density bistable relay card. The operator verifies that the CPC pre-trip and trip contacts function properly by observing the RPS trip and pre-trip indication lights.

D. Design Bases for Fault Detection, Fault Localization, and Fault Isolation and Repair Philosophy:

The CPC system has been designed to facilitate the recognition, location, replacement, repair and adjustment of malfunctioning components and modules as required by Section 4.21 of IEEE 279-1971. This is accomplished through on-line diagnostics, indicators and annunciators, periodic testing, and troubleshooting aids.

The on-line diagnostics are the first line of defense in the recognition and location of faults. A large number of single failures, though not all, are detected and indicated by the on-line diagnostics. The sensor range checks detect all sensor failures outside the normal range, certain multiplexer and A/D converter failures, certain CPU failures and all CEAC failures which cause the transmitted value of penalty factor to exceed the normal range. The memory checksum and hamming code checks detect and correct all single bit memory failures and recognize most memory module failures. The watchdog timer detects all failures which cause a program halt, tight loop or significant slowdown of instruction execution. Examples of failures detected by the watchdog timer include certain CPU and memory failures, certain CPU power supply failures and drift (slowdown) in the CPU clock. Slowdown of the CPU clock is also detected by the time-frame overrun checks in the operating system software. The arithmetic fault interrupts in the CPU detects floating point under-flow and over-flow and fixed point divide faults.

In addition to detecting faults, the on-line diagnostics point the technician to the general area of the fault by means of indicators and annunciators. For example, the sensor failure indication and annunciation would suggest to the technician that troubleshooting efforts be directed toward the sensors and input hardware (multiplexer and A/D converter).

Single failures which are not detected by the on-line diagnostics are detected during periodic testing. For example, a sensor failure within the normal range is detected by the cross-channel comparison of sensor inputs. Regardless of how the failure is initially detected, the next step in the process is detailed troubleshooting. The exact nature of the troubleshooting procedures will depend, to a large degree, on the skill, experience and resourcefulness of the individual technician. However the general procedure is as follows:

1. Bypass the affected channel.

2. Determine the general area of the fault from the on-line diagnostics or periodic test.

3. Troubleshoot that area using the appropriate diagnostic program and test equipment to isolate the fault.

4. Replace or repair the suspected faulty module or component.

5. Confirm fault diagnosis by verifying normal operation (rerun diagnostic program and periodic test).

6. Restore channel to on-line operation.

To assist the technician in the troubleshooting task, diagnostic software is provided to complement the normal test equipment (voltmeters, oscilloscope, etc.) for each of the following:

1. CPU
2. Memory
3. Input/Output chassis
4. Real time clock
5. Memory Address Translator
6. Disk
7. RS-232C ports
8. Loader Storage Unit
9. Floating Point Instructions
10. Operator's Module

The diagnostic programs may not identify failed components or modules explicitly, but they provide important information to aid the technician's diagnosis.

The repair philosophy for the CPC system may be stated as follows:

1. Recognize the fault.
2. Bypass the affected channel and isolate the fault to a replaceable module or component as rapidly as possible.
3. Replace or repair the faulty module or component.
4. Verify the correction of the fault.
5. Restore the channel to operation.

"4.11 Channel Bypass or Removal from Operation"

The system shall be designed to permit any one channel to be maintained and, when required, tested or calibrated during power operation without initiating a protective action at the systems level. During such operation the active parts of the system shall of themselves continue to meet the single failure criterion.

Exception: 1-out-of-2 systems are permitted to violate the single failure criterion during channel bypass provided that acceptable reliability of operation can be otherwise demonstrated. For example, the bypass time interval required for a test, calibration, or maintenance operation could be shown to be so short that the probability of failure of the active channel would be commensurate with the probability of failure of the 1-out-of-2 system during its normal interval between tests."

The LDNBR trip and HLPD trip meet the requirements of Section 4.11 in the following manner:

A. The output contact from any one of the four CPCs may be bypassed at the PPS logic. This converts the PPS trip logic to 2-out-of-3, and the single failure criterion is met for this condition. Only one calculator output can be bypassed at any time. This condition is assured by a hardware interlock at the RPS logic.

B. Testing of a CEAC places the CEAC function in an one-out-of-one situation during the test. In accordance with the requirements of Section 4.11, the Technical Specifications limit the time duration that the CEAC can be placed out of service.

"4.12 Operating Bypasses"

The LDNBR trip and the HLPD trip may be disabled for CEA drop and low power physics testing whenever reactor power is less than the Log Power Bistable reset point. The criteria of Section 4.12 are met by the following design provisions:

A. Manual bypass by use of key lock switch;

B. Bypass is automatically removed from each channel when the corresponding neutron flux measurement channel indicates that reactor power is greater than the Log Power Bistable Setpoint; and,

C. The automatic bypass removal is designed to IEEE 279-1971 criteria.

"4.13 Indication of Bypasses"

"If the protective action of some part of the system has been bypassed or deliberately rendered inoperative for any purpose, this fact shall be continuously indicated in the control room."

Indication of test or bypass conditions or removal of any channel from service is given by lights and annunciations. Bypasses that are automatically removed at fixed setpoints are alarmed and indicated.

"4.14 Access to Means for Bypassing"

"The design shall permit the administrative control of the means for manually bypassing channels or protective functions."

A key is required to gain access to the means for bypassing a protective system channel. An interlock prevents the plant operator from bypassing more than one of four channels of any one type of trip at any one time. All bypasses are visually and audibly annunciated.

"4.15 Manual Initiation"

"Where it is necessary to change to a more restrictive setpoint to provide adequate protection for a particular mode of operation or set of operating conditions, the design shall provide positive means of assuring that the more restrictive setpoint is used. The devices used to prevent improper use of less restrictive setpoints shall be considered a part of the provision system and shall be designed in accordance with the other provisions of these criteria regarding performance and reliability."

Manual setpoint changes are not expected to be required during plant operation.

"4.16 Completion of Protective Action Once it is Initiated"

"The protection system shall be so designed that, once initiated, a protective action at the system level shall go to completion. Return to operation shall require subsequent deliberate operator action.

The RPS logic is designed to assure that a coincidence of two trip channel input signals from the CPCs will go to completion once a reactor trip is initiated. Operator action is required to clear the trip at the systems level of the RPS to return to operation.

"4.17 Manual Initiation"

"The protection system shall include means for manual initiation of each protective action at the system level (for example, reactor trip, containment isolation, safety injection, core spray, etc.) No single failure, as defined by the note following Section 4.2, within the manual, automatic, or common portions of the protection system shall prevent initiation of protective action by manual or automatic means. Manual initiation should depend upon the operation of a minimum of equipment."

Manual trip initiation is provided at the systems level of the RPS in accordance with criteria of Section 4.17. This manual trip initiation is independent of the CPCs.

"4.18 Access to Setpoint Adjustments, Calibration and Test Points"

"The design shall permit the administrative control of access to all setpoint adjustments, module calibration adjustments, and test points."

The DNBR/LPD system has been designed to permit administrative control of access to all setpoint adjustments, module calibration adjustments and test points. Key switch access has been designed for:

1. Enabling data entry of addressable constants.

2. Physical access to each calculator.

"4.19 Identification of Protective Actions"

"Protective actions shall be indicated and identified down to the channel level."

Indication lights are provided for all protective actions, including channel trips.

"4.20 Information Readout"

"The protection system shall be designed to provide the operator with accurate, complete, and timely information pertinent to its own status and to generating station safety. The design shall minimize the development of conditions which would cause meters, annunciators, recorders, alarms, etc., to give anomalous indications confusing to the operator."

The CPCS LDNBR trip and HLPD trip meet the criteria of Section 4.20 in the following manner:

A. Continuous display of DNBR margin, local power density margin and calibrated nuclear power is provided with main control board meters for each channel;

B. Status indication, test and bypass indication, and fault indication is provided at the main control board; and,

C. A main control board mounted display with touch-screen interface is provided for each channel to allow the operator to address and display.

   1. Preselected calculation output;

   2. Any sensor input; and,

   3. The value of all addressable constants and all setpoints in calculator memory.

Means are provided to allow the operator to monitor all CPC system inputs and outputs. The specific displays that are provided for continuous monitoring of inputs are described in Table 7.2-14. Provisions for continuous monitoring of system outputs are listed in Table 7.2-15. System status indication that is provided is shown in Table 7.2-16.

The means provided for information readout in each CPC trip channel satisfy the information readout requirements of IEEE 279-1971, and are equivalent to the readout provided in the direct analog trips in the present design and the analog calculated trips of previously licensed designs such as Calvert Cliffs.

Section 4.20 of IEEE 279-1971 requires that the protection channel readout "...provide the operator with accurate, complete and timely information pertinent to its own status and to generating station safety." The CPC system meets these criteria with three distinct types of displays: system input displays, system internal status displays and system output displays.

<u>System Input Displays</u>

Each system input parameter, with the exception of CEA position, has an indicating device to allow the operator to ascertain the value of the input parameter and the status of the input value relative to the other redundant channels. Table 7.2-14 details these displays. Analog meter indication is provided for system temperature, system pressure, and neutron flux power level. This analog indication is similar to that provided for the direct analog trip parameters.

As an enhancement to the operator interface, all input parameters are range checked each time the parameter is utilized. The range check feature will alert the operator to a sensor failure out of range within a maximum of one second of the failure. The out-of-range condition alarm appears as a hardwired station annunciator window on the main control board and a red status lamp on the operator's module.

Reactor coolant flow is a parameter calculated from the RCP speed sensor input signals. Reactor coolant flow to RCP speed may be displayed on a digital display on the operator's module, upon command of the operator. The RCP speed signal is checked for out-of-range condition for the high limit only, since operating with a limit check only is in conformance with IEEE 279-1971, Section 4.20, which requires that the design "minimize the development of conditions which would cause meters, annunciators, recorders, alarms, etc., to give anomalous indications confusing to the operator."

CEA position input signals are displayed on the CEAC-1 or CEAC-2 Operator's Module on the Main Control Board.

Each Operator's Module can display:

1. Bar chart displays of CEA group position.

2. Bar chart displays of individual CEAs in a selected group.

The bar chart displays are supplemented with status indication of off-normal conditions and alphanumeric displays of group position and position of a deviating CEA.

The displays are functionally equivalent to that provided on previously licensed CE plants.

The information for each redundant sensor set and CEAC is provided at the two, redundant Operator's Modules for Channels B and C.

System Internal Status Displays

Station annunciators and operator's module status lamps are provided by each DNBR/LPR channel to alert the operator of abnormal system status. These alarms are initiated by calculator self checking features and an external watchdog timer. The status of the CPC system can be ascertained by utilizing the binary alarms and status lamps indicated in Table 7.2-16.

The on-line status information described above is provided in a binary alarm format to facilitate timely operator comprehension of overall system status. Once the operator has responded to the alarm condition, off-line diagnostics may be utilized to pinpoint the specific failure to minimize maintenance time and channel outage.

System Output Displays

Information on the status of CPC calculated DNBR and local power density relative to the reactor trip setpoints is provided by the system output displays. Analog meters of DNBR margin and local power density margin are provided for each redundant channel at the main control board. An analog meter of calibrated neutron flux power is also provided.

Station annunciators are provided that alert the operator if either the trip or pre-trip setpoints of any of the redundant channels is exceeded. There is a separate alarm for DNBR trip, LPD trip, DNBR pre-trip and LPD pre-trip.

The time required to make cross channel comparisons of continuously displayed parameters cannot be quantified as it is highly dependent on control board design and readout placement. However, the on-line sensor range checking performed by each calculator will result in an annunciation within one second of sensor failure to alert the plant operator.

Utilization of the operator's module to display intermediate calculated values of the system is not required to ascertain system status, but is provided to augment the system display capability and is utilized for testing. A listing of values that are capable of being displayed from the operator's module is provided in Table 7.2-12.

On-line hardcopy documentation is not provided to further augment the display capabilities because the inclusion of a non-essential electro- mechanical device in the on-line system would considerably lower the overall reliability and availability of the on-line system. Off-line hardcopy of periodic test results is provided. Since the hardcopy device is utilized off-line, when the channel is bypassed, the reliability and availability of the on-line system is not affected.

The CPC system satisfies the intent of Section 4.20 in the following manner.

Information presentation to the operator is divided into two classifications:

A. Information requiring immediate operator attention; and

B. Information not requiring immediate operator attention.

To satisfy the intent of Section 4.20 the information that falls into Category A is presented in a manner consistent with the following criteria:

A. A simplified format of presentation is provided to allow fast operator comprehension; and,

B. The total amount of Category A information is minimized to prevent operator confusion.

The information that is categorized as requiring immediate operator attention is that information necessary to ascertain the minimum number of operable protection channels in accordance with the Technical Specifications.

System failures and input data anomalies detected by the on-line diagnostics produce an immediate audible and visual alert to the operator by means of station annunciators.

The presentation is simple in format and allows easy operator comprehension of system status. This form of status indication is similar to that of other protection system trips.

Information utilized for maintenance failure diagnosis is categorized as information not requiring immediate operator attention.

To meet the intent of Section 4.21 of IEEE 279-1971 the CPC stores the reason for the system failure in memory. This error code may be printed out via the trip buffer report.

When the on-line system detects a failure or data anomaly, the immediate annunciation allows the operator to assess system status and to take appropriate action as required by plant procedures and the Technical Specifications.

Hard copy is not produced at this point in time as it is not required for immediate operator action. The immediate relevant action item for the operator is not what caused the failure but the fact that a failure occurred. The reasons for the failure are stored for printout at a more convenient time.

The detailed hardcopy documentation of the failure is produced by the off-line system test. This program is initiated upon demand of the operator in accordance with plant procedures and Technical Specification surveillance requirements. This maintenance philosophy is consistent with that of the remainder of the PPS and provides for a simplified operator interface. One option of the hardcopy documentation is a list of selected Point ID values at the time of a trip.

Automatic hardcopy documentation is not necessary for immediate operator action. Since the utilization of automatic on-line hardcopy would penalize the reliability and simplicity of the on-line system, the production of hardcopy failure documentation has been designed as an off-line function initiated by operator request.

"4.21 System Repair"

"The system shall be designed to facilitate the recognition, location, replacement, repair, or adjustment of malfunctioning components or modules."

Identification of a defective channel will be accomplished by observation of system status lights or by periodic testing as described. To facilitate the location, replacement, repair and/or adjustment of malfunctioning components or modules, hardware diagnostics are provided.

Replacement or repair of components or modules is accomplished with the affected channel bypassed. The affected trip function then operates in a 2-out-of-3 coincidence logic configuration.

"4.22 Identification"

"In order to provide assurance that the requirements given in this document can be applied during the design, construction, maintenance, and operation of the plant, the protection system equipment (for example, interconnecting wiring, components, modules, etc.) shall be identified distinctively as being in the protection system. In the installed equipments, components, or modules mounted in assemblies that are clearly identified as being in the protection system do not themselves require identification."

All equipment, including panels, modules, and cables associated with the CPC system will be marked in order to facilitate identification.

IEEE 323-1971

The CPC system will be tested to IEEE 323-1971 criteria.

IEEE 344-1971

The CPC system will be tested to IEEE 344-1971 criteria.

7.2.1.1.2.5.1.9 Interface Requirements

The CPC equipment for each channel of the CPC system is contained within a dedicated enclosure. The side walls of each enclosure will act as a physical barrier between these enclosures and the air space between these enclosures will act as a thermal barrier to prevent the possibility of a common event failure.

All designs, components, interfaces and devices which are part of the CPC system are designed to conform to appropriate protection system requirements. Section 4.9 of IEEE 279-1971 requires that the CPC system will "...automatically initiate appropriate protective action whenever a condition monitored by the system reaches a preset level." All elements of the CPC system whose operation is essential to automatic protective action conform to all protection system requirements. Those elements whose operation is not essential to automatic protective

action (e.g. test equipment, analog display), are designed to conform to those requirements which prevent degradation of the automatic protective action during design basis conditions (temperature, humidity, seismic disturbances, etc.).

The design requirements for the mass storage units and display terminal are justified for the following reasons:

A. The channel to be tested must be bypassed at the PPS cabinet. There is a hardwired interlock at the CPC equipment that prevents testing unless the channel is bypassed.

B. Test equipment utilized for testing or maintenance has its power source isolated from the vital power sources of other channels and from the non-vital instrument bus.

C. Administrative procedures prevent the connection of any test equipment until the channel is bypassed. An example of test equipment that must meet these criteria is the hardcopy device furnished for documenting the results of periodic calculator testing and for loading of programs. Since the channel to be tested is bypassed, no failure of the hardcopy devices can prevent the remaining three channels from performing their required function.

D. To assure that program loading occurs correctly, the calculators perform checksum calculations of software transmitted from the load device.

   Either type of mass storage unit, disk or EPROM, contains checksum information. A periodically scheduled software program continually computes protected memory checksums and compares them against those loaded from the mass storage device. Any deviation, at load time or during subsequent on-line operation, causes a channel trip.

   In addition to those items listed above, failure of the operator's module digital displays or annunciator lights during a seismic disturbance does not degrade automatic protective function. Operator's module displays and annunciator lamps are themselves tested before they are used in testing of the CPC system.

Interface design requirements for the power connections to the components and sensors associated with each CPC and CEAC are the same as those for the balance of the PPS and are described in Sections 8.3.1.4 and 7.1.2.2.

7.2.1.1.2.5.2 NRC Review of the Core Protection Calculators and Discussion of 27 Technical Positions

Because the Core Protection Calculator System (CPCS) was considered to be a first of a kind design, i.e. the use of digital computers to perform plant protection functions, the NRC staff performed an extensive review of the system. A large number of reference documents and correspondence were generated during this lengthy review. These have been listed in Section 7.2.1.1.2.5.3.

During the review, the NRC staff generated a number of staff positions (27 positions), which addressed their specific concerns regarding the CPC system design. The following is a summary of the NRC positions and the resolution of each item.

Position 1: Uncertainty Associated With the Algorithms

The NRC believes that it is necessary to experimentally qualify the adequacy of these uncertainties, specifically those associated with the synthesis of axial power distribution. The NRC requires that confirmatory measurements be performed during startup to demonstrate the adequacy of the axial power synthesis by comparing to in-core measurements and analysis for various power conditions.

Resolution

The calculational uncertainties associated with the CPC synthesized local power density are addressed in CENPD-170 and CENPD-145. The techniques used involved the generation of a large number (in excess of 4,200) of power distributions with the three-dimensional core simulators, ROCS and FLARE. The calculations simulated ex-core detector responses for a variety of static and transient core power distributions typical of first cycle operation of the Arkansas Nuclear One - Unit 2 reactor. Abnormal CEA configurations in which individual CEAs and CEA banks were mispositioned were also considered. The simulated detector signals, together with the CEA positions assumed in generating the power distributions of interest, were then processed by a FORTRAN version of the CPC algorithms to produce, for each case, a value of the maximum peaking factor. The algorithm constants employed by the CPCs, including rod shadowing, were calculated by the simulators from the core conditions employed in the simulators. The CPC synthesized peaking factor was then compared with the value produced by the simulator.

The errors between the synthesized and simulator peaking factors were evaluated for all cases involving normal CEA positions.

A maximum uncertainty factor of approximately 1.085 was realized at end of cycle. The uncertainty factor is the factor that must be applied to the CPC synthesized peaking factor to ensure that 95 percent of the true peaking factors are no larger than the calculated values at the 95 percent confidence level.

As noted above, the radial peaking factors used in the analysis corresponded to the calculated values. Thus the impact of the uncertainty on the true radial peaking factor (vs. the calculated value) is not included in the above factors. During startup, the radial peaking factors used in the CPCs were to be verified using in-core detector responses processed with the INCA code. Hence, the radial peaking factors will contain uncertainties associated with the INCA procedure reported in CENPD-145. These uncertainties are combined statistically with the errors reported above to arrive at an uncertainty factor of about 1.10 for the CPC processed peaking factors. The precise value to be applied during operation is based on results of the startup tests and simulator calculations which accurately model the ANO-2 reactor.

The assessment of the peaking factor accuracy for those cases involving CEA misalignment has been handled separately. In lieu of a statistical uncertainty factor, a sufficiently conservative penalty factor is employed to ensure the total peaking factors produced by the CPCs during a misalignment event will always be conservative relative to the actual values. Approximately 600 cases involving CEA misalignment were evaluated to demonstrate the conservatism of the penalty factor.

Of those cases presented for review, the CPCs consistently overestimated the total peaking factor relative to the value calculated by the simulators during the time the CEAs are misaligned. Following alignment, some azimuthal xenon oscillations occur that are not accommodated by

the CPCs, and, during this time, the CPC peaking factor estimate exclusive of uncertainty factors may be non-conservative. However, this effect was on the order of a few percent for the worst cases and was less than the tilt allowance plus the CPC uncertainty previously described. In addition, those cases for which the CPC calculation was slightly non-conservative can only occur for rod configurations associated with power levels well below the licensed value. Therefore, conditions involving non-normal CEA configurations can be accommodated without further increasing the peaking factor error to be incorporated into the CPCs.

The general method for determining the value of the uncertainty and penalty factors described above was found acceptable by the staff. However, the specific values for the uncertainty and penalty factors depend on simulator constants, e.g. rod and temperature shadowing factors, the shape annealing matrix, and boundary point powers, which are to be either calculated or verified during startup and preoperational tests. Although CE submitted a general startup test plan, the staff required a more detailed description of the program to assure that the CPC constants are verified in a manner consistent with the assumptions and applications in the CPC simulator uncertainty analysis. The test plan was required to include specific reactor configurations to be used in verifying each algorithm constant together with acceptance criteria for the difference between calculated and measured values with alternatives proposed, if acceptance criteria are exceeded. In addition, the number and type of cases to be employed to verify uncertainty and penalty factors were required. The tests performed need to be sufficient to demonstrate the conservatism in the approximations to theory required to implement algorithm constants, in particular shape annealing and rod shadowing factors. It was concluded that the inclusion of the above in the startup test program would satisfy the requirements of Position 1.

Although the precise value of the power distribution uncertainty cannot be verified prior to the completion of the startup test program, the staff determined that the concern expressed by Position 1 did not preclude issuance of an Operating License for the following reasons. First, an alternative system (COLSS) is available during startup testing to calculate required power distribution parameters. Secondly, the basic methodology and instrumentation used in previous Combustion Engineering plants to calculate ex-core axial off-set is similar to that employed by the CPCs; thus, errors in the calculated CPC synthesis uncertainty are not expected to be extreme. Third, the plant will operate at less than design power level during the startup verification of the CPC power distribution algorithm to accommodate with margin, credible inaccuracies in the CPC power distribution uncertainty.

Therefore, Position 1 remained outstanding at the issuance of the license with the results of the startup tests to provide the final resolution of this issue.

Position 2: Conservatism of the CPCS Response to Dropped Control Element Assemblies

The NRC requires three-dimensional transient power distribution studies be performed to assure that effects of dropped off-center CEAs are conservatively predicted by each of the four CPC channels. Our concerns are the adequacy of delta temperature power basis for rapid transients when ex-core sensors are not available.

Resolution

The staff (with assistance from its consultants at Brookhaven National Laboratory) completed a review of the equations used in the synthesis process (as presented in CENPD-170).

The specific application of the power distribution algorithms to the dropped off-center CEA transient was addressed. A review of the analysis by the staff led to the conclusion that the CPC methodology is adequate for conservatively predicting three-dimensional power distributions during this transient, thus satisfying the concerns of Position 2.

Position 3: I/I Converter Isolation Device

It is the NRC's position that the current-to-current (I/I) converter isolation devices be qualified in accordance with specified criteria, and that the results of the qualification tests be submitted for our review including the test plan, test set-up, test duration and acceptability requirements.

Resolution

Information from the process instrumentation sensors is used by the non-Class 1E plant computer and the CPCs. A current to current (I/I) isolation device is used to isolate the Class 1E from non-Class 1E circuits. The staff reviewed the qualification, test procedures and test report, and concluded that the isolation device (I/I) was qualified in accordance with the Commission's requirements and was acceptable.

Position 4: CEAC Separation Criteria at the Output of the Optical Isolator Cards

The NRC requires that the applicant identify their design basis events for the CEAC and verify that no credible single event either internal or external to the CEAC will result in loss of function.

Resolution

During the review the staff requested a demonstration that the output of the optical isolator cards within the CEAC met the single failure criteria. Card slots 11 through 15 of the MACS Universal Chassis within the CEAC encompass the output cards to Channels D, C, plant computer, B, and A, respectively. All five cards are located within a 3.5-inch section of the chassis.

A Failure Mode and Effects Analysis (FMEA) was performed in response to this concern. Based on the information provided in the FMEA, the effect of a single failure in the CEAC on the CPC was to reduce the auctioneering logic for CEA deviation (penalty factor) to a 1-out-of-1 in the CPC (not a loss of function).

In order to close Position 4, the staff required a satisfactory resolution of Position 26. (See "Resolution" of Position 26.)

Position 5: Cable Separation

The applicant identified an area where safety-related control rod drive position sensor cables are run together with non-safety cable. The applicant will re-evaluate this design and advise the staff as to its resolution.

The review of the process instrumentation for the CPCS revealed that all of the analog sensor signal processing for the entire RPS was being processed and housed within the Process Protection Cabinet 2C15. This cabinet is 16 feet long and 10 feet high and is physically separated into four redundant channels. During the drawing review an associated circuit problem was identified within the 2C15 cabinet. The concern expressed by the staff was the close proximity of the Class 1E and non-Class 1E wiring, and the susceptibility of the Class 1E circuits to noise or Electro-Magnetic Interference (EMI) from the non-Class 1E circuits. This concern was formalized as Safety Position 5.

Due to the physical constraints in the reactor vessel head area, both Class 1E and non-Class 1E signals (for CEA position) are transmitted within the same cable assembly from the reactor vessel head to a point outside containment. Within this cable assembly, six of the conductors are used for discrete position information (non-Class 1E) which is transmitted to the CEDMCS and three are inputs to the CPCS. For example, Channel "C" CPC has 61 CEAs; therefore, 366 conductors that are transmitted to the CPCS are non-Class 1E and 183 are Class 1E analog signals. It was noted that all of these conductors are contained in the same raceway, inside containment. Accordingly, the Class 1E conductors are dominated by non-Class 1E conductors and a concern for noise susceptibility existed.

In response to Position 5, a test program was proposed. A noise immunity qualification susceptibility test on the single channel CPC system was performed. This test determined the susceptibility of the system to EMI. A graph of susceptibility field strengths and corresponding frequencies was established as a baseline. The staff reviewed the test procedures, and test report, and concluded that the noise immunity tests were an acceptable subject to satisfactory completion of EMI measurements.

A commitment was made to measure the actual levels and frequencies of EMI onsite to confirm that these measurements fall within the acceptable range of the baseline graph. The results of the onsite measurements were submitted as part of the Startup Test Report. This resolved this particular concern.

Position 6: Position Isolation Amplifiers

It is the NRC's position that the isolation amplifiers be qualified in accordance with the specified criteria and that the results of the qualification tests be submitted for our review, including the test plan, test set-up, test procedures and acceptability requirements.

Resolution

The isolation amplifiers are located in Channels A and D which transmit 20 CEA position information to the CEACs in Channels B and C, respectively. These isolation amplifiers are used to maintain channel independence.

The staff reviewed the test procedures and test report and concluded that the position isolation amplifiers were qualified in accordance with the Commission’s requirements and was acceptable.

Position 7: Protected Memory

The ANO-2 memory protection hardware causes instructions attempting to write into protected memory to be converted into read instructions. No safety credit is allowed for this feature unless failures in the system that result in attempts to write in protected memory are annunciated to the operator. Furthermore, if safety credit is desired, the NRC requires that a status lamp seal indicate the state of operation.

Resolution

During the review, the staff identified the fact that the design does not include means for alerting the operator to violations of protected memory. As a result, no safety credit would be given for this feature. This was agreed to and the issue was therefore resolved.

Position 8: Time Interval of Periodic Testing

A. An acceptable analysis of the CPCS reliability will be developed in accordance with the requirements of Section 4.4 of IEEE Standard 279-1971 and Section 4.2 and 4.3(1) and (7) of IEEE Standard 338-1971. This analysis will provide the basis for evaluating the performance data obtained in Parts 8B and 8C, and for establishing and modifying the periodic test interval after the initial operation period.

B. Completion of the supplemental qualification testing identified in the staff's July 7, 1976 letter and documentation of the system reliability during this test interval is required.

C. During the first six months of operation, the periodic test interval should be significantly more frequent than the proposed 30 days. The interval could in part be based on the results of "A" and "B" above.

   All failures during this period should be carefully recorded, classified and analyzed. At the end of the 6-month period, the performance of the CPCS should be analyzed using the model developed in "A" above and the operational reliability assessed. Based on these results, the test interval could then be modified.

Resolution

During the review of the periodic tests, the staff questioned the basis for the CPCS time interval of periodic testing. The CPCS design represents a new configuration for RPSs. In addition, many of the components in the CPCS (digital computers and I/O interfaces, CEA position transmitters, pump speed sensors and CEA isolation amplifiers) were being used for the first time in a protection system. Several were also first-of-a-kind designs. Therefore, the staff concluded that the past experience with analog protection systems could not be directly applied to the CPCS and required additional justification of the periodic test interval.

In conjunction with the CPC qualification test report, an evaluation of the CPCS reliability (to justify the test intervals for the CPCS periodic tests and for the CPCS system functional tests) was submitted. The staff reviewed the reliability analyses of the CPCS and concluded that the reports did not provide an acceptable basis for establishing the CPCS reliability and test intervals for periodic tests and system functional tests.

The staff believed that use of reliability analysis to establish the initial periodic test intervals was too difficult due to the lack of operating experience with digital computer equipment in safety systems applications. The lack of specific regulatory criteria for reliability evaluations and probabilistic analyses in the licensing review of safety instrumentation and control systems further complicated the development of an acceptable reliability analysis of the CPCS. As a result, they concluded that further reliability analysis would not provide useful information for resolving the initial periodic test interval concerns identified in Position 8. They decided to resolve the concerns regarding periodic testing and functional testing by establishing more conservative test intervals and additional CPCS surveillance requirements in the Technical Specifications until operating experience is gained. This was believed to be consistent with the approach used in previous safety reviews. Based on this Technical Specification approach, this matter was resolved.

Position 9: System Functional Testing

The applicant has not provided definitive and adequate procedures for periodically checking and verifying the functional operation of the CPCS in accordance with the requirements of General Design Criterion 21, "Protection System Reliability and Testability" and the guidelines of Section 4.3 of IEEE Standard 338-1971, "Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems." To verify the functional performance of the CPCS and to insure adequate overlap, the periodic test program should be modified to include procedures for testing each trip function in each channel from sensor input to the CPCS to trip output to the reactor trip system. The procedures should be sufficient to verify that the protective action for each function will ensue for the expected extremes for each sensor.

Resolution

During the review of the periodic tests, the staff questioned the adequacy of the test procedures and the off-line tests for periodically checking and verifying the functional operation of the CPCS in accordance with the requirements of General Design Criterion 21 and Section 4.10 of IEEE 279-1971. They required that the periodic test program be modified to include procedures for testing each trip function in each channel from sensor input to the CPCS to trip output to the reactor trip system. It was felt that the proposed periodic tests were based on the overlap testing philosophy and were adequate for verifying the functional operation of the CPCS. However, the staff took the position that the proposed overlap tests are inadequate and that a functional operation check from CPCS sensor inputs to the trip output was required to adequately ensure that that CPCS is operational. They stated further that this test should be accomplished by injecting a test signal for each sensor input as close as practical to the sensor and monitoring for proper trip output when the trip setpoint is reached.

In response, a commitment was made to perform periodic functional operation checks from CPCS sensor inputs to the trip outputs. The test would be accomplished by injecting a test signal for each sensor input at the MACS input/output (MACS I/O) connectors of the CPCS and CEACS and monitoring for trip output when the setpoint is reached. This was found to be acceptable.

Position 10: Periodic Testing, Addressable Constants

For any changes to addressable constants, the test program will identify calculation errors which may or may not be actual errors. The NRC requires that the applicant develop practical techniques and procedures for verifying calculated results after changes to addressable constants.

Resolution

Changes were implemented in the CPCS off-line test program and test procedures to automatically accommodate changes to addressable constants when verifying CPCS program calculations. The staff reviewed and audited the changes to the periodic test programs and the off-line test procedures and they concluded that the techniques and procedures for using the off-line program were acceptable.

Position 11: Environmental Performance Qualification

and

Position 13: Sensor Qualification

In accordance with the requirements of IEEE Standard 279-1971, Sections 4.1, 4.3, and 4.4, and IEEE Standard 323-1971, Section 4.3, prior to initial operation, a satisfactory environmental test of the integrated system (exclusive of sensors) should be performed or an acceptable analysis clearly establishing the adequacy of component testing is required for staff evaluation. The staff's July 7, 1976 letter includes the requirements for this qualification testing.

For those unique sensors (RCP speed and CEA position) the applicant is required to submit documentation to verify their environmental performance qualification.

Resolution

The CPCS environmental qualification program was based upon the guidelines of IEEE 323-1971. In accordance with Section 4.3 of this standard, the CPCS equipment was qualified by type testing of components. The environmental test conditions for the CPCS components were determined by classifying and identifying safety equipment environmental design categories based upon equipment location and functional requirements. Test plans, test procedures, and the test reports were submitted for the following equipment:

A. CPC central processing unit and MACS modules,

B. CPC power supply,

C. CEA position isolation amplifier,

D. CPC operator's modules,

E. RCP speed sensor and signal processor,

F. CEA reed switch position transmitter, and

G. Current-to-current isolation transmitters.

Based on the staff review of the information provided to demonstrate the radiation exposure qualification of the CEA RSPT, it was concluded that the CEA RSPTs met the environmental qualification requirements for radiation exposure and were acceptable. This resolved Position 13.

Based on the review of the results of the thermal tests of the process protective cabinets, it was concluded that the environmental conditions within the process protective cabinets will be maintained within the minimum CPCS environmental design conditions for the maximum ambient environmental design cabinets in the plant area where the plant protective cabinets are installed. On this basis, it was concluded that the CPCS equipment housed in the process protective cabinets met the environmental qualification requirement and was acceptable. This resolved Position 11.

Position 12: Electrical Noise and Isolation Qualification

Tests for electrical isolation separation and noise susceptibility will be required. The applicant will develop and submit for approval test plans and detailed procedures for these tests prior to their undertaking. In addition, due to the CPCS design and packaging, these tests should be performed on the fully configured integrated system or an acceptable analysis clearly establishing the adequacy of component testing is required for staff evaluation. The staff's July 7, 1976 letter provides supplemental details on this concern.

Resolution

The effects of exposure of the optical isolators to Radio Frequencies (RF) greater than 100 Megahertz (MHz) and the resultant effects upon the response of the CPCS were discussed.

The concern was responded to by performing a noise susceptibility test of radio frequencies from 35 MHz through 2GHz on the CPCS. During this test several susceptible frequencies were encountered within this range. However, at each susceptibility point, the CPCS responded in a fail-safe manner, i.e. a trip. At the frequency band of the radio transceivers (walkie-talkies) to be used in ANO-2 plant, extended tests were run at power levels up to 17 volts per meter to verify that the CPCS was not susceptible.

In response to Positions 5 and 12, a noise immunity qualification susceptibility test on the single channel CPC system was performed. This test determined the susceptibility of the system to EMI. A graph of susceptibility field strengths and corresponding frequencies was established as a baseline. The staff reviewed the test procedures, and test report, and concluded that the noise immunity tests were acceptable subject to satisfactory completion of EMI measurements.

A commitment was made (and license condition added) to measure the actual levels and frequencies of EMI onsite to confirm that these measurements range of the baseline graph. The results of the onsite measurements were submitted in the startup test report. It was the staff's opinion that the frequencies and levels of the radiated EMI, that the single channel was exposed to during the noise susceptibility test, were conservative with respect to the expected onsite measurements, thus justifying the initial operation of the CPCS.

Position 14: Seismic Qualifications

The staff has found the seismic qualification test plan not acceptable. Current criteria for multi-frequency input and sine beat tests for seismic qualification have been provided to the applicant. Submittal date for a satisfactory seismic qualification plan and review completion date have yet to be determined.

Resolution

Topical Report CENPD-182 was submitted for seismic qualification of electrical equipment for the NSSSs. This report included the seismic qualification of the CPCS equipment as follows:

A. Temperature transmitter

B. Current-to-current isolation transmitter

C. CPC mass storage unit

D. CPC MACS modules and unit CPU.

E. CPC power supply

F. CEA position isolation amplifier

G. RCP speed signal processor

H. CPC operator's module

I. Temperature sensor

J. RCP speed sensor

K. CEA reed switch position transmitter

The staff requested additional information on the seismic qualification test configuration and test procedures used to verify the operability of the unique CPCS equipment. Based on the review of these procedures, it was concluded that the test configuration and test procedures were acceptable for verifying the functional operability of this equipment before, during, and after the seismic excitation.

The staff requested additional information to verify the adequacy of the seismic loads used for testing the CPCS equipment housed in the Plant Protection Cabinet (PPC), i.e. "A" through "G" on the preceding list. Information to support the ability of the PPC to survive the seismic events was also requested.

The staff reviewed the analysis for the Plant Protection Cabinet (PPC) and the testing for CPC modules and concluded that the analysis was acceptable to ensure structural integrity of PPC under seismic loads. However, the analysis was inconclusive for verifying the adequacy of testing input motions used for seismic qualification tests of CPC modules mounted on the PPC.

Additional information was provided. The staff reviewed the submittals and concluded that the seismic qualification of the CPCS components was acceptable for ANO-2 specific application and also that the seismic qualification programs for the other identified equipment was acceptable. This resolved Position 14.

Position 15: Addressable Constants

Any changes in addressable constants must be provided with adequate safeguards to protect against unreasonable entries. The proposed safeguards against unreasonable entries are basically administrative and are subject to human error. To enhance safety by minimizing human error and to utilize capabilities of the computer to audit the input, the staff requires that the computer program be modified to conduct reasonability tests and to reject unreasonable values of addressable constants as they are entered from the operator's module. The operator is to be notified upon failure of the reasonability test. Qualification testing of the modification must also be conducted.

Resolution

The staff concluded that all addressable constants had acceptable range limit checks with the exception of the Shape Annealing Matrix (SAM) components. (The staff required reasonability checks of addressable constants as a method for detecting gross errors upon operator entry.

Conceptually, the reasonability checks are the equivalent of the limits of an adjustable potentiometer in conventional analog hardwired type of protection systems.) The staff required the identification of acceptable range limits on the shape annealing matrix components based on ANO-2 design calculations.

As a result of the review of the response, the staff determined that the existing large range limits for the SAM components were acceptable and were not required to be more restrictive. The response demonstrated that the deviation of any single SAM component from its correct value will lead to increased conservatism in the prediction of the power distribution parameters. In addition, the administrative procedure employed when SAM components are entered into the CPCs was reviewed during Phase II testing and was found to be a significant deterrent to the entering of erroneous SAM components. With this information, Position 15 was resolved.

Position 16: Quality Assurance Plan

The results from the NRC's recent audits of the hardware and the software have served to focus the NRC's concerns upon the quality assurance program used for system development. Upon evaluation of these results, the NRC has concluded that Arkansas Power & Light is not complying with the quality assurance plan with regard to the following 10 CFR 50 criteria:

A. Criterion 1, Quality Standards and Records, Appendix A - General Design Criteria for Nuclear Reactor Plants, and

B. Appendix - Quality Assurance Criteria for Nuclear Power Plants and Reprocessing Plants.

The bases for this conclusion are deviations from stated positions, the lack of documented system software development guidelines, and design errors uncovered in our review to date.

As stated in Appendix B of 10 CFR 50, the Quality Assurance Program must be applied to the design, fabrication, construction and testing of the structures, systems, and components of the facility. It is our position that a Quality Assurance Plan is required for the core protection calculator system to embrace all activities from the current frozen design (as of November 24, 1975) to the final design of the installed system. An effective quality assurance program is required to minimize design errors and is an important component to the qualitative reliability of the system. The acceptability of the Quality Assurance Plan and the compliance with the plan must be assessed by the staff prior to the completion of the safety evaluation.

In addition to the criteria stated in Appendix B to 10 CFR 50, the staff desires to emphasize the positions entitled, "Performance Qualification of Software Change Procedures," with respect to the Quality Assurance Plan.

Resolution

It was concluded that the response to the staff's quality assurance concerns proposed a program which, if properly implemented, would comply with the applicable requirements of 10 CFR 50, Appendix B.

Based on an audit, it was concluded that the program was not being implemented properly.

Follow-up audits concluded that the quality assurance procedures were greatly improved. The designer provided an improved means for monitoring the operating system for changes to the core memory. This was accomplished by adding the capability of reading check-sum values via the Operator's Module. This design feature provides a definitive method for independent auditors to reassess the software quality and guard against unannounced changes to the core memory. The check-sum automatic audit program provides continuous on-line protection against hardware failures that cause memory faults as well as protection against unauthorized attempts to change any program. The staff independently analyzed the CPC and CEAC memory dumps and concurred with the check-sum values for each block of memory.

The Office of Inspection and Enforcement (OIE) of NRC conducted an inspection to verify the implementation of the quality assurance program for software design verification and qualification of software changes as conducted by Combustion Engineering in the design of the CPCS. Based on their inspection report, the Office of Inspection and Enforcement concluded that the implementation of the quality assurance program for software design verification and qualification of software changes was in accordance with the quality assurance program description of the CPCS and complied with the requirements of Safety Position 16.

Position 17: Performance Qualification Testing

For evaluation of dynamic test results, the NRC requires submittal of Fortran Codes test results for selected cases to permit comparison with CPCS performance qualification test results. In addition, the NRC requires that transient analyses be performed for selected dynamic test cases using the codes normally employed by Combustion Engineering for Chapter 15 transient analyses. This will enable the staff to determine if the time to trip output on the CPCS based on projected DNBR of 1.3 is reached. The trip signal input to the more sophisticated codes will be the time to trip for respective cases on the CPCS.

The staff will accept for review the Phase II test results previously obtained on the plant system. However, all software revisions since those tests must be implemented in accordance with qualified change procedures (per Position 19) and all Phase II test cases must be repeated on the FORTRAN version of the final program. If final test results are not essentially identical to previous results, a repeat of Phase II test on the plant system configuration will be required.

Resolution

See resolution of Position 24.

Position 18: Burn-In Test

The NRC finds the proposed duration of the burn-in test (three to six months) acceptable subject to their review of test ground rules and acceptance criteria which must be submitted in the form of the test plan before the test commences. The NRC requires that the software on the system during the test incorporate all design changes which have been identified prior to a new freeze on the design. The staff will require testing of the total system after installation of the CPCS and associated process instrumentation in the plant protection system cabinet number 2C15. Failure to incorporate this equipment for the burn-in test will necessitate a more extensive field test program for the entire system.

The staff has reviewed the supplemental response to Position 18, which deals with the burn-in test. Based on the new information presented and the additional testing proposed, the execution of the burn-in test with the frozen software is acceptable, subject to the conditions stated herein.

Conditions for Hardware Burn-In Test:

A. A staff review of the test procedures to be used in hardware burn-in test is in progress. These procedures must be consistent with industrial practice for computer system testing and acceptable to the staff.

B. Additional tests to demonstrate and evaluate the integrity of software and the integrated system are needed. The staff requires a minimum test period of two weeks, with the system operating continuously on live input signals in addition to satisfactory performance of static and dynamic test cases to demonstrate the integrity of the integrated system. This test must be conducted with the same configuration and the same environment as that used for the hardware burn-in test conducted with the frozen software. This is required to assure that problems encountered after installation of the system in a new environment (the ANO-2 site) do not interfere with evaluation of the final software.

<u>Resolution</u>

In response to the staff requirements, revised test procedures were submitted, additional integrated system testing at the plant site from February 11 to February 25, 1978 was performed and a test report, summarizing results of the testing at ANO-2 and the testing at Systems Engineering Laboratories during July 27 to August 7, 1977 was submitted.

The staff reviewed the cited submittals and the test logs were audited by a staff consultant. It was concluded that the test procedures incorporated the required modifications.

Four software coding errors were identified during the software burn-in period of Systems Engineering Laboratories. One of these errors involved a non-significant range-limit error for one of the addressable constants in the CPC. The other three errors were in the CEAC software and, it was felt, indicative of a need for more attention to the scope of CEAC testing for quality assurance of software modifications. Necessary software modifications were performed and the affected modules were Phase I retested. The changes were implemented on the single channel system at Windsor and the affected disk tracks were regenerated. The modifications necessitated a repeat of the 2-week software burn-in test in accordance with the test procedure.

The test configuration at the plant site incorporated the test panel from the Combustion Engineering signal channel test facility to provide the input signals to the integrated 4-channel system. Repeated auto-restarts were experienced on CPC Channel A during testing in a simulated static power condition. The problem was traced to the Interdata Universal Clock Module (UCM) which experienced intermittent loss of interrupts and was replaced on February 20, 1978. Since the failure did not necessitate a design change, test procedures did not require a restart of the test. CPC Channels B, C, and D and one of the CEA channels operated continuously for the 2-week period with no auto-restarts or other anomalies.

The staff noted that the test history of the CPCS has resulted in a number of clock problems. The periodic test program is designed to detect timing errors of the type previously encountered. This periodic test did not detect the above failure which was attributed to an intermittent loss of

interrupts. The periodic test intervals required by the Technical Specifications had been chosen with due regard to test failures, including the previous clock failures. In addition, the Technical Specifications require demonstration of calculator operability when three or more auto-restarts are experienced in a 12-hour interval. The staff believed that these provisions of the Technical Specifications provided adequate safeguards against the existence of undetected clock failures on more than one CPCS calculator at any given time.

The audit of test data and test logs did not reveal any records which were inconsistent with the results and conclusions of the integrated system burn-in report.

The staff concluded that the software burn-in test report and test results were acceptable.

Position 19: Qualification Of Software Change Procedures

Following are the primary requirements for qualification of software change procedures:

A. All changes are to be performed strictly in accordance with the documented quality assurance which is to be available for review by the staff. The documentation must accurately reflect the status of the altered program.

B. The FORTRAN version of the modified program is to be subjected to a complete static and dynamic test program to demonstrate conservatism with respect to trip requirements defined by the ANO-2 accident analysis.

C. The assembly language version of the qualified FORTRAN is to be subjected to a static and dynamic test program on an acceptable test system. The test program is to include sufficient reactor simulated transient test cases, static test cases and single parameter transient test cases to demonstrate that the program response corresponds to its FORTRAN version. The test program is also to include testing of the man-machine interface.

D. The software is to be transferred to the plant system in accordance with the utility's proposed procedures prior to the burn-in test. All four channels will again be subjected to static and dynamic test cases to demonstrate that the response is identical to that observed on the test bed system. This step is to demonstrate the adequacy of the quality assurance procedures for transfer from the test bed to the plant system.

E. Step D need not be repeated for future software revisions. All software design changes and revisions to constants in memory (except addressable constant) are subject to documentation, review and approval by the Regulatory Staff.

Resolution

As part of the resolution of Position 19, the following items were required:

A. An acceptable test program was required for demonstration of the following single channel test system capabilities:

   1. testing of interfaces between the CEAC, CPC, and operator's module,

   2. execution of either option for high power selection, and

   3. testing of multi-variable transients.

B. Additional analyses, supported by test data, were required to complete the evaluation of the single channel test system as an acceptable test system for final qualification testing of modified CPC software.

C. A license condition was included to prohibit changes to the qualified ANO-2 software until a change procedure has been fully qualified, and the Technical Specification were to address the software change restrictions, including documentation and submittal of information on all changes to the staff.

D. An acceptable test program for final testing of modified software was required to assure that software changes do not result in errors or unexpected effects on the functional performances of the CPCS.

With respect to "A", the single channel test system is to be modified to enable multi-variable transients to be performed. This will be accomplished by a Dynamic Software Verification Test (DSVT) in which portions of the CPC executive and unused core are overlayed in order to process predefined time variant CPC inputs to the CPC protection algorithms and data base. Since the inputs can be synchronized with time in the same manner as the corresponding CPC FORTRAN test cases, test results can be compared to the FORTRAN test results without regard to the uncertainties associated with live inputs. Differences in results are then clearly due to software error or machine processing differences. Selected dynamic test cases for qualification of the DSVT program are defined and the test results are to be submitted. The DVST program would be used in lieu of Phase II type multi-variable live input cases for testing of future software modifications. Live input tests in the single variable mode would be retained.

All dynamic test cases were to be re-executed with the high power select option of the software in a normal state.

The single channel system is being modified to include a separate CEAC calculator (and data link) to the CPC. The resulting CPC/CEAC/operator's module configuration will permit testing of all interfaces. Test Case 21 (CEA drop) will be re-executed using the CEAC to generate and transmit the resulting penalty factors. The operator's module interface with the CPC and CEAC are also to be exercised.

The results were to be submitted later.

It was emphasized that all changes to the software design and non-addressable constants would be performed in accordance with 10 CFR 50.59 (including reporting requirements), i.e. the licensee would be responsible to determine if the software change requires a license amendment per 10 CFR 50.59 which must be submitted to the staff. This was considered to be in conflict with the original Position 19E and "D" of the above status summary.

Information was supplied to address the staff requirement ("B") for additional testing to demonstrate the dynamic response of the single channel system. A commitment was made to use the DSVT program executed on the single channel test system and on the Louisiana Power and Light CPCS to demonstrate that the dynamic response of the single channel system is identical to that of the CPCS. The Louisiana Power and Light CPCS hardware configured at Systems Engineering Laboratories in Ft. Lauderdale is a duplicate of the ANO-2 hardware and was chosen to minimize impact on the ANO-2 startup schedule. The execution of these tests was audited by a staff consultant and his audit report, confirmed execution in accordance with test procedures and anticipated results.

Summary:

The staff reviewed test commitments and found the proposed test commitments and modifications to the single channel test system to be an acceptable basis for resolution of the staff concerns expressed in "A" and "B" of the preceding status summary.

The staff slightly modified the position ("C"). It was decided with respect to Position 19E, that they would not require that all software changes be submitted to the staff and would permit the licensee to make a determination of the safety significance. However, all aspects of the software program which affect the margin to trip cannot be modified without prior NRC approval. In addition, a requirement was made that a software consultant who is fully qualified to evaluate the safety significance of proposed software changes be included on the On-Site Safety Review Committee. This requirement was reflected in the Technical Specifications, but relocated to the QA Manual Operations with approval of Amendment 160 to the Operating License. The Nuclear Software Expert position on the OSRC was subsequently eliminated.

A commitment was made to provide information which reflected a test program consistent with the upgraded single channel test capability. This test program was intended to satisfy "D" of the preceding status summary.

Position 19 remained outstanding, pending the submittal to and approval by the staff of the following:

A. Revision of the Software Change Procedure

B. Supplement to the Single Channel Qualification Test Report (including results of the DSVT tests).

C. Designation of a qualified software consultant on the On-Site Safety Review Committee.

D. A description of a noise test program to be used in the qualification of software changes. Also, a description of the noise synthesis capabilities of the single channel test facility.

With the exception of "B" above, commitments were made to provide the information requested and resolve the concerns prior to Mode 2 operation. Because of equipment acquisition and installation delays to the single channel test facility, the test report required in "B" was to be delayed beyond the start of Mode 2 operation. It was proposed that the concerns related to "B" be resolved prior to Mode 1 operation rather than Mode 2 operation. The staff found this acceptable provided that no modifications to the CPCS are defined and/or required during Mode 2 operation. Should a modification be required during Mode 2 operation, it was required that all facets of Position 19 be acceptably resolved prior to the execution of the modification.

<u>Position 20</u>: <u>Data Link to Plant Computer</u>

The CPCS is designed with a data link and a special program module in each protection computer to service the plant computer. These data links and programs are an addition to the traditional plant computer interconnects in analog, hardwired protection system which are also included in the ANO-2 RPS. It is the NRC's position that these data links and the plant computer service program do not satisfy the requirements of General Design Criterion 24, "Separation of Protection and Control Systems," and IEEE 279-1971, Section 4.7, "Control and

Protection System Interaction," regarding independence of protection systems. Therefore, the NRC will require that the plant computer service data links to the protection computers be removed and that the plant computer service routine be deleted from automatic program scheduling.

Resolution

Because this position was not acceptable to AP&L, a compromise to the original position was offered by the NRC staff as follows:

A. Only one channel of the PPS (CPC & CEAC) would be allowed to communicate with the plant computer via a data link. The remaining three channels would not be allowed to communicate to the PCS. The one channel can be manually connected from the PPS to the PCS.

B. This means only one CPC and one CEAC will be connected to the computer at any one time.

The compromise was proposed on the basis that it would allow the use of the PCS to automatically collect data for use in evaluating and confirming the CPCS design bases analyses and functional performance (this was identified as a primary function of the data links). At the same time, the compromise would resolve staff concerns regarding the CPCS independence and acceptably minimize the potential adverse effects of the additional CPCS design complexity required to implement that data link feature.

This compromise was rejected on the following bases:

A. The proposed compromise would not allow the significant benefits afforded by the system as presently configured to be realized. Specifically, simultaneous data from all four CPC channels and both CEAC channels would not be available to support startup and inservice testing; comparison of data from all channels to detect an input or output change or early detection of sensor failure would not be possible; and, the increased periodic test interval by use of the computer would not be possible.

B. The staff's bases for not accepting the use of the data links were that the data links "compromise the independence of the protection systems and add an unnecessary degree of complexity to the CPCS design." The proposed compromise in itself would increase the complexity of the design.

C. The compromise would have an impact in terms of additional cost and schedule to make the changes noted in "B" above as well as changing the plant computer software and operating procedures.

An appeals meeting was held on August 16, 1977. At this meeting information was provided by the staff, and their consultant, in support of the removal of the data links. AP&L and Combustion Engineering presented information to support retention of the PCS data link feature.

In response to the appeal, the staff's position remained "that based upon General Design Criterion 24, regarding separation of protection and control systems, the data links should be removed." The staff also stated that they would evaluate alternate CPCS configurations which would allow the data links to be connected between the CPCS and the PCS in a limited manner. The staff identified two possible alternates as follows:

A. The data links would be allowed to be connected to all six CPCS computers during startup operations for a sufficient period of time to allow for collection of data prior to the end of the startup testing phase of operations. Similar operation would be allowed on subsequent startups after refueling. To evaluate this alternative, we requested information describing (a) the specific uses and benefits of the PCS during this period which relied upon the data links; (b) the required duration of operation with the links connected; (c) the procedures for disconnecting the links at the end of this period; and (d) the test criteria and test methodology to be employed to ensure that the data links have been correctly implemented.

B. The data links would be allowed to be utilized as described in Alternative A. In addition, at the end of the startup operations, three of the four channels would be disconnected from the PCS with the remaining channel connected and in continuous operation. Rotation of the connection link to the PCS among the four channels could also be done. To evaluate this alternative, the information required to evaluate Alternative A would also be required. In addition, the staff stated that they would require that a comprehensive long-term monitoring program of the data links be implemented to provide data to the staff to demonstrate the reliability of operation of the data links and to quickly detect anomalies or failures, subject to staff review and approval. In conjunction with the monitoring program, the staff stated that they would also conduct a review of the PCS software as it related to the data transmission between the CPCS and the PCS.

These alternatives were rejected on the bases that neither alternative would accommodate the PCS periodic assessment of CPCS calculations and the PCS surveillance of the CPCS functions. In lieu of the two alternatives, it was proposed that all CPC-PCS data links be connected and operable during power ascension and initial commercial operation. During this period, (a minimum of six months at a power level greater than 20 percent), the data links would be intensively monitored according to a pre-determined and mutually acceptable set of criteria and procedures. The acceptability of continued operation of the data links would be based on the outcome of the monitoring program.

The staff concluded that this alternate was essentially the equivalent of the original design for the PCS to CPCS data link feature and was, therefore, unacceptable as stated. In addition, the staff assumed that Alternate B, was completely unacceptable. Therefore, it was concluded that unless the first alternative was reconsidered, i.e. use of all the data links to collect data only during initial startup and startup after each refueling, and the information as required by the staff was provided, it would be required that the plant computer data links to the protection computers be removed and that the plant computer service program be deleted from automatic program scheduling in the CPCS.

It was agreed to use and operate the data links in accordance with the staff position. That is, all data links between the protection computers and the plant computers would be connected during startup and power ascension testing. Within 10 days after completion of the power ascension tests, the six data links would be removed.

The data links would be used during the startup and power ascension tests to obtain the data to be analyzed and used to verify the following calculated CPCS data base constants:

- Shape annealing factor matrix constants
- Boundary point power correlation constants
- CEA shadowing factors
- Temperature shadowing factors
- CEA deviation penalty factors

Upon completion of the data collection, the data link cables would be disconnected and stored in accordance with approved procedures for storage and handling of Class 1E electric equipment. After removal of the data link, CPCS operation would be verified by performing a periodic test of each CPC and CEAC.

The staff reviewed the information provided by the applicant for using the data links between the CPCS and plant computer system during initial startup and power ascension tests and at each refueling and also reviewed the procedures for disconnecting the links at the end of this period. Based on the information provided, it was concluded that the concerns regarding the data links from the CPCS to the plant computer system were resolved.

Subsequently the NRC agreed to allow permanent connection of the data links per SER (2CNA068103) as discussed in amendment 24 to the Facility Operating License as follows:

ANO-2 had proposed to permanently connect the plant computer, a non-safety grade computer, to the core protection calculators (CPC) and control element assembly calculators (CEAC), part of the safety grade protection system. A similar proposal was made during the operating license (OL) review but was rejected by the staff because of concerns that the connection added unnecessary complexity to the CPC/CEAC design, and that there might be an adverse indirect effect on the protection system if data from the plant computer were used in calibration of the CPC addressable constants. The issue was discussed in the NRC's safety evaluation report for ANO-2 OL, NUREG-0308, and in particular in relation to Position 20 of Table 7.1 of that document and its supplements.

The concern that data from the plant computer might be used to modify CPC addressable constants and thereby adversely affect the CPCs has been addressed by establishing controls on the modifications of CPC addressable constants in the Technical Specifications. Changes to addressable constants based on data from the plant computer may be made only upon approval of the On-Site Safety Review Committee.

The staff concern about the unnecessary complexity associated with the data link design at the time of OL review was a general concern rather than one based on a potential deficiency in the measures taken to physically isolate the plant computer from the CPCs and CEACs. The use of qualified optical isolation devices at both ends of the digital data links and use of qualified current-to-current isolation devices for the analog data links to the plant computer preclude the possibility of a fault in the plant computer being propagated to the CPCs or CEACs. Furthermore, the watch-dog timers are used to prevent delay in a needed CPC trip should an inordinate time be spent in processing data through the data links to the plant computer.

Although the existence of the data links adds some complexity to the CPC/CEAC design as stated in the OL SER (NUREG-0308), the NRC reconsidered the issue and believes that the possibility of an adverse impact on safety is remote. Also, the controls on CPC addressable constant modifications prevent an unacceptable impact on the CPCs from recalibration using plant computer data. The NRC, therefore, concluded that the permanent connection of the data links between the CPC/CEAC and the plant computer was acceptable.

Position 21: Check-Sum

and

Position 22: Timeout Error Detection for Penalty Factor Transmission

and

Position 23: Watchdog Timer

The NRC's review of the paper tape memory dump representing the frozen design revealed that the check-sum values are not the same in all redundant channels.

For consistency and inspection purposes, the NRC require that a procedure be implemented that will result in check-sum agreement between corresponding blocks of all redundant computer channels in the system. Furthermore, the checksums in each channel must be available for inspection purposes through the operator's module.

The NRC has also noted that the written instruction designed to transmit the penalty factor from each CEAC to each of the CPCs does not have an error response routine for Input/Output (I/O) timeout. Since all other I/O operations in the system have this feature, the NRC requires that the CEAC penalty factor write commands be likewise provided with error test and response routines.

A. Core Protection Calculator

The NRC requires an automatic (hardwired) trip of the associated protection channel upon timeout of the watchdog timer. From the safety review of the design information submitted to date, the NRC has concluded that a significantly larger number of the CPCs safety functions would be monitored if the watchdog timer reset command were moved from the clock interrupt handler to the trip sequence program. In the interest of safety the NRC requires that the watchdog timer be reset from this trip sequence program.

B. Control Element Assembly Calculator

Upon timeout of the watchdog timer, the NRC requires that the "fail bit" be set in the CEAC output. From the safety review of the design information submitted to date, the NRC has concluded that a significantly larger number of the CEACs safety functions would be monitored if the watchdog timer reset command were moved from the clock interrupt handler to the penalty factor algorithm module. In the interest of safety the NRC requires that the watchdog timer be reset from the penalty factor algorithm module.

Resolution

With respect to the automatic tests, it was required that the watchdog timer circuits and program be modified (Positions 21, 22, and 23). Additional program design changes to improve the automatic detection of arithmetic overflow and underflow errors were also identified. The final designs for the watchdog timer and for the program modifications were submitted for review.

In response to Position 21, the design was changed to make the check-sum (an automatic on-line test parameter) values the same for corresponding blocks in all redundant channels. This was accomplished by setting unused memory locations to zero prior to loading and linking the system software. A secondary benefit is derived from this change because any fault in the system that might attempt to use any of these memory locations will cause an immediate channel trip. This occurs because zero is an illegal instruction in this computer and a fault instruction interrupt causes a channel trip.

The staff concluded that the automatic on-line test features have been implemented without restricting the primary safety functions of the CPCS and that they provide additional capabilities for detecting equipment failures which do not exist in present designs for analog hardwired systems. Therefore, it was concluded that the automatic on-line testing for the CPCS complies with the staff requirements in Positions 22 and 23 and was acceptable.

<u>Position 24</u>: <u>Phase II Test and Test Report</u>

Upon review of the Combustion Engineering Topical Report CENPD-22, "Core Protection Calculator System (CPCS) Phase II Design Qualification Test Report," the NRC has concluded that the computer program has not been tested to quality standards commensurate with the importance of the safety functions to be performed. On this basis, the NRC finds the Phase II Test Report unacceptable, including the test procedures and acceptance criteria utilized for the tests. Furthermore, the test report is incomplete in the analysis of test cases. This has raised concerns about the functional adequacy of the system. Because of these deficiencies, the NRC does not consider the Phase II Test Report as an acceptable verification of the CPCS computer program.

Our major areas of concern are as follows (Sequence is of no significance; all concerns are of equal importance.):

A. Of the 36 static test cases, 18 failed the stated acceptance criteria. Coding error was the prime cause of not satisfying criteria for 14 cases. For verification purposes, the coding error was deliberately inserted into the FORTRAN simulation program to generate erroneous simulation results to compare with the results produced by the CPCS. These procedures are unacceptable. Also, these actions are in direct violation of the stated test procedures described in the section entitled, "Design and Performance Qualification Testing" within Section 7.2.1.1.2.5.1.7.

   From the test report, it appears that the coding errors of a fixed point multiplication overflow and a floating point multiplication underflow were detected in the execution of the static test cases with known coding errors in the computer program violates the test procedures stated in the previously referenced section.

   Thus, because of the procedures used in the execution of the Phase II test cases (both static and dynamic test cases), the NRC finds the test results unacceptable. Also because of the large error tolerances used for evaluating acceptability of test results, the NRC concludes that the verification of the correct implementation of the CPCS protection algorithms is not shown in the test report.

   The NRC requires that the verification of the correct implementation of the protection algorithms be conducted with procedures which as a minimum are described in Section 7.2.1.1.2.5.1.7. In addition, acceptance criteria must be specified and justified.

B. As a result of the analysis of the test cases, several computer program changes have been proposed and are identified in the test report. In general, the test report does not provide the basis of change, such as test case results with explanations of why the change is required. In order to conduct an independent review of the proposed changes, the staff required the basis for all proposed changes to the program. This must include all changes identified in the test report along with supporting test cases and explanations such as the results for and explanation of dynamic test Cases 11 and 21.

C. In the discussion on dynamic test acceptance criteria, it is assumed that the initial steady state deviations may be applied as a uniform bias throughout the transient. An analysis to support this assumption will be required.

D. In the discussion of dynamic test Case 15, the 8-second delay in trip time is attributed to improper initial conditions of the test case. For this dynamic test case, it is not clear that the delay in trip is uniquely attributable to initial offset in parameters. The NRC requires that detailed information be provided to support this conclusion.

E. The analyses of the selected dynamic test cases presented in the report are incomplete. Trip time data for each channel and the FORTRAN simulation trip time are presented, but the response comparisons are only conducted for the trip point. No quantitative evaluation of error and error time history between the state variables presented for the FORTRAN simulation and the corresponding CPCS state variables is made. The lack of this comparison does not allow for an assessment of the implementation adequacy of the dynamic algorithms. The NRC requires that a comparison of the response of principle state variables from the FORTRAN simulation be made with the corresponding state variables of the CPCS. The resulting error history should be sufficiently small (and acceptable to the staff) to demonstrate adequate implementation of the dynamic algorithms. Furthermore, a summary table of trip times for all of the dynamic test cases is required for review purposes.

F. The ex-core detector readings presented in the description do not appear to include sufficient variation in relative magnitude to test all of the various correction options inherent in the local power density trip functional program. The NRC requires documentation to clearly demonstrate that the shape correction routines were all correctly implemented and tested.

G. In evaluating the static test cases, the staff had difficulty in assessing test procedures, the input parameters used in the test cases and the analysis of the limited number of intermediate and output parameters presented for testing. In evaluating the input data that were used in the static test cases, the NRC found that the input has been modified for greater than 50 percent of the cases.

   To evaluate the above problems, AP&L's test plan must be provided on which the Phase II test report is based. The test plan should include acceptance criteria, the procedures used in the testing, a description of and objectives of each test case, the input data to be used in each case, and especially the parameters and variables to be recorded and analyzed for each test case.

H. The Phase II test report does not address a test observed by the staff during which a channel failed to trip. (Trip Report - Documentation of CPC Testing - November 24-26, 1975). The NRC requires an analysis of this case as part of the test program.

I. Static Test Acceptance Criteria: The error bands specified for static test acceptance criteria must be clarified and justified. The clarification should include identification and qualification of error components comprising the overall uncertainty band, the description of how they are combined to obtain the overall uncertainty tolerance. All CPC error components inherent in the Phase II test configuration must be included in the analysis, i.e. analog to digital conversion error, simulator errors, noise effects, and processing error in the digital computation must be quantified and justified in supporting documentation.

   Support data must be provided to justify the increase in acceptance criteria (+5 percent error) due to the Power Utility Plant Simulator (PUPS) output hardware, cabling, and noise effects.

J. Dynamic Test Acceptance Criteria: The previous position of the staff on "Performance Qualification Testing" requires that transient analysis be performed for selected dynamic test cases using the codes normally employed for Chapter 15 transient analyses.

   The required time of trip to prevent DNBR from going below 1.3 as determined by these analyses should be specified for applicable cases as one of the acceptance criteria.

K. Scaling Errors: The staff requires evidence that steps have been taken to preclude additional errors in the scaled range of program variables such as occurred for Static Test Case 14.

L. Round Off Errors: The staff requires further analysis of the Static Test Case 11 error. It is not clear why the results should be sensitive to an exact equality of two different instrument signals, since the inherent measurement error makes such a comparison meaningless. Discuss provisions which are being taken to assure that other errors of similar logic origin do not exist. The logic should be justified and the deviation in results due to this logic should be quantified.

M. Auto-Restarts: The effect of recurring auto-restarts that occurred during the use of Test Procedures C and D should be discussed. The staff requires details of the program changes designed to resolve this problem. The staff also requires details of the testing planned to conclusively demonstrate that the problem is resolved.

N. Dynamic Test Cases: A repetition of the dynamic tests will be required. The dynamic test cases are the primary basis for evaluation of the dynamic algorithms. The staff regards that it is necessary to demonstrate the qualification of the corrected design as identified by Position 18. All design changes cannot be adequately evaluated without this testing.

<u>Resolution</u>

The vendor developed a 2-phase test methodology based on individual program modules, whole program units and finally the entire system of programs running in real time with simulated reactor inputs.

An audit of the initial Phase I testing was conducted at the vendors plant. The filing and formality of data record numbering was considered inadequate; however, it was greatly improved in a later docketed Phase I Test Report. This report was to be replaced by a report that will apply to the ANO-2 final software.

The Phase II Test Report, CENPD-222, was reviewed by the staff and found to be unacceptable. The concerns were issued as Position 24. As a result, the following commitments/resolutions were submitted.

A. A commitment was made to re-perform the Phase I and Phase II test series with the final CPC algorithms and executive system software.

B. An attempt was made to document all software modifications from the "frozen" design, although the staff's review has identified several changes which were not clearly specified.

C & D. A commitment was to include justifications in the Phase II Test Report on the final software design to satisfy concerns expressed in Items C and D of Staff Position 24.

E. It was proposed that single variable transient tests on the channel system and on the configured four channel system be performed during Phase II testing to supplement the evaluation of dynamic algorithm implementation in response to the NRC concerns expressed in Item E of Position 24.

F. An audit of the Phase I test results resolved this concern.

G. It was agreed that a Phase II test plan be submitted prior to the Phase II test of the final design software. The staff will review the test plan to determine if the content is acceptable with respect to Item G of Position 24.

H. A commitment was made to submit documentation which would explain the anomalies observed by the staff during testing of the computer protection system (refer to Item H of Position 24).

I. A commitment was made to address all CPC error components pertinent to the Phase II acceptance criteria for static tests as required by Item I of Position 24. The acceptability of the response was to be evaluated during review of the Phase II test documentation which would contain this information.

J. Exception was taken to Item J of Position 24, which indicates that transient analyses for selected dynamic test cases should be used to specify acceptance criteria for reactor trip times. However, a commitment was made to provide analyses using codes normally employed for Chapter 15 transient analyses. This was found acceptable since the submittals would enable the staff to make the desired trip time evaluation.

K. Software modifications addressed the concerns regarding errors in the scaled range of variables as expressed in Item K of Position 24.

L. A commitment was made to provide, during Phase II testing of the "frozen" software, additional analyses to address concerns about round off errors.

M. Software modifications were made to address concerns about recurring automatic restarts that occurred due to out-of-range multiplicative values obtained during Phase II testing of the "frozen" software.

N. Phase II dynamic testing will be reperformed on the configured four channel system with all changes from the "frozen design" incorporated.

The total acceptability of the final design software with respect to Position 24 concerns was evaluated based on the submittals and test programs committed by the applicant.

Phase II Test Plan:

The staff reviewed the final Phase II test plan, including acceptance criteria for test results, which is described in CEN-55(A)-P, and Supplement 1-P of that document. The primary objective of the Phase II testing was to verify that the CPC and CEAC algorithms have been properly integrated with executive software and the system hardware. Each of the system components are verified by separate Phase I testing and by hardware qualification testing prior to testing of the integrated system.

The Phase II test program consisted of 36 static test cases comprising a representative set of steady state operating conditions and 26 dynamic test cases consisting of a representative set of CPC design basis events, anticipated plant transients, and artificial single parameter transients. Acceptance criteria for the Phase II tests are defined based on a comparison of the CPC system response to the response predicted by the CPC FORTRAN simulation code of the CPC software for corresponding test cases. The acceptance band included a tolerance for steady state variations as described in CEN-55(A)-P.

The magnitudes of the expected ranges for each test case was quantified based on detailed analyses of the above effects, including runs for each test case on the CPC FORTRAN Simulation Program. The CPC processor uncertainty was obtained by comparison of input sweep test results obtained on the Windsor Single Channel Test Facility versus those obtained from the execution of the CPC FORTRAN Simulation Program.

The range of acceptable trip times for dynamic test cases was determined by the effects of the uncertainties considered for the static test cases plus the time offset for initiation of the transient in relation to the start of a CPC or CEAC computational cycle. The latter effect is large in comparison to other uncertainties.

In response to staff positions, analyses were performed for five selected dynamic test cases using Combustion Engineering design codes to determine the latest trip time required to prevent DNBR of less than 1.3. The analysis was not provided for dynamic Case 3, 1-out-of-3 reactor coolant pump loss of flow, since the system was not being qualified for part loop operation. (This analysis must be submitted if the system is to be qualified for part loop operation.)

Also in response to staff positions, a time history analysis of the CPC DNBR margin and LPD margin was obtained from the CPC FORTRAN Simulation Program to determine the range of time history response for five single parameter dynamic test cases.

The staff found the test plan acceptable and responsive to staff position 24G.

Phase II Test Results:

The staff reviewed the Core Protection Calculator Phase II Test Report for qualification of the ANO-2 final design software. The staff also conducted an audit of the Phase II test. The Phase II test program was performed in its entirety to supercede the earlier Phase II testing of "frozen" design software which was unacceptable to the staff.

Preliminary analysis of the Phase II test results revealed some deficiencies in the modeling of the system to generate the acceptance criteria. The tolerance bands of expected values were revised to reflect refinements in the simulation of the PUPS function, modeling of noise, and application of the input sweep test results. The staff reviewed the test results in comparison to both the original range of expected values provided in the Phase II test report. It was concluded that the adjustments were small and facilitated the analysis of test results without prejudice to the conclusions, and were, therefore, acceptable.

Test results for DNBR values in 20 of the 36 static test cases were outside of the acceptance range on one or more CPC channels, and required further analysis and explanation. Most of the out-of-range cases were attributed to noise amplitude either greater (low out-of-range) or less (high out-of-range) than assumed when computing the expected values. Four cases were further biased on the high out-of-range side by deviations in the PUPS analog outputs with higher values than expected. All static cases which were outside of the acceptance range were rerun on the Windsor Single Channel Test Facility and results were compared to outputs on the CPC FORTRAN Simulation Program for noise amplitude of zero on all inputs. The DNBR results were in close agreement and were acceptable to the staff.

Peak LPD results were within the expected ranges for 30 of the 36 static test cases. As for the DNBR results, noise was the primary factor responsible for the six out-of-range cases. This was confirmed by running these cases on the Windsor Single Channel Test Facility with fixed inputs. It was concluded that in all cases, the single channel result and CPC FORTRAN Simulation Program results were in acceptably close agreement.

As for the static test cases, initial measured DNBR values for dynamic test cases were affected by noise and PUPS output values different from those assumed when computing expected test results. Only five of the 26 dynamic test cases were within the expected range for initiation of the transients. Out-of-range LPD values were observed in four of the 26 dynamic test cases. Deviations were attributed to noise characteristics of the PUPS system and PUPS analog output uncertainties.

Sixteen of the 26 dynamic test cases met the acceptance criteria for time to trip or reset in all four channels. Out-of-range results for seven cases were shown to be due to noise and output uncertainties with the PUPS system.

Two cases, 23 and 25, were affected by fast CPU clocks in CPC channels A and B. The system surveillance performed during the software burn-in test revealed that the clocks which generate the interrupt signals were running fast, resulting in interrupts occurring at a 10 percent faster rate than intended. The impact of the increased interrupt rate on Phase II testing was analyzed and found to be small with significant impact only on the two cited cases. The dynamic algorithms include derivatives based on the design sampling rate; fast interrupts affect the sampling rate and result in erroneous derivative calculations. The cause of the problem was traced to faulty integrated circuits on CPU clock boards; the circuits were repaired. The periodic test is designed to test the clock and detect anomalies of the type described above.

Test Case 14, which was also out-of-range, is 100 percent to 90 percent step power decrease which results in DNBR increase with no trip output during the transient. Expected results were based on the final time at which the DNBR increases above 2.2. The DNBR did increase above 2.2 at approximately the expected time but dropped below that value much later in the transient (50 to 65 seconds) due to a series of downward spikes in DNBR. This was attributed to effects external to the CPC/CEAC system after extensive analysis of the case failed to reveal any software errors.

Dynamic test cases 17 through 22 are single variable transient tests. The time history of the DNBR and LPD output response compared well to the same cases performed on the CPC FORTRAN simulation.

Analyses were performed using design codes to determine the trip time response necessary to preclude violation of fuel design limits for five relatively limiting design basis events. The actual trip times obtained with the CPCs provided substantial margin over the trip times required.

Conclusions – Phase II Test Program:

The staff review of the Phase II test program included an evaluation of conformance to pertinent staff positions and previous commitments. It was concluded that Position 17 requirements for performance qualification testing were satisfied by the Phase II test program and this issue was resolved.

Position 24 staff concerns were also reviewed and resolved as follows:

Position 24A - The staff concluded that the Phase II test program is acceptable for verification of the correct implementation of the final design software.

Position 24B - Changes to the "frozen" design software were documented and justified, including a CEAC software correction and modification to one erroneous DNB constant which was discovered at the start of the Phase II testing. The documentation of software modifications was concluded to be acceptable.

Position 24C - The time history analysis provided in the Phase II test report acceptable for resolution of this staff concern.

Position 24D - The Phase II test report did not directly address concerns with dynamic test case 15 results during Phase II testing of "frozen" software. However, the satisfactory results of final software testing for this case were acceptable to alleviate this concern.

Position 24E - The analysis of dynamic test cases presented in the Phase II test plan and test report were acceptable for resolution of this position.

Position 24F - This concern was resolved earlier.

Position 24G - The Phase II test plan resolved this staff requirement.

Position 24H - An analysis of the problem defined by this staff position was provided. The software change and subsequent testing provided adequate assurance that the deficiency was corrected.

Position 24I - Static test acceptance criteria in conjunction with the analysis provided in the Phase II test report was acceptable for resolution of this concern.

Position 24J - Dynamic test acceptance criteria included transient analyses using design codes for selected test cases as required by this position. The results were acceptable.

Position 24K - Phase II test results for final design software indicated that previous scaling errors were resolved.

Position 24L - Software changes and subsequent testing adequately resolved this concern.

Position 24M - Software changes and subsequent testing provided acceptable resolution of the recurring auto-restart problem.

Position 24N - Dynamic test cases were repeated as required by this position.

The staff concluded that the final design test results were acceptable, subject to a satisfactory software burn-in test.

Although the integrated system test results were acceptable for qualification of the final design ANO-2 software implementation, the staff was still concerned about the effects of process noise on CPCS performance. The difficulties encountered in predicting the noise effects and the apparent sensitivity of the power calculations to the dynamic component of the thermal power algorithm were examples cited as pertinent to Position 12. The staff required that the impact of process noise on CPCS performance during the startup testing program be fully evaluated. Position 12 remained outstanding until such an evaluation was completed. The requirements for the resolution of Position 12 were stipulated in a condition to the operating license (see Position 12).

Position 25: Maintainability of the Core Protection Calculator System

IEEE 279-1971, Section 4.21, "System Repair," identifies maintainability as one of the requirements for the RPS. The discussions in Sections 7.2.1.1.2.5.1.8 and 7.2.1.1.2.5.1.7 did not adequately address the maintainability of the CPCS. Industrial experience with process computer systems had identified several concerns regarding maintainability of digital computer systems over the operating life of the plant. These concerns are summarized as follows:

A. Lack of standardization in hardware and software design has led to difficulties in identifying second sources of parts supply.

B. The short commercial life cycle of electronic parts compared to plant operating life has resulted in obsolescence of equipment and unavailability of spare parts.

C. Suppliers' and users' lack of experience, trained technicians to maintain equipment.

D. Incomplete maintenance and trouble shooting procedures and system documentation has made maintenance difficult.

As a result of these concerns, and since the ANO-2 represented the first system of its type for use in a RPS, the staff required that the CPCS maintainability plan for the life of the plant be documented and docketed for the Regulatory staff's review and evaluation. The plan was required to address the following:

A. The maintenance actions, i.e. preparation, failure verification and fault location, replacement part procurement, repair and verification tests, required.

B. The maintenance diagnostic and repair features, e.g. displays and controls, external accessibility, test points, cables and connectors, internal accessibility, manuals and test equipment.

C. Hardware and software maintenance support to be provided by vendors (and/or others) and personnel qualification and training to support this maintenance service.

D. Hardware and software maintenance to be provided to the applicant and personnel qualification and training to support this maintenance.

Resolution

In response to these concerns, information was provided describing the procedures for diagnosing CPCS failures. The staff determined that these procedures did not consider the maintainability plan of the CPCS for the life of the plant.

An overall maintainability plan for the CPCS was submitted. The information identified maintenance actions, diagnostic and repair features, personnel training, and other procedures which were to be implemented to ensure that the CPCS can be maintained consistent with the performance requirements of Sections 4.1 and 4.21 of IEEE 279-1971. This was subsequently found acceptable.

Position 26: Optical Isolator

It is the staff's position that as the optical isolator is to be utilized as an electrical isolation device, the applicant must demonstrate that any single credible fault (125-volt AC and 125-volt DC) applied to the device output will not degrade the operation of the circuit connected to the device input. Also, the application of the same credible fault must be applied to the input of the device with no degradation of the circuit connected to the device output.

Resolution

A test program was proposed for the optical isolators. The staff reviewed the procedures and concluded that they were acceptable. The staff also reviewed the test report, and concluded that the test results did not satisfy the acceptance criteria and thus the test report was not acceptable.

The applicant submitted a new test procedure, and test report, which included the design changes that would combat the failures experienced during the first qualification test. Also an analysis was performed to prove the functional correctness of the modifications made to the CPC system's Digital Input (DI) and Digital Output (DO) data link cards. The staff reviewed the analysis and test procedures and concluded that they were acceptable.

The staff also reviewed the test report, and expressed the following concern to the modifications made to the DI card:

A. A fusible resistor was used to prevent the high energy source from initiating a resistor fire upon a fault. The concern was that the fusible resistor would not open fast enough to prevent a fault from exploding the input diode of the isolator. Also the repeatability of the test data for the modified design to perform its function upon application of a fault was a concern.

B. A diode was installed back to back with the input diode of the isolator to prevent damage from the high reverse voltage that would be seen with a 120-volt AC fault. The concern here was the need for the diode modification and the potential requirement for periodic test.

The applicant submitted a new test procedure for evaluating the repeatability of test data on fault performance and to determine if periodic testing is necessary for the protection diode. This test procedure was reviewed and found acceptable.

On May 18, 1978 the staff met with Arkansas Power & Light Company and Combustion Engineering, Inc. in Windsor, Connecticut, to audit the optical isolator qualification test. The tests were conducted on the single channel CPC system in accordance with test procedures. The single channel was configured as a CEAC and a 120-volt AC was applied across the signal lead and the +12-volt return. No abnormal behavior was observed and the on-line diagnostic verified that Bit 7 did fail. Both the DI card and D0 card were pulled from the chassis, and the isolation impedance was verified to be greater than 20 Megohm. There was no evidence of damage on adjacent circuit boards. The cards were returned to the chassis and the system configured as a CPC, and a 120-volt AC was applied across the signal lead and the +12-volt DC supply. Again there was no evidence of damage to the board or the adjacent circuit boards.

An additional 16 tests were run to verify that the modified data link card could withstand the maximum credible fault. Eight tests were run with the back diode in the circuit, and then eight circuits were faulted with the diode removed. The test results demonstrated that the CPC data link isolation circuitry can successfully withstand the maximum credible fault without propagating the fault. It was also demonstrated that periodic testing of the reverse voltage diode circuit is not necessary.

The staff reviewed the test report and found it acceptable. Therefore it was concluded that all of the concerns in Position 26 were addressed and that the optical isolators were acceptable to be used as isolation devices in the CPCs.

<u>Position 27</u>: <u>Periodic Testing of Isolation Devices</u>

The unique design of the CPCS relies on many isolation devices, i.e. optical isolators for CEAC to CPC data transfer and CEA position signals, to maintain electrical independence among the protection channels. The ability of these devices to maintain the isolation among channels is one of the bases for accepting the design of the CPCS. It is the NRC's concern that failures of the isolation characteristics of these devices would seriously compromise the ability of the CPCS to function. The current periodic test procedures do not include provision for verifying that the isolation characteristics of these devices have not failed. Therefore, it is the NRC's position that periodic tests to verify the isolation characteristics of those isolation devices used to ensure channel independence should be performed. The NRC requires that a test procedure for periodically checking the isolation characteristics be submitted for NRC review and approval.

Resolution

Test procedures for periodically checking the isolation characteristics of the CEA position isolation amplifiers and of the optical isolators were submitted. The staff reviewed the test procedures for periodically checking the isolation characteristics of the optical isolators and concluded that they were acceptable. A specific concern regarding the adequacy of the CEA position isolation amplifier isolation tests was identified. In response to this concern, a revised test procedure was submitted to provide a more comprehensive test for periodic verification of the CEA position isolation amplifier input-to-output isolation characteristics. The staff reviewed these test procedures and concluded that they were acceptable.

The current CPC system is designed and installed consistent with the 27 positions above. A position by position analysis of the current CPC system is as follows:

Position 1: Uncertainty Associated with the Algorithms

The implementation of the current CPC system has no impact on the resolution of this position.

Position 2: Conservatism of the CPCs Response to Dropped Control Element Assemblies

The implementation of the current CPC system has no impact on the resolution of this position.

Position 3: I/I Converter Isolation Device

The implementation of the current CPC system has no impact on the resolution of this position.

Position 4: CEAC Separation Criteria at the Output of the Optical Isolator Card

The current implementation of the CPC system will exhibit the same failure mode as originally determined; that is the effect of a single failure in the CEAC on the CPC is to reduce the auctioneering logic for CEA deviation (penalty factor) to a 1 out of 1 in the CPC (not a loss of function).

The isolation provided in the current system between the CEAC and the CPC has been upgraded by the use of fiber optic cable as the isolation device. (See "Resolution" of Position 26).

Position 5: Cable Separation

The CPC system physical enclosure has been improved by moving the location of the system to a place which improves technician access. The CPC equipment has been relocated to this area from the 2C15 enclosure. The non-CPC equipment remains in the 2C15 enclosure. The cabling between the 2C15 enclosure and the new cabinet will be routed to maintain the current degree of separation between Class 1E channels and non-Class 1E equipment and wiring.

The noise immunity qualification testing program originally performed to resolve position 5 will be re-run to verify that the system remains immune to the existing site noise sources.

Position 6: Position Isolation Amplifiers

The current implementation of the CPC system utilizes fiber optic devices for CEA position signal isolation. Seismic and environmental qualification tests have been performed on the new devices.

Position 7: Protection Memory

The memory protection design of the current CPC system has been upgraded to provide annunciation of detected failures. Also, the diagnostic design has been expanded to include monitoring of inappropriate memory read and execute operations in addition to the write protect of the original design.

No safety credit is assumed for this function thus, the resolution of Position 7 remains unchanged.

Position 8: Time Interval of Periodic Testing

Position 8 reflected a concern on the part of the NRC staff during the initial CPC licensing that insufficient data existed to base the establishment of a periodic test interval on. Since that time, a considerable amount of operating experience has been developed upon which the current periodic test interval is based.

The current CPC system replaces the original CPC system with hardware of equal or better reliability. Thus, the current technical specification of testing intervals will be maintained for the current system.

Position 9: System Functional Testing

The current periodic test procedures are identical in function to the original procedures. Some detailed changes were made to accommodate changes in the test interfaces of the new equipment.

Position 10: Periodic Testing Addressable Constants

The current procedure for verification of addressable constant changes is identical in function to the original procedure. Some detailed changes have been made to incorporate changes in the operator's module hardware.

Position 11: Environmental Performance Qualification

and

Position 13: Sensor Qualification

The current implementation of the CPC system has no impact on the resolution of Position 13.

The qualification tests for the current equipment will be performed to the ANO-2 design basis conditions in accordance with IEEE-323-1971 to verify their adequacy.

Position12: Electrical Noise and Isolation Qualification

The EMI/Noise Susceptibility tests will be re-performed to verify system adequacy. A resurvey of the site environment will also be performed. These tests will be performed in a manner essentially identical to the original system tests.

The position isolators will be analyzed to verify that the original isolation testing remains valid.

The CEAC to CPC data links will be analyzed to demonstrate their isolation capability since the current design utilizing fiber optic cable does not provide any path to conduct energy from the isolator input to output. The CPC and CEAC data links to the Plant Computer will be similarly analyzed to demonstrate the adequacy of the isolation.

Position 14: Seismic Qualification

Seismic qualification of the current CPC system will be performed in accordance with IEEE - 344-1971 to the ANO-2 design basis environment similar to that performed on the original system.

Position 15: Addressable Constant

The current implementation of the CPC system has no impact on the resolution of Position 15.

Position 16: Quality Assurance Plan

The current CPC system is designed, fabricated, integrated and tested in accordance with the appropriate requirements of 10 CFR 50, Appendix B.

The current CPC system software has been maintained consistent with the requirements of CEN-39-(A)-P which has been reviewed and approved by the NRC.

Position 17: Performance Qualification Testing

Complete Phase I and Phase II test programs will be run to verify the current CPC system in accordance with CEN-39-(A)-P developed in response to Position 19.

Position 18: Burn-in Test

The burn-in test required by position 18 was appropriate at that time as the ANO-2 CPC system was the first application of a new technology.

Since the time of the original position 18 test, three additional systems of a similar design were produced for the SONGS 2 and 3 plants and the Waterford Plant.

The CPC system was modernized for CE's Systems 80 Palo Verde Nuclear Generating Stations Units 1, 2, and 3. More current equipment was utilized for the computer, input/output system, data links and operator's module.

A burn-in test was not deemed necessary for Palo Verde due to the significant amount of operating experience accumulated with the CPC system.

A formal burn-in test will not be performed for the current CPC system. The operating experience available for the CPC system is adequate to base a periodic test interval on. The software and integrated system performance will be verified with tests performed in accordance with CEN-39-(A)-P.

The full system will be staged for Factory Acceptance Testing and will be restaged at the plant site prior to installation. During these staging periods, failure and repair records will be maintained and reviewed for the hardware. Software change requests generated during this period will be documented and maintained consistent with CEN-39-(A)-P.

Position 19: Qualification of Software Change Procedures

A new single channel will be qualified to reflect the hardware of the current system. A testing program functionally identical to that performed for the qualification of the System 80 CPC system will be performed to verify the adequacy of the single channel (Reference CEN 255).

The CPC system software will continue to be maintained in accordance with the criteria imposed in CEN-39-(A)-P.

Position 20: Data Link to Plant Computer

The current implementation of the CPC system does not have any impact on the resolution of Position 20.

Position 21: Checksum

and

Position 22: Timeout Error Detection for Penalty Factor Transmission

and

Position 23: Watchdog Timer

The current hardware and software have been designed such that a hardware watchdog timer monitors the execution frequency of each calculator.

In a CPC, the watchdog timer is periodically reset by software that is resident in the trip sequence subroutine. If the CPC does not reset the watchdog timer than the timer "times out" forcing the CPC outputs to a trip state. Annunciation of this occurrence is provided.

In a CEAC, the watchdog timer is periodically reset by software resident in the penalty factor algorithm module. When the CEAC fails to reset its watchdog timer the failure is annunciated. The CPCs will detect the CEAC data links in a non-operable condition and will also annunciate the occurrence. The CPC will use the other CEAC.

The current system satisfies the function requirements imposed by Positions 22 and 23.

Checksums in the current CPC system are the same for corresponding blocks of memory in each redundant channel in the CPCs.

All unused locations will be set to zero.

The current implementation satisfies the functional requirements of Position 21.

Position 24: Phase II Test Report

The current CPC system software will continue to be maintained consistent with the requirements of CEN-39-(A)-P which include the requirements for Phase II testing and documentation.

The current CPC system meets the requirements of Position 24.

Position 25: Maintainability of the Core Protection Calculator System

Procedures and plans for the maintenance of the CPC system are maintained for the current CPC system. Operating experience has shown that the CPC system can be maintained consistent with the performance requirements of Sections 4.1 and 4.21 of IEEE-279-1971 and therefore meet the requirements of Position 25.

Position 26: Optical Isolator

The current CPC system utilizes a fiber optic, non-conducting medium to isolate the CPC and CEAC data link.

Since there is no path for transmission of energy between input and output, the current CPC data links satisfy the fault requirements of Position 26. An analysis has been prepared to document the fault isolation capability of the fiber optic isolator consistent with the faults required by Position 26.

Position 27: Periodic Testing of Isolation Devices

Due to the inherent isolation capability of the fiber optic cable, periodic testing of the fault isolation capability will no longer be performed. As documented in the isolation analysis, the fiber optic cable retains its isolation capability for all design basis environmental conditions appropriate to its location including time dependent (aging) effects.

The CEA position isolation will continue to be tested consistent with established intervals in the technical specifications.

7.2.1.1.2.5.3 Additional Information

7.2.1.1.2.5.3.1 Supporting Documentation for CPC Licensing

The review of the CPCs involved much correspondence and topical reports including some proprietary information. The following is a chronological listing of additional information supplied to the Nuclear Regulatory Commission in support of the licensing of the CPCs.

Correspondence

Letter from Phillips, J. D. (AP&L) to A. Giambusso (NRC), 2CAN057505, May 16, 1975. Submits listing of AP&L disagreement with certain NRC positions.

Letter from Phillips, J. D. (AP&L) to A. Giambusso (NRC), 2CAN067508, June 19, 1975. Forwards CEN-20(A)-P. Responses to FSAR Questions 222.25 through 222.48 on the CPC system are included in this report.

Letter from Phillips, J. D. (AP&L) to A. Giambusso (NRC), 2CAN067509, June 19, 1975. Forwards CPC and CEAC functional block diagrams per response to FSAR Question 222.26 submitted in AP&L 6/20/75 letter to the NRC.

Letter from Cavanaugh, William (AP&L) to A. Giambusso (NRC), 2CAN077505, July 16, 1975. Submits Combustion Engineering's responses to NRC's comments on CEN-8(A)-P, Supplement 1, and a summary of AP&L's position on the precritical vibration monitoring program for ANO-2.

Letter from Phillips, J. D. (AP&L) to A. Giambusso (NRC), 2CAN077506, July 22, 1975. Notifies that AP&L must also appeal Question 222.20 regarding new requirements on the qualification of the post-accident monitoring instrumentation.

Letter from Cavanaugh, William (AP&L) to Robert S. Boyd (NRC), August 29, 1975. Forwards proprietary CPC hardware drawings.

Letter from Woodward, J. H. (AP&L) to Robert S. Boyd (NRC), 2CAN097505, September 10, 1975. Appeals certain FSAR questions regarding (1) request for a feedwater line break analysis in the accident section of the ANO-2 FSAR, and (2) request for plots of peaking factors and DNBR as a function of time during the return to power phase of the steam line break accident taking into account thermal hydraulic feedback effects and considering various degrees of thermal mixing of the reactor coolant from the intact steam generator and broken steam generator loops.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), 2CAN107506, October 22, 1975. Discusses NRC questions directed to AP&L regarding the CPC system Topical Report CENPD-170-P.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), 2CAN117501, November 3, 1975. Forwards CE proprietary material in response to FSAR Questions 241.6 and 241.32 regarding fuel rod pressurization and fuel rod cladding temperature during normal and anticipated operational occurrences.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), November 12, 1975. Forwards responses to FSAR Questions 222.64, 222.68, 222.70, 222.72, 222.73, 222.76 and 222.79 regarding the CPC system. Some responses contain proprietary information.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), November 26, 1975. Forwards partial response to NRC request for additional information related to the NRC review of CENPD-170-P.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), December 4, 1975. Forwards responses to FSAR Questions 222.61, 222.62, 222.63, 222.67, 222.71, 222.77, 222.131, 222.136, 222.141, 222.144, 222.149, 222.155, 222.157 and 222.163 regarding the CPC system. Some responses contain proprietary information.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), 2CAN127504, December 5, 1975. Discusses FSAR question response status.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), December 10, 1975. Forwards responses to FSAR Questions 222.65 and 222.66 regarding the CPC system. Some responses contain proprietary information.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), December 22, 1975. Forwards responses to FSAR Questions 222.59, 222.60, 222.69, 222.75, 222.80, 222.102, 222.113, 222.118, 222.120, 222.123, 222.125, 222.128, 222.134, 222.135, 222.137, 222.138, 222.139, 222.140, 222.142, 222.143, 222.146, 222.147, 222.148, 222.153, 222.154, 222.156, 222.158, 222.159, 222.160 and 222.161 regarding the CPC system. Some responses contain proprietary information.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), 2CAN017610, January 1976. Forwards additional copies of drawings requested by FSAR Question 222.97 with the exception of the PPS cabinet electrical schematics.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), 2-016-3, January 9, 1976. Forwards responses to FSAR Questions 222.145 and (partial response to) 222.146 regarding the CPC system. Some of the response content contains proprietary information.

Letter from Cavanaugh, William (AP&L) to J.F. Stolz (NRC), 2-026-1, February 2, 1976. Responds to CPC system Questions 222.109 and 222.152.

Letter from Cavanaugh, William (AP&L) to J.F. Stolz (NRC), 2-026-5, February 17, 1976. Forwards response to FSAR Question 222.83.

Letter from Cavanaugh, William (AP&L) to J.F. Stolz (NRC), 2-036-3, March 4, 1976. Forwards responses to FSAR Questions 214.39, 214.41 and 214.42.

Letter from Cavanaugh, William (AP&L) to A. Schwencer (NRC), 2-036-8, March 12, 1976. Notifies that Combustion Engineering transmitted FORTRAN expected results for all 36 static test cases for the CPC system Phase II testing program. Contains some proprietary material.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), 2-056-6, May 12, 1976. Forwards responses to Arkansas Nuclear One - Unit 2 FSAR Questions 222.74, 222.132, 222.150, 222.151, 222.152, 222.162 and 222.164. Areas covered included expected results for selected Phase II dynamic test cases and CPC algorithm descriptions.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), 2-066-12, June 30, 1976. Forwards responses to FSAR Questions 222.126 and 222.127 regarding the CPC system. Responses contain some proprietary information.

Letter from Cavanaugh, William (AP&L) to Hazel Smith (NRC), 2-076-09, July 13, 1976. Forwards list of all proprietary transmittals made on Docket 50-368 since docketing of FSAR on 4/17/74.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), July 20, 1976.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), August 3, 1976.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), 2-086-9, August 6, 1976. Forwards responses to FSAR Questions 222.166 through 222.173. Areas covered included optical isolators, trip delay time for low DNBR trips, anticipated transients without scrams and areas described as most susceptible to common mode failures.

Letter from Cavanaugh, William (AP&L) to J. F. Stolz (NRC), 2-086-10, August 9, 1976. Confirms delivery on ANO-2 docket of two Systems Engineering Laboratories' manuals per response to Questions 222.166 and 222.167. Documents are proprietary.

Letter from Stolz, John F. (NRC) to Rueter D. A., (AP&L) September 22, 1976. Discusses CEA calculator separation criteria.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), September 22, 1976.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), September 24, 1976.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), September 24, 1976.

Letter from Cavanaugh, William (AP&L) to Robert S. Boyd (NRC), September 30, 1976.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-096-19, September 30, 1976. Confirms delivery on ANO-2 docket on 9/24/76 of System Qualification Test Procedure for CE CPC system, dated 9/23/76.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), October 8, 1976.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), October 12, 1976.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-106-10, October 14, 1976. Forwards proprietary and nonproprietary versions of 16x16 Fuel Assembly Pluck Impact Test, 8/25/76 (TR-ESE-128P and TR-ESE-128NP).

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-017-7, January 11, 1977. Forwards response to reissued FSAR Questions 222.170 and 222.171 regarding backup trips for anticipated events for which CPC system may provide initial trip action, and assessment of common mode failure potential of this system.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz, (NRC) 2-027-7, February 15, 1977. Discusses status of CPC position responses. Forwards reports: CPC Functional Description, Control Element Assembly Calculator Functional Description and CPC Software Modification From "Frozen" Design.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-027-10, February 25, 1977. Confirms submittal of test procedure regarding test plan for EMI/RFI noise test on CPCs.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), February 25, 1977.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-037-3, March 9, 1977. Responds to NRC CPC task force request that relationship between CPC protection algorithms presented in CENPD-170-P, Appendix A, and CENPD-44(A)-P be clarified.

Letter from Arkansas Power & Light Company to J. F. Stolz (NRC), March 14, 1977. Discusses RSPT irradiation with regard to CPCs.

Letter from Arkansas Power & Light Company to J. F. Stolz (NRC), 2-037-7, March 14, 1977. Discusses CPC Staff Position 25.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), March 28, 1977.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-047-8, April 11, 1977. Forwards response to Question 222.172 (reissued).

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-047-14, April 25, 1977. Forwards "Documents, Data and Audits Required for Safety Review of Core Protection Calculator System." Discusses AP&L commitment to hardware "burn-in" test with "frozen design" software.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-047-14, April 25, 1977. Forwards response to Enclosure 1 of 3/29/77 letter regarding CPCs. "Documents, Data, and Audits Required for the Safety Review of the Core Protection Calculator System" is enclosed.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-057-7, May 25, 1977. Forwards EMI test report, CEN-52(A), on Combustion Engineering's single channel CPC system, fulfilling commitments made in the NRC Staff Safety Positions 5 and 12.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-057-8, May 25, 1977. Forwards system qualification final test report for the CPC system, CEN-51(A), documenting findings from five months of surveillance testing from November 11, 1976 through April 10, 1977, and summarizing system failure rate calculations.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-067-3, June 13, 1977. Submits additional information on CPC SER Positions 10 and 15. Forwards description of CPC design modifications.

Letter from Phillips, J. D. (AP&L) to Director of Nuclear Reactor Regulation (NRC) July 7, 1977. Discusses CPC Position 20.

Letter from Rueter, Donald A. (AP&L) to J. F. Stolz (NRC), 2-077-10, July 19, 1977. Notifies that the use of CEN-44(A)-P and CEN-45(A)-P, providing CPC and CEAC software functional descriptions, has led to four modifications to CPC functional description document.

Letter from Phillips, J. D. (AP&L) to Director of Nuclear Reactor Regulation (NRC) July 29, 1977. Forwards attachment, "Arkansas Nuclear One - Unit 2, Core Protection Calculators, Position 20."

Letter from Stolz, John F. (NRC) to William Cavanaugh (AP&L), September 7, 1977. Requests additional information with regard to CPCs.

Letter from Stolz, John F. (NRC) to William Cavanaugh (AP&L), September 16, 1977. Requests additional information on CPC system.

Letter from Boyd, Robert S. (NRC) to Arkansas Power & Light Company, September 20, 1977. Discusses CPC Position 20.

Letter from Cavanaugh, William (AP&L) to Director of Nuclear Reactor Regulation (NRC), October 25, 1977. Discusses CPC Position 20.

Letter from Stolz, John F. (NRC) to William Cavanaugh (AP&L), December 9, 1977. Discusses CPC system preoperational test for ANO-2.

Letter from Arkansas Power & Light Company to Director of Nuclear Reactor Regulation (NRC), January 10, 1978. Discusses CPC system Position 24.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-127-8, January 16, 1978. Forwards CEN-65(A)-P, containing slides, handouts and other material generated and used in support of NRC audit of CPC Phase I testing and design files held July 28 & 29, 1977. Also forwards other CPC-related material.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-018-15, January 18, 1978. Submits results of testing according to criteria in CEN-70(A) to demonstrate optical isolator characteristics. Addresses requirements for qualification of optical isolators as suitable isolation devices in the CPC system design.

Letter from Boyd, Robert S. (NRC) to Arkansas Power & Light Company, January 19, 1978. Discusses CPC Position 20.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-038-10, March 10, 1978. Discusses NRC November 21 & 22, 1977 review of CPC Phase II test report.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-038-27, March 27, 1978. Provides CPC documentation. Forwards CEN-57(A)-P, providing the CPC software specification document committed to in AP&L August 6, 1976 letter, and CEN-69(A)-P, containing executive software requirements.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-048-1, April 4, 1978. Forwards CEN-63(A), Supplement 1(P) regarding CPC supplemental shape annealing matrix information, and CEN-86(A)-P regarding test results of CPC integrated system burn-in test.

Letter from Williams, Daniel H. (AP&L) to Director of Nuclear Reactor Regulation (NRC), 2-058-11, May 11, 1978.

Letter from Williams, Daniel H. (AP&L) to Director of Nuclear Reactor Regulation (NRC), 2-058-12, May 17, 1978.

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-068-3, June 7, 1978. Discusses test results of CPC system optical isolation feature per NRC Position 26 for CPCs. Forwards "Test Report of the Core Protection Calculator Data Link Reverse Voltage Diode and Repeatability Determination."

Letter from Williams, Daniel H. (AP&L) to J. F. Stolz (NRC), 2-068-42, July 3, 1978. Discusses CPC system. Includes assembler information and identification of acceptable range limits on shape annealing matrix components. Forwards "Test Procedure for EMI Site Survey of Arkansas Nuclear One - Unit 2 CPC System."

Letter from Trimble, David C. (AP&L) to J. F. Stolz (NRC), 2-049-8, April 17, 1979. Forwards proposed revision to Section 2.6 of CEN-39(A)-P, Revision 2, dated December 21, 1978, per April 10, 1979 telephone conversation.

7.2.1.1.2.5.3.2 Further Documentation on Major Topic Areas (After Initial Licensing)

Due to the unique application of the CPCs, e.g. use of digital computers in plant protection systems, further staff review continued in this area resulting in additional information being supplied regarding Arkansas Nuclear One - Unit 2.

The following documentation provides a summary of the information on the major topic areas discussed.

A. Data Links (See also Position 20 discussion.)

Letter from Trimble, David C. to Robert A. Clark, 2-090-06, September 3, 1980. Discusses NRC concern regarding CPC/CEAC plant computer data link. Requests that data link operate permanently.

Letter from Clark, R. A. (NRC) to Cavanaugh, W. (AP&L) Docket SO-368, 2CNA068103, June 19, 1981. To the ANO-2 Operating License. Resolved position 20 via transmission of SER on Amendment 24.

Letter from Trimble, David C. to Robert A. Clark, 2R-0281-12, February 28, 1981. Discusses AP&L request that CPC/CEAC plant computer data links remain in use permanently.

B. Addressable Constants (See also Position 15 discussion.)

Letter from Trimble, David C. to Robert A. Clark, 2CAN058113, May 26, 1981. Documents understanding reached between NRC and AP&L regarding description of how CPC addressable constants are determined for referencing in bases to Arkansas Nuclear One - Unit 2 Technical Specifications.

Letter from Trimble, David C. to Robert A. Clark, 2CAN088103, June 10, 1981. Modifies September 20, 1979 response to NRC July 23, 1979 letter regarding secondary water chemistry program. Forwards proposed licensing amendment for implementation of program.

Letter from Trimble, David C. (AP&L) to Robert A. Clark (NRC), 2CAN098103, September 11, 1981. Forwards proprietary version of MSS-NA2-P, "Arkansas Nuclear One - Unit 2 Core Protection Calculator Addressable Constant Determination Methodology."

Letter from Trimble, David C. (AP&L) to Robert A. Clark (NRC), 2CAN098110, September 30, 1981. Forwards nonproprietary version of MSS-NA2, "Arkansas Nuclear One - Unit 2 Core Protection Calculator Addressable Constant Determination Methodology."

C. Software Modifications (See also Position 19 discussion.)

Letter from Trimble, David C. to Robert W. Reid, 2-050-04, May 6, 1980. Forwards safety evaluation of CPC Modification 2B/3 software changes.

CEN-308-P, "CPC/CEAC Software Modifications for the CPC Improvement Program," August, 1985.

7.2.1.1.2.5.3.3 Summary of CPC/CEAC Software Modifications for Cycle 2

The CPCs and the CEACs of ANO-2 Cycle 2 are basically identical hardware with a modified version of the software from that of Cycle 1. The software modifications are described in CEN-143(A)-P.

Since the Cycle 1 CPC/CEAC was reviewed extensively and approved, the NRC Staff's review effort of the Cycle 2 CPC/CEAC concentrated on the software modifications. The following is a list of software modifications.

A. Addressable constants have been added for CEA shadowing factor adjustments, planar radial peaking factor adjustments, and boundary point power correlation coefficients. These addressable constants have been added to adjust CPC power distributions based on startup measurement tests. Cycle 1 operating experience has shown that this improves the accuracy in calculations of core power and power distribution.

B. Some fixed numbers in the power distribution calculation (POWER) have been changed to data base constants. The original fixed numbers were based on Cycle 1 design conditions. Making them data base constants provides flexibility to change plant-specific or cycle dependent values without changing the CPC functional specifications.

C. Planar radial peaking factors are now adjusted by a correction factor based on the Combustion Engineering value of a reactor parameter. This modification provides a more accurate calculation of power distribution for various core conditions.

D. The boundary point power correlation has been simplified and the constant coefficients in the correlation have been made addressable. Cycle 1 startup experience has shown that the previous dependencies in the algorithm are not necessary.

E. A pre-selected axial power distribution is now used during low power operation. This provides a conservatively independent axial power distribution at low power levels.

F. The slope of the coolant temperature shadowing factor has been made an addressable constant. The slope was previously a non-addressable data base value. However, since the shadowing factor is verified during startup testing, the slope can be adjusted based on test measurements. This will result in more accurate CPC calculations of neutron flux and power distribution.

G. The pump-dependent uncertainty on LPD is revised to be applied to the DNBR and LPD update program, UPDATE, instead of the trip sequence program. This change results in including the uncertainty in the LPD margin to the CPC operator's module.

H. The DNBR and LPD pre-trip setpoints have been made addressable constants. This change adds flexibility in setting pre-trip alarm setpoints and allows for adjustment of the setpoint without a revision to the data base. The change does not require a change to the DNBR pre-trip logic. However, the LPD pre-trip setpoint has to be converted from the unit of kW/ft to percent of core average power density.

I. Two new curve fits are used for the core coolant enthalpy/temperature ratio and the normalized specific volume as functions of pressure and temperature. The enthalpy/temperature ratio curve fit is good for the temperature range from 455 °F to 5 °F below saturation temperature. If the hot leg temperature is within 5 °F of the saturation temperature, the CPC will initiate the hot leg saturation trip.

J. The Cycle 2 CPC now uses CETOP2/CE-1 for minimum DNBR calculations compared to CPCTH/W-3 used in ANO-2 Cycle 1. This modification creates the most impact on core operating thermal margin. CETOP2 is the fourth generation of the steady state thermal margin analysis code, TORC. The first generation TORC requires 3-stage core modeling to determine the hot channel minimum DNBR. The second generation simplified TORC (CENPD-206-P) requires 2-stage core modeling. The third generation CETOP-D uses 1-stage lumped channel modeling and transport coefficients for the treatment of crossflow and turbulent mixing between adjoining channels. CETOP-D also uses a prediction-correction method instead of the iteration method used in TORC to solve the conservation equations. The difference in modeling and solution technique results in a very large difference between the TORC and CETOP-D codes even though the same conservative equations are used. CETOP2 used in the CPC is the offspring of CETOP-D. CETOP2 uses constant transport coefficients rather than calculating them as is done in the CETOP-D. Any error resulting from this simplification is accommodated by an algorithm uncertainty factor applied to the CETOP2 core power to ensure that the CETOP2 calculated DNBR is conservative with respect to the CETOP-D with 95/95 probability/confidence level.

7.2.1.1.2.5.4 Reload Information

As part of the reload of Arkansas Nuclear One - Unit 2, information regarding the CPC (in particular, software changes noted in Section 7.2.1.1.2.5.5.3) is submitted as necessary to support conclusions that the plant will continue to meet the safety design bases.

For additional reload information, see the cycle-specific Reload Report.

7.2.1.1.2.6 Trip Generation

Signals from the trip parameter process measurement loops are sent to voltage comparator circuits (bistables) where the input signals are compared to predetermined trip values. Whenever a channel trip parameter reaches the trip value, the channel bistable de-energizes the bistable output relay.

In the case of trips generated by the CPCs an external trip contact deenergizes the bistable output relays. The bistable output relays are in the trip logic (see Section 7.2.1.1.3).

Variable setpoints are provided for the pressurizer and steam generator pressure bistables to permit a safe and orderly plant shutdown. In each protective channel, there is one reset switch for the low pressurizer pressure bistable and another reset switch for both of the low steam generator pressure bistables. As system pressure is decreased below its normal operating range and the trip setpoint is approached, the operator can manually reset the setpoint a fixed increment below the actual system pressure. By continuing to reset each time the pre-trip setpoint is reached, the plant can be cooled down and depressurized without causing any unnecessary protective actions. If system pressure rises above the point at which it was last reset, the trip setpoint will rise to provide protection. If system pressure is then reduced, the setpoint will hold and the operator must again reset the setpoint as the trip point is approached. Figure 7.2-4 illustrates this process for the steam generator setpoint based on design pressure of 900 psia. The actual setpoints are displayed on control board meters near the variable reset switches for each measurement channel.

The remaining trip bistable setpoints are adjustable from the PPS cabinet. Access is limited, however, by means of a key operated cover, with an annunciator indicating panel access. The annunciator indicates that the PPS cabinet has been entered, not that the setpoint adjustment panel cover has been opened. All bistable setpoints are capable of being read out on a meter located on the PPS cabinet.

Pre-trip bistables and relays are also provided.

7.2.1.1.3 <u>Logic</u>

The above trips are each generated in four channels, designated A, B, C and D. The RPS logic utilized these trip signals to generate, on a 2-out-of-4 basis, signals to the final actuation devices for a reactor trip.

Tripping of a bistable (or trip contact closure in the case of a calculated trip) results in a channel trip which is characterized by the de-energization of three trip relays. A trip of any two bistables in a group of four like protection trip paths will result in a trip of all four channels (A,B,C and D).

The contacts of the four sets of three trip relays in the four like protection channels have been arranged into six logic ANDs designated AB, AC, AD, BC, BD, and CD. This represents all possible 2-out-of-4 trip combinations for the four protection channels.

The contacts of the four sets of three trip relays in all other groups of four protection channels monitoring other selected NSSS parameters are arranged in a similar fashion.

The logic ANDs of identical trip designation are connected in series (Logic OR) to form a logic matrix. The six matrices are also designated AB, AD, AC, BC, BD and CD. Each logic matrix is connected in series with four parallel matrix relays.

Trip paths are formed by connecting contacts from one matrix relay in each of the six sets of matrix relays in series in an output relay circuit which controls power interruption to the actuation devices. The trip path initiation relays serve to de-energize the trip switchgear circuit breakers as discussed in Section 7.2.1.1.4.

7.2.1.1.4 Actuated Devices

The above logic causes the de-energizing of the four trip path initiation relays whenever any one of the logic matrices is de-energized as described. Each trip path initiation relay in turn will cause two trip circuit breakers in the trip switchgear to open.

Power input through the trip switchgear breaker contacts to the CEA holding coils comes from two full capacity motor generator sets so that the loss of either set does not cause a release of the CEAs. Each line passes through two trip circuit breakers (each actuated by a separate trip path) in series so that, although both sides of the branch lines must be de-energized to release the CEAs, there are two separate means of interrupting each side of the line. Upon removal of power to the CEDM power supplies, the CEAs are inserted into the reactor core by gravity.

Two sets of manual trip pushbuttons are provided to open the trip circuit breakers, if desired. The manual trip completely bypasses the trip logic. Both manual trip pushbuttons in a set must be depressed to initiate a reactor trip.

The trip switchgear is housed in a separate cabinet from the RPS. In addition to the trip circuit breakers, the cabinet also contains a bus tie breaker and current monitoring devices which indicate on the local status panels for testing.

7.2.1.1.5 Bypasses

The bypasses listed in Table 7.2-1 are provided to permit testing, startup, and maintenance.

The DNBR and local power density bypass, which bypasses the low DNBR and high local power density trips from the CPC, is provided to allow system tests at low power when pressurizer pressure may be low or reactor coolant pumps may be off. The bypass may be manually initiated and is automatically removed as shown in Table 7.2-1.

The RPS/ESFAS pressurizer pressure operating bypass is provided for two conditions: (1) system tests at low power and low pressure, and (2) heatup and cooldown with shutdown CEAs withdrawn. The bypass is manually initiated and is either manually or automatically removed as shown in Table 7.2-1.

The RPS/ESFAS High/Low Steam Generator Level Bypass is provided for system tests during shutdown conditions. The bypass is manually initiated and is either manually or automatically removed as shown in Table 7.2-1.

The high logarithmic power level operating bypass is provided to allow the reactor to be brought to the power range during a reactor startup. The bypass is manually initiated and is automatically removed as shown in Table 7.2-1.

The trip channel bypass is provided to remove a trip channel from service for maintenance or testing. The bypass is also provided to remove a trip channel from service for an extended period without affecting plant safety or availability in the event of an equipment failure not readily repairable or accessible. The trip logic is thus converted to a 2-out-of-3 basis for the trip type bypassed; other type trips which do not have a bypass in any of their four channels remain in a 2-out-of-4 logic.

The bypass is manually initiated and manually removed. This circuit, which is repeated for each type of trip, contains an electrical interlock which allows only one channel for any one type trip to be bypassed at one time.

All bypasses are annunciated visually and audibly to the operator.

7.2.1.1.6 Interlocks

The following interlocks are provided:

A. Trip Channel Bypasses

An interlock prevents the operator from bypassing more than one trip channel at a time for any one type trip. Different type trips may be simultaneously bypassed, either in one channel or in different channels. Since some parameters may be used in several different functional units, Technical Specifications require that when bypassing a parameter or functional unit in a channel, the operator must bypass all the interdependent parameters or trip units in the same channel.

B. Matrix Tests

During system testing an electrical interlock will allow only the matrix relays in one of the six matrix test modules to be held at a time. The same circuit will allow only one process measurement loop signal to be perturbed at a time. The matrix relay hold and loop perturbation switches are interlocked so that only one or the other may be done at any one time.

C. Nuclear Instrumentation Test

Placement of a nuclear instrument drawer calibration switch to other than the "OPERATE" position or removal of any level test switch from the "OFF" position will cause a power trip test interlock to trip low DNBR and high local power density bistables. Placement of a linear or logarithmic calibration switch to other than the "OPERATE" position will cause a channel high power level or high logarithmic power level trip.

D. Core Protection Calculator Test

The low DNBR and high local power density channel trips are interlocked such that they must be bypassed to test a CPC system.

E. Test Power Supply

A rotary switch ensures that power from the test power supply may be applied to only one channel at a time.

7.2.1.1.7 Redundancy

Redundant features of the RPS include:

A. Four independent channels, from process sensor through and including channel trip relays. The CEA position input is from two independent channels;

B. Six logic matrices which provide the 2-out-of-4 logic. Dual power supplies are provided for the matrix relays;

C. Four trip paths, including four control logic paths and four trip path output relays;

D. CEDM power from two power buses, including two full capacity motor generator sets;

E. Two sets of manual trip switches (either set is sufficient to initiate a reactor trip); and,

F. AC power for the system is derived from four separate 120-volt vital AC buses. DC power for reactor trip switchgear control is provided from two separate DC buses plus rectified AC derived from 2 additional AC buses.

The result of the redundant features is a system which meets the single failure criterion, which can be tested during reactor operation, and which can be shifted to 2-out-of-3 logic.

In order to alleviate concerns regarding redundant power supply independence, testing was performed on PPS power supplies. The purpose of this testing was to show that the DC power supplies involved, when auctioneered, will provide adequate separation between vital power buses and will perform that function in accordance with the criteria set forth in IEEE 279 and IEEE 323-1971. The benefit of a system with four independent and redundant channels is that the system can be operated, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criteria. The only operating restriction while in this condition (effectively one-out-of-two logic) is that no provision is made to bypass another channel for periodic testing or maintenance. The system logic must be restored to at least a two-out-of-three condition prior to removing another channel for maintenance.

7.2.1.1.8 Diversity

The system is designed to eliminate credible multiple channel failures originating from a common cause. The failure modes of redundant channels and the conditions of operation that are common to them are analyzed to assure that a predictable common failure mode does not exist. The design provides reasonable assurance that:

A. The monitored variables provide adequate information during design basis events (Design basis events are listed in Sections 7.2.2.1.1 and 7.2.2.1.2.);

B. The equipment can perform as required;

C. The interactions of protective actions, control actions and the environmental changes that cause, or are caused by, the design basis events do not prevent the mitigation of the consequences of the event; and,

D. The system will not be made inoperable by the inadvertent actions of operating and maintenance personnel.

In addition, the design is not encumbered with additional components or channels without reasonable assurance that such additions are beneficial.

The system incorporates functional diversity to accommodate the unlikely event of a common mode failure concurrent with any of the accident conditions listed in Section 7.2.2.1.2.

Protection from a postulated common mode failure during an ATWS event is accomplished by the Diverse Scram System (DSS). Conformance to 10CFR50.62, known as the ATWS Rule, requires that the RPS/RTS be diverse and independent from the DSS from sensor output to interruption of power to the control rods. In addition, the RPS/RTS must be diverse from the Diverse Emergency Feedwater Actuation System (DEFAS) since the DEFAS is an ATWS system that uses the same types of equipment as the DSS. (Reference Section 7.7.1.6 for the DSS and Section 7.7.1.7 for the DEFAS)

7.2.1.1.9 Testing

Provisions are made to permit periodic testing of the complete RPS, with the reactor operating at power or when shut down. These tests cover the trip actions from sensor input through the protective system and the trip switchgear. The system test does not interfere with the protective function of the system. The testing system meets the criteria of IEEE 338-1971, "IEEE Trial - Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems" and of Regulatory Guide 1.22, "Periodic Testing of Protection System Actuator Functions." Jumpers or other temporary forms of bypassing are not used during testing.

The individual tests are described briefly below. Overlap between individual tests exists so that the entire RPS can be tested. Frequency of testing is given in the Technical Specifications.

7.2.1.1.9.1 Sensor Check

During reactor operation, the measurement channels providing an input to the RPS are checked by comparing the outputs of similar channels and cross-checking with related measurements.

During extended shutdown periods or refueling, these measurement channels (where possible) are checked and calibrated against known standards.

7.2.1.1.9.2 Trip Bistable Tests

Testing of the trip bistables is accomplished by manually varying the input signal up to or down to the trip setpoint level on one bistable at a time and observing the trip action.

The digital voltmeter indicates the value of the test signal and is compared with an NIST traceable meter. The circuit permits various rates of change of signal input to be used. Trip action (de-energizing) of each of the bistable trip relays is indicated by individual lights on the front of the cabinet, indicating that these relays operate as required for a bistable trip condition.

When one of the four bistables of a protective channel is in the tripped condition (versus being bypassed), a channel trip exists and is annunciated on the control room annunciator panel. In this condition, a reactor trip would take place upon receipt of a trip signal in one of the other three like trip channels.

The trip channel under test is therefore bypassed for this test, converting the RPS to a 2-out-of-3 logic for the particular trip parameter. In either case, full protection is maintained.

7.2.1.1.9.3 Core Protection Calculator Tests

The sensor inputs to each calculator are compared between units. Predetermined test data are then accessed by one calculator at a time via a test panel. The calculator outputs are then checked for specific values. Multiple tests can be performed to check each phase of the calculator program (see Section 7.2.1.1.2.5).

The checking of the trip relays for the calculator generated trips is conducted as described in Section 7.2.1.1.9.2.

7.2.1.1.9.4 Logic Matrix Test

This test is carried out to verify proper operation of the six 2-out-of-4 logic matrices, any of which will initiate a system trip for any possible 2-out-of-4 trip condition from the signal inputs from each measurement channel.

Only the matrix relays in one of the six logic matrix test modules can be held in the energized position during tests. If, for example, the A-B logic matrix hold switches are held actuated, actuation of the other matrix hold switches will have no effect upon their respective logic matrices.

Actuation of the switch will apply a test voltage to the test system hold coils of the double coil matrix relays. This voltage will provide the power necessary to hold the relays in their energized position when de-actuation of the bistable trip relay contacts in the matrix ladder being tested causing de-energization of the primary matrix relay coils.

The logic matrix to be tested is selected using the system channel trip select switch. Then while holding the matrix hold switch in its actuated position, rotation of the channel trip select switch will release only those bistable trip relays that have operating contacts in the logic matrix under test. The channel trip select switch applies a test voltage of opposite polarity to the bistable trip relay test coils so that the magnetic flux generated by these coils opposes that of the primary coil of the relay. The resulting flux will be zero, and the relays will release.

Trip action can be observed by illumination of the trip relay indicators located on the front panel and by loss of voltage to the four matrix relays, which is indicated by extinguishing the indicator lights connected across each matrix relay coil.

During this test, the matrix relay "HOLD" lights will remain on, indicating that a test voltage has been applied to the holding coils of the logic matrix module under test.

The test is repeated for all six matrices and for each actuation signal. This test will verify that the logic matrix relays will de-energize if the matrix continuity is violated. The opening of the matrix relays is tested in the trip path tests.

Each logic matrix test module provides the associated test circuitry for both the RPS and ESFAS logic matrices. The system channel trip select switch permits the selection of the desired actuation logic matrix to be tested.

7.2.1.1.9.5 Trip Path/Circuit Breaker Tests

Each trip path is tested individually by depressing a matrix hold switch (holding the matrix relays), selecting any trip position on the channel trip select switch (opening the matrix), and selecting a matrix relay on the matrix relay trip select switch (de-energizing one of the four matrix relays). This will cause one, and only one, of the trip paths to de-energize, causing two trip circuit breakers to open. CEDMs remain energized via the other trip circuit breakers.

The drop out lamps are used to provide additional verification that the matrix relay has been de-energized, i.e. the 6AB-1 matrix relay contact energizes the drop out lamp. Since the matrix test modules are also utilized for the Engineered Safety Features Actuation System (ESFAS) logic matrix testing, this drop out lamp is also shared via contacts 1AB-1 through 5AB-1. Proper operation of the actual trip path matrix relay contacts is verified by the trip path lamp located on the trip status panel.

Proper operation of all coils and contacts is verified by lights on a trip status panel; final proof of opening of the trip circuit breakers is the lack of indicated current through the trip breakers.

The matrix relay trip select switch is turned to the next position, re-energizing the tested matrix relay and allowing the trip breakers to be manually reset.

This sequence is repeated for the other three trip paths from the selected matrix. Following this the entire sequence is repeated for the remaining five matrices. Upon completion, all 24 matrix relay contacts and all four trip paths and breakers will have been tested.

7.2.1.1.9.6 Manual Trip Test

The manual trip feature is tested by depressing one of the four manual trip switches, observing a trip of two trip breakers, and resetting the breakers prior to depressing the next manual trip switch.

7.2.1.1.9.7 Bypass

The system bypasses, listed in Table 7.2-1, are tested by appropriate test circuitry. Testing includes both initiation and removal features.

7.2.1.1.9.8 Response Time Tests

These tests are performed according to Technical Specification requirements.

The capability exists to independently test the shunt and UV trip coils in-place and to obtain a response time for the reactor trip breakers (during periodic PPS channel testing) via the plant computer/sequence of events recorder. A spring-return-to-center switch is used to bypass the shunt trip in the "shunt bypass" position for testing the UV trip. Conversely, the undervoltage trip is bypassed in the "UV bypass" position for testing the shunt trip.

7.2.1.1.10 Vital Instrument Power Supply

The vital instrument power supply for the RPS is described in Section 8.3.1.1.6.

7.2.1.2 Design Bases

The RPS is designed to ensure adequate protection of the fuel, fuel cladding and RCS boundary during anticipated operational occurrences. In addition, the system is designed to assist the Engineered Safety Features (ESF) system in limiting the consequences of postulated accidents.

The system is designed on the following bases to assure adequate performance of its protective function.

A. The system is designed in compliance with the applicable criteria, "General Design Criteria for Nuclear Power Plants," (Appendix A of 10CFR50, July 15, 1971).

B. Instrumentation, function and operation of the system conforms to the requirements of IEEE 279-1971, "Criteria for Protective Systems for Nuclear Power Plants."

C. System testing conforms to the requirements of IEEE 338-1971, "Trial Use Criteria for Periodic Testing of Nuclear Power Generating Station Protection Systems" and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions."

D. The system is designed to determine the following plant conditions in order to provide adequate protection during anticipated operational occurrences (see Table 7.2-4 for more details):

   1. Core power high;
   2. RCS pressure* high/low;
   3. Low DNBR in the limiting coolant channel in the core;
   4. High local power density in the limiting fuel rod in the core; and,
   5. Steam generator water level low.

   *Further RCS over-pressurization protection is provided by the DSS (Section 7.7.1.6).

E. The system is designed to determine the following generating station conditions in order to provide protective action assistance to the ESF system during accidents (see Table 7.2-4 for more details):

   1. Core power high;
   2. RCS pressure high/low;
   3. Steam generator pressure low; and,
   4. Containment pressure high.

F. The system is designed to monitor all variables required to ensure adequate determination of the conditions given in "D" and "E" above, over the entire range of normal operation and transient conditions. The full power nominal values and the maximum and minimum values that can be sensed for each monitored plant variable are given in Table 7.2-2.

   The type, number and location of the sensors provided to monitor these variables are given in Table 7.2-3. There is no spatial dependence resulting from the location of sensors.

G. The system is designed to alert the operator when any monitored plant condition is approaching a condition that would initiate protective action.

H. The system is designed so that protective action will not be initiated due to normal operation of the generating station.

Nominal full power values of monitored conditions and their corresponding allowable protective action (trip) setpoints are given in Table 7.2-4.

The selection of these trip setpoints is such that adequate protection is provided when all sensor and processing time delays and inaccuracies are taken into account.

The required ranges for instruments used in reactor protection, ESF, and other safety-related systems are a function of the most limiting values of the instrumented variables attainable during conditions where the instrumentation is required. These limiting values are obtained through analyses of normal plant operation, anticipated operational occurrences, and postulated accidents. In these analyses, possible degraded conditions of operable equipment are considered where these affect parameter ranges. The instrumentation ranges determined as described above are adequate to accommodate all conditions for which the reactor protection, ESF and other safety-related systems are intended to operate.

In determining setpoints for these safety-related systems, analyses of postulated events are performed to determine values for the process parameters where safety system actuation is required in order to prevent the violation of one or more safety limits. These values are then biased by a factor which includes allowances for measurement errors and uncertainties and drift. The biased values are used as setpoints in the safety systems.

Channel drift is accommodated both by Technical Specification surveillance requirements and by incorporated drift allowances in the biases applied to the safety system setpoints. The plant Technical Specifications include requirements for a periodic complete channel calibration. The setpoint bias includes an allowance for sensor drift for the calibration interval. In addition, a channel functional test is required by the Technical Specifications. This test includes the injection of a simulated process signal into each safety channel to verify the channel setpoint. Therefore, the setpoint bias includes an allowance for channel drift (excluding the sensors) over this time interval. The sensor and channel drift allowances are obtained by test and/or analysis. The Technical Specifications also require interchannel comparisons of sensor readings. This provides assurance that the drift allowances used are not exceeded during plant operation.

Since safety channel non-linearities are considered in formulating the setpoint biases, no additional criteria are required to determine what portion of the range of an instrument may be used for automatic initiation of a protective function. However, it is Combustion Engineering practice to avoid the use of the extreme upper and lower ends of an instrument range, where practicable.

I. All system components are qualified for the environmental conditions addressed in Section 3.11. In addition, the system is capable of performing its intended function under the most degraded conditions of the energy supply, as addressed in Chapter 8.

J. The system is designed with four independent and redundant channels. The benefit of a system that includes four independent and redundant channels is that the system can be operated, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criteria. The only operating restriction while in this condition (effectively 1-out-of-2 logic) is that no provision is made to bypass another channel for periodic testing or maintenance. The system logic must be restored to at least a 2-out-of-3 condition prior to removing another channel for maintenance.

K. The RPS is powered by four independent 120 VAC vital power sources. RPS channel trips are generated by loss of vital AC to the CPC. With power maintained to the bistable power supplies, de-energization of the process loops using increasing signal setpoints results in inability of the channel to perform its safety function. De-energization of the power to channel A or D bistable power supplies results in a channel trip. For the DC bus failure scenario resulting in loss of the vital AC channel pairs, (1 and 3 for 2D01 de-energization) or (2 and 4 for 2D02 de-energization), RPS trips are generated by CPC channels (A and C) or channels (B and D). RPS trip also results from de-energization of trip paths (1 and 3) or (2 and 4). The RPS trip path logic is (TP1 or TP2) and (TP3 or TP4).

7.2.2 ANALYSIS

7.2.2.1 Introduction

The RPS is designed to provide the following protective functions:

A. Initiate automatic protective action to ensure that acceptable RCS and fuel design limits are not exceeded during anticipated operational occurrences, and

B. Initiate automatic protective action during accident conditions to aid the ESF systems in limiting the consequences of the accidents.

7.2.2.1.1 Anticipated Operational Occurrences

The anticipated operational occurrences that are accommodated by the system are those conditions of normal operation which are expected to occur one or more times during the life of the plant. In particular, the occurrences considered include single operator errors or single component or control system failures resulting in transients which could lead to a violation of acceptable plant and fuel design limits if protective action were not initiated.

The fuel design and Reactor Coolant Pressure Boundary (RCPB) limits used to define the RPS design are:

A. The DNBR in the limiting coolant channel in the core, will not be less than the DNBR SAFDL.

B. The peak local power density, in the limiting fuel pin in the core, shall not be greater than the kW/ft safety limit corresponding to the onset of centerline fuel melting; and,

C. The RCS pressure shall not exceed those values permitted by the ASME Code, Section III. In addition, the DSS (Section 7.7.1.6) provides further protection from RCS over-pressurization.

The anticipated operational occurrences that were used to determine the system design requirements are:

A. Insertion or withdrawal of CEA groups, including:

   1. Uncontrolled sequential withdrawal of CEA groups;

   2. Out-of-sequence insertion or withdrawal of CEA groups; and,

   3. Excessive insertion of CEA groups.

B. Insertion or withdrawal of CEA subgroups including:

   1. Uncontrolled insertion or withdrawal of a CEA subgroup;

   2. Dropping of a single CEA subgroup; and,

   3. Static misalignment of CEA subgroups comprising a designated CEA group.

C. Insertion or withdrawal of a single CEA, including:

   1. Uncontrolled insertion or withdrawal of a single CEA;

   2. Dropped CEA;

   3. A single CEA sticking with the remainder of the CEAs in that group moving; and,

   4. A statically misaligned CEA.

D. Excessive dilution of the soluble boron concentration, when CEAs are withdrawn;

E. Excessive load demands;

F. Change of forced reactor coolant flow, excluding RCP shaft shear or seizure;

G. Inadvertent pressurization or depressurization of RCS, excluding a loss of coolant;

H. Change of normal heat transfer capability between steam and the RCSs, including improper feedwater flow and loss of load; and,

I. Loss of off-site power.

Prior to Cycle 12, ANO-2 had 8 part-length CEAs. These CEAs were replaced with full length CEAs. Insertion and withdrawal of these part-length CEAs were considered in determining the requirements of the system design.

7.2.2.1.2 <u>Accidents</u>

The accident conditions for which the system will take action are those unplanned events under any conditions that are expected to occur once during the life of several stations, and arbitrary combinations of unplanned events and degraded systems that are never expected to occur.

The consequences of most of these accidents will be limited by the ESF system; the RPS will function to assist in limiting these conditions for those accidents but does not have the major role in assuring that the plant is maintained within applicable limits. The accident conditions for which the RPS will provide protective action assistance are:

A. LOCA, including double-ended rupture of the largest pipe in the RCS;

B. Ejection of any single CEA;

C. Steam system pipe rupture, including a double-ended rupture;

D. Steam generator tube rupture; and,

E. RCP shaft seizure.

7.2.2.2 Trip Bases

The RPS consists of 13 trips in each RPS channel. This includes two trips (one per steam generator) for each of the three steam generator parameters. Each trip will initiate the required automatic protective action utilizing 2-out-of-4 coincidence.

A brief description of the inputs and purpose of each trip is presented in Sections 7.2.2.2.1 through 7.2.2.2.10.

7.2.2.2.1 High Linear Power Level Trip

Input: Neutron flux power from the ex-core neutron flux monitoring system.

Purpose: To provide a reactor trip and assist the ESF system in the event of an ejected CEA accident, and to limit the maximum steady state power level in addition to the DNBR and high local power density trips.

7.2.2.2.2 High Logarithmic Power Level Trip

Input: Neutron flux power from the ex-core neutron flux monitoring system.

Purpose: To ensure the integrity of the fuel cladding and RCPB in the event of unplanned criticality from a shutdown condition, resulting from either dilution of the soluble boron concentration or withdrawal of CEAs. Automatic action will be initiated if CEAs are withdrawn. An alarm is provided to alert the operator to take appropriate action in the event of an unplanned criticality when all CEAs are inserted.

7.2.2.2.3 High Local Power Density Trip

Input:

A. Neutron flux power and axial power distribution from the ex-core neutron flux monitoring system.

B. Radial peaking factors from the CEA position measurement system (reed switch assemblies).

C. ΔT power from coolant temperature and flow measurements.

Purpose: To prevent the linear heat (kW/ft) in the limiting fuel rod in the core from exceeding the fuel design limit in the event of any anticipated operational occurrence.

7.2.2.2.4 Low DNBR Trip

Input:

A. Neutron flux power and axial power distribution from the ex-core neutron flux monitoring system.

B. RCS pressure from pressurizer pressure measurement.

C. ΔT power from coolant temperatures and flow measurements.

D. Radial peaking factors from the CEA position measurement system (reed switch assemblies).

E. Reactor coolant mass flow from RCP speed.

F. Core inlet temperature from reactor coolant cold leg temperature measurements.

Purpose: To prevent the DNBR in the limiting coolant channel in the core from exceeding the fuel design limit in the event of any anticipated operational occurrence. In addition, this reactor trip will assist the ESF system in limiting the consequences of the accident conditions listed in Section 7.2.2.1.2.

7.2.2.2.5 High Pressurizer Pressure Trip

Input: Reactor coolant pressure from pressurizer pressure measurement.

Purpose: To help ensure the integrity of the RCS boundary for any event which could lead to an overpressurization of the RCS. Also, reference Section 7.7.1.6 for DSS protection of RCS over-pressurization.

7.2.2.2.6 Low Pressurizer Pressure Trip

Input: Reactor coolant pressure from pressurizer pressure measurement.

Purpose: To provide a reactor trip in the event of reduction in system pressure, in addition to the DNBR trip, and to provide a reactor trip to assist the ESF system in the event of a LOCA.

7.2.2.2.7 Low Steam Generator Water Level Trips

Input: Level of feedwater in each steam generator from differential pressure measurements.

Purpose: To provide protective action to ensure that there is sufficient time for actuating the emergency feedwater pumps to remove decay heat from the reactor in the event of a reduction of feedwater flow.

7.2.2.2.8 Low Steam Generator Pressure Trips

Input: Steam pressure in each steam generator.

Purpose: To provide a reactor trip to assist the ESF system in the event of a steam line rupture accident.

7.2.2.2.9 High Containment Pressure Trip

Input: Pressure inside reactor containment.

Purpose: To assist the ESF system by tripping the reactor in the event of a steam line rupture accident inside containment, coincident with the initiation of safety injection.

7.2.2.2.10 High Steam Generator Level

Input: Level of water in each steam generator from differential pressure measurements.

Purpose: To prevent excessive moisture carryover from the steam generators which could result in damage to the turbine generator. This trip is not required to fulfill the protective functions given in Section 7.2.2.1.

7.2.2.3 Design

7.2.2.3.1 General Design Criteria

Appendix A of 10CFR50, "General Design Criteria for Nuclear Power Plants," establishes minimum requirements for the principal design criteria for water-cooled nuclear power plants. This section describes how the requirements that are applicable to the RPS are satisfied.

Criterion 1: Quality Standards and Records

The quality assurance program for the plant is described in the Quality Assurance Program Manual. These procedures ensure that the system has been designed in accordance with required codes and standards.

Criterion 2: Design Bases for Protection Against Natural Phenomena

This criterion applies to earthquakes, tornadoes, floods, etc. The design bases for protection against earthquakes are described in Section 3.10. The RPS is protected from tornadoes and floods by being housed in Category I structures (see Sections 3.3 and 3.4).

Criterion 3: Fire Protection

See Section 3.1.

Criterion 4: Environmental and Missile Design Bases

Environmental design bases are described in Section 3.11. Missile design bases are described in Section 3.5.

Criterion 5: Sharing of Structures, Systems and Components

No RPS components are shared with any other reactor facilities.

Criterion 10: Reactor Design

The RPS, in conjunction with the plant control systems and Technical Specification requirements, provides sufficient margin to trip setpoints so that: (1) during normal operation protective action will not be initiated, and (2) during anticipated operational occurrences fuel design limits will not be exceeded. Typical margins for each trip parameter are shown in Table 7.2-4.

Criterion 12: Suppression of Reactor Power Oscillations

The axial power distribution is continually monitored by the RPS and factored into the Low DNBR and high local power density trips. This ensures that acceptable fuel design limits are not exceeded in the event of axial power oscillations. Allowances are made in the trip setpoints for azimuthal power tilts.

Criterion 13: Instrumentation and Control

Sensor ranges are sufficient to monitor all pertinent plant variables over the expected range of plant operation for normal and transient conditions. All variables that affect plant and fuel design limits are monitored by the RPS. The safety-related information readout for plant monitoring is described in Section 7.5.

Criterion 15: Reactor Coolant System Design

The high pressurizer pressure trip and high logarithmic power level trip are provided to help ensure the integrity of the RCPB. In addition, the DSS (Section 7.7.1.6) will ensure the integrity of the RCPB.

Criterion 20: Protection System Functions

The RPS monitors all plant variables that affect plant and fuel design limits. These limits are given in Section 7.2.2.1.1. A reactor trip will be initiated to prevent these limits from being exceeded for all the anticipated operational occurrences listed in Section 7.2.2.1.1.

Criterion 21: Protection System Reliability and Testability

Functional reliability is ensured by compliance with the requirements of IEEE 279-1971, as described in Section 7.2.2.3.2. Testing is in compliance with IEEE 338 and Regulatory Guide 1.22, and is described in Section 7.2.2.3.3.

Criterion 22: Protection System Independence

See Section 3.1.

Criterion 23: Protection System Failure Modes

The RPS is designed to fail into a safe state in the event of loss of power supply, disconnection of the system, or module removal, as noted in Section 7.2.2.3.2. Where protective action is required under adverse environmental conditions during postulated accidents, the components of the system are designed to function under such conditions.

Criterion 24: Separation of Protection and Control Systems

The protection system is separated from the control systems.

Criterion 25: Protection System Requirements for Reactivity Control Malfunctions

Open circuit of the signal leads has the same effect as a loss of signal.

The RPS is designed to ensure that acceptable fuel design and RCPB limits are not exceeded for the reactivity control malfunctions stated in Section 7.2.2.1.1.

Criterion 29: Protection Against Anticipated Operational Occurrences

The RPS is designed to ensure a very high probability of accomplishing the protective functions given in Section 7.2.2.1. Further RCS over-pressurization protection is provided by the DSS (Section 7.7.1.6).

7.2.2.3.2 Equipment Design Criteria

IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes minimum requirements for safety-related functional performance and reliability of the RPS.

This section describes how these requirements listed in Section 4 of IEEE 279-1971 are satisfied.

"4.1 General Functional Requirement"

The RPS is designed to limit reactor fuel, fuel cladding and coolant conditions to levels within plant and fuel design limits. Instrument performance characteristics, response time, and accuracy are selected for compatibility with and adequacy for the particular function. Trip setpoints are established by analysis of the system parameters. Factors such as instrument inaccuracies, bistable trip times, CEA travel times, valve travel time, circuit breaker trip times, and pump starting times are considered in the design of the system.

"4.2 Single Failure Criterion"

The RPS is designed so that any single failure within the system will not prevent proper protective action at the system level. The wiring in the system is grouped so that no single fault or failure, including either an open or shorted circuit, will negate protective system operation. Signal conductors are protected and routed independently.

The following is an evaluation of the effects of specific single faults in the analog portion of the system:

A. A loss of signal in a measurement channel initiates channel trip action for the low pressurizer pressure, low steam generator water level and low steam generator pressure trips;

B. Shorting of the signal leads to each other has the same effect as a loss of signal. Shorting a lead to a voltage has no effect since the signal circuit is ungrounded;

C. Single grounds of the signal circuit have no effect. Periodic checking of the system will provide assurance that the circuit remains ungrounded.

The following is an evaluation of the effects of specific single faults in the logic portion of the system:

A. Inadvertent operation of the relays and relay contacts in the matrices will be identified by plant annunciation and indicating lights;

B. Shorting of the pairs of contacts in the matrices will prevent the matrix relay sets from being released. Such shorts are detectable in the testing process by observing that the matrix relays cannot be dropped out. Testing is accomplished by successive opening of the logic matrix contact pairs;

C. Shorting of the matrices to an external voltage has no effect since the matrix is ungrounded. Equipment is provided to detect grounds on the matrices;

D. The logic matrices will each be supplied by two power sources. Loss of a single power source has no effect on operation. Loss of both power sources to a logic matrix initiates a reactor trip;

E. Failure of a matrix relay to de-energize has no effect since there are six matrix relay contacts in series in the trip path and any one contact initiating trip action will cause the action to be completed;

F. The failure of one trip breaker or control circuit has no effect since there are two trip breakers with independent control circuits in series, either of which will provide the necessary action;

G. Single grounds or accidental application of potential to single leads in the trip path circuits have no effect since the circuit is ungrounded. Testing and observation of ground detectors will indicate these problems; and,

H. The CEDM power supply circuits operate ungrounded so that single grounds have no effect. The CEDMs are supplied in two groups by separate pairs of power supplies to further reduce the possibility of a CEA being improperly held. The CEDM load requirements are such that the application of any other local available supply would not prevent CEA release.

"4.3 Quality Control of Components and Modules"

The quality assurance program is covered in the Quality Assurance Program Manual (QAPM). This program includes appropriate requirements for design review, procurement, inspection and testing to ensure that the system components shall be of a quality consistent with minimum maintenance requirements and low failure rates.

"4.4 Equipment Qualification"

The RPS meets the equipment requirements described in Sections 3.10 and 3.11.

"4.5 Channel Integrity"

Type testing of components, separation of sensors and channels, and qualification of cabling are utilized to ensure that the channels will maintain the functional capability required under applicable extremes of conditions relating to environment, energy supply, malfunctions and accidents.

Loss of or damage to any one path will not prevent the protective action. Sensors are piped so that blockage or failure of any one connection does not prevent protective system action. The process transducers located in the containment building are specified and rated for the intended service. Components which must operate during or after the LOCA are rated for the post-LOCA environment. Results of type tests are used to verify these ratings. In the control room the nuclear instrumentation and protective system trip paths are located in four compartments. Mechanical and thermal barriers between these compartments reduce the possibility of common event failure. Outputs from the components in this area to the control boards are isolated so that shorting, grounding, or the application of the highest available local voltage does not cause channel malfunction. Where signals originating in the RPS feed the computer, signal isolation is provided; where the RPS is feeding annunciators, isolation is ensured through the use of relay contacts.

"4.6 Channel Independence"

The locations of the sensors and the points at which the sensing lines are connected to the process loop have been selected to provide physical separation of the channels, thereby precluding a situation in which a single event could remove or negate a protective function. The routing of cables from protective system transmitters is arranged so that the cables are separated from each other and from power cabling to minimize the likelihood of common event failures. This includes separation at the containment penetration areas. In the control room, the four nuclear instrumentation and protective system trip channels are located in individual compartments. Mechanical and thermal barriers between these compartments minimize the possibility of common event failure. Outputs from the components in this area to the control boards are isolated so that shorting, grounding, or the application of the highest available local voltage do not cause channel malfunction.

The criteria for separation and physical independence of channels are based on the need for decoupling the effects of accident consequences and energy supply transients and for reducing the likelihood of channel interaction during testing or in the event of a channel malfunction.

The electrical power sources to the RPS and ESFAS sensors and signal process modules are described in Section 8.3.1.1.6.

A description of the method by which separation is maintained between redundant sensor signals throughout the system is described in Section 8.3.1.2, "Regulatory Guide 1.75 Compliance Analysis," and in Section 8.3.1.4, "Independence of Redundant Systems."

As stated in Section 8.3.1.4.6 (E) and (F), sensor signal cables are run in separate trays from other circuits such as power and control throughout the system.

Historical data removed - To review the exact wording please refer to Section 7.2.2.3.2 of the FSAR.

"4.7 Control and Protection System Interaction"

No portion of the RPS is used for both control and protection functions.

"4.8 Derivation of System Inputs"

This criterion requires that insofar as is practicable, system inputs are derived from signals that are direct measures of the desired variables. Variables which are measured directly include neutron flux, temperatures and pressures. Level information is derived from appropriate differential pressure measurements. Flow information is derived from RCP speed measurement.

"4.9 Capability for Sensor Checks"

RPS sensors are checked by cross-checking between channels. These channels bear a known relationship to each other, and this method ensures the operability of each sensor during reactor operation.

"4.10 Capability for Test and Calibration"

Testing is described in Section 7.2.1.1.9 and is in compliance with IEEE 338-1971 as discussed in Section 7.2.2.3.3.

"4.11 Channel Bypass or Removal from Operation"

Any one of the four protective system channels may be tested, calibrated, or repaired without detrimental effects on the system. Individual trip channels may be bypassed to effect a 2-out-of-3 logic on remaining channels. The single failure criterion is met during this condition.

Testing of each of the two CEA position input channels can be accomplished in a very brief time period. Probability of failure of the other system is acceptably low during such testing periods.

"4.12 Operating Bypasses"

Operating bypasses are provided as shown in Table 7.2-1. The operating bypasses are automatically removed when the permissive conditions are not met. The circuitry and devices which function to remove these inhibits are designed in accordance with IEEE 279-1971.

"4.13 Indication of Bypasses"

Indication of test or bypass conditions or removal of any channel from service is given by lights and annunciation. Bypasses that are automatically removed at fixed setpoints are alarmed and indicated.

"4.14 Access to Means for Bypassing"

An interlock prevents the plant operator from bypassing more than one of the four channels of any type trip at any one time. All bypasses are visually and audibly annunciated.

"4.15 Multiple Setpoints"

Manual reduction of setpoints for low pressurizer pressure and low steam generator pressure trip allows for the controlled reduction of pressurizer pressure and steam generator pressure during plant cooldown and depressurization, and are discussed in Sections 7.2.1.1.1.6 and 7.2.1.1.1.8. The setpoint reductions are initiated by control board mounted switches which, upon actuation, adjust the setpoint to a value which is a pre-selected distance below the operating pressure existing at the time the switch is actuated. A separate switch is provided for each protection channel.

This method of setpoint reduction provides positive assurance that the setpoint is never decreased below the existing pressure by more than a predetermined amount.

The setpoint is automatically increased by the Plant Protection System (PPS) as the measured pressure is increased.

"4.16 Completion of Protective Action Once It Is Initiated"

The system is designed to ensure that protective action (reactor trip) will go to completion once initiated. Operator action is required to clear the trip and return to operation.

"4.17 Manual Initiation"

A manual trip is effected by depressing either of two sets of trip switches. No single failure will prevent a manual trip.

"4.18 Access to Setpoint Adjustments, Calibration and Test Points"

An administratively controlled key is required for access to setpoint adjustments, calibration and test points. Access is also visually and audibly annunciated.

"4.19 Identification of Protective Action"

Indicating lights are provided for all protective actions, including identification of channel trips.

<u>"4.20 Information Readout"</u>

Means are provided to allow the operator to monitor all trip system inputs, outputs and calculations. The specific displays that are provided for continuous monitoring are described in Section 7.5. System status displays are provided.

<u>"4.21 System Repair"</u>

Identification of a defective channel will be accomplished by observation of system status lights or by testing as described in Section 7.2.1.1.9. Replacement or repair of components is accomplished with the affected channel bypassed. The affected trip function then operates in a 2-out-of-3 trip logic.

<u>"4.22 Identification"</u>

All equipment, including panels, modules, and cables associated with the trip system, will be marked in order to facilitate identification. Interconnecting cables will be color coded on a channel basis.

7.2.2.3.3 <u>Testing Criteria</u>

IEEE 338-1971, "Trial Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems," September 1971, and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions," provide guidance for development of procedures, equipment, and documentation of periodic testing. The basis for and the scope and means of testing are described in this section. Test intervals and their bases are included in the Technical Specifications. The organization for testing and for documentation is described in Chapter 13.

Since operation of the RPS will be infrequent, the system is periodically and routinely tested to verify its operability. A complete channel can be individually tested without initiating a reactor trip, without violating the single failure criterion, and without inhibiting the operation of the system. The system can be checked from the sensor signal through the power supply circuit breakers of the CEDMs. The RPS functional modules can be tested during reactor operation. The sensor can by checked by comparison with similar channels or channels that involve related information. Minimum frequencies for checks, calibration, and testing of the instrumentation are given in the Technical Specifications. Overlap in the checking and testing is provided to assure that the entire channel is functional. The use of individual trip and ground detection lights, in conjunction with those provided at the supply bus, provides assurance that possible grounds or shorts to another source of voltage will be detected.

The testing scheme is presented in detail in Section 7.2.1.1.9.

The response time from an input signal to the protection system trip bistables through the opening of the trip circuit breakers is verified by measurement during plant startup testing and periodically thereafter. Sensor responses are measured during factory acceptance tests and will be periodically re-measured to assure their continued adequate response.

7.2.2.4 Failure Modes and Effects Analysis

A failure modes and effects analysis for the RPS is provided in Table 7.2-5. It should be noted that this analysis was performed assuming three operable PPS channels with one channel in the bypass condition. It is intended to operate Arkansas Nuclear, One Unit 2 with all four channels operable under normal conditions. The analysis of Table 7.2-5 demonstrates for the more limiting case of three channels operable that the design criteria for the PPS are met.

7.3 ENGINEERED SAFETY FEATURES SYSTEMS

The safety-related instrumentation and controls of the Engineered Safety Features (ESF) systems include: (1) the Engineered Safety Features Actuation System (ESFAS) which consists of the electrical and mechanical devices and circuitry (from sensors to actuation device input terminals) involved in generating those signals that actuate the required ESF system, and (2) the arrangement of components that perform protective actions after receiving a signal from either the ESFAS or the operator.

The ESFAS includes sensors to monitor selected generating station variables. Table 7.3-5 presents instrument ranges, nominal setpoints and margins to actuation for ESFAS sensors and for other safety-related system instrumentation. A comparison of the instrument ranges and actuation setpoints in this table indicates that, with two exceptions, none of the instrument setpoints will ever be within the upper or lower 10 percent of their range.

One exception is the variable low steam generator pressure setpoint. The variable feature of the low steam generator pressure setpoint is used during plant cooldowns to the cold shutdown condition to allow controlled steam generator pressure reductions during cooldown without initiating a Main Steam Isolation Signal (MSIS). During cooldowns, the setpoint is periodically manually reset to a pressure 200 psi below the existing generator pressure to provide continuing MSIS capability during the cooldown period. Accordingly, the trip setpoint can be reduced below 120 psia (the lower 10 percent of the instrument range) during the last portion of the plant cooldown evolution. The instrument error associated with this measurement channel has been included in the determination of the setpoint. This instrument error is valid over the entire range of operation of the steam generator pressure instrument.

The second exception is the Refueling Water Tank (RWT) low level signal which initiates the Recirculation Actuation Signal (RAS). The nominal setpoint is shown in Table 7.3-5. Instrument error is valid over the entire scale and has been included in determination of the setpoint. Since the RWT has a vortex breaker installed over the outlet line, no loss of suction due to entrainment of air is possible before the tank is empty.

The following actuation signals are generated by the ESFAS when the monitored variables reach the levels that are indicative of conditions which require signal initiation:

A. Containment Isolation Actuation Signal (CIAS)
B. Containment Spray Actuation Signal (CSAS)
C. Containment Cooling Actuation Signal (CCAS)
D. Main Steam Isolation Signal (MSIS)
E. Safety Injection Actuation Signal (SIAS)
F. Recirculation Actuation Signal (RAS)
G. Emergency Feedwater Actuation Signal (EFAS)

The ESF system actuation device circuitry receives (1) actuation signals from the ESFAS or the operator, and (2) permissive signals based on conditions that affect ESF component performance. The signals from the ESFAS actuate the ESF system equipment. The permissive signals provide additional interlocks, blocks and sequencing necessary to provide proper ESF component operation, such as control switch not in “pull to lock”, adequate bus voltage, MOV logic, and the EDG load sequencing logic.

The ESF systems automatically actuated by signals from the ESFAS are:

A. Containment Isolation System (CIS)
B. Containment Spray System (CSS)
C. Containment Cooling System (CCS)
D. Safety Injection System (SIS)
E. Penetration Room Ventilation System (PRVS)
F. Main Steam Isolation System (MSIS)
G. Emergency Feedwater (EFW) System

7.3.1 DESCRIPTION

ESFAS actuation circuits for all systems are described below in one section as these circuits, except for specific inputs, bypasses, and actuated devices, are identical. The specific instruments and controls associated with each system are discussed separately in Section 7.3.1.1.11.

7.3.1.1 Engineered Safety Features Actuation System

The actuation system consists of the sensors, logic and actuation circuits which monitor selected plant parameters and provide an actuation signal to each individual actuated component in the ESF system if these plant parameters reach pre-selected setpoints. The actuation system for each ESF system is identical, except that specific inputs (and bypasses where provided) vary from system to system and the actuated devices are different.

Two-out-of-four coincidence of like initiating trip signals from four independent measurement channels is required to actuate any ESF system. Each actuation system's initiation circuits and logic, including testing features, is similar to the logic for the Reactor Protective System (RPS), and is contained in the same physical enclosure, except for the EFAS which also contains initiation logic from the DEFAS housed in the DEFAS Cabinet. The combination of the ESFAS and RPS is termed the Plant Protection System (PPS).

These same features include the capability of the ESFAS to operate, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criteria. The only operating restriction while in this condition (effectively one-out-of-two logic) is that no provision is made to bypass another channel for periodic maintenance. The system logic must be restored to at least a two-out-of-three condition prior to removing another channel for maintenance.

A discussion of the ESF systems' seismic and environmental qualification is found in Sections 3.10.2 and 3.11.2, respectively.

A discussion of the ESF system testability is found in Section 7.3.1.1.9.

The ESFAS functional logic is shown in Figures 7.3-1a, b, and c and consists of bistables, bistable output relays, matrix relays, initiation channel output relays, manual testing controls, indicating lights, power supplies, and interconnecting wiring. In addition, the EFAS actuation logic contains diverse and independent actuation logic from the DEFAS (reference Section 7.7.1.7 for the DEFAS).

7.3.1.1.1 Measurement Channels

Process measurement channels similar to those described in Section 7.2.1.1.2.1 are utilized to perform the following functions:

A. Continuously monitor each selected generating station variable.

B. Provide indication of operational availability of each sensor to the operator.

C. Transmit analog signals to bistables within the ESFAS measurement channel.

D. Compare the analog signals with protective preset levels in the bistables.

E. Provide a variable setpoint where necessary for plant startup, shutdown, and low power testing.

F. Provide wired logic for EFAS determination to either feed or block EFW based on secondary steam generator pressure and steam generator water level.

All protective parameters are measured with four independent process instrument channels.

A typical protective measurement channel is shown on Figure 7.2-1. The measurement channels consist of instrument sensing lines, sensors, transmitters, power supplies, isolation devices, indicators, computer inputs, current loop resistors, interconnecting wiring, operating bypasses, bistable relays, and bistable relay contacts (excluding interconnecting wiring).

Each measurement channel is separated from other like measurement channels to provide physical and electrical isolation of the signals to the ESFAS logic. The output of each transmitter is typically an ungrounded current loop which has a live zero. Signal isolation is provided for computer inputs and control board indicators.

Display information, which provides the operator with the operational availability of each measurement channel, is described in Section 7.5.

Signals from the protective measurement channels are sent to voltage comparator circuits (bistables) where the input signals are compared to predetermined setpoints. Whenever a channel parameter reaches the predetermined setpoint, the channel bistable de-energizes the bistable output relays. As established by the matrices, contacts of the bistable output relays form the ESFAS 2-out-of-4 coincidence logic. The bistable setpoints are adjustable from the front of the PPS cabinet. Access is limited, however, by means of a key operated cover, with an annunciator indicating cabinet access. All bistable setpoints are indicated on a meter on the PPS cabinet.

The ESFAS initiation signals are each generated in four channels, designated A, B, C, and D. Two-out-of-four coincidence of like initiating signals from four protective measurement channels generates all ESFAS initiation signals.

Tripping of a bistable results in a measurement channel trip characterized by the de-energization of three trip relays. De-energization of any two of the four like bistables results in de-energization of two sets of three trip relays.

7.3.1.1.2 Logic

7.3.1.1.2.1 Matrix Logic

The Matrix logic performs the following:

A. Forms 2-out-of-4 coincidence of like signals which have reached preset levels.

B. Provides a means for manual bypassing of signals if permissive conditions are met.

C. Provides channel and signal status information to the operator.

The contacts of the four sets of three trip relays have been arranged in six logic ANDs designated AB, AC, AD, BC, BD, and CD, which represent all possible 2-out-of-4 combinations for the four measurement channels. To form and AND circuit, the trip relay contacts of two like protective measurement channels are connected in parallel, i.e. one from A and one from B. This process is continued until all combinations have been formed. In cases where more than one plant parameter can initiate an ESF trip signal, the parallel pairs of trip relay contacts, each pair representing a monitored plant parameter, are connected in series (Logic OR) to form six logic matrices. The six matrices are also designated AB, AC, AD, BC, BD, and CD.

Each logic matrix is connected in series with a set of four parallel logic matrix output relays (matrix relays). Each logic matrix is powered from dual DC power supplies. Section 7.3 describes the power distribution system.

7.3.1.1.2.2 Initiation Logic

The initiating logic performs the following:

A. Combines the six matrix output logic into four trip paths.

B. Provides four ESFAS initiation signals to the ESFAS initiation logic located in two independent auxiliary relay cabinets (ARCs).

The ESFAS initiating logic is physically located in the PPS cabinet. The output contacts of the matrix relays are combined into four trip paths, one trip path per channel.

Each ESFAS trip path is formed by connecting six contacts, one matrix relay contact from each of the six logic matrices, in series. The six series contacts are in series with the trip path initiation relays (SSRA and SSRB) and a lockout relay. The lockout relay ensures that the trip path initiation relay remains de-energized upon initiation. The EFAS trip paths do not have the lockout feature. The trip path initiation relay contacts form the ESFAS actuating logic.

7.3.1.1.2.3 Actuating Logic

The ESFAS actuating logic performs the following:

A. Receives ESFAS signals from the ESFAS initiating logic (additionally, the EFAS actuating logic receives DEFAS initiating signals):

B. Forms selective 2-out-of-4 coincidence of like ESFAS trip paths;

C. Provides a means for manual initiation; and,

D. Provides status information to the operator.

The ESFAS actuating logic is physically located in two ESFAS auxiliary relay cabinets. One cabinet contains the logic for ESF Load Group I equipment, while the other cabinet contains the logic for ESF Load Group II equipment. In addition, the EFAS actuation logic contains DEFAS initiation signal contacts arranged in a 2-out-of-2 logic as described in Section 7.7.1.7.

Four ESFAS initiation signal contacts are arranged in a selective 2-out-of-4 coincidence logic. Each signal except the Emergency Feedwater Actuation Signal (EFAS) (see Section 7.3.1.1.11.8.) also de-energizes the lock-out relays of its associated channel. The lock-out relays ensure that the signal is not automatically removed once initiated, with the exception of the EFAS. Receipt of two selective ESFAS initiation channel signals will de-energize the ESF subgroup relays, which generate the actuation channel signals. This process is done independently in both auxiliary relay cabinets, generating both Load Group I and II signals.

Section 7.3.1.1.2.4 describes the power distribution.

In a typical ESFAS logic, there are only two initiating circuits per channel (Steam Generator 1 and Steam Generator 2), and thus each matrix ladder consists of only two AND circuits in series which form the steam generator low auctioneering circuit. The four matrix relay outputs from each logic matrix again form four trip paths. Each trip path initiation relay, instead of controlling trip circuit breakers as in the RPS, controls a contact of the selective 2-out-of-4 circuit for the group actuation. Group actuation is described in Section 7.3.1.1.3.

Testing of each ESF subgroup of components is accomplished by use of a test module. Groups are selected such that testing may be accomplished without affecting normal plant operation.

The testing of the logic and trip paths is described in Section 7.3.1.1.9.

7.3.1.1.2.4 Power Supply Logic

The power supply logic:

A. Maintains system level functions with single channel 120 VAC vital instrument power failures.

B. Maintains system level functions with a specific power train single failure, de-energization of vital 120 VAC channel pairs (1 and 3) or (2 and 4). This power train de-energization results from failure of a 125 VDC bus causing de-energization of power sources to the two associated uninterruptible power sources.

MEASUREMENT CHANNEL POWER SUPPLIES

Single channel power sources are used in measurement channels A and D including both process and bistable power. Single channel power assures all functions trip with de-energization of the single channel power source.

With the exception of channels B and C RWT level, the process instrument channels have single channel power sources for the process input to the bistables and auctioneered power supplies for the bistables. RWT level channels B and C have power supplies auctioneered between load groups.

The following summarizes the measurement channel response.

De-energization of Vital AC Channels 1 and 3

Function	Parameter		Measurement Channel** 1	2	3	4	ESFAS Coincidence Logic: Channel Bypassed*	ESFAS Coincidence Logic: No Channel Bypassed
SIAS	Containment Pressure	↑	T	O	F	O	1-out-of-1 logic	1-out-of-2 logic
SIAS	RCS Pressure	↓	T	O	T	O	A and C Trips	A and C Trips
CSAS	Containment Pressure	↑	T	O	F	O	1-out-of-1 logic	1-out-of-2 logic

* Channel bypassed on operable power group.
** T = failed to safe state, F = unable to perform function (unable to trip or measure) and O = operable

MATRIX CHANNEL POWER SUPPLIES

Each ESFAS matrix ladder is powered by two matrix power supplies, one from each load group. Load group one powers the matrix output relay pair, 1 and 3. Load group two powers the matrix output relay pair, 2 and 4. The contact arrangement in the ladder network assures that both parallel contacts must open to de-energize both pairs of output relays.

The trip channel bypass is powered by two auctioneered power supplies, one from each load group. This arrangement ensures that a bypassed measurement channel will not trip as a result of loss of 120 VAC vital power to a bypassed channel.

INITIATING CHANNEL POWER SUPPLIES

Each trip path has a single channelized power supply. De-energization of a load group results in de-energization of trip paths (1 and 3) or (2 and 4).

ACTUATING CHANNELS (ARCs)

The two actuation channels (load groups I and II) consist of two trip legs. Load group I is actuated from 2C39, and Load group II is actuated from 2C40. Each actuation channel has two trip legs, one consisting of trip path 1 and 3 contacts in series and the second consisting of trip path 2 and 4 contacts in series. The power sources for each trip leg is auctioneered power supplies powered by load group I and II. Specifically, auctioneered power supplies for trip legs in 2C39, load group I, are powered by channel 1 and 2 of the vital AC system Auctioneered power supplies for trip legs in 2C40, load group II, are powered by channel 3 and 4 of the vital AC system. With this power supply arrangement, an ESFAS actuation channel trip will not directly result from a single load group power supply de-energization.

7.3.1.1.3 <u>Group Actuation</u>

The components in each ESF system are placed into various groups. Components of each group are actuated by one group relay. Group relay contacts are in the power control circuit for the actuated components of each ESF system.

The logic described in Section 7.3.1.1.2 causes the opening of the contacts in a selective 2-out-of-4 circuit whenever any one of the logic matrices is de-energized. Upon opening of selective contacts in the 2-out-of-4 logic, the group relays de-energize and actuate the ESF system components.

Sequencing of component actuation, where required, is accomplished in the power control circuit of each actuated component. Sequencing is described in Sections 7.3.1.1.8 and 8.3.1.1.

7.3.1.1.4 <u>Bypasses</u>

Bypasses are provided as shown in Table 7.3-1. The trip channel bypass is identical to the RPS trip channel bypass (Section 7.2.1.1.5) and is employed for maintenance and testing of a channel.

The bypass is also provided to remove a trip channel from service for an extended period without affecting plant safety or availability in the event of an equipment failure not readily repairable or accessible.

The RPS/ESFAS pressurizer pressure bypass is provided to allow plant depressurization without undesired actuation of ESF equipment. The bypass must be initiated manually by switches in each protective channel. Bypassing is not possible if pressurizer pressure is above the bypass permissive, which is less than 400 psia. Once a bypass has been initiated, it is automatically removed before pressurizer pressure rises to 500 psia. All bypasses are annunciated visually and audibly to the operator.

The RPS/ESFAS High/Low Steam Generator Level bypass is provided for system tests during shutdown conditions. The bypass must be initiated manually by switches in each protective channel. Bypassing is not possible if RCS temperature is above 200 °F. Once a bypass has been initiated, it is automatically removed if RCS temperature rises to 200 °F.

The ESFAS RWT Low Level bypass is provided for system tests during shutdown conditions. The bypass is paralleled to the RPS/ESFAS pressurizer pressure bypass and is instated and removed at the same signal levels.

7.3.1.1.5 <u>Interlocks</u>

The following interlocks are provided:

A. Trip Channel Bypasses

An interlock prevents the operator from bypassing more than one trip channel at a time for any one type trip. Different type trips may be simultaneously bypassed, either in one channel or in different channels. Since some parameters may be used in several different functional units, Technical Specifications require that when bypassing a parameter or functional unit in a channel, the operator must bypass all the interdependent parameters or trip units in the same channel.

B. Matrix Tests

During system testing, an electrical interlock will allow only the matrix relays in one of the six matrix test modules to be held at a time. The same circuit will allow only one process measurement loop signal to be perturbed at a time. The matrix relay hold and loop perturbation switches are interlocked so that only one or the other may be done at any one time.

C. Test Power Supply

A rotary switch ensures that power from the test power supply may be applied to only one channel at a time.

During system testing, an electrical interlock will allow only the matrix relays in one of the six matrix test modules to be held at a time. The same circuit will allow only one process measurement loop signal to be perturbed at a time. The matrix relay hold and loop perturbation switches are interlocked so that only one or the other may be used at any one time.

7.3.1.1.6 Redundancy

Redundant features of the ESFAS include:

A. Four independent channels, from process sensor through and including channel trip relays.

B. Six logic matrices which provide the 2-out-of-4 logic. Dual power supplies are provided for each matrix. One power supply powers matrix output relays for trip paths 1 and 3. The second powers matrix output relays for trip paths 2 and 4.

C. Four trip paths for each actuation signal.

D. Four independent bistables to provide bypass permissive signals for each actuation signal which can be bypassed.

E. Generation of each actuation signal in two output trains so that redundant system components may be actuated from separate trains.

F. Two sets of manual trip pushbuttons for each actuation signal (one set on each auxiliary relay cabinet). Each set of pushbuttons actuates the components of the ESF train associated with that relay cabinet.

G. AC power for the system provided from four separate buses. Power for control and operation of redundant actuated components comes from separate buses.

This redundancy enables the systems to meet the single failure criterion, to be tested during plant operation, and to be shifted to 2-out-of-3 logic.

The benefit of a system with four independent and redundant channels is that the system can be operated, if need be, with up to two channels out of service (one bypassed and another tripped) and still meet the single failure criteria. The only operating restriction while in this condition (effectively one-out-of-two logic) is that no provision is made to bypass another channel for periodic testing or maintenance. The system logic must be restored to at least a two-out-of-three condition prior to removing another channel for maintenance.

7.3.1.1.7 Diversity

The system is designed to eliminate credible multiple channel failures originating from a common cause. The failure modes of redundant channels and the conditions of operation that are common to them are analyzed to assure that a predictable common failure mode does not exist. The design provides assurance that:

A. The monitored variables provide adequate information during the accidents;

B. The equipment can perform as required;

C. The interactions of protective actions, control actions and the environmental changes that cause, or are caused by, the design basis events do not prevent the mitigation of the consequences of the event; and,

D. The system will not be made inoperable by the inadvertent actions of operating and maintenance personnel.

E. Reference section 7.3.1.1.2.4 for the system response to de-energization of vital AC channel pairs (1 and 3) or (2 and 4).

In addition, the design is not encumbered with additional components or channels without reasonable assurance that such additions are beneficial.

The system incorporates functional diversity to accommodate the unlikely event of a common mode failure with any of the accident conditions listed in Section 7.2.2.1.2.

Protection from a postulated common mode failure during an ATWS event is accomplished by the Diverse Emergency Feedwater Actuation System (DEFAS). Conformance to 10CFR50.62, known as the ATWS Rule, requires that the PPS/ESFAS be diverse and independent from the DEFAS from sensor output to (but not including) the final actuation device. In addition, the PPS/ESFAS must be diverse from the Diverse Scram System (DSS) since the DSS is an ATWS system that uses the same types of equipment as the DEFAS (reference Section 7.7.1.6 for the DSS and Section 7.7.1.7 for the DEFAS).

7.3.1.1.8 <u>Sequencing</u>

In the event of loss of off-site power during an accident, all emergency bus loads are automatically shed. Diesel generators are automatically started on SIAS. Essential ESF equipment is sequentially loaded. The sequencing operation is discussed in Section 8.3.1.1.

7.3.1.1.9 <u>Testing</u>

Provisions are made to permit periodic testing of the complete ESFAS. These tests cover the trip actions from sensor input through the protection system and the actuation devices. The system test does not interfere with the protective function of the system. The testing system meets the criteria of IEEE 338-1971, "IEEE Trial - Use Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems," and of Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions." Jumpers or other temporary forms of bypassing are not used during testing.

The individual tests are described below. Overlap between individual tests exists so that the entire ESFAS can be tested. Frequency of testing is given in the Technical Specifications.

7.3.1.1.9.1 <u>Sensor Checks</u>

During reactor operation, the measurement channels providing an input to the ESFAS are checked by comparing the outputs of similar channels and cross-checking with related measurements.

During extended shutdown periods or refueling, these measurement channels (where possible) are checked and calibrated against known standards.

7.3.1.1.9.2 <u>Trip Bistable Tests</u>

Testing of the trip bistable is accomplished by manually varying the input signal to the trip setpoint level on one bistable at a time and observing the trip action.

Varying the input signal is accomplished by means of a trip test circuit which consists of a test circuit used to vary the magnitude of the test signal similar to that supplied by the measurement channel to the bistable signal input. The trip test circuit is interlocked electrically so that it can be used in only one channel at a time. A switch is provided to select the measurement channel input and a pushbutton is provided to apply the test signal. An NIST traceable voltmeter indicates the value of the test signal. The test circuit permits various rates of change of signal input to be used. Trip action (de-energizing) of each of the bistable trip relays is indicated by individual lights on the front of the cabinet, indicating that the bistable trip unit and the trip relays operate as required for a trip condition.

When one of the four trip bistables of a protective channel is in the tripped condition (versus being bypassed), a channel trip exists and is annunciated on the control room annunciator panel. In this condition, an actuation signal would take place upon receipt of a trip signal in one of the other three like trip channels. Therefore, the trip channel under test is bypassed for this test, converting the PPS to a 2-out-of-3 logic for the particular trip parameter. In either case, full protection is maintained.

7.3.1.1.9.3 Logic Matrix Tests

This test is carried out to verify proper operation of the six 2-out-of-4 logic matrices, any of which will initiate one or more bonafide Engineered Safety Features System trip(s) for any possible 2-out-of-4 trip condition from the signal inputs from each measurement channel. The matrix output relay hold switch permits only one of the 2-out-of-4 logic matrices to be tested at a time.

Only the matrix relays in one of the six logic matrix test modules can be held in the energized position during tests. If for example, the A-B logic matrix hold switch is held in the hold or tripped position, actuation of the other matrix hold switches will have no effect upon their respective logic matrices. In addition, a selector switch is utilized to provide test power to only one bay at a time.

Actuation of a matrix hold switch will apply a test voltage to the test system hold coils of the selected double coil matrix relays. This voltage will provide the power necessary to hold the matrix relays in their energized position when the bistable trip relay contacts in the matrix ladder being tested open, thus causing de-energization of the primary matrix relay coils.

The logic matrix to be tested is selected using the system channel trip select switch. While holding the matrix hold switch in its actuated position, rotation of the system channel trip select switch will release only those bistable trip relays that have operating contacts in the logic matrix under test. The system channel trip select switch applies a test voltage of opposite polarity to the bistable trip relay test coils so that the magnetic flux generated by those coils opposes that of the primary coil of the relay. The resulting flux will be zero, and the relays will release.

Trip action can be observed by illumination of the trip relay indicators located on the front panel and by loss of voltage to the four matrix relays, which is indicated by extinguishing the indicator lights connected across each matrix relay coil.

During this test, the matrix relay "HOLD" lights will remain on, indicating that a test voltage has been applied to the holding coils of matrix relays of the logic matrix under test.

The test is repeated for each actuation signal, by use of the system channel trip select switch, and for all six logic matrices. This test will verify that the logic matrix relays will de-energize, if the matrix continuity is violated. The opening of the matrix relays is tested in the trip path tests.

7.3.1.1.9.4 Trip Path/Initiation Channel Tests

Each trip path is tested individually by actuating a matrix hold switch (holding four matrix relays), selecting any trip position of the system channel trip select switch (opening the matrix), and selecting a position on the matrix relay trip select switch (de-energizing one of the four matrix relays in each ESFAS). This causes one of the initiation channels in each of the affected ESFAS's to de-energize. Proper operation of both initiation channel output relay coils and contacts is verified by monitoring the current through the appropriate leg(s) of the actuation logic selective 2-out-of-4 circuit(s).

The matrix relay trip select switch is turned to the next position, re-energizing the tested matrix relay(s) and allowing for the appropriate initiation channel(s) to be manually reset. This sequence is repeated for the other three trip paths from the selected matrix. The entire test sequence is repeated for the remaining five matrices. Upon completion of testing, all six matrices, all 24 matrix relay contacts and all eight initiation channel output relays for each ESFAS have been tested.

7.3.1.1.9.5 ESFAS Actuating Logic Tests

The selective 2-out-of-4 logic circuit of each ESFAS load group system is tested in a manner similar to the RPS trip breaker system (see Section 7.2.1.1.9.5). One current path of the selective 2-out-of-4 logic matrix is interrupted by opening one of the path contacts and loss of path current is verified. Every contact in both current paths is checked in this manner.

The manual trips are checked one at a time from their remote locations; the lockout contacts are checked via the group relay test system (Section 7.3.1.1.9.6) and the initiation relay contacts are checked as described in Section 7.3.1.1.9.4.

This test verifies the proper operation of the ESFAS actuating logic circuits.

In addition, the EFAS trip paths may be tested by manually tripping the associated DEFAS trip relay as described in Section 7.7.1.7.

7.3.1.1.9.6 ESFAS Actuating Device Test

Proper operation of the ESFAS group relays is accomplished by de-energizing the group relays one at a time via a test relay contact and verifying proper operation of all actuated components in that group. The design of the test system is such that one and only one group relay may be de-energized at one time. The test switch must be positioned to the group to be tested; selection of more than one group is impossible. The test circuit is electrically locked out upon actuation of a particular test group and another test group cannot be actuated for one minute after selecting another switch position. This time delay feature is a "stop and think" feature to assist the operator in conducting tests; should it not function and should the operator violate test procedures, the worst that could happen is inadvertent actuation of ESF components or an ESF system.

Since this test causes the ESF components to actuate by interrupting the normal safety signal current to individual group relays, the propagation of a valid trip during testing will not be impeded, and the system will proceed to full actuation.

This test verifies the operation of the ESFAS group relays and the individual ESF component actuation devices.

7.3.1.1.10 Vital Instrument Power Supply

The vital instrument power supply for the ESFAS is described in Sections 8.3.1.1.6 and 7.3.1.1.2.4.

7.3.1.1.11 Actuated Systems

The ESF systems consist primarily of components and equipment maintained in a standby mode during normal operations. Actuating signals generated by the ESFAS are combined with ESF component permissive signals within the actuation device circuitry (e.g., control switch not in “pull to lock”, EDG load sequencing, etc.) to assure that the ESF systems provide the required protective functions. All valves which receive an ESF signal are designed not to return to their normal mode upon removal of the ESF signal. An additional reset action is required to return the valve to its normal mode.

The following sections describe the instrumentation and controls for each ESF system. Table 7.3-2 presents the design basis events which require specific ESFAS action. Table 7.3-3 presents the monitored variables required for ESFAS actuation.

7.3.1.1.11.1 Containment Isolation System

See Section 6.2.4 for a description of this system.

The system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability necessary to isolate the containment following those design basis events shown in Table 7.3-2 which require containment isolation.

The CIS is automatically actuated by a CIAS from the ESFAS. In addition, certain CIS valves are automatically actuated (closed) by a SIAS from the ESFAS. (See Table 6.2-26 for specific valves and Section 7.3.1.1.11.5 for SIAS initiation logic description.) This provides diverse signals for these valves for containment isolation.

The CIAS is initiated by 2-out-of-4 containment pressure signals. The measurement channels which generate the CIAS also provide signals to the SIAS, CSAS and CCAS. Manual initiation of the CIS is provided in the control room.

The safety-related display instrumentation for the CIS which provides the operator with sufficient information to monitor and perform the required safety functions is described in Section 7.5.

7.3.1.1.11.2 Containment Spray System

See Section 6.2.2 for a description of the CSS.

The system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events shown in Table 7.3-2 which are mitigated by the CSS.

The CSS is automatically actuated by a CSAS from the ESFAS. The CSAS is initiated by coincidence of 2-out-of-4 high-high containment pressure signals and an SIAS signal. Manual initiation of the CSS is provided in the control room.

The SIAS and high-high containment pressure signals are combined in four AND circuits within the ESFAS initiating logic. The AND circuits prevent inadvertent operation of the CSS upon generation of an SIAS only. The CSAS actuating logic is separate from the SIAS logic.

The operating mode of the CSS is automatically changed by a RAS from the ESFAS. The RAS is generated by 2-out-of-4 low refueling water tank level signals. The RAS is described in Section 7.3.1.1.11.6.

7.3.1.1.11.3 Containment Cooling System

See Section 6.2.2 for a description of the CCS.

The system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events shown in Table 7.3-2.

The CCS instrumentation and controls are designed for one operating mode during emergency operating conditions and another operating mode during normal plant operation.

During emergency conditions, the operating mode of the CCS is automatically changed by a CCAS from the ESFAS. The CCAS is initiated by either 2-out-of-4 low pressurizer pressure signals or 2-out-of-4 high containment pressure signals.

Manual initiation of the CCS is provided in the control room.

Manual reduction of pressurizer pressure trip setpoints and the RPS/ESFAS pressurizer pressure bypass permit shutdown and depressurization of the RCS without automatic actuation of the CCS. Automatic CCS operation is actuated at the pressure shown in Table 7.3-5 during plant operation.

The CCAS automatically starts all four containment emergency air cooling fans, opens service water valves and opens bypass dampers on each cooling unit.

The safety-related display instrumentation for the CCS which provides the operator with sufficient information to monitor and perform the required safety functions is described in Section 7.5.

7.3.1.1.11.4 Main Steam Isolation System

See Section 10.3 for a description of the Main Steam Isolation System (MSIS).

The system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the valves in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the valves in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability necessary to prevent blowdown of both steam generators following those design basis events shown in Table 7.3-2 which require main steam isolation.

The MSIS closes both main steam isolation valves and the four main feedwater isolation valves, stops both main feedwater pumps, stops all four condensate pumps, and stops the AFW pump.

The MSIS is initiated by 2-out-of-4 low steam generator pressure signals. The 2-out-of-4 logic is provided for each steam generator.

A manual control switch for each valve is provided in the control room to permit manual isolation of the main steam and feedwater lines.

System-level manual initiation of the MSIS is also provided in the control room.

Automatic main steam and feedwater isolation is initiated at a pressure setpoint as shown in Table 7.3-5 during normal operation. A variable setpoint is implemented to allow controlled pressure reduction during shutdown without initiating a MSIS. The pressure setpoint is automatically increased as the steam pressure is increased.

The safety-related display instrumentation for the MSIS, which provides the operator with sufficient information to monitor and perform the required safety functions, is described in Section 7.5.

7.3.1.1.11.5 Safety Injection System

See Section 6.3 for a description of the SIS.

The system is composed of redundant Load Groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability following those design basis events shown in Table 7.3-2 which are mitigated by the SIS.

The SIS is automatically actuated by an SIAS from the ESFAS. The SIAS is initiated by either 2-out-of-4 low pressurizer pressure signals or 2-out-of-4 high containment pressure signals. Capability to bypass individual channels for these parameters to allow maintenance and testing is provided as discussed in Section 7.3.1.1.4.

The measurement channels which generate low pressurizer pressure and high containment pressure signals also provide signals to the CCAS and CSAS. The measurement channels which generate the high containment pressure signals also provide signals to the CIAS.

Key locked control switches are provided in the control room to permit manual closing of the safety injection tank isolation valves for shutdown and depressurization. When pressurizer pressure rises above the setpoint, the valves are automatically opened (see Section 7.6).

Manual initiation of the SIS is provided in the control room.

The operating mode of the SIS is automatically changed by a RAS from the ESFAS. Generation of the RAS is described in Section 7.3.1.1.11.6.

Automatic SIS operation is actuated at a pressurizer pressure as shown in Table 7.3-5 during operation. During startup and shutdown operations, a variable setpoint is used as described in Section 7.2.1.1.1.6.

The safety-related display instrumentation for the SIS which provides the operator with sufficient information to monitor and perform the required safety functions, is described in Section 7.5.

7.3.1.1.11.6 Recirculation Actuation Signal

The RAS is generated by 2-out-of-4 low refueling water tank level signals. Capability to bypass individual channels to allow maintenance and testing is provided as discussed in Section 7.3.1.1.4. The sensors are physically separated. Instrumentation and High Pressure Safety Injection (HPSI) system designs are discussed in Sections 6.2.2.5.1 and 6.3.2.2.4, respectively.

The RAS automatically stops the low pressure safety injection pumps. The RAS also automatically changes the high pressure safety injection pump suction from the refueling water tank to the containment recirculation sump. This allows long term core cooling of the reactor core following a LOCA by recirculating water in the containment sump using the HPSI pumps. The recirculated sump water is injected to the core and the mechanism for residual heat removal is boil-off of fluid in the reactor vessel.

Manual initiation of the RAS is provided at the auxiliary relay cabinets which are located behind the main control panels in the control room.

Key locked control switches are provided for remote-manual operation of the containment sump isolation valves and the refueling water tank isolation valves. The locked open and locked closed positions of these valves are indicated and annunciated in the control room.

7.3.1.1.11.7 Penetration Room Ventilation System

See Section 6.5 for a description of the penetration room ventilation system.

Upon receipt of a CIAS, following an incident, the 3-way solenoid valves mounted in the air lines to the pneumatic operators on the penetration room ventilation duct isolation dampers are automatically de-energized, closing off the air supply to the operators. These isolation dampers are designed to fail-closed upon loss of instrument air pressure, providing sealed penetration rooms. Indicating lights in the control room show their closed position. Both fans receive a CIAS, however, only one fan is required.

A motor operated valve which opens when the fan starts is provided at the suction of each fan. When one of the two fans is stopped, its respective valve is automatically closed to prevent recirculation through the idle fan.

In the original design of the penetration room ventilation system, if a fan fails or is stopped after it has been running for a prolonged period of time, a manually controlled recirculation valve can be opened from the control room to maintain adequate cooling air drawn by the operating fan through the idle filter train. Subsequent calculations have documented adequate cooling will be maintained even without the operation of these valves and air flow secured. Flow indication is provided in the control room for this recirculation cooling air as part of the original design.

This system is not utilized, i.e., taken credit for, in the calculation of off-site doses after an accident.

7.3.1.1.11.8 Emergency Feedwater System

See Section 10.4.9 for a description of the Emergency Feedwater (EFW) system.

The system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability necessary to automatically actuate the EFW system following those design basis events shown in Table 7.3-2 which require emergency feedwater.

The EFW system instrumentation and controls are designed for operation during all phases of plant operation. The system is designed to be operated manually, typically utilizing the auxiliary feedwater pump during normal transients such as startup, shutdown, and hot standby and automatically utilizing the emergency feedwater pumps during emergency situations such as steam line rupture, loss of normal feed and plant blackout.

The EFAS performs the following functions:

A. Starts the emergency feedwater pumps;

B. Determines whether a steam generator is intact;

C. Opens the emergency feedwater valves to the intact steam generator; and,

D. Prevents a high level condition in the intact steam generator(s) by closing the emergency feedwater valves when the water level is re-established above the low level trip setpoint.

The EFAS is initiated to Steam Generator 1 either by a low steam generator level coincident with no low pressure trip present on Steam Generator 1 or by a low steam generator level coincident with a differential pressure between the two steam generators with the higher pressure in Steam Generator 1 (an identical EFAS is generated for Steam Generator 2). The valve open logic, (TP1 or TP3) and (TP2 or TP4) (TPs de-energized), is not latched in the actuated state. Following initial actuation when the level is re-established above the low level actuation point, or when the proper pressure conditions are no longer met, the valve close logic,

(TP1 and TP3) or (TP2 and TP4), closes the valves (TPs energized). When the conditions for valve opening are again met, or when the operator takes action, the valves are reopened. The pumps are latched on as shown whenever an EFAS signal occurs for either steam generator. The 2-out-of-4 logic is provided for each steam generator.

Manual control switches for the emergency feedwater pumps and emergency feedwater valves are provided in the control room.

A list of typical trip setpoints for EFW actuation is contained in Table 7.3-5.

The safety-related display instrumentation for the EFW system, which provides the operator with sufficient information to monitor and perform the required safety functions, are described in Section 7.5.

7.3.1.1.12 <u>ESF Supporting Systems</u>

The ESF supporting systems are listed below and described in the referenced sections.

A. Service Water System (see Section 9.2.1).

B. Electrical Power Distribution Systems (see Sections 8.3 and 7.3.1.1.2.4).

7.3.1.2 <u>Design Basis Information</u>

The ESFAS is designed to provide initiating signals for components which require automatic actuation following rupture of the reactor coolant pressure boundary or of a main steam line.

The systems are designed on the following bases to assure adequate performance of their protective functions.

A. The system is designed in compliance with the applicable criteria, "General Design Criteria for Nuclear Power Plants" (Appendix A of 10CFR50, 1971).

B. System testing conforms to the requirements of IEEE 338-1971, "Trial Use Criteria for Periodic Testing of Nuclear Power Generating Station Protection Systems" and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions."

C. IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes specific protection system design bases. The following sections describe how these design bases listed in Section 3 of IEEE 279 are implemented.

   1. "Generating Station Conditions Which Require Protective Action"

      Rupture of reactor coolant pipe
      Rupture of small reactor coolant pipes or cracks in large reactor coolant pipe
      Steam generator tube rupture
      Steam line break
      Minor secondary system pipe break

2. "Generating Station Variables to be Monitored to Provide Protective Action"

   Reactor coolant system pressure
   Containment pressure
   Refueling water tank level
   Steam generator pressures
   Steam generator level

3. "The Number and Location of the Sensors Required to Monitor the Variables Listed in Basis (2)"

   These variables are listed in Table 7.3-4.

4. "Prudent Operational Limits for Each Variable Listed in Basis (2) for Each Applicable Reactor Operation Mode"

   The normal operation limits for each variable listed in basis (2) are provided in Table 7.3-5.

5. "The Margin, With Appropriate Interpretive Information, Between Each Operational Limit and the Level Considered to Mark the Onset of Unsafe Conditions"

   This information is provided in Table 7.3-5.

6. "The Levels That When Reached Will Require Protective Action"

   This information is provided in Table 7.3-5.

7. "The Range of Transient and Steady State Conditions of Both the Energy Supply and the Environment During Normal, Abnormal and Accident Circumstances Throughout Which the System Must Perform"

   Systems components are qualified for the environmental conditions discussed in Section 3.11. In addition, the system is capable of performing its intended functions under the most degraded conditions of the electrical support system as discussed in Section 8.3.

8. "The Malfunctions, Accidents or Other Unusual Events Which Could Physically Damage Protection System Components or Could Cause Environmental Changes Leading to Functional Degradation of System Performance, and for Which Provisions Must Be Incorporated to Retain Necessary Protective Action"

   The ESFAS is designed with consideration given to unusual events which could degrade system performance so that:

   a. A loss of power to the measurement channels and/or to the logic system causes acceptable system response. Section 7.3.1.1.2.4 further describes PPS response to loss of power events.

b. Any single failure within the system shall not prevent proper protective action at the system level. The single failure criterion is discussed in Section 7.3.2.2.2.

c. The environmental conditions under which the ESFAS shall be capable of performing its intended function are described in Section 3.11.2.

d. The seismic conditions under which the ESFAS shall be capable of performing its intended function are described in Section 3.10.

9. "Minimum Performance Requirements Including System Response Times, Accuracies, and Ranges of the Magnitude and Rates of Change of Sensed Variables to be Accommodated Until Proper Conclusion of the Protective Action is Assured"

The minimum performance requirements of the ESFAS are as follows:

a. The ESFAS system response times are a portion of the total response time measured from when the monitored process parameter exceeds the actuation setpoint at the channel sensor until the actuated ESF equipment is capable of performing its safety function. The response times utilized in the Safety Analysis are listed in Chapter 15.

b. The ranges of ESFAS monitored plant variables are provided in Table 7.3-6.

7.3.2 ANALYSIS

7.3.2.1 Introduction

The design of each of the ESF systems, including design bases and evaluation, is discussed in Chapter 6 and Chapter 10. The following analyses address the ESFAS and instrumentation only.

7.3.2.2 Design

As previously described, the major portion of the ESFAS is functionally identical to the RPS. The logic for the ESFAS and RPS, are located in the same enclosures and share a common logic testing scheme. Because of this, many of the responses to the requirements of the general design criteria, IEEE 279-1971 and IEEE 338-1971 are similar to the responses in Section 7.2.2.

7.3.2.2.1 General Design Criteria

Appendix A of 10CFR50, "General Design Criteria for Nuclear Power Plants," establishes minimum requirements for the principal design criteria for water-cooled nuclear power plants. This section describes how the requirements that are applicable to the ESFAS are satisfied.

Criterion 1: Quality Standards and Records

The quality assurance program for the plant is described in the Quality Assurance Program Manual (QAPM). These procedures ensure that the system has been designed in accordance with required codes and standards.

Criterion 2: Design Bases for Protection Against Natural Phenomena

The design bases for protection against natural phenomena are described in Section 3.10 and 3.11.

Criterion 3: Fire Protection

See Section 3.1.

Criterion 4: Environmental and Missile Design Bases

Environmental design bases are described in Section 3.10. Missile design bases are described in Section 3.5.

Criterion 5: Sharing of Structures, Systems and Components

No ESFAS components are shared with any other reactor facilities.

Criterion 13: Instrumentation and Control

Sensor ranges are sufficient to monitor all pertinent plant variables over the expected range of plant operation for normal and transient conditions. The information shown in Table 7.5-2 is provided for the operator's use.

Criterion 20: Protection System Functions

ESF action will be initiated upon sensing the presence of accident conditions.

Criterion 21: Protection System Reliability and Testability

Functional reliability is ensured by compliance with the requirements of IEEE 279-1971, as described in Section 7.3.2.2.2. Testing is in compliance with IEEE 338-1971 and Regulatory Guide 1.22, and is described in Section 7.3.2.2.3.

Criterion 22: Protection System Independence

(See Section 3.1)

Four independent sensor channels are provided for all inputs. Two independent output paths are provided.

Criterion 23: Protection System Failure Modes

The ESFAS is designed to fail in a safe state in the event of loss of power. Loss of power responses are discussed in section 7.3.1.1.2.4. Failure modes of the ESF system components are discussed in Chapter 6 and Chapter 10.

ESFAS components are designed to function under adverse environmental conditions during postulated accidents, if required.

Criterion 24: Separation of Protection and Control Systems

The protection system is separated from the control systems.

Criteria 34, 35, 37, 38, 40, 41, 43, 44, 46:

The actuation portion of these criteria are met by the ESFAS, which meets the requirements of IEEE 279-1971 and IEEE 338-1971. The single failure criterion is met for all ESF systems and the ESFAS is fully testable.

7.3.2.2.2 ESFAS Equipment Design Criteria

IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes minimum requirements for safety-related functional performance and reliability of the ESFAS. This section describes how the requirements listed in Section 4 of IEEE 279 are satisfied.

"4.1 General Functional Requirement"

The ESFAS is designed to actuate the appropriate ESF systems, when required, to mitigate the effects of certain accidents. Instrument performance characteristics, response time, and accuracy are selected for compatibility with and adequacy for the particular function. Trip setpoints are established by analysis of the system parameters. Factors such as instrument inaccuracies, bistable trip times, valve travel time, and pump starting times are considered in establishing the margin between the trip setpoints and the safety limits. The time response of the sensors and protective systems are evaluated for abnormal conditions. Since all uncertainty factors are considered as cumulative for the derivation of these times, the actual response time may be more rapid. However, even at the maximum times, the system provides conservative protection.

There are no ESFAS sensors for which the trip setpoints are within five percent of the high or low end of the calibrated range.

"4.2 Single Failure Criterion"

The ESFAS is designed so that any single failure within the system shall not prevent proper protective action at the system level. No single failure will defeat more than one of the four protective channels associated with any one trip function. Section 7.3.1.1.2.4 describes a power source failure that impacts more than a single protective channel.

The following is an evaluation of the effects of specific single faults in the analog portion of the system:

A. A loss of signal in a measurement channel initiates channel trip action for the low pressurizer pressure, low steam generator water level and low steam generator pressure trips;

B. Shorting of the signal leads to each other has the same effect as a loss of signal. Shorting a lead to a voltage has no effect since the signal circuit is ungrounded;

C. Single grounds of the signal circuit have no effect. Periodic checking of the system will provide assurance that the circuit remains ungrounded.

The following is an evaluation of the effects of specific single faults in the logic portion of the system:

A. Inadvertent operation of the relays and relay contacts in the matrices will be identified by plant annunciation and indicating lights;

B. Shorting of the pairs of contacts in the matrices will prevent the matrix relay sets from being released. Such shorts are detectable in the testing process by observing that the matrix relays cannot be dropped out. Testing is accomplished by successive opening of the logic matrix contact pairs;

C. Shorting of the matrices to an external voltage has no effect since the matrix is ungrounded. Equipment is provided to detect grounds on the matrices;

D. The logic matrices will each be supplied by two power sources. Loss of a single power source has no effect on operation; however, a half leg actuation results. Loss of both power sources to a logic matrix initiates an actuation of the associated EFSAS functions;

E. Failure of a matrix relay to de-energize has no effect since there are six matrix relay contacts in series in the trip path and any one contact initiating trip action will cause the action to be completed;

F. The failure of one actuation channel (ARC) has no effect since there are two actuation channels with independent control circuits in parallel, either of which will provide the necessary action;

G. Single grounds or accidental application of potential to single leads in the trip path circuits have no effect since the circuit is ungrounded. Testing and observation of ground detectors will indicate these problems; and,

H. Single faults of actuation relays or actuation relay buses have no effect as a selective 2-out-of-4 logic is required for actuation. For single faults of a component or components within one of the two redundant actuation trains, actuation of the remaining trains components are sufficient for the protective action.

"4.3 Quality Control of Components and Modules"

The quality assurance program is described in the Quality Assurance Program Manual (QAPM). This program includes appropriate requirements for design, review, procurement, inspection, and testing to ensure that the system components shall be of a quality consistent with minimum maintenance requirements and low failure rates.

"4.4 Equipment Qualification"

The ESFAS meets the equipment requirements described in Sections 3.10 and 3.11.

"4.5 Channel Integrity"

Type testing of components, separation of sensors and channels, and qualification of cabling are utilized to ensure that the channels will maintain the functional capability required under applicable extremes of conditions relating to environment, energy supply, malfunctions and accidents.

Loss of or damage to any one path will not prevent the protective action. Sensors are piped so that blockage or failure of any one connection does not prevent protective system action. The process transducers located in the containment building are specified and rated for the intended service. Components which must operate during or after the LOCA are rated for the LOCA environment. Results of type tests are used to verify these ratings. In the control room, protective system trip paths are located in four compartments. Mechanical and thermal barriers between these compartments reduce the possibility of common event failure. Outputs from the components in this area to the control boards are isolated so that shorting, grounding, or the application of the highest available local voltage does not cause channel malfunction. Where signals originating in the PPS feed the computer, signal isolation is provided; where the ESFAS is feeding annunciators, isolation is ensured through the use of relay contacts.

"4.6 Channel Independence"

The locations of the sensors and the points at which the sensing lines are connected to the process loop have been selected to provide physical separation of the channels, thereby precluding a situation in which a single event could remove or negate a protective function. The routing of cables from protective system transmitters is arranged so that the cables are separated from each other and from power cabling to minimize the likelihood of common event failures. This includes separation at the containment penetration areas. In the control room, protective system trip channels are located in individual compartments. Mechanical and thermal barriers between these compartments minimize the possibility of common event failure. Outputs from the components in this area to the control board are isolated so that shorting, grounding, or the application of the highest available local voltages do not cause channel malfunction.

The criteria for separation and physical independence of channels are based on the need for decoupling the effects of accident consequences and energy supply transients and for reducing the likelihood of channel interaction during testing or in the event of a channel malfunction.

Historical data removed - To review the exact wording please refer to Section 7.3.2.2.2 of the FSAR.

"4.7 Control and Protection System Interaction"

No portion of the ESFAS is used for both control and protection functions.

"4.8 Derivation of System Inputs"

ESFAS inputs are derived from signals that are direct measures of the desired variables. Variables which are measured directly include pressurizer, steam generator, and containment pressures. Refueling water tank and steam generator levels are derived from differential pressure measurements.

"4.9 Capability for Sensor Checks"

ESFAS sensors are checked by cross-checking between channels. These channels bear a known relationship to each other, and this method ensures the operability of each sensor during reactor operation.

"4.10 Capability for Test and Calibration"

Testing is described in Section 7.3.1.1.9 and is in compliance with IEEE 338-1971 as discussed in Section 7.3.2.2.3.

"4.11 Channel Bypass or Removal From Operation"

Any one of the four protective system channels may be tested, calibrated, or repaired without detrimental effects on the system. Individual trip channels may be bypassed to effect a 2-out-of-3 logic on the remaining channels. The single failure criterion is met during this condition.

"4.12 Operating Bypasses"

Operating bypasses are provided as shown in Table 7.3-1. The operating bypasses are automatically removed when the permissive conditions are not met. The circuitry and devices which function to remove these inhibits are designed in accordance with IEEE 279-1971.

"4.13 Indication of Bypasses"

Indication of test or bypass conditions or removal of any channel from service is given by lights and annunciation. Bypasses that are automatically removed at fixed setpoints are alarmed and indicated.

"4.14 Access to Means for Bypassing"

An interlock prevents the plant operator from bypassing more than one of the four channels of any one type trip at any one time. All bypasses are visually and audibly annunciated.

"4.15 Multiple Setpoints"

Manual reduction of setpoints for main steam isolation and safety injection actuation CCAS is allowed for the controlled reduction of pressurizer pressure and steam generator pressure as discussed in Section 7.2.1.1.2.6. The setpoint reductions are initiated by a control board mounted pushbutton, which upon actuation adjusts the setpoint to a value a pre-selected distance below the operating pressure which exists at the time the pushbutton is actuated. A separate pushbutton is provided for each protection channel. This method of setpoint reduction provides positive assurance that the setpoint is never decreased below the existing pressure by more than a predetermined amount.

The setpoint will be automatically increased by the PPS as the measured pressure is increased.

"4.16 Completion of Protective Action Once It is Initiated"

The system is designed to ensure that protective action will go to completion once initiated. Operator action is required to clear the actuation signal and return to operation except for EFAS where the operator must clear the low steam generator water level to return to operation.

"4.17 Manual Initiation"

In general a manual actuation can be initiated by depressing either of two sets of pushbuttons. Except for RAS, each set of pushbuttons will actuate both load groups. On EFAS and MSIS the eight EFW discharge valves are configured such that all four switches/buttons are necessary to send the manually initiated signals to all of the discharge valves. The RAS can be manually actuated by depressing both sets of pushbuttons on the two auxiliary relay cabinets. Each set of RAS manual pushbuttons will actuate the RAS components associated with the respective train (i.e. load group).

The remote manual switches de-energize the solid state relays, whose contacts interrupt power to the group relays. The remote manual switches are located in the control room. The switches are paired AB and CD, each pair located on a different control board. As shown in the above referenced figures, either pair is capable of actuating both auxiliary relay cabinets at the system level regardless of whether means are also provided downstream at the component level. The ESFAS manual initiation feature is in complete conformance with Regulatory Guide 1.62, "Manual Initiation of Protective Actions."

"4.18 Access to Setpoint Adjustments, Calibration and Test Points"

An administratively controlled key is required for access to setpoint adjustments, calibration and test points. Access is also visually and audibly annunciated.

"4.19 Identification of Protective Action"

Indication lights are provided for all protective actions, including identification of channel trips.

"4.20 Information Readout"

Means are provided to allow the operator to monitor all trip system inputs and outputs. The displays that are provided for continuous monitoring are described in Section 7.5. System status displays are provided.

"4.21 System Repair"

Identification of a defective channel will be accomplished by observation of system status lights or by testing as described in Section 7.3.1.1.9. Replacement or repair of components is accomplished with the affected channel bypassed. The affected trip function then operates in a 2-out-of-3 trip logic.

"4.22 Identification"

All equipment, including panels, modules, and cables associated with the actuation system, will be marked in order to facilitate identification. Interconnecting cables will be color coded on a channel basis.

7.3.2.2.3 Testing Criteria

IEEE 338-1971, "Trial Use Criteria for the Periodic Testing of Nuclear Generating Station Protection Systems," and Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions," provide guidance for development of procedures, equipment, and

documentation of periodic testing. The basis for the scope and means of testing are described in this section. Test intervals and their bases are included in the Technical Specifications. Since actuation of the ESF systems is not expected during normal operation, the systems are periodically tested without initiating protective action, without violating the single failure criterion, and without inhibiting the operation of the systems.

The systems can be checked from the sensor signal through the actuated devices. The functional modules in the sensors system can be tested during reactor operation. The sensors can be checked by comparison with similar channels.

Those actuated devices which are not tested during reactor operation, e.g. main feedwater isolation valves, will be tested during scheduled reactor shutdowns to ensure that they are capable of performing the necessary functions. Minimum frequencies for checks, calibration and testing of the ESFAS instrumentation are given in the Technical Specifications. Overlap in the checking and testing is provided to ensure that the entire channel is functional. The use of individual trip and ground detection lights, in conjunction with those provided at the supply bus, ensure that possible grounds will be detected.

The response time from an input signal to protection system trip bistables through the opening of the actuation relays is verified by measurement during plant startup testing and periodically thereafter. Sensor responses are measured during factory acceptance tests and will be periodically remeasured, either independently or as part of the total instrument loop response time, to ensure their continued adequate timely response.

7.3.2.3 Failure Modes and Effects Analysis

A failure modes and effects analysis for the PPS, RPS, and ESFAS is provided in Table 7.2-5. It should be noted that this analysis was performed assuming three operable PPS channels with one channel in the bypass condition. Arkansas Nuclear One, Unit 2 is expected to operate with all four channels operable under normal conditions. The analysis of Table 7.2-5 demonstrates for the more limiting case of three channels operable that the design criteria for the PPS are met.

7.4 SYSTEMS REQUIRED FOR SAFE SHUTDOWN

This section describes the instrumentation and control systems which are required to maintain the reactor in a safe shutdown condition. These instrumentation and control systems are in many cases utilized in the performance of normal plant operations and as such cannot be exclusively identified for safe shutdown functions. Complete descriptions of these systems and their operation may be found in other sections of the Safety Analysis Report. Piping and instrumentation diagrams are included in other sections as referenced.

7.4.1 DESCRIPTION

7.4.1.1 Emergency Power Systems

The emergency power systems are described in Section 8.3.1.1.7. The design bases for electrical power systems are described in Sections 8.3.1.2, 8.3.1.4 and 8.3.2.2.

7.4.1.2 Emergency Feedwater Systems

The Emergency Feedwater (EFW) system is described in Section 10.4.9. Automatic initiation of the EFW system is described in Section 7.3.

7.4.1.3 Chemical and Volume Control System (Boron Addition Portion)

The boron addition portion of the Chemical and Volume Control System (CVCS) is used during normal plant operation for long-term reactivity changes and during shutdown. The boric acid concentration is controlled during shutdown and cooldown to compensate for reactivity changes associated with a decreasing coolant temperature in order to ensure that a sufficient shutdown margin is maintained. Concentrated boric acid is mixed with demineralized water and injected into the RCS to achieve the desired coolant concentration by continuous letdown and makeup. The CVCS is discussed in Section 9.3.4.

The system instrumentation and controls utilized to affect long-term reactivity changes and achieve plant shutdown are discussed in the following sections.

7.4.1.3.1 Initiating Circuits and Logic

Boron addition and dilution are accomplished by the following methods:

A. Coordinated control of the charging pumps, letdown control valves and letdown back pressure valves to adjust and maintain the correct pressurizer water level; and,

B. Periodic sampling and adjustment of the boron concentration to compensate for the temperature decrease and other variables until shutdown concentration is reached.

The charging pumps are used to inject water and/or concentrated boric acid into the Reactor Coolant System (RCS) as required. With one pump normally in operation, the other charging pumps are automatically started by the pressurizer level control system as required (see Section 7.7.1).

Upon actuation of an SIAS, the charging pump suction is shifted from the volume control tank to the boric acid pump discharge for boric acid injection. The SIAS also unisolates a gravity feed line from the boric acid makeup tanks to the charging pump suction in case the boric acid

pumps fail to start. A separate (diverse) flow path is also available from the refueling water tank. Should the charging line inside the reactor containment be inoperative for any reason, the line may be isolated outside of the reactor containment, and charging flow can be injected via Safety Injection Header 1.

Control board process indication and status instrumentation is provided to enable the operator to evaluate system performance and control system operation. This instrumentation is discussed in Section 7.5.

7.4.1.3.2 Interlocks, Sequencing and Bypasses

System operation is achieved by the coordinated operation of the charging pump and boric acid pump control circuits. The charging pump control circuit sequences charging pump operation in response to pressurizer water level control circuit requirements as discussed in Section 7.7.1.1.3. The boric acid pump control circuit sequences boric acid pump and valve operation to achieve the desired boric acid concentration (see Section 9.3.4).

Manual control of any portion of these systems can be achieved while allowing the remainder to continue functioning in automatic.

7.4.1.3.3 Redundancy and Diversity

Three charging pumps are provided. The charging pumps and supporting instrumentation are powered from two separate electrical buses. The charging pumps can take suction from either the volume control tank, the refueling water tank, or the boric acid makeup tank to supply borated water into the RCS. Additional information on the CVCS design is contained in Section 9.3.4.

7.4.1.3.4 Supporting System

The boron addition and charging subsystems use portions of the CVCS flow path and have instrumentation in common.

7.4.1.4 Service Water System

The Service Water System is described in Section 9.2.1. The safety-related portion of the service water system is composed of redundant load groups: Load Group I and Load Group II. The instrumentation and controls of the components and equipment in Load Group I are physically and electrically separate and independent of the instrumentation and controls of the components and equipment in Load Group II. Independence is adequate to retain the redundancy required to maintain equipment functional capability following design basis accidents.

The Service Water System instrumentation and controls are designed for operation during all phases of plant operation. The Service Water System is manually controlled from the control room in the normal operating mode. The operating mode of the Service Water System is automatically transferred to the emergency operating mode by a Safety Injection Actuation Signal (SIAS) or Main Steam Isolation Signal (MSIS) from the Engineered Safety Features Actuation System (ESFAS). Generation of the SIAS and MSIS are described in Section 7.3.1.1.11.5, "Safety Injection System," and in Section 7.3.1.1.11.4, "Main Steam Isolation System." Service Water System indications and alarms are described in Table 9.2-6.

7.4.1.5 Emergency Shutdown From Outside the Control Room

In the unlikely event that the control room becomes inaccessible, sufficient instrumentation and controls are provided outside the control room to:

A. Achieve prompt hot shutdown of the reactor;

B. Maintain the unit in a safe condition during hot shutdown; and,

C. Achieve cold shutdown of the reactor through the use of suitable procedures.

A remote shutdown panel is provided outside of the control room. The panel is designed to Seismic Class 1 requirements and is located in a Seismic Class 1 area. The panel includes instrumentation and controls as described in Sections 7.4.1.5.1 and 7.4.1.5.2.

Postulated conditions or events resulting in control room inaccessibility are not defined; however, it is assumed these circumstances are not attended by destruction of any equipment within the control room.

7.4.1.5.1 Hot Shutdown

Sufficient instrumentation and controls are provided to achieve and maintain hot shutdown of the reactor should the control room become inaccessible.

Display of the following Nuclear Steam Supply System (NSSS) parameters is provided at the remote shutdown panel:

A. Neutron log power level;

B. Neutron count rate, (0CAN068301);

C. Reactor coolant temperature;

D. Pressurizer pressure;

E. Pressurizer level;

F. Steam generator pressure;

G. Steam generator level;

H. Letdown temperature;

I. Regenerative heat exchanger outlet temperature;

J. Letdown pressure;

K. Condensate storage tank level; and,

L. Condenser vacuum.

Control of the following equipment is provided at the remote shutdown panel:

A. Pressurizer spray control valves;

B. Letdown control valves; and,

C. Steam Dump and Bypass System (the available equipment enables the operator to prevent excessive cooldown under certain conditions coincident with control room inhabitability by shutting all Steam Dump and Bypass Control System Valves; control consists of an emergency off switch and emergency off/condenser vacuum interlock reset switch).

Manual control of the equipment listed below is provided at the appropriate switchgear, distribution center, or local control center:

A. Reactor trip circuit breakers;

B. Steam dump and bypass valves;

C. Feedwater control valves;

D. Reactor coolant pumps;

Certain pumps and valves in the charging system;

F. Certain pumps and valves in the feedwater trains; and,

G. Certain pumps and valves in the Service Water System.

Manual control of proportional pressurizer heaters is provided at local panels 2C117 and 2C118.

7.4.1.5.2 <u>Cold Shutdown</u>

Cold shutdown (Mode 5) can be achieved from outside the control room through the use of suitable procedures and by virtue of local control of the equipment listed below in conjunction with the instrumentation and controls described above.

Display of the following additional parameters is provided at the remote shutdown panel to facilitate bringing the plant to the cold shutdown condition:

A. Letdown flow;

B. Reactor coolant pump status;

C. Volume control tank level;

D. Volume control tank pressure;

E. Shutdown cooling flow;

F. RPS/ESFAS pressurizer pressure pretrip indication (four channels);

G. Low steam generator pressure pretrip indication (four channels); and,

H. RPS/ESFAS pressurizer pressure trip bypass indication (four channels).

Control of the following additional equipment is also provided at the remote shutdown panel to bring the plant to a cold shutdown condition:

A. Auxiliary spray control valve;

B. Shutdown cooling flow control valves;

C. Letdown diversion control valve;

D. Letdown backpressure control valve;

E. Volume control tank vent valve;

F. RPS/ESFAS pressurizer pressure trip setpoint reset, (four channels);

G. RPS/ESFAS pressurizer pressure trip bypass, (four channels); and

H. Low steam generator pressure trip setpoint reset, (four channels).

Local control of the equipment listed below in conjunction with the instrumentation and controls described above will permit the plant to be brought to a cold shutdown condition:

A. Safety injection tank isolation valves;

B. Safety injection loop isolation valves;

C. Certain valves in the shutdown cooling system;

D. Low pressure safety injection pumps;

E. Certain valves in the CVCS; and,

F. Certain valves in the boron management system.

7.4.2 ANALYSIS

7.4.2.1 Conformance to IEEE 279

IEEE 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," establishes minimum requirements for the reactor protective and engineered safety features instrumentation and control systems. The instrumentation and controls associated with the safe shutdown systems are not defined as a protective system in IEEE 279; however, many criteria of IEEE 279 have been incorporated in the design of the instrumentation and controls for safe shutdown systems. Conformance with the applicable portions of IEEE 279, Section 4, is discussed in the following sections. This analysis does not apply to the instrumentation associated with emergency shutdown from outside the control room.

"4.1 General Functional Requirements"

The instrumentation and controls of the safe shutdown systems enable the operator to:

A. Determine when a condition monitored by display instrumentation reaches a predetermined level requiring action; and,

B. Manually accomplish the appropriate safety actions.

"4.2 Single Failure Criterion"

The instrumentation and controls required for safe shutdown are designed and arranged such that no single failure can prevent a safe shutdown, even in the event of loss of off-site power. Single failures considered include electrical faults, e.g. open, shorted or grounded circuits, and physical events, e.g. fires, missiles, resulting in mechanical damage. Compliance with single failure criterion is accomplished by providing redundancy of power supplies, actuation circuits, and by separating the redundant elements electrically and physically to achieve the required independence. Each of the provisions is discussed below.

A. Redundancy

Each of the systems required for safe shutdown consists of redundant subsystems and/or components for maximum system reliability. The emergency power system consists of two redundant emergency diesel generator sets. Each of the redundant components has automatic and/or manual actuation circuits which are separate from those provided for its redundant counterpart. Redundant instrumentation is provided to monitor RCS conditions. Each steam generator is provided with separate pressure and level monitoring instrumentation.

B. Electrical Separation

Control power for redundant circuits is fed from separate 125-volt DC buses. Power for redundant pumps and valves is supplied from separate emergency diesel generators. Components are divided into two independent load groups. Electrical separation between the electrical load groups is discussed in Section 8.3.

C. Physical Separation

Protection against the possibility of mechanical damage to both redundant portions of any instrumentation and control system required for safe shutdown has been achieved by spatial separation and/or the provision of physical barriers between redundant elements.

Physical separation within control panels is achieved by providing spatial separation between redundant circuitry or by a fire barrier. This separation is provided between control switches, controllers, relays and wiring necessary to actuate and control redundant components.

Cable trays and conduits containing redundant wiring and cables necessary to actuate and control redundant components are physically separated as discussed in Section 8.3.1.4.

Redundant system pumps, piping and other components are physically separated to ensure that no single failure can cause damage to both redundant components. This separation afforded by component separation is maintained for redundant instrumentation which is mounted on the piping or components and which is required for safe shutdown.

The redundant wiring and circuitry of the instrumentation and control systems required for safe shutdown are marked and identified as described in Section 8.3.1.4.

"4.3 Quality Control of Components and Modules"

The quality control enforced during design, fabrication, shipment, field storage, installation and component checkout used for instrumentation and control components required for safe shutdown and the documentation of control is in accordance with the quality assurance program covered in the Quality Assurance Program Manual (QAPM).

"4.4 Equipment Qualification"

The instrumentation and controls necessary to achieve safe shutdown are designed to operate in the design ambient conditions in the area in which they are located. Components located in the control room, which is normally air conditioned, are designed to operate in the ambient conditions associated with loss of air conditioning for the time necessary to achieve safe shutdown. Environmental design and qualification of electrical and instrumentation equipment is discussed in Section 3.11. Seismic qualification and testing are discussed in Section 3.10.

"4.5 Channel Integrity"

Preoperational testing and inspection is performed to verify that all components, automatic and manual controls, and sequences of the integrated systems provided for safe shutdown accomplish the intended design function.

"4.6 Channel Independence"

Safe shutdown system channel independence is achieved by electrical and physical separation as described in Item 4.2.

"4.7 Control and Protection System Interaction"

This requirement is not directly applicable. The entire discussion involves control systems.

"4.8 Derivation of System Inputs"

The safe shutdown system monitoring signals are direct measures of the desired variables except that level information is derived from appropriate differential measurements and reactor coolant flow is derived from RCP speed.

"4.9 Capability for Sensor Checks"

The safe shutdown system monitoring sensors are checked by either perturbing the monitored variable, by introducing and varying a substitute input to the sensor similar to the measured variable, or by cross-checking between channels.

"4.10 Capability for Test and Calibration"

The instrumentation and control components required for safe shutdown which are not normally in operation will be periodically tested. All automatic and manual actuation and control devices will be tested to verify their operability. Periodic testing is described in Section 4 of the Technical Specifications.

"4.17 Manual Initiation"

The safe shutdown systems are manually actuated. No single failure will prevent safe shutdown.

"4.20 Information Readouts"

All safe shutdown system monitoring and control channels are indicated. See Section 7.5 for a discussion of safety related display instrumentation.

"4.21 System Repair"

The safe shutdown systems are actuated manually; therefore, replacement or repair of components can be accomplished in reasonable time when the systems are not actuated. Outage of system components for replacement or repair will be limited by the Technical Specifications.

"4.22 Identification"

Identification of redundant channels is as described in Sections 7.1.2 and 8.3.

7.4.2.2 Conformance to IEEE 308

The electrical circuitry associated with the safe shutdown systems conforms to IEEE 308, "IEEE Standard Criteria for Class IE Electric Systems for Nuclear Power Generating Stations." The safe shutdown systems are described in Section 8.3.

7.4.2.3 Conformance to the Requirements of General Design Criterion 19

As described in Section 7.4.1.5, local emergency control is provided to maintain the plant in the hot shutdown condition in the event that the control room must be abandoned. See Section 3.1.

7.4.2.4 Consideration of Selected Plant Contingencies

7.4.2.4.1 Loss of Instrument Air Systems

None of the essential control or monitoring instrumentation is pneumatic. Electrical instrumentation is powered from the emergency power system. Therefore, the loss of instrument air will not degrade instrumentation and control systems required for shutdown of the plant.

7.4.2.4.2 Loss of Cooling Water to Vital Equipment

None of the instrumentation and controls required for safe shutdown rely on cooling water for operation.

7.4.2.4.3 Turbine Trip and Loss of Off-Site Power

In the event of loss of off-site power associated with turbine trip, power for safe shutdown is provided by the onsite emergency power system. The description and analysis of the emergency power system are discussed fully in Section 8.3. The emergency diesel generators will provide power for operation of pumps and valves. The station batteries will provide DC power for operation of control and instrumentation systems required to actuate and control essential components.

7.4.2.5 Emergency Shutdown From Outside the Control Room

Equipment and arrangements described in Section 7.4.1.5 are in response to General Design Criterion 19 which requires certain functional capabilities outside of the control room that are met as described in the following sections.

7.4.2.5.1 Design Capability for Prompt Hot Shudown and to Maintain Hot Shutdown

Should the control room become inaccessible, the reactor may be manually tripped from the control room as it is being evacuated or from the reactor trip switchgear cabinet. Hot shutdown conditions may be maintained external to the control room as described in Section 7.4.1.5 by control of pressurizer pressure and level, feedwater flow, and atmospheric steam dump.

7.4.2.5.2 Cold Shutdown Through Suitable Procedures

Cold shutdown of the reactor without access to the control room is possible by means of instrumentation and controls described in Section 7.4.1.5 and suitable procedures.

7.5 SAFETY-RELATED DISPLAY INSTRUMENTATION

7.5.1 DESCRIPTION

This section provides a description of that display instrumentation available to the operator enabling the operator to adequately monitor conditions in the reactor, the Reactor Coolant System (RCS), containment, and safety-related process systems, and to perform any required manual safety functions.

The display instrumentation is tabulated in the following categories:

A. Plant Process Display Instrumentation

   Information available to the operator for monitoring conditions in the reactor and related systems.

B. Reactor Protective System (RPS) Monitoring

   Information available to the operator for monitoring the status of the RPS.

C. Engineered Safety Features (ESF) System Monitoring

   Information available to the operator for monitoring the status of each ESF system.

D. Control Element Assembly (CEA) Position Indication

   Information available to the operator for monitoring the position of the CEAs.

E. Post Accident Monitoring Instrumentation

   Information available to the operator for monitoring the status of the reactor during and following an accident.

7.5.1.1 Plant Process Display Instrumentation

Table 7.5-1 lists the significant process instrumentation which is provided to inform the operator of the status of the reactor plant. This information, which is used for the startup, operation, and shutdown of the plant, is provided on the main control board. The information is provided in a form that is useful to the operator and may be indicated, recorded, or monitored in conjunction with a controlling function. Alternate indication and control instrumentation is provided at local stations outside the control room to allow reactor shutdown and maintenance of the reactor in a safe condition during hot shutdown or cold shutdown should the control room become inaccessible (see Section 7.4.1.5).

7.5.1.2 Reactor Protective System Monitoring

Even though the RPS is automatic and does not require operator action, sufficient information is provided in the control room to allow the operator to confirm that a limiting safety system setting has been reached and a trip has taken place. This information consists of indication of (1) process parameters which initiate reactor trip; (2) trip, pretrip, and bypass lights; (3) audible alarms; (4) CEA position information; and, (5) trip switchgear circuit breaker position indication.

Operating bypass indication as described in Section 7.1.2.9 is provided on the remote modules which are located on the main control board. Individual trip channel bypass indication is provided locally at the Plant Protection System (PPS) as well as on the remote modules on the main control board (see Sections 7.2.1, 7.5.1.1 and 7.5.1.4).

7.5.1.3 Engineered Safety Features Monitoring

The Engineered Safety Features Actuation System (ESFAS) continuously monitors the various system input parameters and performs the actuation logic required to initiate safeguards should these inputs reach their trip setpoints. The ESF systems are designed such that their actuation occurs automatically in the event of an accident without the requirement for operator action.

After the automatic actuation of the ESF systems, they will continue to function properly without operator action. When the transfer of safety injection pump suction from the refueling water tank to the containment sump is required, the Recirculation Actuation Signal (RAS) will automatically actuate this transfer.

Post-accident information is available in the control room to allow the operator to monitor system performance. This information consists of valve position indication, pump operating status, flow indication, and indication of the process parameters which actuate ESF systems (see Section 7.5.1.5). In addition, four control modules, each associated with one channel of the PPS are located on the control board to provide indication of the pretrip, trip, and bypass condition of each of the actuation system input signals. Individual trip channel bypass indication is provided locally at the PPS as well as on the remote modules of the main control board.

7.5.1.4 CEA Position Indication

Two diverse, independent systems of CEA position indication provide CEA position information to the operator. The systems are the pulse counting CEA position indication system and the reed switch CEA position indication system. These systems are described below.

7.5.1.4.1 Pulse Counting CEA Position Indication System

The pulse counting CEA position indication system infers each CEA position by maintaining a record of the "RAISE" and "LOWER" control pulses sent to each magnetic jack Control Element Drive Mechanism (CEDM). The pulse counting CEA position signal associated with each CEA is reset to zero whenever the rod drop contact (located within the reed switch position transmitter housing) is closed. This permits the pulse counting system to automatically reset the position to zero whenever a reactor trip occurs or whenever a CEA is dropped into the core. This system is incorporated in the plant computer. A printout is available, on operator demand, of selected CEA positions. The plant computer also provides CEA deviation information.

The pulse counting CEA position indication system provides position information to CEA related alarm programs and the Core Operating Limit Supervisory System (COLSS) contained in the plant computer. The plant computer CEA and COLSS alarms can be displayed on the plant computer monitors and hard copy printouts are available on demand. The alarms are included in the system design to provide the operator with information required to maintain proper CEA control and to aid in the monitoring of CEA limits. The following alarms are provided by the pulse counting CEA position indication system:

A. Power Dependent Insertion Limits (PDIL) Alarms

An alarm is provided in the event CEA insertion exceeds predetermined limits required to maintain adequate shutdown margin and to ensure CEA insertion consistent with the CEA ejection analysis. Further definition of the PDIL function is provided in Section 7.7.1.4.

B. Pre-Power Dependent Insertion Limits (PPDIL) Alarm

This alarm is provided to advise the operator of an impending approach to PDIL.

C. Out of Sequence Alarm

An alarm is provided to alert the operator in the event the CEA groups are inserted in a sequence other than the pre-determined acceptable sequence.

D. CEA Deviation Alarm

An alarm is provided to alert the operator in the event the deviation in position between the highest and lowest CEA in any group exceeds a predetermined allowable deviation.

E. Core Operating Limit Supervisory System Alarms

The pulse counting CEA position indication system provides input data to COLSS. This data is used in the COLSS power distribution calculations and alarms are initiated in the event the affected COLSS limits are reached. The basis for the COLSS alarms is discussed in Section 7.7.1.3.2 and the use of the pulse count CEA position information is discussed in Section 7.7.1.3.3.3.

7.5.1.4.2 Reed Switch CEA Position Indication System

The reed switch CEA position indication system utilizes a series of magnetically actuated reed switches (reed switch position transmitters) to provide signals representing CEA position. Two independent reed switch position transmitters are provided for each CEA. The Reed Switch Position Transmitter (RSPT) provides an analog position indication signal and three physically separate discrete reed switch position signals. The analog position indication system utilizes a series of magnetically actuated reed switches spaced at 1½-inch intervals along the RSPT assembly and arranged with precision resistors in a voltage divider network. The RSPT is affixed adjacent to the CEDM pressure housing which contains the CEA extension shaft and actuating magnet. The analog output signal is proportional to the CEA position within the reactor core. The three discrete reed switch position signals are contact closure signals from three separately located reed switches. These signals are an upper electrical limit, a lower electrical limit and a rod drop contact.

The analog reed switch CEA position signals are input to the DNBR/LPD calculation system (see Sections 7.2.1.1.2.2 and 7.2.1.1.2.5). CEA position information is provided to the Core Protection Calculators (CPCs) directly and also to the CEA calculators (see Section 7.2.1.1.2.5). The CEA Calculators display CEA position to the operator in a bar chart format and in inches withdrawn on the CPC/CEAC operator's modules in Channels B and C on the main control board. In addition, a digital readout is provided which can be utilized to read the position of a CEA group and deviated CEA. The operator can address any analog position signal for display

on the operator's module. In addition to the displays, CEA deviation information is provided by the CEA calculators to the CPCs and a CEA deviation alarm. The CEA deviation alarm is provided to the the plant annunciator system in the event a CEA calculator indicates that the difference between the highest and lowest CEA positions in a group exceeds a predetermined allowable deviation. The CEA deviation information is used in the CPCs determination of power distribution as defined in Section 7.2.1.1.2.5. The power distribution is then factored into the low Departure from Nucleate Boiling Ratio (DNBR) and high local power density trip function. Pretrip alarms are initiated in the event the DNBR or local power density trip limits are approached. A pretrip alarm light is provided on the PPS control panel (both local and remote). Also, a pretrip alarm is provided to the plant annunciator system.

The three discrete CEA position switches provide signals (contact closure signals) to the Control Element Drive Mechanism Control System (CEDMCS) as shown in Figure 7.2-14. The signals are utilized to provide CEA limit indication on the main control board and also to provide input to the CEA control interlocks. Each of the three discrete reed switch contacts actuates an interface relay located within the CEDMCS. These relays provide contact signals for indication and control and, in the case of the rod drop switch, an additional contact signal is provided to the plant computer to set the pulse counting system (see Section 7.5.1.4.1). The upper and lower electrical limits indication appears as two separate lights on the CEDMCS Control Panel mounted on the main control board. The CEA drop indication is available on the SPDS CEA mimic display.

7.5.1.5 Post Accident Monitoring Instrumentation

Indications of plant variables are required by the control room operating personnel during accident situations to (1) provide information required to permit the operator to take preplanned manual actions to accomplish safe plant shutdown; (2) determine whether the reactor trip, safety-feature systems, and manually initiated safety systems and other systems important to safety are performing their intended functions (i.e., reactivity control, core cooling, maintaining reactor coolant system integrity, and maintaining containment integrity); and (3) provide information to the operators that will enable them to determine the potential for causing a gross breach of the barriers to radioactivity release (i.e., fuel cladding, reactor coolant pressure boundary, and containment) and to determine if a gross breach of a barrier has occurred. In addition to the above, indications of plant variables that provide information on operation of plant safety systems and other systems important to safety are required by the control room operating personnel during an accident to (1) furnish data regarding the operation of plant systems in order that the operator can make appropriate decisions as to their use and (2) provide information regarding the release of radioactive materials to allow for early indications of the need to initiate action necessary to protect the public and for an estimate of the magnitude of any impending threat.

7.5.2 ANALYSIS

7.5.2.1 Analysis of Plant Process Display Instrumentation

Plant process instrumentation is provided to give the operator sufficient information to monitor conditions in the plant and perform any operations that are required. The following design criteria were used in the selection of plant instrumentation:

A. To provide continuous monitoring of process parameters required by the operator;

B. To provide a permanent record of those parameters for which trend information is useful;

C. To provide display information to the operator that is reliable, comprehensible, and timely;

D. To provide multiple channels of indication for RPS and ESFAS process parameters to allow cross-checking of channels; and,

E. To provide instrumentation display that adequately monitors the parameter over the range required for various conditions.

The information provided is sufficient to allow the operator to accurately assess the conditions within the plant systems and, in a timely manner, perform those appropriate actions to maintain the plant systems within the conditions assumed in the safety analysis, Chapter 15. In addition, the information allows cross-checking of RPS and ESFAS measurement channels to assure operational availability of these channels as discussed in Sections 7.2.1 and 7.3.1.

7.5.2.2 Analysis of Reactor Protective System Monitoring

Sufficient information is provided to allow confirmation that a trip has occurred and to determine the process parameter that has provided a trip input.

CEA insertion information can be determined by the operator after a trip by CEA Calculator Operator's Module Displays and CEA limit light indication (see Section 7.5.1.4).

Indication of neutron levels as well as other reactor and RCS information is provided for the operator in the control room.

The following design criteria were used in the selection of information that is provided to the operator:

A. System conditions requiring operator attention during routine plant operations and at the time of reactor trip are displayed on the control board;

B. Annunciation at the control board of all operations performed at the PPS cabinet affecting the function of the system;

C. Annunciation and indication at the control board of any plant variables that are manually bypassed at the PPS cabinet; and,

D. Indication of removal of a bypass.

7.5.2.3 Analysis of Engineered Safety Features Monitoring

Sufficient information is provided to the operator to allow monitoring of the status of the ESF systems. The following design criteria were used in the selection of information that is provided to the operator:

A. System conditions requiring operator attention or action during routine plant operations are displayed and/or controlled at the control board;

B. Annunciation at the control board of all operations performed at the cabinet affecting the function of the system;

C. Indication of plant variables that are manually bypassed; and,

D. Indication of automatic removal of bypasses.

Consistent with the above criteria, the information shown in Table 7.5-2 is provided for the operator's use.

The information provided is sufficient to allow the operator to determine that manual actuation of an ESF system is required and to confirm proper system operation after automatic initiation.

Input parameters used for actuation are indicated on the control board as are positive indications that pumps and valves have actuated and that flows have been established.

7.5.2.4 Analysis of Control Element Assembly Position Indication

CEA position indication is provided to allow the operator to easily determine the position of all of the CEAs within the reactor core. The information is presented in a form that can be easily assessed by the operator. He can easily determine that the CEAs are in the required position, that a CEA has dropped into the core, or that the CEA positions are as required after a reactor trip.

The CEA position indication system is designed to provide the following:

A. Position readouts of all CEAs (multiple CEAC operator's module displays are required);

B. A means of alerting the operator to deviation of CEAs within a group;

C. A permanent record of the position of any or all CEAs;

D. Separate "full-in" and "full-out" indication for each CEA; and,

E. Redundant and diverse means of indicating CEA position.

7.5.2.5 Analysis of Post-Accident Monitoring Instrumentation

Table 7.5-3 lists the variables committed to by ANO and recommended by Regulatory Guide 1.97, Revision 3. The table includes the assigned category, range, redundancy, power supply, type of control room display, availability on the Safety Parameter Display System (SPDS), and comments.

7.5.2.5.1 Table Format

The power supply column specifies the type of available power as follows:

1E - instrument is powered from a qualified 1E power source.

UPS - instrument is powered from a battery backed uninterruptable power source

DG - instrument is powered from a source that is backed by the emergency diesel generators.

OP - instrument is powered from the normal offsite power source.

The SPDS column specifies whether the variable is available on the SPDS display. The SPDS display is located in both the Unit 1 and Unit 2 Control Rooms, the Technical Support Center, and the Emergency Offsite Facility.

Another type of Control Room Display is the Radiological Dose Assessment Computer System (RDACS). The RDACS is a computerized dose projection system which combines effluent release data with real time meteorological data. RDACS terminals are located in the same facilities as the SPDS.

7.5.2.5.2 Definition of Variables

The variables identified in Table 7.5-3 are divided into five types in accordance with Regulatory Guide 1.97. The definition for each type of variable is as follows:

Type A - Those variables which provide the primary information required to permit the control room operators to take specific manual actions for which no automatic control is provided, and that are required for a safety system to accomplish its safety function for design basis accident scenarios. Type A variables are plant specific and were selected based on a review of Emergency Operating Procedures to identify information essential for the direct accomplishment of specified safety functions. As a result of a review of the ANO-2 Emergency Operating Procedures, the following variables were identified as Type A:

RCS Hot Leg Water Temperature
RCS Pressure
Steam Generator Level
Steam Generator Pressure

HPSI System Flow has subsequently been upgraded to Type A

Type B - These variables provide information to indicate whether plant safety functions are being accomplished. Plant safety functions are defined as: reactivity control, core cooling, maintaining reactor coolant system integrity, and maintaining containment integrity.

Type C - These variables provide information to indicate the potential for breach of the barriers to fission product release. The barriers are defined as: fuel cladding, primary coolant pressure boundary, and containment.

Type D - These variables provide information to indicate the operation of individual safety systems and other systems important to safety. These variables help the operator make appropriate decisions in using the individual systems important to safety in mitigating the consequences of an accident.

Type E - These variables provide information for use in determining the magnitude of the release of radioactive materials and for use in assessing the consequences of such releases.

7.5.2.5.3 Evaluation Criteria

As recommended by Regulatory Guide 1.97, each variable type was evaluated based on the importance to safety of the measurement of the specific variable. The criteria are therefore separated into three categories for a graded approach as follows:

Category 1: provides the most stringent requirements and is intended for key variables. Type A, B and C key variables fall into this category.

Category 2: provides less stringent requirements and applies to instrumentation designated for indicating system operating status. Type D and E key variables fall into this category.

Category 3: provides requirements that will ensure that high quality off-the-shelf instrumentation is obtained and applies to backup and diagnostic instrumentation. This category is also used when the state-of-the-art will not support requirements for higher qualified instrumentation. All backup variables fall into this category.

The specific design and qualification criteria used to evaluate each variable, based on the category classification, are presented below:

Category 1:

Environmental Qualification - Currently installed instrumentation was evaluated to determine if, as a minimum, the equipment meets the requirements of IE Bulletin 79-01B and 10 CFR 50.49. This determination was based on having either actual environmental qualification documentation available or documentation on similar equipment available.

Seismic Qualification - Currently installed instrumentation was evaluated against the seismic qualification criteria used as a basis for the plant operating license. These criteria are described in Section 3.10. The ANO-2 seismic criteria are synonymous with the requirements for Class 1 equipment as defined in IEEE Standard 344-1971, 1975, or 1987. New instrumentation will be installed in accordance with the criteria specified.

Redundancy and Sensor Location - A response of "Yes" in the redundancy column indicates that redundant channels are available up to and including any isolation device and that the channels are both electrically independent and physically separate from each other and from non-safety equipment in accordance with IEEE Standard 279-1971. This standard was used as the basis for the ANO-2 operating license and meets the intent but not all the strict requirements for physical separation of redundant channels as defined in Regulatory Guide 1.75. Where applicable, the general sensor location is listed.

Power Supply - All Category 1 instruments are supplied with power from a Class 1E power supply. The ANO-2 Class 1E power system is designed to meet the requirements of IEEE 279-1971, IEEE 308-1971, 10CFR50 including Appendices A and B, and Regulatory Guide 1.6.

Quality Assurance - All instrumentation was, and will continue to be, purchased and installed in accordance with the provisions of the NRC approved Quality Assurance Program described in the Quality Assurance Program Manual.

Control Room Display and Recording - Continuous real-time display of at least one channel is provided in the Control Room. Recording of the instrument readout information is provided for at least one of the redundant channels, although this recording may be "Non-Q". It may also be used for the continuous display above if qualified. Variables which input to the SPDS may be displayed and/or trended on demand. Where it has been determined that direct and immediate trend or transient information is essential for operator information or action (type A variable), a continuous dedicated recorder is provided with redundant backup recording and trending available on SPDS and redundant dedicated indicators in the control room that can be utilized for trend information if necessary (one of the redundant dedicated indicators may be the continuous dedicated recorder listed above).

Category 2:

Environmental Qualification - Same as Category 1.

Seismic Qualification - No specific provision.

Redundancy - Not required.

Power Supply - Powered by DG or UPS, both considered to be highly reliable.

Quality Assurance - Same as Category 1.

Control Room Display - "On-demand" or continuous display is provided in the control room. No direct or immediate trend or transient information was determined to be essential for operator information or action.

Category 3:

Environmental Qualification - Not required.

Seismic Qualification - Not required.

Redundancy - Not required.

Power Supply - Powered by an available source of power.

Quality Assurance - Same as Category 1.

Control Room Display - Same as Category 2.

7.6 ALL OTHER SYSTEMS REQUIRED FOR SAFETY

7.6.1 DESCRIPTION

This section includes a description of those systems required for safety which have not been discussed in Sections 7.2 through 7.5. These systems include instrumentation to prevent overpressurization of low pressure systems.

7.6.1.1 Shutdown Cooling System Interlocks

7.6.1.1.1 Description

The Shutdown Cooling (SDC) System, described in Section 9.3.6, is designed as a low pressure system. The shutdown cooling suction line inside containment contains two normally closed, locked-closed, motor operated valves in series (2CV-5084-1 and 2CV-5086-2), ensuring that the low pressure piping is not exposed to normal Reactor Coolant System (RCS) pressure. Administrative controls, procedures and interlocks prevent opening these valves before the RCS has been depressurized.

Key locked control switches are provided in the control room to permit opening of the isolation valves. Interlocks prevent the valves from being opened unless the RCS pressure is below 350 psia. If a valve is open and RCS pressure rises above the setpoint, an alarm is received in the control room; however, operating limits are bounded by Section 3.6.1. All other interfaces between the RCS and systems with lower design pressures are addressed in Section 5.2.1.19.

Two independent and diverse pressurizer pressure measurement channels and bistables provide the permissive signals for SDC isolation valve interlocks. Pressure measurement channel 2PC-4623-1 supplies a permissive signal for SDC isolation valve 2CV-5084-1. This channel also supplies a permissive signal for two safety injection tank isolation valves, 2CV-5003-1 and 2CV-5023-1. Pressure measurement channel 2PS-4623-2 supplies a permissive signal for SDC isolation valve 2CV-5086-2. This channel also supplies a permissive signal for the other two safety injection tank isolation valves, 2CV-5043-2 and 2CV-5063-2. Isolation is provided between SDC valve interlocks and the Safety Injection Tank (SIT) valve interlocks by means of two interposing relays per pressure channel which are an integral part of the electronic bistable controller. One relay isolates SDC interlock and the other isolates the SIT interlocks. The instrument channels 2PC-4623-1 and 2PS-4623-2 are more fully described in Section 7.6.2.2.1.

Loss of electric power to either pressure measurement channel can cause the associated SDC valve mispositioned alarm to actuate. The logic for valve 2CV-5084-1 is identical with the exception of being served by pressure channel 2PC-4623-1.

7.6.1.1.2 Design Basis Information

The design basis for the shutdown cooling interlocks is to prevent an equipment fault or an operator action from producing an unsafe condition. The interlocks have no protective function as defined in IEEE 279-1971. However, using Section 3 of IEEE 279-1971 as a guideline, the following paragraphs respond to the provisions identified in Section 3 insofar as they are applicable:

A. The interlocks will function to prevent opening the shutdown cooling line isolation valves whenever pressurizer pressure exceeds a preset value;

B. Pressurizer pressure will be monitored to provide the required function;

C. Two separate, physically independent and diverse pressure sensors located on separate pressurizer nozzles are provided, either of which will perform the required function;

D. Operating procedures, administrative controls and the interlocks all serve to ensure that the isolation valves are not open when pressure in the RCS is greater than the design pressure of the shutdown cooling suction lines; and,

E. When system pressure exceeds the setpoint and the valve is open, an alarm is received in the control room.

7.6.1.2 Safety Injection Tank Isolation Valve Interlocks

7.6.1.2.1 System Description

Four safety injection tanks are provided to flood the reactor vessel with borated water following RCS depressurization as a result of a Loss of Coolant Accident (LOCA). During normal plant operation, each Safety Injection Tank (SIT) is isolated from the RCS by two check valves in series. The safety injection tanks automatically discharge into the RCS if system pressure decreases below the SIT pressure.

It is essential that the isolation valves on the SITs remain open whenever the RCS is at pressure. To ensure that the SIT valves remain open, these fail-as-is valves are normally key locked open in the control room and one of the series of motor circuit breakers for each valve is locked open, effectively blocking power to the valve operator. Under normal operating conditions, the closed position of the valve is annunciated in the control room. In addition, a Safety Injection Actuation Signal (SIAS) "OPEN" signal is provided to each valve even though the valves are locked open.

The closing of a safety injection tank discharge valve can be accomplished by:

A. Manual operation of a control switch in the control room; or

B. Manual operation of a control switch at the Motor Control Center (MCC).

The control room switch is a maintained contact, key-operated switch; it is locked in the valve-open position.

These design features ensure that no single failure, including a hot short, will cause valve closure during normal reactor operations.

Visual indication of the open or closed status of the valve is provided by indicator lights, actuated by a separate set of stem mounted valve position limit switches. The indicator lights are powered from Class 1E 125-volt DC supply totally independent of the 480-volt AC valve operator power supply. In addition, the reactor coolant pressure signal is interlocked with a separate valve position limit switch to sound an alarm in the control room if the valves are not fully open when the pressurizer pressure is above 675 psia.

Pressurizer pressure interlocks are provided to automatically open these valves (should they be closed) when increasing RCS pressure reaches 675 psia. The interlocks are served by pressurizer pressure measurement channels 2PC-4623-1 and 2PS-4623-2, which also serve the SDC isolation valve interlocks.

7.6.1.2.2 Design Basis Information

The design basis for the safety injection tank isolation valve pressure interlocks is to provide a means of ensuring that the safety injection tanks are not isolated from the RCS when the system pressure exceeds a preset value. The interlocks have no protective function as defined in IEEE 279-1971. However, using Section 3 of IEEE 279-1971 as a guideline, the following discussion responds to the provisions identified in Section 3, insofar as they are applicable:

A. The pressure interlocks shall function to open the safety injection tank isolation valves whenever pressurizer pressure exceeds a preset value;

B. Pressurizer pressure shall be monitored to provide the required function;

C. Two separate, physically independent pressure sensors on separate pressurizer nozzles shall be provided, either of which will perform the required function;

D. Operating procedures, administrative controls and the interlocks all serve to ensure that the isolation valves are open when pressure in the RCS is greater than a preset value; and,

E. No protective operator action is required. When system pressure exceeds the setpoint, the interlock functions to open the valves.

The design of the control circuits for the SIT isolation valves incorporates the following features:

A. Automatic opening of the valves when either (1) the RCS pressure exceeds a pre-selected value, or (2) a safety injection signal has been initiated. Both signals are provided to the valves.

B. In the event of loss of power supply, pressurizer pressure measurement channel output relays and also the SIAS group relays fail to the "SAFE" position generating a "VALVE OPEN" command signal.

C. Visual indication of the open or closed status of the valves, actuated by sensors on the valves is provided in the control room. The indication is independent of the valve power supply.

D. An audible and visual alarm is provided, actuated by a sensor on the valves when the valves are not in the fully open position and indicates the "SYSTEM INOPERABLE" status.

E. A SIAS is provided to open the valves. There are no overrides or bypasses that would inhibit the SIAS signal and prevent the valves from opening when required.

7.6.1.3 Low Temperature Overpressure Protection (LTOP)

7.6.1.3.1 System Description

Two LTOP relief valves (2PSV-4732 and 2PSV-4742) are operator enabled during cooldown with RCS temperature between 275 °F and 270 °F and isolated during heatup between 275 °F and 280 °F. The setpoint of the LTOP relief valve is less than or equal to 430 psig. Overpressure protection may also be provided by an equivalent RCS opening. Examples of equivalent RCS openings are removal of the steam generator primary manway on the hot leg, removal of the pressurizer safety valve, removal of the pressurizer manway, or removal of the reactor vessel head.

The design requires only that the operator line up the low setpoint relief valves during cooldown and isolate during heatup. An alarm circuit is provided to alert the operator if the RCS temperature drops to 270 °F and any isolation valve is not fully open.

7.6.1.3.2 Design Basis Information

This system design meets the following criteria.

A. LTOP Design Basis Event – The relief capacity of one relief valve (2PSV-4732 or 2PSV-4742) can accommodate mass or energy addition events. The limiting LTOP design basis event is the energy addition event. The analyses assume that the safety injection tanks (SITs) are either isolated or depressurized such that they are unable to challenge LTOP relief setpoints. The relief valves will be able to mitigate (1) the starting of the first reactor coolant pump when the pressurizer water volume is < 910 ft^3, and when the secondary water temperature of the steam generator is less than or equal to 100 °F above the RCS temperature (energy addition event), or (2) the simultaneous injection of one HPSI pump and all three charging pumps (mass addition event). Because the SDC system effectively becomes an extension of the RCS when SDC is in service, the LTOP relief valves act as overpressure protection devices for the SDC system.

B. Credit for Operator Action - No credit has been taken for operator action after the low setpoint relief valves have been lined up or an equivalent RCS opening has been established.

C. Single Failure Criteria - In order that the RCS be protected from a single failure in the protection system, a redundant relief valve train is included in the protection system design. If redundancy is not available, an equivalent RCS opening is established.

D. Testability - The capability to test the relief valves has been incorporated into the system design. The testing will be done to the guidelines contained in ASME OM Code.

E. Seismic Design and IEEE 279 Criteria - The relief valve isolation valve control and alarm circuitry meets Seismic Category 1 and IEEE 279 criteria. Also, the overpressure protection relief valves meet Seismic Category 1 criteria (see Section 7.6.2.3 for further details).

7.6.1.4 Other Systems

Historical data removed - To review the exact wording please refer to Section 7.6.1.3 of the FSAR.

7.6.2 ANALYSIS

7.6.2.1 Shutdown Cooling System Interlocks

7.6.2.1.1 Requirements

There are no specific regulatory guides or general design criteria which apply to these interlocks.

The requirements of IEEE 279-1971 are written expressly for protection systems, and as such, they are not directly applicable to these interlocks. A discussion of the extent to which these interlocks comply with IEEE 279 is provided below:

The following discussion refers to the requirements set forth in the respective items of Section 4 of IEEE 279-1971;

"4.1 General Functional Requirement"

The interlocks have been designed as Class 1E circuits.

"4.2 Single Failure Criterion"

Any single failure leading to loss of one channel will not result in opening both of the valves installed in series. Loss of both interlock channels, coupled with violation of administrative controls and procedures is required to remove the pressure boundary between the RCS and the piping comprising the SDC suction lines.

"4.3 Quality Control of Components and Modules"

The sensors for these interlocks are subject to the same quality requirements that are imposed on protection system instrumentation.

"4.4 Equipment Qualification"

Type tests are performed on the instrumentation to assure operation during expected conditions of seismic activity.

"4.5 Channel Integrity"

The interlocks are only required to maintain functional capability in the normal plant operating environment. They serve no protective function during abnormal or accident situations, as defined in IEEE 279-1971.

"4.6 Channel Independence"

The pressure transmitters are located on separate pressurizer nozzles, and separation is maintained between channels.

"4.7 Control and Protection System Interaction"

The interlocks have no protective function during abnormal or accident situations, as defined in IEEE 279-1971. Thus, there is no control and protective system interaction.

"4.8 Derivation of System Inputs"

Pressurizer pressure is used as the signal for these interlocks.

"4.9 Capability for Sensor Checks"

The operational availability of the two pressure sensing channels can be determined by comparing their outputs when the pressure is in the range of interlock operation.

"4.10 Capability for Test and Calibration"

Since the interlocks will be in effect when the plant is at operating pressure, the capability of testing their function will be available by observing that the valve does not open when the hand switch is moved to the open position. Additional testing of the pressure interlock can be performed when the plant is shut down and in a reduced pressure condition by inserting a test signal to the bistable.

"4.11 Channel Bypass or Removal From Operation"

Removal of one instrument channel for testing does not compromise system reliability. Failure of the remaining instrument channel during a test outage would not create an unacceptable situation, since administrative controls (key locks) effectively preclude inadvertent opening of the valves by the operator.

"4.19 Identification of Protective Action"

The isolation function is indicated by the valve position indication.

"4.20 Information Readout"

The readout consists of two pressure indicators and position indication for each of the valves. This provides the operator with clear, concise information.

"4.21 System Repair"

The components are accessible for repair. One channel can be placed out of service without jeopardizing the isolation of SDC.

"4.22 Identification"

The instrumentation and cables associated with SDC interlocks will not be uniquely identified as such. The channels will, however, be identified to distinguish between redundant channels.

7.6.2.2 Safety Injection Tank Isolation Valve Interlocks

7.6.2.2.1 Requirements

Historical data removed - To review the exact wording please refer to Section 7.6.2.2.1 of the FSAR.

There are no specific regulatory guides or general design criteria which apply to these interlocks. However, instrument channels 2PS-4623-2 and 2PC-4623-1 provide permissive interlocks for SDC, as described in Section 7.6.1.1.1. 2PS-4623-2 and 2PC-4623-1 are, however, provided with separate switch contacts and setpoints for SDC interlocks and the SIT isolation valves. Either an SIAS or a manual control switch, e.g. 2HS-5023-1, "OPEN" signal will open the respective SIT isolation valve regardless of the switch status of any of the 2PC-4623-1 or 2PS-4623-2 interlock contacts. The above provisions ensure that no single failure of SDC isolation valves will prevent the opening of any one of the SIT isolation valves.

The requirements of IEEE 279-1971 are written expressly for protection systems, and as such, they are not directly applicable to these interlocks. A discussion of the extent to which these interlocks apply to this IEEE standard is provided below.

The following discussion refers to the requirements set forth in the respective items of Section 4 of IEEE 279-1971.

"4.1 General Functional Requirement"

The interlocks have been designed as Class 1E circuits and will function under abnormal and accident conditions.

"4.2 Single Failure Criterion"

Loss of the interlock channels, coupled with violation of administrative controls and procedures is required to prevent the isolation valves from opening as RCS pressure is increased or to permit closing a valve when at pressure. No single failure of an interlock channel can prevent system operation when it is required.

"4.3 Quality Control of Components and Modules"

The sensors for these interlocks are subject to the same quality requirements that are imposed on protection system instrumentation.

"4.4 Equipment Qualification"

Type tests (as described in Sections 3.10 and 3.11) are performed on the instrumentation to ensure operation during expected conditions of seismic activity.

"4.5 Channel Integrity"

The interlocks have been designed to maintain functional capability when exposed to accident environments. They will not preclude safety injection during accident conditions.

"4.6 Channel Independence"

The pressure transmitters are located on separate pressurizer nozzles, and separation is maintained between channels.

"4.7 Control and Protection System Interaction"

The interlocks automatically open the valves when RCS pressure reaches 675 psia.

"4.8 Derivation of System Inputs"

Pressurizer pressure is used as the signal for these interlocks.

"4.9 Capability for Sensor Checks"

The operational availability of the two pressure sensing channels can be determined by comparing their outputs when the pressure is in the range of interlock operation.

"4.10 Capability for Test and Calibration"

The capability of testing the interlock function at operating pressure is available. Additional testing of the pressure interlock can be performed when the plant is shut down and in a reduced pressure condition by inserting a test signal to the bistable.

"4.11 Channel Bypass or Removal from Operation"

Removal of one instrument channel for testing does not compromise system reliability. Failure of the remaining instrument channel during a test outage would not create an unacceptable situation, since administrative controls (key locks) effectively preclude inadvertent opening of the valves by the operator.

"4.19 Identification of Protective Action"

The isolation function is indicated by the valve position indication.

"4.20 Information Readout"

The readout consists of two pressure indicators and position indication for each of the valves. This provides the operator with clear, concise information.

"4.21 System Repair"

The components are accessible for repair. One channel can be placed out of service without jeopardizing the isolation of SDC.

"4.22 Identification"

The instrumentation and cables associated with SDC interlocks will not be uniquely identified as such. The channels will, however, be identified to distinguish between redundant channels.

7.6.2.3 Low Temperature Overpressure Protection

7.6.2.3.1 Requirements

The alarm circuit, which ensures that the control room operator is alerted if the temperature of the RCS drops below 270 °F and if any of the isolation valves are not fully open, meets the design basis and requirements of IEEE 279-1971, as delineated below.

Design Basis

The only variables which are needed to effect Low Temperature Overpressure Protection (LTOP) operation are pressure and temperature. The temperature inputs to the system logic are fully qualified channels and are physically separated from one another. The temperature limits (setpoints) selected are 270 °F and 280 °F. The dead-band allows sufficient time for the control room operator to open the valve so that the system is operable below 270 °F. The equipment has been seismically qualified to Arkansas Nuclear One - Unit 2 design basis requirements so it is able to withstand the anticipated transients for the system. The accuracies of the instrumentation are adequate for the appropriate operation of the system. The ranges of measured variables are sufficient to assure proper action is taken.

Design Requirements

The following discussion refers to the requirements set forth in the respective items of Section 4 of IEEE 279-1971.

"4.1 General Functional Requirement"

As no automatic function is performed by the system design, this requirement is not applicable.

"4.2 Single Failure Criterion"

The alarms for LTOP are on separate safety channels and are generated by redundant sensors.

"4.3 Quality Control of Components and Modules"

The quality control enforced for LTOP is in accordance with the quality assurance program covered in the Quality Assurance Program Manual (QAPM).

"4.4 Equipment Qualification"

All electrical components have been seismically qualified in accordance with design basis requirements.

"4.5 Channel Integrity"

The temperature inputs to the system logic are fully qualified channels and are physically separated from one another.

"4.6 Channel Independence"

Channel independence is achieved by physical and electrical separation.

"4.7 Control and Protection System Interaction"

1. Classification of Equipment - Not applicable.

2. Isolation Devices - Qualified isolators are utilized to isolate the LTOP alarm circuitry from the inputs to other systems.

3. Single Random Failure - The system has been designed to be immune to any single random failure. The failure of a control system will not affect the design.

4. Multiple Failures Resulting From a Credible Single Event - The failure of a control system will not affect this design.

"4.8 Derivation of System Inputs"

All inputs to the alarm logic come from direct measurements.

"4.9 Capability for Sensor Checks"

The alarm logic can be tested from the sensor to the alarm without compromising the RCS integrity.

"4.10 Capability for Test and Calibration"

The alarm logic can be tested from the sensor to the alarm and the isolation valves can be individually tested without compromising the system.

"4.11 Channel Bypass or Removal From Operation"

The isolation valves can be individually tested without compromising the system.

"4.18 Access to Setpoint Adjustments, Calibration, and Test Points"

All electrical setpoints can be administratively adjusted.

"4.20 Information Readout"

All indication is derived directly from the sensors. Indication is continuous.

"4.21 System Repair"

Any electrical malfunction can be identified and corrected.

"4.22 Identification"

All components are identified with unique identification.

7.6.2.4 Other Systems

Historical data removed - To review the exact wording please refer to Section 7.6.2.3 of the FSAR.

7.6.2.5 Safety Parameter Display System (SPDS)

The SPDS is a computer-based system designed to monitor and display to the operator a concise set of parameters from which the safety status of the plant can be readily and reliably ascertained. The system functions as the SPDS for both the ANO-1 and ANO-2 Control Rooms and provides plant status information for the Technical Support Center (TSC) and Emergency Operations Facility (EOF).

7.6.2.5.1 Background

The development of an SPDS began in 1979 as part of an in-house initiated EOP upgrade program and expanded the development early in 1980, in response to the "Lessons Learned" NUREGs 0578 and 0585. NUREG-0737, issued in October 1980, required the implementation of the plant SPDS. NUREG-0737 referenced NUREG-0696 for use as the criteria for design of the SPDS and Technical Support Center (TSC)/Emergency Response Facility (ERF) instrumentation systems. However, NUREG-0696 was not issued until March 1981, so several modifications were required to the original computer system design as a result of the new guidance. Supplement 1 of NUREG-0737 was issued in December 1982 to provide additional clarification to certain NUREG-0737 requirements.

Supplement 1 also promoted an integrated approach for the implementation of the SPDS, upgraded Emergency Operating Procedure (EOP), control room design reviews, emergency response facilities and Regulatory. Guide 1.97 instrumentation reviews. The present SPDS computer system is designed to meet the objectives of the above referenced NRC documents as described in the ANO-2 SPDS safety analysis submitted to the NRC April 30, 1984 (2CAN048402).

The SPDS concept was to display a small but critical subset of the information already presented by control room instrumentation in order to minimize information overload. Critical safety functions identified by NUREG 0737, Supplement 1 were carefully identified and parameters for their display selected in order to provide the operators with a concise set of data to aid them in rapidly and reliably determining the safety status of the plant. Selection of these parameters was also coordinated with the development of the upgraded ANO-2 EOP.

7.6.2.5.2 Design Basis

In accordance with NUREG 0737, Supplement 1, the SPDS was designed to assist the operator in implementing the upgraded EOP. The ANO-2 EOP was developed to achieve timely and accurate safety status assessment either with or without the SPDS. The design of the specific SPDS graphic displays correspond to specific sections of the upgraded EOP, so the SPDS will complement the use of the upgraded EOP.

The basic configuration of the SPDS consists of redundant data acquisition, processing and display devices. The SPDS computers access the necessary input parameters from sensors in ANO-1 and ANO-2, process these signals, and provide displays to each control room as well as to the TSC and EOF. The SPDS performs no plant control action, but serves as a human-engineered data display system to aid the operator in rapidly and reliably determining plant safety status. The SPDS design should provide enhanced capabilities for responding properly to both anticipated and unanticipated plant conditions.

The SPDS design also includes displays in the TSC and EOF. This improves the operational aids available to the plant technical staff to assist them in evaluating transient conditions and providing guidance and direction to the operations staff. The TSC and EOF both have access to the large-scale data storage and retrieval capabilities of the SPDS to assist in event diagnosis and historical documentation.

Considerable effort has been expended during the initial design of the SPDS to incorporate human factors principles. In addition, the ANO Operations staff has played a vital role in the SPDS design and implementation to ensure that the system will be responsive to the needs of the operators during normal and emergency conditions. The SPDS was included in the scope of the Control Room Design Review (CRDR) program to formally evaluate the proper incorporation of human factors principles including equipment location, display formats and characteristics, operator interfaces and compatibility with the EOP.

The SPDS was designed to be isolated from electrical and electronic interference with equipment and sensors that are in use for safety systems and was reviewed with respect to IEEE Standard 384-1977, Section 6.2, and found to be in compliance with the isolation criteria. The specific methods of isolation include current transformers for the analog signals, and optical couplers and relays for the digital signals requiring interference isolation.

The SPDS was subjected to a verification and validation process to ensure that applicable requirements were met. This verification included a system requirements review and a design review based on the system requirements. Validation included testing and evaluation of the completed system, hardware and software, to ensure compliance with design, function, performance and interface requirements. The SPDS verification and validation process was performed and documented in accordance with NRC guidelines in NUREG-0737, Supplement 1.

A description of the ANO-2 SPDS was transmitted to the NRC as a part of the initial response to NUREG-0737 Supplement 1, dated April 15, 1983 (0CAN048312). The ANO-2 SPDS safety analysis was transmitted to the NRC by our letter 2CAN048402 dated April 30, 1984.

7.6.2.5.3 <u>Basis for Parameter Selection and Displays</u>

The EOPs for both ANO-1 and 2 have their origin in the Babcock & Wilcox Abnormal Transient Operating Guideline (ATOG) program. From this program it was determined, following a reactor trip and verification of shutdown, that there are three symptoms of primary interest to a pressurized water reactor operator to prevent core and reactor coolant system damage: 1) inadequate subcooling of the primary system inventory, 2) inadequate primary to secondary heat transfer, and 3) excessive primary to secondary heat transfer. These symptoms are important for the following reasons:

1. Inadequate primary inventory subcooling: If the operator knows the primary fluid is in a liquid state, he is assured that it is available and capable of removing heat from the core. If subcooling is lost, these issues are in doubt, and he is therefore directed to make every effort to regain subcooling.

2. Inadequate primary to secondary heat transfer: This symptom addresses the heat transfer coupling across the steam generator. It describes the ability of the system to keep the flow of energy moving from the reactor coolant system to the ultimate heat sink.

3. Excessive primary to secondary heat transfer: In this case, the symptom is indicative of a secondary side malfunction (e.g., loss of steam pressure control or steam generator overfill). The heat transfer is again unbalanced and the operator's attention is directed toward generic actions to restore this balance.

The ATOG pressure-temperature diagram (P-T Diagram) was developed to provide the above described information to the plant operator in a timely fashion with little or no effort on his part. The P-T Diagram is the top level display for the ANO-2 SPDS for this reason.

To further enhance the operator's ability to assess the plant's response to transients and to more precisely monitor specific safety functions, additional displays were developed for the ANO-2 SPDS. These additional displays were carefully created to be used in conjunction with the ANO-2 EOP which aid the operator in the implementation of this procedure as well as some select abnormal operating procedures. A description of the P-T diagram display and these additional displays is provided below. Implicit in the B&W ATOG program was the consideration of the five critical safety functions identified in NUREG-0737, Supplement 1. Correlation between the following described SPDS displays and the five critical safety functions are also discussed below.

<u>Pressure-Temperature (P-T)</u>

The P-T diagram basic features include a grid of RCS pressure versus RCS temperature with fixed curves showing the saturation line, a 30 °F margin to saturation line and the RCS NDT limits for normal operation. During power operation the Reactor Protection System (RPS) pressure trip limits are shown along with a normal transient window showing the minimum and maximum pressures and temperatures expected immediately following a trip. A small box will appear inside this window showing the expected pressure-temperature relationship for normal hot shutdown conditions. If no forced RCS flow is indicated, the single small box will be replaced by two boxes showing the expected T_{cold} and T_{hot} conditions during natural circulation at hot shutdown.

The dynamic elements of the display include a bar graph representation of steam generator levels, digital values of selected parameters displayed below the P-T grid, and points identifying T_{cold} and T_{hot} versus pressure. Following a reactor trip, the past plotted values of temperature versus pressure remain on the screen showing the trajectory which they are following. The values shown at the bottom of the screen are reactor building temperature and pressure, A and B steam generator pressures and the average of the five highest core exit tempermocouple temperature.

Figures 7.6-3 through 7.6-6 show the SPDS P-T display for reactor trips under various conditions. These figures are based on a design RCS pressure of 2250 psia and T_{hot} of 615 °F.

A typical plant response to a reactor trip is shown in Figure 7.6-3. T_{cold} should merge with T_{hot} as the decay heat rapidly drops. Both temperatures should then move toward normal hot shutdown pressure and temperature conditions. If they do not, a departure from normal is indicated. If they move outside a larger normal transient limit area, the definite need for operator action is indicated.

Each of the three basic symptoms discussed earlier leave their unique signature on the P-T diagram as displayed in Figures 7.6-4, 7.6-5 and 7.6-6. Use of this tool enables an operator's priority to be fixed on controlling the plotted parameters within target bounds. If successful, he will be able to bring the reactor to a safe condition. This will be the case regardless of whether

or not he has properly diagnosed (or diagnosed at all) the event which has occurred. However, use of the SPDS in conjunction with the EOP does not discourage an operator from diagnosing the cause of the transient. The SPDS and EOP are based on directing the operator to take proper actions without diagnosis or with misdiagnosis.

Primary to Secondary Heat Transfer (PSHT)

The primary to secondary heat transfer display was designed to provide more detailed historical data on some of the parameters shown on the P-T diagram. This display specifically addresses the reactor core cooling and heat removal critical safety function. This display presents data in a scrolling trend versus time graph which results in a familiar, easily readable and understandable display.

This display has trends for average core exit temperature, loop average hot leg temperature, loop average cold leg temperature, saturation temperature for steam generator pressure, feedwater flow, steam generator level and steam generator pressure for both RCS loops.

This display will be particularly valuable in natural circulation conditions where RCS temperature can be closely monitored.

Reactivity Control (RHO)

The reactivity control display was provided to aid the operator in immediate verification that the reactor is indeed tripped and remains shutdown. This display specifically addresses the reactivity control critical safety function and has trends of wide range and source range neutron flux.

Steam Generator Tube Rupture (SGTR)

A steam generator tube rupture is treated as a unique event in both the Abnormal Transient Operating Guidelines and the EOP. This event is unique in that it has the potential for a direct release of radiation to the environment. The steam generator tube rupture display is designed to aid the operator in diagnosing a tube rupture, determining the affected generator, and cooling the plant down to a condition where the primary to secondary leakage can be terminated. This display shows trends of RCS hot leg temperature, steam generator levels, condenser off-gas and main steam line radiation.

RCS Inventory (RCSI)

The RCS inventory display is provided to aid the operator in assessment and maintenance of RCS inventory. This display specifically addresses the RCS integrity critical safety function. This display has trends of volume control tank level, pressurizer level, pressurizer pressure, narrow range containment sump level, charging flow, letdown flow and RCS average temperature.

Trends shown on this display may also aid in the diagnosis of the initiating event. For example, the behavior of RCS temperature while pressurizer level and pressure are decreasing is the key to differentiating between a small loss of coolant accident and an overcooling event. Both events will show decreasing pressure and pressurizer level; however, rapidly decreasing temperature would indicate an overcooling event while a constant or very slight decrease in temperature would indicate a loss of coolant.

Containment Conditions

The containment conditions display was developed to show containment parameters which may be useful in assessing and maintaining containment integrity. The display specifically addresses the containment integrity critical safety function. This display has trends of containment hydrogen concentration, and high range radiation, containment temperature, pressure and wide range containment water level.

The radioactivity control critical safety function is not specifically addressed by any single SPDS display; however, as discussed above, various radiation monitor indications are included on the appropriate displays.

Auxiliary Displays

In addition to the dedicated SPDS displays described above, there are auxiliary displays which may be selected. These are special purpose displays designed for operator convenience and assistance.

7.6.2.5.4 Hardware Description

The computer system was chosen primarily because of its flexibility, reliability, and maintainability. Flexibility is needed to permit the incorporation of future modifications without unwarranted difficulty. The computer hardware selected is similar to existing hardware already in use at ANO. This hardware has been proven to be reliable. Furthermore, Entergy Operations, Inc. personnel have considerable experience in maintaining this equipment which should improve the overall reliability of the system.

The computer system is an integrated network which is designed to perform the functions required for the ANO-1 SPDS, the ANO-2 SPDS, the Technical Support Center Data Display System, and the Emergency Operations Facility Data Display System. To achieve these functions, the SPDS computer accesses necessary input parameters from sensors in ANO-1 and ANO-2, processes these signals, and provides displays to each control room as well as to the TSC and the secondary TSC portion of the EOF. Suitable isolation is provided between the SPDS data acquisition system and class IE sensors. In each control room color graphic displays are provided for the operators. Color graphic displays are also provided in the TSC as well as the EOF. "Touch screen" controls are utilized on the color graphic displays to allow for rapid access of the information necessary to determine safety status of the plant.

Several features have been incorporated into the SPDS design in order to approach the availability goals specified in the NRC guidance and to allow for incorporation of future modifications while the system is operating. These features include redundant CPUs, redundant data acquisition hardware, redundant networks, and redundant color graphic displays in each control room. Except for the TSC equipment, which is powered from a diesel generator backed panel, the SPDS power is supplied from an uninterruptable power supply (UPS). The SPDS computer room is provided with its own air conditioning system.

7.6.2.5.5 Software Description

The operating system software for the SPDS is a real-time data acquisition system with alarm capabilities. Parts of this operating system and some of the associated application programs were modified by the ANO Computer Support Department to facilitate the special requirements of the SPDS.

The SPDS software provides applicable data over redundant networks to display units in the control room, EOF, and TSC. Each display unit generates appropriate screens and processes user commands.

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

7.7.1 DESCRIPTION

The control and instrumentation systems whose functions are not essential for the safety of the plant include plant instrumentation and control equipment not addressed in Sections 7.1 through 7.6. The general descriptions given below permit an understanding of the reactor and important subsystem control methodology.

7.7.1.1 Control Systems

7.7.1.1.1 Reactor Control Systems

The reactor is controlled by reactivity adjustments with Control Element Assemblies (CEAs) and with boric acid dissolved in the reactor coolant. Rapid changes in reactivity are compensated for, or are initiated by, CEA movement. Long-term variations in reactivity due to fuel burnup and fission product concentration changes are controlled by manually adjusting the boric acid concentration.

The boron concentration in conjunction with CEAs must be controlled to ensure that adequate shutdown margin is maintained for the reactor. This margin is maintained while critical by preventing the boron concentration from decreasing to a point beyond which the corresponding CEA worth is insufficient to shut down the reactor with adequate margin (see Section 7.7.1.1.6).

The plant is capable of following ramp load changes between 15 to 100 percent of full power at a rate of five percent per minute and at greater rates over smaller load change increments up to a step change of 10 percent, except as limited by xenon. This is accomplished by manually moving one or more pre-selected groups of CEAs and/or adjusting boron concentration in response to the requirements of the temperature programmer.

The Control Element Drive Mechanism Control System (CEDMCS) receives manual group motion demand signals from the CEDMCS control panel and sequential permissive (group stop) signals from the Plant Computer. A motion demand signal with no existing group stop limits will allow DC voltage to be applied to the CEA coils in the proper levels and sequence for CEA motion. A reactor trip initiated by the Reactor Protective System (RPS) causes the input motive power to be removed from CEDMCS by the trip switchgear, which in turn causes all CEAs to be inserted by gravity. Thus, the CEDMCS is not required for safety (see Figure 7.7-3). There are three different modes of control of the CEAs available: manual individual, manual group, and manual sequential. The manual sequential mode of operation applies only to the regulating groups 1 through 5. (See Section 4.2)

Regulating CEAs, Groups 1 through 5, may be moved as a group in manual group mode or in manual sequential mode. Individual CEAs may be moved in manual individual control. During sequential group movement, when the moving group reaches a programmed low (high) position, the next group begins inserting (withdrawing), thus providing overlap in the motion of the regulating groups. The initial group stops upon reaching its lower (upper) limit. Applied successively to regulating groups 1 through 5, the procedure allows a smooth and continuous rate-of-change of reactivity. The CEDMCS accepts signals from the plant computer to effect this sequencing of the regulating CEA groups. The CEDMCS utilizes sequential permissive signals from the plant computer which are derived from the CEDMCS up-down pulse counters. There is no tie-in to the CEA reed switch assembly sensors used in the RPS.

The shutdown and Groups P and 6 CEAs are moved in the manual individual or manual group control modes only. A selector switch permits withdrawal of no more than one of these groups at any time.

7.7.1.1.2 Reactor Coolant System Pressure Control System

The RCS pressure control system maintains system pressure within specified limits by the use of pressurizer heaters and spray valves.

During normal operation, two small groups of heaters are proportionally controlled to maintain operating pressure. If the pressure falls below the setpoint by approximately 50 psia, all of the backup heaters are also energized. Above the normal operating pressure range, the spray valves are proportionally opened to increase the spray flow rate as pressure rises. A small, continuous spray flow is maintained through the spray lines at all times to keep the lines warm and thereby reduce the thermal transient when the control valves open, and to ensure that the boric acid concentration in the coolant loops and pressurizer is in equilibrium.

A high pressurizer level energizes the backup heaters to minimize the subcooling during the largest insurge transients. A low pressurizer water level de-energizes all heaters, thereby providing heater protection.

Two channels of control are provided and the controlling channel is selected by means of a switch on the control board. Automatic control is normally used during operation but manual control of the heaters and the spray may be selected at any time.

7.7.1.1.3 Pressurizer Level Control System

The pressurizer is a surge tank which is provided to accommodate expansion and contraction of the reactor coolant due to temperature changes. Therefore, during normal operation, the pressurizer level is programmed as a function of the average coolant temperature. The pressurizer level control system controls the water level in the pressurizer to its programmed value by means of adding water to the RCS (by charging pumps) or by removing water from the system (through letdown valves).

Two channels of control are provided and the controlling channel is selected by means of a switch located on the control board. Automatic control is normally used, but manual control may be selected at any time. In the automatic mode, the level controller compares the measured and programmed level signals and generates a level error signal which modulates the letdown control valves to restore the level to the programmed value (see Table 5.5-13). Separate "ON-OFF" controllers start the backup charging pumps at low level error setpoints. One charging pump is operated continuously in order to provide makeup flow for pump seal leakage and to limit letdown temperature changes.

Backup control action is provided by several "ON-OFF" controllers. A high level error signal stops both backup charging pumps and activates an alarm. A low level error signal provides a backup signal to start all charging pumps and also activates an alarm.

The design bases for the pressurizer are described in detail in Section 5.5.10.1. The criteria which have been used to establish the pressurizer level program are as follows:

A. Sufficient water volume is maintained to prevent draining the pressurizer as a result of a reactor trip. The minimum pressure following a trip is limited to prevent actuating safety injection (This is an operational consideration.);

B. Sufficient water volume is maintained to ensure that the pressurizer heaters will not be uncovered by an outsurge following RCS average temperature changes associated with load decreases, including 10 percent step load decreases and five percent per minute ramp load decreases between 100 and 15 percent power;

C. The steam volume is sufficient to yield acceptable pressure response to normal load changes;

D. The water volume is kept no greater than that assumed in the analysis of the LOCA (This is to ensure acceptable energy release and containment pressure during such an event.);

E. The steam volume is large enough to accept the primary coolant insurge resulting from loss of load without the water level reaching the safety valves; and,

F. During load following transients, the total charging and letdown flow rates are kept as small as possible and are compatible with the capacities of the volume control tank, charging pumps, and letdown valves.

To ensure operation consistent with the stated bases, the pressurizer water level is controlled automatically or manually, in accordance with a specified level control program, and the reactor coolant temperature is maintained at or below a specified value.

7.7.1.1.4 Feedwater Control System

The two steam generators are operated in parallel with each generator's Feedwater Control System (FWCS) maintaining its downcomer water level within acceptable limits. The FWCS for each steam generator consists of a low power mode and a high power mode. In the low power mode, the FWCS operates as a single element control system based on steam generator level. In the high power mode, the FWCS operates as a three-element control system based on steam generator level, feedwater flow, and main steam flow. The FWCS program logic develops a flow demand which controls the main and bypass control valves and feedwater pump speed to maintain steam generator levels at the desired setpoint.

The FWCS includes a High Level Override (HLO) mode in which the main and bypass feedwater regulating valves are closed upon the detection of high downcomer water level. This feature is designed to prevent excessive moisture carryover into the main turbine caused by high steam generator water levels. This signal is automatically removed when the abnormal condition clears.

The FWCS includes a Reactor Tripped Override (RTO) mode that is initiated upon a reactor trip. In the RTO mode the FWCS decreases the feedwater pump to a minimum speed, shuts the main feedwater control valve, and adjusts the bypass feedwater control valve. The RTO feature is designed to limit the possibility of overcooling the RCS after a reactor trip by limiting the post-trip feedwater flow rate.

The manual control mode of each FWCS may be selected by the operator at any power level. When in manual control, the operator in the control room can utilize a master control station to simultaneously adjust valve positions and pump speed setpoints to maintain the generator downcomer level or, utilizing individual control stations, he can choose to control the valves and pump speed setpoints independently. Control at the master control station is the preferred manual operating mode since this minimizes operator control actions.

7.7.1.1.5 Steam Dump and Bypass Control System

This system is provided to improve plant availability by making full utilization of the dump/bypass valve capacity to remove Nuclear Steam Supply System (NSSS) thermal energy. This objective is achieved by the selective use of turbine bypass and atmospheric dump valves to avoid unnecessary reactor trips and to prevent the opening of secondary side safety valves whenever this can be averted by the controlled release of steam.

The steam dump and bypass control system compares the actual steam pressure and a steam pressure setpoint generated as a function of NSSS load (steam flow) to provide an error signal to a proportional-plus-integral-plus- derivative controller. The output signal from the controller is fed through a master control station to individual valve group opening demand programmers. These programmers generate signals for modulation of the valve groups in a sequential manner. From the programmers, a separate signal is sent to each valve control station. The valve control signals are sent to the valve actuators through individual gates responding to a redundant dump/bypass demand signal, ensuring that not more than one valve will open as the result of any single equipment failure or operator error.

A valve quick-opening demand signal is generated whenever the size of the load rejection is such that it cannot be accommodated with the normal valve modulation speed. This is determined on the basis of the magnitude and rate of change of a combination of the decrease in steam flow from the steam generators and the increase in pressurizer pressure. Redundant signals are generated and these signals are routed through independent channels to eliminate the possibility of opening more than one valve with any single equipment failure. The quick-opening signal is fed to a valve actuator only when that valve control station is in the automatic mode. Because the Steam Dump and Bypass Control System (SDBCS) is designed to provide the best possible transient response, the number of valves to which the quick-opening signal is applied is made to be a function of the magnitude and rate of change of steam flow and pressurizer pressure. The signal is blocked to the two upstream atmospheric dump valves on a reactor trip and to all dump and bypass valves if average temperature reaches a predetermined setpoint following a reactor trip.

The steam dump and bypass valves are discussed in Section 10.3. Two of the four atmospheric dump valves are located outside the containment upstream of the main steam isolation valves. These are fail-open valves, and are normally kept isolated by motor-operated gate valves. The balance of the dump and bypass valves are located downstream of the main steam isolation valves. The two upstream valves and their isolation valves are available to remove decay heat from the steam generator in the event of loss of off-site power. The decay heat is dissipated by venting steam to the atmosphere. In this way, the RCS may either be maintained at hot standby or hot shutdown or it may be cooled down.

The atmospheric dump valves are controlled manually from either the control room by means of hand indicating controllers located on the control panel or locally. The isolation valves are controlled manually from either handswitches on the control panel and on the MCC, or locally via valve handwheels.

In the event of failure of both sets of valves, reactor decay heat will be removed through the main steam safety valves and the RCS will remain at hot shutdown. Cooldown can be accomplished through manual operation of the atmospheric dump valves. Each valve has a handwheel which can be operated locally.

7.7.1.1.6 Boron Control System

Boron concentration control is normally accomplished by manual dilution and boration as described in Section 9.3.4. During normal operation, boron concentration is measured by radiochemistry analysis.

7.7.1.1.7 In-Core Instrumentation System

The in-core instrumentation system is used to evaluate core power and temperature distributions, perform periodic calibrations of the out-of-core flux measurement system, and provide inputs to the Core Operating Limit Supervisory System (COLSS). This system is used for confirmation and calibration of neutron flux measurements.

There are 42 in-core monitoring assemblies spaced radially and axially to permit flux mapping of the core. (See Figure 7.7-5) At each of the selected locations, an instrument assembly is inserted into the center of the fuel assembly. Each instrument assembly contains five rhodium self-powered detectors placed at selected axial locations and an outlet thermocouple. The assemblies contain background detectors to provide a means of determining signal noise. The rhodium detectors produce a current proportional to the beta emission from a central rhodium wire following activation by neutron capture.

The plant computer system corrects the in-core detector signals for background pickup and changes in sensitivity with burnup. Chromel-Alumel thermocouples are positioned to read coolant exit temperatures from the fuel assemblies.

Detector assemblies are routed into the reactor vessel through eight in-core instrumentation nozzles in the reactor vessel head. An instrumentation support plate assembly within the reactor vessel guides the detector assemblies into selected fuel assemblies.

The fixed in-core instrumentation system is designed to perform the following functions:

A. To determine the gross power distribution in the core at different operating conditions over the range from 10 to 125 percent average reactor power;

B. To provide data to estimate the fuel burnup in each fuel assembly;

C. To provide data for the evaluation of thermal margins in the core;

D. To provide data which will be used to check that the core power distribution is consistent with calculated values;

E. To provide information to calibrate and to assure correct operation of the reactor protection and control systems; and,

F. To provide signals for use in the COLSS.

When the incore instrumentation system is used to perform the functions listed above, it must consist of:

1. At least 75% of all incore detectors operable (165 detectors) with at least one incore detector in each quadrant at each level, and

2. At least 75% of all incore detector locations operable (33 locations), and

3. Sufficient operable incore detectors to perform at least six tilt estimates with at least one tilt estimate at each of three levels.

Section 15.1.15 describes the Fuel Misloading event and the analysis of record (AOR) for this event. The AOR allows for only one random failed incore instrument string (in addition to locations E8 and N8) during startup testing (Section 4.5.3.2) for each cycle. With additional strings of ICI failures, the results of the AOR could be invalidated. Specifically, if multiple failed ICI strings were located near a misloaded assembly, then some misloads that could result in fuel damage may not be detected prior to full power operation. To prevent fuel damage, either the required overpower margin (ROPM) must be substantially increased or alternate requirements on ICI operability must be imposed.

If less than 41 incore detector strings were operable during the 30% power distribution measurements at initial startup during each cycle, then the following additional requirements ({i, ii} and/or {A,B}) must be satisfied at all times during the cycle, including during the power distribution measurement:

i. Sufficient operable incore detectors to perform at least six tilt estimates on each of at least three levels.

ii. All fuel assemblies except those with one or more full faces to the core shroud must satisfy one of the following criteria:

  ii.a Be within one assembly of at least one operable ICI detector string (see Figure 7.7-7 for acceptable configurations).

  ii.b Be within two assemblies of two operable ICI detector strings (see Figure 7.7-8 for acceptable configurations).

If {i} was not satisfied during the 30% power distribution measurement, then one of the following actions must be completed prior to exceeding 50% power:

A. Perform CEA symmetry checks for at least one CEA group having a CEA within two assemblies of the assembly not in compliance with {ii} above.

B. Perform an evaluation to determine the ability of the incore detector system to detect average power asymmetry of at least 10% between quadrant 4 x 4 groups of assemblies with the actual operable incore detector pattern and make suitable adjustments to COLSS and CPCs to assure conservative indications of the DNBR and LHR margins.

If {i} is satisfied, but not {ii} during the power distribution measurement, then power ascension can proceed to 70% power before completing one of the above actions. If the non-compliance with {i} and/or {ii} occurs after the power distribution measurement, then one of the above actions must be completed within 14 EFPD upon discovery.

If these minimum conditions are not met, the incore instrumentation system is not used for the above listed applicable monitoring or calibration functions.

For a portion of Fuel Cycle 10 the incore instrumentation system was allowed to be used to perform the functions listed above with < 75% and ≥ 50% of all incore detectors (< 165 and ≥ 110 detectors) and detector locations (< 33 and ≥ 22 locations) provided appropriate penalties were applied to the COLSS and CPCs.

The penalties were based on a full 1.0% increase in overall uncertainty on the CECOR F_{xy} measurement.

An operable incore detector location consists of a fuel assembly containing a fixed detector string with a minimum of three operable rhodium detectors.

A tilt estimate can be made from two sets of symmetric pairs of incore detectors. Two sets of symmetric pairs of incore detectors are formed by two pairs of diagonally opposite symmetric detectors, one incore detector per quadrant.

Operability of the incore instrumentation is demonstrated by the performance of a channel check within 24 hours prior to use and at least once per 7 days thereafter when required for monitoring the azimuthal power tilt, radial peaking factors, local power density or DNB margin. In addition, operability is demonstrated at least once per 18 months by the performance of a channel calibration operation which exempts the neutron detectors, but includes all electronic components. The neutron detectors are calibrated prior to installation in the reactor core.

Core power distribution information is available at 210 locations, and temperature distribution information is available at 42 locations throughout the core. The full system has more capability than is needed to verify power and temperature distributions and to calibrate the out-of-core neutron detectors.

The confirmation of power and temperature distribution and calibration of the out-of-core detectors are done on a periodic basis as specified in the Technical Specifications. The frequency is chosen to assure that all protective and control system settings, that depend on core burnup and thermal and hydraulic properties, are maintained at conservative values.

7.7.1.1.8 Megawatt Demand Setter

This section has been intentionally deleted since the Megawatt Demand Setter System has been removed.

7.7.1.1.9 Shutdown Cooling System

The Shutdown Cooling (SDC) System is discussed in Section 9.3.6. The system instrumentation and controls necessary to bring the plant to a cold shutdown condition are discussed in the following sections.

The SDC System is manually initiated. SDC interlocks (see Section 7.6.2.1) prevent overpressurization of the low pressure portions of the system. The redundant isolation valves for the pump suction line are controlled by redundant control channels powered from separate supplies. The cooldown rate is adjusted by throttling the heat exchanger outlet valve, using the control board mounted hand indicating controller. The flow indicator controller maintains a constant total shutdown cooling flow rate to the core by adjusting the heat exchanger bypass flow to compensate for changes in flow rate through the heat exchangers.

Control board process indication and status instrumentation is provided to enable the operator to evaluate system performance and detect malfunctions. Control panel hand switches and valve position limit indicating lights are provided for the shutdown cooling isolation valves and the shutdown cooling heat exchanger inlet, outlet, and bypass valves. Control panel hand switches and valve position indicators are provided for the low pressure injection valves. Indication is provided of low pressure safety injection pump discharge header pressure and temperature, shutdown cooling heat exchanger outlet temperature, shutdown cooling injection flow and temperature, LPSI pump suction pressure (0 - 50 psig only), LPSI pump motor current, LPSI pump delta-P, RCS refueling level, and CET temperature. Low pressure safety injection pump operating status is also indicated on the control board.

The SDC System has been provided with electrical interlocks to prevent any possibility of overpressurizing the low pressure portions of the system. The redundant interlocks allow opening the isolation valves only when the RCS pressure is below a preset setpoint value. Section 7.6.2.1 contains a detailed description and analysis of the interlocks.

System sequencing is controlled manually by the operator in accordance with approved operating procedures.

SDC instrumentation has no bypass features which would allow an operator to jeopardize the protection afforded by the interlocks or allow degradation of any other control functions. Sufficient instrumentation is supplied to assure adequate system monitoring during all modes of system operation.

The SDC System utilizes the low pressure safety injection pumps and the service water system for heat removal. Either of the two pumps and either of the two heat exchangers are sufficient for proper system operation.

7.7.1.2 Design Comparison

Historical data removed. To review the exact wording please refer to Section 7.7.1.2 of the FSAR.

7.7.1.3 Core Operating Limit Supervisory System

7.7.1.3.1 General

The COLSS consists of process instrumentation and algorithms used to continually monitor the limiting conditions for operation on:

A. Peak linear heat rate;

B. Margin to Departure from Nucleate Boiling (DNB);

C. Total core power; and,

D. Azimuthal tilt.

The COLSS continually calculates DNB margin, peak linear heat rate, total core power, and azimuthal tilt magnitude and compares the calculated values to the limiting condition for operation on these parameters. If a limiting condition for operation is exceeded for any of these parameters, a COLSS alarm is initiated and operator action is taken as required by the Technical Specifications.

The selection of limiting safety system settings, core power operating limits, and the azimuthal tilt operating limit are specified such that the following criteria are met:

A. No safety limit will be exceeded as a result of an anticipated operational occurrence; and,

B. The consequences of postulated accidents will be acceptable.

The Reactor Protective System (RPS) functions to initiate a reactor trip at the specified limiting safety system settings. The COLSS is not required for plant safety since it does not initiate any direct safety-related function during anticipated operational occurrences or postulated accidents. The Technical Specifications define the Limiting Conditions for Operation (LCO) required to ensure that reactor core conditions during operation are no more severe than the initial conditions assumed in the safety analyses and in the design of the low DNBR and high local power density trips. The COLSS serves to monitor reactor core conditions in an efficient manner and provides indication and alarm functions to aid the operator in maintenance of core conditions within the LCOs given in the Technical Specifications. When COLSS is out of service, certain technical specification action statements become applicable.

The COLSS algorithms are executed in the plant computer. The calculational speed and capacity of COLSS enables numerous separate plant operating parameters to be integrated into two more easily monitored parameters: (1) margin to a limiting core power (based upon margins to DNBR, peak linear heat rate and licensed power limits), and (2) azimuthal tilt. If COLSS were not provided, maintenance of reactor core parameters within the LCOs, as defined by the Technical Specifications, would be accomplished by monitoring and alarms on the separate non-safety-related process parameters utilized in the COLSS calculations. Therefore, the essential difference in utilizing COLSS in lieu of previous monitoring concepts is the integration of many separate process parameters into a few easily monitored parameters. The conciseness of the COLSS displays has distinct operational advantages, since the number of parameters that must be monitored by the operator is reduced.

Sensor validity checks are performed by COLSS on those measured input parameters used in the COLSS calculations. The validity checks consist of checking sensor inputs against the following criteria:

A. Sensor out of range; and,

B. Deviations between like sensors:

The following options are available for dealing with non-valid sensors.

A. Automatic replacement of the failed sensor by a redundant sensor (when available).

B. In 4-pump operation, automatic replacement of a failed primary system sensor with its corresponding similar sensor (hot leg RTDs, cold leg RTDs in the same coolant loop).

C. Automatic algorithm alteration for certain functional inputs by the generation of software flags when no redundant sensors are available.

D. Substitution of constants for selected COLSS inputs (performed under administrative control).

In the event that a non-valid sensor is detected, an alarm to the operator is actuated and corrective action is automatically initiated (where applicable).

A more detailed discussion of sensor validity checks is included in the Combustion Engineering topical report entitled "Assessment of the Accuracy of PWR Operating Limit as Determined by the Core Operating Limit Supervisory System (COLSS)," CENPD-169, issued July, 1975.

Detailed process testing of COLSS is performed to assure proper system performance. While COLSS is off-line, sets of stored constants are substituted for live sensor inputs and COLSS is executed. Comparison of the results with known outputs is then made to assure continuity of all COLSS algorithms. While COLSS is on-line, hard copy printout of the COLSS input, intermediate calculated values and results are provided during the test. Comparison of this information with intermediate calculated values and results from an off-line COLSS program using the same input values can provide additional assurance of proper operability of the COLSS program. Testing will be performed under administrative control on a periodic basis to assure proper performance of COLSS. Since COLSS is not required for plant safety, COLSS testing requirements are not included in the Technical Specifications.

7.7.1.3.2 System Description

The core power distribution is continually monitored by COLSS and a core power operating limit based on peak linear heat rate is computed. Operation of the reactor at or below this operating limit power level ensures that the peak linear heat rate is never more adverse than that postulated in the loss of coolant analyses.

Core parameters affecting the margin to DNB are continually monitored by COLSS and a core power operating limit based on margin to DNB is computed. Operation of the reactor at or below this operating limit power level ensures that the most rapid DNB transient which can result from an anticipated operational occurrence will not result in a DNBR reduction to a value less than the DNBR SAFDL.

The core power operating limit based on licensed power level is also monitored by COLSS. Operation of the reactor at or below this operating limit ensures that the total core power is never greater than that assumed as an initial condition in the accident analyses.

The core power and the core power operating limits based on peak linear heat rate, margin to DNB and licensed power level are continually indicated on the control board. The margin between the core power and the nearest core power operating limit is calculated by COLSS and is available for display in the Control Room. An alarm is initiated in the event that the COLSS calculated core power level exceeds a COLSS calculated core power operating limit.

In addition to the above calculations, the azimuthal flux tilt is calculated in COLSS. The azimuthal flux tilt is not directly monitored by the Plant Protection System (PPS). An azimuthal flux tilt allowance, based on the maximum tilt anticipated to exist during normal operation, is an input to the protection system and is used in the low DNBR and high local power density trip calculations. The azimuthal flux tilt is continually monitored by COLSS and an alarm is initiated in the event that the azimuthal flux tilt exceeds the azimuthal flux tilt allowance setting in the PPS.

The COLSS sensors provided for generating the input data required to compute the core power, the core power operating limits, and the azimuthal tilt, are given in Table 7.7-1. A functional block diagram of the COLSS is presented in Figure 7.7-2.

The algorithms below are executed in COLSS:

A. Reactor Coolant Volumetric Flow Rate

B. Core Power as determined by:

   1. Reactor coolant ΔT;

   2. Secondary system calorimetric; and,

   3. Turbine first stage pressure.

C. Core Power Distribution

D. Core Power Operating Limit Based on Peak Linear Heat Rate

E. Core Power Operating Limit Based on Margin to DNB

The algorithms are executed in the plant computer. Technical Specifications on the reactor core provide alternate means of monitoring the limiting conditions for operation in the event that the plant computer is out of service. Certain action statements are applicable when the plant computer is out of service.

Control board indication of the following COLSS parameters is continually available to the operator:

A. Core power operating limit based on peak linear heat rate

B. Core power operating limit based on margin to DNB

C. Total core power

D. Core average axial shape index.

COLSS alarms are initiated for the following conditions.

A. Core power exceeds a core power operating limit.

B. Azimuthal flux tilt exceeds azimuthal flux tilt allowance.

C. Azimuthal flux tilt exceeds Technical Specification azimuthal flux tilt limit.

In addition to the descriptions of COLSS algorithms given in Section 7.7.1.3.3, COLSS algorithm descriptions, a COLSS uncertainty analysis and a discussion of the treatment of COLSS input information is included in the COLSS Topical Report CENPD-169, issued July, 1975. Table 7.7-1 provides a listing of the types, quantities and ranges of sensors which provide input information for the COLSS algorithms.

7.7.1.3.3 Description of COLSS Algorithms

7.7.1.3.3.1 Reactor Coolant Volumetric Flow Rate

The margin to DNB is a function of the reactor coolant volumetric flow rate. The four reactor coolant pump rotational speed signals and pump differential pressure signals are monitored by COLSS and used to calculate the volumetric flow rate. The pump characteristics were determined from testing conducted at the pump vendors test facility. Correlations between the pump rotational speed, pump differential pressure, and the volumetric flow rate were developed. The 4-pump volumetric flow rates are summed to obtain the reactor's total volumetric flow rate.

Analyses performed in support of Amendment 286 to the Technical Specifications determined optimum values for COLSS flow algorithm constants and justified use of the COLSS flow algorithm as a reference quality flow indication. Either calorimetric calculations or COLSS indicated flow may be used to satisfy Technical Specification flow surveillances. The flow uncertainties associated with the revised, reference quality COLSS flow indication are accounted for in the DNBR power operating limit uncertainty analysis. Necessary allowances for core bypass flow, flow factors, reactor coolant temperature, etc. are factored into the value of flow used in the DNBR calculation.

Reactor coolant pump differential pressure and cold leg temperature instrumentation supplying input to the COLSS flow algorithm are periodically analyzed to identify anomalies that have the potential to impact the accuracy of the COLSS flow indication. Surveillance criteria consist of the following for differential pressure instruments:

- Verification that instrument quality indicated by the plant computer remains acceptable. Unacceptable or questionable instrument quality is monitored by COLSS cross checks of preferred and alternate instruments.

- The pump differential pressure (ΔP) instrumentation for each cold leg (preferred and alternate) are verified to remain constant within 1.0 psi of each other or each are individually verified to remain constant within 1.0 psi over time (i.e., between calibrations or over the course of the cycle).

- At 100% power following refueling, average instrument readings are compared to equivalent average reading from the previous cycle and verified to agree within 1.0 psi.

If the above deviations exceed the specified tolerances, the impact of the difference are evaluated based on a sensitivity of 0.30% flow / psid. If non-conservative deviations beyond the specified tolerances can not be attributed to actual process changes, flow penalties are applied to reduce the COLSS indicated total flow rate.

Surveillance criteria consist of the following for cold leg temperature instruments:

- Verification that instrument quality indicated by the plant computer remains acceptable. Unacceptable or questionable instrument quality is monitored by COLSS cross checks of preferred and alternate instruments.

- The temperature instrumentation for each cold leg (preferred and alternate) is verified to remain constant within 2.0 °F of each other or each are individually verified to remain constant within 2.0 °F over time (i.e., over the course of the cycle).

- At 100% power following refueling, average instrument readings are compared to equivalent average readings from the previous cycle and verified to agree within 1.0 °F.

If the above deviations exceed the specified tolerances, the impact of the difference is evaluated based on a sensitivity of 0.07% flow / °F. If non-conservative deviations beyond the specified tolerances can not be attributed to actual process changes, flow penalties are applied to reduce the COLSS indicated total flow rate.

7.7.1.3.3.2 Core Power Calculation

The reactor coolant ΔT power and the secondary calorimetric power are computed in COLSS. The reactor coolant ΔT power is a less complex algorithm than the secondary calorimetric power and is performed at a more frequent interval. The secondary calorimetric power is used as a standard to periodically adjust the gain coefficient (technically, not a gain coefficient but an additive correction term) on the calculation of the reactor coolant ΔT power. This arrangement provides the benefits of the secondary calorimetric accuracy and the reactor coolant ΔT power dynamic response characteristics.

The reactor coolant ΔT power is calculated based on the reactor coolant volumetric flow rate, the reactor coolant cold leg temperature, and the reactor coolant hot leg temperature. A gain coefficient on the calculated ΔT power is periodically adjusted based on the secondary calorimetric power.

The secondary calorimetric power is based on measurements of feedwater flow rate, feedwater temperature, feedwater pump discharge pressure, steam flow and steam pressure. A detailed energy balance is performed for each steam generator. The energy output of the two steam generators is summed and allowances made for reactor coolant pump heat, pressurizer heaters, and primary and secondary system energy losses.

7.7.1.3.3.3 COLSS Determination of Power Distribution

The determination of $F_q^{''}$, $F_r^{''}$, the power shape in the hottest channel, and the azimuthal tilt magnitude is performed based on in-core measurements of the flux distribution, processed by pre-programmed algorithms and stored constants. A brief description is given here of the data processing approach employed by COLSS to yield the desired power distribution information. This analysis is repeated at least once per minute, and thus represents continual on-line monitoring.

The core is regarded as being divided into several radial regions in the X-Y plane. The regions are selected taking into account the locations of the regulating CEA groups and the locations of the various generations of reload fuel. Within each region, a sufficient number of strings of fixed rhodium in-core detectors are assigned to the COLSS computation to provide a representative measure of the axial power distribution.

The dynamic response characteristic of the self-powered rhodium in-core detectors is a function of both prompt and delayed components of electrical current generated in the detector and cabling. The delayed portion of the current signal is governed by the decay of isotopes of rhodium having half-lives of 0.7 and 4.4 minutes. To provide the capability to compensate for the delayed portion of the signal, the COLSS power distribution determination includes a compensation algorithm for the in-core signals used as input to COLSS. The algorithm approximately represents the inverse of the in-core detector dynamic response, such that the combination of detector response and dynamic compensation produces a signal representative of the actual neutron flux response. The basis for the dynamic compensation is described in the Topical Report CENPD-169 on COLSS entitled "Assessment of the Accuracy of PWR Operating Limits as Determined by the Core Operating Limit Supervisory System (COLSS)."

The capability for signal filtering is provided through selection of algorithm constants. With the capability for dynamic compensation and filtering on the in-core signals, changes in local flux level during operational load follow transients are adequately represented by the COLSS power distribution determination.

Following correction of the fixed detector signals for background and burnup, five axially distinct retain-average power integrals, corresponding to the five rhodium detector segments, are constructed for each X-Y region, taking into account signal-to-power conversion factors, burnup in the surrounding fuel and the location of the CEAs. Multi-node axial power shapes are constructed from the appropriate set of axial power integrals using fits based on combinations of simple nodal shapes.

Employing tables of factors relating power in the hot pin to the region average F_q^n, F_r^n, the axial power profile in the hot pin, is computed for each region for use in the margin computation.

Mal-positioning of a CEA or CEA group, the uncontrolled insertion or withdrawal of a CEA or CEA group, or a dropped CEA will be detected by COLSS with inputs received from the pulse counting CEA position indicating system described in Section 7.5.1.4.1. It is noted that pulse counters do not automatically recognize these CEA deviations in all cases. In some cases, operator action to update the pulse counters to indicate the correct position is required. Should these deviations occur, adjustments to planar radial peaking factors are performed to ensure that the COLSS DNB and peak linear heat rate calculations remain valid. For most CEA deviations, the adjustments to the planar radial peaking factors cause COLSS to not execute the DNB and peak linear heat rate calculations. During these CEA deviations, power operating

limits are limited by Technical Specifications. The non-execution of the COLSS DNB and peak linear heat calculations are indicated on the plant computer. It is noted that COLSS only provides a monitoring function. The protective action for the CEA-related anticipated operational occurrences defined in Section 7.2.1.1.2.5 is provided by the CEAC/CPC system described in Section 7.2.1.1.2.5.

Flux tilts are detected by comparison, at various levels in the core, of signals from symmetrically located sets of fixed in-core detectors and the region-wise power distribution data modified appropriately before proceeding with the margin computation. In this way, postulated non-separable asymmetric xenon shifts are identified and reflected in the power distribution assessment. Radial xenon redistributions are accounted for through the use of a region-wise combination of local-to-average and axial data discussed above. Alarms are provided by COLSS when the xenon tilt exceeds the allowances for these effects carried in the Core Protection Calculators (CPCs) as penalties.

If an inoperable detector is identified during internal consistency checks of the data, the inoperable detector is deleted from the COLSS calculations.

The COLSS power distribution algorithms, region selection, and initial set of stored constants are validated during the preoperational phase by analytical means, including processing in-core instrument signals produced by a three-dimensional reactor simulation code, and comparing the COLSS power distribution assessment to that of the 3-D simulator. This is done for steady state and power maneuvering conditions, including simulations of conditions resulting from operator error.

After the inception of operation, periodic confirmation of the COLSS assessment of the power distribution, including the suitability of any updated stored constants, is obtained by comparison with a more detailed, off-line processing of an extensive in-core flux map produced by the fixed in-core instrument system. One means of analyzing the detailed flux map is to compare it with detailed calculations of the power distribution which include computations of the flux at the instrument location. Folding this together with other analyses of the ability of the detailed calculation to estimate the local pin-by-pin power distribution (see Section 4.3.3.1.2) enables an overall assessment of the COLSS power distribution error. This is factored into the margin assessment as noted in Section 7.7.1.3.4.

7.7.1.3.3.4 <u>Core Power Operating Limit Based on Peak Linear Heat Rate</u>

The core power operating limit based on peak linear heat rate is calculated as a function of the core power distribution (F_q). The power level that results from this calculation corresponds to the limiting condition for operation of peak linear heat rate.

7.7.1.3.3.5 <u>Core Power Operating Limit Based on Margin to DNB</u>

The core power operating limit based on margin to DNB is calculated as a function of the reactor coolant volumetric flow rate, the core power distribution, the maximum value of the four reactor coolant cold leg temperatures, and the RCS pressure. The W-3 correlation was used in Cycle 1 in conjunction with an iterative scheme to compute the operating limit power level. The power level that resulted from this calculation corresponded to the limiting condition for operation for DNB margin. The CE-1 critical heat flux correlation replaced the W-3 correlation for DNBR analysis subsequent to cycle 1.

7.7.1.3.4 Calculation and Measurement Uncertainties

The uncertainties in COLSS algorithms can be categorized as:

A. Uncertainties associated with the computation methods used to correlate the monitored variables to the calculated parameters; and,

B. The measurement uncertainties associated with the COLSS process instrumentation.

Key algorithms used in COLSS are biased such that, for a fixed set of input values, the calculated parameter in COLSS is equal to or conservative with respect to the value of that same parameter calculated using standard design methods. Standard design methods are discussed in Chapters 4 and 15. Periodic checks are made throughout core life to assure that this objective is achieved.

Each input sensor to COLSS is automatically checked for an out of range condition before it is used in the COLSS calculation. In addition, allowances for measurement uncertainties are applied to the DNBR and (LPD) kW/ft power operating limits and to plant power to ensure that the COLSS-indicated margin to both of these operating limits is conservative.

7.7.1.4 Computer Systems

The ANO-2 computer system consists of the plant computer, and the Safety Parameter Display System (SPDS). The SPDS is discussed in Section 7.6.2.5; the plant computer is discussed in the following sections. These computer systems are designed and configured as general purpose facilities for plant monitoring, alarming and reporting purposes. They include the capability of direct interaction with plant control systems to provide permissive or control inputs to these systems based upon calculational determination of plant conditions.

The computer programs, exclusive of COLSS, which provide either a reactor monitoring or Plant Protection System (PPS) monitoring function are described below:

A. The incore detector signals are used by the off-line computer code CECOR to calculate the spatial power distribution in the core including the tilt and power peaking factors.

B. Power Dependent Insertion Limits (PDILs) are operating limits on allowable insertion of full length CEAs used on the Arkansas Nuclear One - Unit 2, and similar Combustion Engineering plants, to maintain operation consistent with shutdown margin (when the reactor is critical) and ejected CEA worth (when the reactor is critical) constraints. PDILs utilize reactor power and CEA position signals.

C. Buffered output signals from each CPC channel (including calibrated ex-core neutron flux power and margin to DNBR and local power density trip setpoints) are sent to the computer.

D. The post-trip review program monitors pre-selected process inputs at selected intervals before and after a reactor trip. This program provides a means of determining the cause of reactor trip.

E. The sequence-of-events program monitors PPS bistable trip units and records status changes (channel trips) with a resolution of several milliseconds as a means of determining the cause of reactor trip.

Each of these computer functions is intended to assist the plant operator in supervision or analysis of plant conditions.

None of these functions are required to ensure plant safety or permit plant operation.

The computer programs which provide input to plant control systems are described in the following paragraph:

A. The CEA group sequencing program provides input to the CEDMCS in the form of permissive signals. These signals permit sequential insertion and withdrawal of regulating CEA groups 1 through 5 by the CEDMCS with a pre-programmed overlap between consecutive groups during the manual sequential mode of operation.

   The computers monitor the following functions during sequential modes of CEA group operation: (1) withdrawal sequence which starts with Group 1 and ends with regulating group 5 in consecutively increasing numbers, and (2) the insertion sequence which starts with regulating group 5 and ends with Group 1 in consecutively decreasing numbers. Proper sequencing of the group necessitates that the preceding group reach a specified limit before the next group is permitted to move. One sequential permissive contact output is initiated for each regulating group when the permissive conditions for that group have been met. In addition to sequential permissive outputs for regulating groups 1 through 5, one contact output for out-of-sequence alarming is provided.

B. The computers also provide normal CEA control limits for all CEAs. These limits include the upper (lower) group stops for full length CEAs. These control limits are provided to the CEDMCS to automatically terminate CEA motion upon reaching the CEA limits of travel.

Each of these computer functions is intended to enhance flexibility of plant operation. None are required to ensure plant safety or permit plant operation.

All other functions implemented in the computers are solely for operator and administrative convenience and involve neither the PPS nor plant control. None of the computer functions are required to ensure plant safety or permit plant operation.

7.7.1.5 Ex-Core Neutron Flux Monitoring System

The ex-core neutron flux monitoring system includes neutron detectors located around the reactor core and signal conditioning equipment located in the control room area. Neutron flux is monitored from source levels through full power operation, and signal outputs are provided for reactor protection and for information display. A total of six channels of instrumentation are furnished.

Two startup channels provide source level neutron flux information and boron dilution event monitoring for use during extended shutdown periods, initial reactor startup and startups after extended periods of reactor shutdown such as core refueling operations. Each channel consists of a detector assembly, an amplifier assembly, a signal processor, a boron dilution event monitor and associated cabling. One channel is electrically isolated from the control room with a buffer/isolator to provide alternate shutdown indication for fire protection. The detector assembly houses two fission chambers which have the capability to measure power range

neutron flux in addition to source range neutron flux. The amplifier assembly is located outside containment and houses the electronics to condition the detector signals and provides outputs to the signal processor assembly. The signal processor drawer converts the amplifier signals into signals that represent source range countrate, reactor power level, and the rate of change of reactor power level. These parameters are transmitted to indicators, recorders, alarms, and the computer for display.

The boron dilution event monitor receives the source range countrate signal from the signal processor and provides an alarm when the countrate increases by an amount equal to the alarm ratio which is set into the shutdown monitor. This alarm is indicative of a reduction in shutdown margin either from an unplanned boron dilution or other causes. (2CAN088201)

Both startup channels provide readout, audio countrate information, and alarms only and have no direct control or protective functions.

Four safety channels provide neutron flux information from routine startup neutron flux levels to 200 percent of rated power covering a single range of approximately 10^{-8} to 200 percent power (10 decades). Each channel consists of three fission chambers, a preamplifier and a signal processing drawer containing power supplies, a logarithmic amplifier (including combination counting and mean square variation techniques), linear amplifiers, test circuitry and a rate of change of power circuit.

These channels feed the RPS and provide information for rate of change of power display, DNBR, local power density, and overpower protection. (see Sections 7.2.1.1.1.1, 7.2.1.1.1.2, 7.2.1.1.1.3, and 7.2.1.1.1.4)

The fission chambers in each RPS channel are stacked vertically to permit an axial power shape measurement. Each chamber is operated in the current mode with each chamber feeding a linear amplifier to provide neutron flux information in the power operating range of 1 - 200 percent power. The center chamber, operating also in the pulse counting mode, feeds the wide range logarithmic amplifier (from a preamplifier) to provide single range neutron flux information from routine startup neutron flux levels to 200 percent of rated power.

The neutron detectors are mounted in holder assemblies and located in instrument wells (thimbles) external to the reactor vessel. They are located as shown in Figure 7.7-4 such that optimum representative core neutron flux is monitored.

7.7.1.6 <u>Diverse Scram System (DSS) with Diverse Turbine Trip (DTT)</u>

The DSS is a functionally non-safety related system designed to prevent an Anticipated Transient Without Scram (ATWS) event by tripping the reactor upon pressurizer pressure greater than 2450 psia. An ATWS event is any RCS overpressurization Anticipated Operational Occurrence (AOO) concurrent with a common mode RPS/RTS failure that could lead to the over-stressing of RCS components beyond their designed stress limits, thereby resulting in a challenge to the RCS integrity. The over-stress limit is considered to be 3200 psia.

The DSS is designed in conformance with 10CFR50.62, known as the ATWS Rule, and is therefore diverse and independent from the existing RTS from transmitter output to final actuation device. The DSS is a 2-out-of-4 energize-to-actuate logic system that monitors pressurizer pressure. The system is designed as a highly reliable system such that no single failure will result in a spurious reactor trip.

Installation of the DSS inherently provides for a DTT in compliance with 10 CFR 50.62. The DTT utilizes the existing CEDM undervoltage turbine trip circuitry which consists of four undervoltage channels configured in a selective 2-out-of-4 logic. When the DSS causes a reactor trip, it also results in a turbine trip because the DSS interrupts power to the Control Element Assembly (CEA) coils upstream of the rod power bus undervoltage relays in the Control Element Drive Mechanism Control System (CEDMCS). These relays actuate the turbine trip circuitry. All DTT components downstream of the DSS are diverse and independent from the RTS. Therefore, since the DSS is diverse and independent from the RTS, the entire DTT is also diverse and independent from the RTS.

The DSS is a 2-out-of-4 logic system designed to trip the reactor upon detection of pressurizer pressure greater than 2450 psia on any two channels. Each of the four pressurizer pressure signals is input to four 2-out-of-4 logic circuits. Upon actuation of the 2-out-of-4 logic circuits, power will be interrupted to the CEA coils by tripping a DSS contactor at the output of the non-safety related CEDM motor generator sets 2MG01 and 2MG02, thus resulting in a reactor trip. Both contactors must be tripped to trip the reactor, with trip channels 1 and/or 3 tripping the 2MG01 output DSS contactor and trip channels 2 and/or 4 tripping the 2MG02 output DSS contactor. A bypass breaker is provided around each DSS contactor to facilitate maintenance, testing, and start-up.

The DSS and DTT designs do not contain any Class 1E to non-Class 1E interfaces.

The DSS design consists of the following functional requirements:

- DSS utilizes a 2-out-of-4 logic system with pressurizer pressure as the parameter indicative of RCS over pressurization.

- The DSS setpoint and response time are coordinated with the RPS setpoints and response times so that a competing condition between the RPS and DSS is prevented.

- The DSS uses a micro-computer with solid state I/O modules as contrasted with the RPS which uses analog bistable trip units. The DSS is an energize-to-actuate system while the RPS is a de-energize-to-actuate system.

- DSS will trip the reactor upon pressurizer pressure exceeding a nominal setpoint of 2450 psia.

- DSS equipment is qualified for its environment due to AOO's.

- DSS is designed under the suitable Quality Assurance procedures consistent with the requirements and clarification of 10CFR50.62 contained in NRC Generic Letter 85-06.

- DSS logic power is separate and independent from the RPS power and is capable of providing uninterruptible power for a minimum of 15 minutes following the loss of its power source. Power for the DSS contactors is separate and independent from the RPS power and is supplied from a station non-1E UPS.

- Manual initiation of DSS is provided locally at cabinets 2C407 & 2C408 and 2C409 and remotely in the Control Room.

- The DSS is sealed-in upon an automatic or manual trip and must be manually reset.

- The DSS is placed in service during Mode 1 operating conditions. However, the system may be taken out of service during Mode 1 for corrective maintenance or surveillance testing purposes.
- DSS includes capabilities to allow testing DSS at power.
- DSS includes features that provide alarms, plant computer data, and other operator interfaces to indicate system status and meet operability requirements.

In summary, the DSS (and inherently the DTT) is a highly reliable system designed to trip the reactor diversely and independently from the RTS due to common mode failures of the RTS during AOO's that could result in RCS overpressurization.

7.7.1.7 Diverse Emergency Feedwater Actuation System (DEFAS)

The DEFAS is a non-safety related system designed to mitigate the consequences of an Anticipated Transient Without Scram (ATWS) by initiating EFW during conditions indicative of an ATWS event. An ATWS event is any RCS overpressurization AOO concurrent with a common mode RPS/RTS failure that could lead to the overstressing of RCS components beyond their designed stress limits, thereby resulting in a challenge to the RCS integrity.

The DEFAS is designed in commitment to 10CFR50.62, known as the ATWS Rule. In conformance with the ATWS Rule, the DEFAS is diverse from the existing RTS from sensor output to the final actuation devices. The DEFAS is a 2-out-of-4 energize-to-actuate logic system that monitors steam generator level. The system is designed as a highly reliable system such that no single failure will result in spurious EFW actuation.

Functionally, the DEFAS will actuate EFW to a steam generator when the steam generator's level reaches a low-low setpoint after the Diverse Scram System (DSS) has actuated, and confirmation that a MSIS and EFAS have not been initiated.
